Materials Discovery One Standard Deviation from The Mean: Finding Avalanches in Nanoparticles Bruce E. Cohen; Lawrence Berkeley National Laboratory, United States

The first applications of luminescent nanocrystals to bioimaging were semiconductor quantum dots with optoelectronic properties that largely mirrored those of organics and proteins, but with substantially increased stability and brightness that have enabled single molecule and other challenging imaging applications. Building on this success, newer nanocrystals have been engineered with optical properties unlike anything found in traditional probes, including perfect photostability,[1] anti-Stokes emission a billion-fold more efficient than 2-photon excitation,[2] and most recently, photon avalanches hosted within nanostructures.[3] Avalanches are steeply nonlinear events in which outsized responses arise from a series of minute inputs. With light, photon avalanching (PA) had been observed only in bulk materials and aggregates, often at cryogenic temperatures, preventing its application to bioimaging. In two recent studies,[3,4] we describe the engineering and imaging of avalanching nanoparticles (ANPs), which are ~25-nm Tm^{3+}-doped $NaYF_4$ upconverting nanoparticles that efficiently convert near infrared excitation to higher energy emission. Avalanches are steeply nonlinear events in which outsized responses arise from a series of minute inputs and, with light, photon avalanching had been observed only in bulk materials, often at cryogenic temperatures. The extreme nonlinearity of ANP emission enables sub-70 nm spatial resolution using only simple scanning confocal microscopy and before any computational analysis. Two-way NIR photoswitching of ANPs enables full optical control of photodarkening and photobrightening, and we find indefinite photoswitching of individual nanoparticles in ambient or aqueous conditions without measurable photodegradation. This enables unlimited photon collection for calculation of sub-Ångstrom localization accuracies, and we can distinguish individual ANPs within tightly packed clusters. For application of ANPs to live-cell imaging, we have developed synthetic chemistry-free methods for conjugating engineered antibodies to NP-surface SpyCatcher proteins,[5] which bind and spontaneously form covalent isopeptide bonds with cognate SpyTag peptides. This enables controlled and irreversible attachment of antibodies to nanoparticle surfaces, for specific targeting of cell-surface receptors in quantitative live-cell study of their distribution, trafficking, and physiology.

Design of Iron Oxide Nanocatalysts for The Magnetic Induction-Assisted Degradation of Emergent Contaminants Alvaro Gallo Cordova, Belen Corrales-Perez, Jesus G. Ovejero and M. Puerto Morales; Instituto de Ciencia de Materiales de Madrid, Spain

The application of nanomaterials in environmental remediation is of utmost importance in addressing the pressing ecological challenges of our time. Nanomaterials offer unique advantages, such as their high surface area and reactivity, which make them exceptionally effective in adsorbing, degrading, and immobilizing various pollutants in air, water, and soil. Within these nanomaterials, iron oxide nanoparticles (IONPs) stand out as great alternatives due to their low price, biodegradability and magnetic properties. Specifically, IONPs when subjected to alternating magnetic fields (AMF), generate localized heat through their physical motion or rotation of their magnetic moments [1]. This controlled heating can be harnessed to accelerate the degradation of various pollutants, including emerging contaminants (*e.g.* microplastics, antibiotics, cosmetics, etc.). Furthermore, the ability to manipulate the nanoparticles' movement through the application of external magnetic fields enables reduced operational costs for separation processes, while minimizing ecological disruption.
In this study, we developed a catalytic system via the polyol process, designed specifically for the magnetic induction-assisted degradation of organic matter. The resulting nanocatalyst (NC) displayed a multi-core structure measuring 40 nm, comprising small magnetic cores of 12 nm each [2]. These magnetic cores exhibited a well-ordered crystalline aggregation, which contributed to a collective magnetic behavior, enhancing magnetic induction heating and facilitating efficient separation due to the substantial magnetic moment per particle. To assess the industrial applicability of this approach, we

successfully scaled up the production of NCs to a gram-level with remarkable reproducibility in terms of both structure and magnetic properties.
The scaled NCs were used for the magnetic induction-assisted degradation of microplastics (MPs). For this purpose, polyethylene MPs were extracted from a commercial facial scrub and we investigated a combined treatment approach for their degradation. Initially, we subjected the MPs to a hydrolysis process at 150 ºC, breaking them down into monomers. Subsequently, we conducted a Fenton-like reaction, employing the as-prepared NCs in the presence of hydrogen peroxide, to degrade the hydrolyzed molecules via highly oxidative species. To assess the efficacy of this process, we monitored the changes in the Total Organic Carbon (TOC) content of the supernatant before and after each stage, which provided insights into the MPs' degradation. Notably, we observed that the mineralization of TOC was temperature-dependent, increasing from 20 to 65% at room temperature (RT) and 90 ºC. This yield saw a further boost when employing IONPs as a heat source under the influence of an alternating magnetic field, likely attributable to the creation of hot spots on the surface at temperatures exceeding 80 ºC.
In general, the use of magnetic nanoparticles in environmental remediation processes brings the advantages of magnetic induction heating, which can significantly reduce energy consumption and enhance the overall catalytic efficiency. As we continue to tackle the challenges of diminishing contamination and advancing sustainable energy solutions, magnetic nanoparticles represent a compelling avenue for achieving environmental remediation, making them a promising technology with the potential to reshape our approach to mitigate climate change.

The Future of Industrial Decarbonization and Nanotechnology through Atomic Layer Processing David S. Bergsman; University of Washington, United States

Recent years have seen a surge of interest in the development of scalable tools for nanomaterials synthesis. Many emerging technologies, like solar cells, batteries, catalysts, and membranes, rely on atomically-precise materials design to operate effectively. Tools for creating these materials with increased scalability and decreased costs are thus required to enable the widespread adoption of these technologies. One suite of tools, known collectively as atomic layer processing (ALP), is particularly interesting for nanomaterials synthesis, due to its ability to create ultrathin films with sub-nanometer thickness and compositional control. ALP has also been used in the semiconductor industry over several decades, making it easy to deploy in other manufacturing processes. Commercial solar panels and battery electrodes have already started to incorporate ALP-deposited films as passivation layers. However, as demand for nanotechnology increases, there is a continued need to expand the library of materials that can be made with these tools and to accelerate the pace with which these materials are deployed.

In this presentation, in addition to highlighting my journey navigating the academic job search as a qay scientist, I will highlight how my research group at the University of Washington is expanding the applicability of ALP to create new technologies in sustainability. First, the use of vapor phase infiltration (VPI) to modify polymers will be discussed, highlighting our work to make polymer membranes conductive and to upgrade their chemical and thermal stability. Next, I will describe how molecular layer deposition (MLD) can be used create hybrid organic-inorganic thin films, exploring our work to make atomically precise catalysts for improved electrochemical stability and activity. Last, I will describe how high-throughput materials testing is needed for rapid materials deployment, exploring our group's work to construct a high-throughput deposition system and to collect data on processing conditions into a database for additional analysis. Through these projects, our group expects to greatly expand the library of materials accessible to ALP and improve the speed with which these new materials can be translated into commercial technologies.

11:30 AM *BI01.01.04
Materials Science Challenges in Ocean-Based Carbon Removal Solutions Kristin M. Poduska; Memorial University, Canada

There is a critical knowledge gap in understanding the kinetics and mechanisms of mineral formation and degradation in the context of potential technologies that are targeted for carbon capture, utilization, and storage [1]. Both crystallization and dissolution of carbonate minerals figure prominently in many such climate-change-mitigation strategies that aim for carbon dioxide removal. For example, different approaches to ocean-based alkalinity enhancement involve processes that depend on mineral surface and interfacial chemistry in order to increase water pH with concomitant atmospheric carbon removal. In this context, I will describe my team's work related to tracking changes in carbonate mineral phases, including surfaces and bulk structures, due to dissolution and recrystallization processes. In doing so, I will emphasize the urgent need for collaborations between researchers who do foundational materials science with those involved in developing monitoring, reporting, and verification protocols for potential carbon dioxide removal strategies.

Wednesday Morning, April 24, 2024
Room 326, Level 3, Summit

8:30 AM BI01.02.01
Interrogating the Effects of Neutron Activation on Noble Metal Nanoparticles Simon Scheel, Liane M. Moreau and Debashree Roy; Washington State University, United States

Gold nanoparticles are widely explored for applications in energy and medicine. One potential application of gold nanoparticles is the use of Au-198 nanoparticles as effective agents in prostate cancer therapy. One challenge to the synthesis of such nanoparticles is the high radioactivity and short half-life of beta-emitting Au-198 as a radiotherapeutic isotope. One solution towards generating Au-198-containing nanoparticles would be to use in-situ neutron activation of Au-197 nanoparticles. This would reduce the need to handle active material and open up options for the wide library of Au nanoparticle morphologies and ligand chemistries that have been developed. Unfortunately, to date, there is not a comprehensive understanding of how Au nanoparticles would behave in the high temperature high neutron-flux environment of a nuclear reactor. In our studies, we are looking at Au nanoparticle structure pre-

and post-irradiation within a nuclear reactor. We are using both morphology and local-structure techniques to evaluate the change in chemistry that occurs upon irradiation. In particular, SAXS and TEM will be used to analyze nanoparticle size and shape changes and XAFS and gamma spectroscopy will be used to characterize composition and local structure changes upon irradiation and beta decay of Au-198 into Hg-198.
As an LGBTQ-identifying researcher, I am deeply committed to fostering an inclusive and diverse environment within the STEM research community. It is crucial to acknowledge that embracing a broad spectrum of identities not only enriches the fabric of our scientific endeavors but also serves as a cornerstone for dismantling the challenges faced by LGBTQ+ scholars and other marginalized groups within this field. In the past, my identity has often left me feeling alienated and unwelcome in academic spaces. In primary and high school, I had to hide who I am and who I like. The schools were filled with bigotry towards the LGBTQ+ community, which left me not knowing if I was "normal" in comparison to others. This along with my parents being unsupportive of who I am made it hard for me to be excited about academia and STEM even though it's a passion of mine. In college, I have had to actively search for spaces that are explicitly LGBTQ+ friendly, which has allowed me to discover more about myself due to being able to be the true me in these situations. Luckily, in the Moreau group, I have found a scholarly space that is exceedingly accepting and inclusive of all identities. Inclusivity is more than a mere act of acceptance; it is the active cultivation of an environment where everyone can engage in their scholarly pursuits without fear of prejudice or discrimination. When the research community honors and respects the identities and experiences of all its members, it not only amplifies creativity and innovation but also empowers individuals to bring their authentic selves to their work. This authenticity, in turn, drives excellence and propels scientific progress.

8:45 AM *BI01.02.02
Modeling Small Polaron-Induced Ultrafast Ferroelectric Relaxation in $BiFeO_3$ Xiaosong Li[1] and Wei Xiong[2]; [1]University of Washington, United States; [2]University of California, San Diego, United States

In this report, we employed a combination of ultrafast spectroscopic techniques and high-level calculations to uncover the complex interplay between electronic and lattice degrees of freedom in a class of strongly correlated materials. Our observations revealed a transient reduction in the electronic dipole upon optical excitation, which then recovers on 0.5 and 10 ps timescales. Time-dependent density functional theory calculations show that both ligand-to-metal charge transfer and local excitation transitions can be excited. The transient EUV dynamics captured both ultrafast free charge carrier relaxation to excitons and polaron formation. Multireference configuration interaction calculations suggest that only polaron formation is associated with the 0.5 ps electronic dipole relaxation, while the faster electronic relaxation does not contribute to changes in ferroelectric properties. Our results decode the multi-degrees of freedom associated with this ultrafast ferroelectric modulation and pinpoint the critical motion—a local polaron formation—essential for rapid ferroelectric recovery. These findings offer crucial insights into the specific lattice distortions capable of modulating the properties or phase transitions of strongly correlated materials.

9:15 AM BI01.02.03
Elimination of Tg-Confinement Effects and a Recently Revealed, Technologically Important Interfacial Phenomenon in Styrene-Based Random Copolymers Containing 2-Ethyl Hexyl Acrylate John M. Torkelson; Northwestern University, United States

For two decades, i.e, slightly more than half of my professorial career, my research group has been interested in nanoscale confinement effects and the important roles of polymer interfaces, including the polymer-air interface or free surface, polymer-substrate interface, and polymer-polymer interface, on polymer dynamics. Much of this work has concerned confinement effects on the glass transition temperature (Tg) and physical aging. With ultrathin polystyrene (PS) films, the free surface plays a significant role in perturbing polymer chain dynamics, with Tg decreasing significantly with decreasing thickness below ~100 nm. Past studies by my research group have shown that changes to the PS chain architecture, from linear PS coils to cyclic PS chains with no chain ends, dense PS brushes, or PS bottlebrushes can eliminate the Tg-confinement effect in PS films as thin as ~15 nm. However, such unusual polymer architectures are unlikely to be mass produced or adopted at large scale because of complex syntheses and purifiction steps. Recently, we have demonstrated that such Tg-confinement effects can be eliminated in simple styrene (S)-based random copolymers containing very low levels (2 mol%, 6 mol%) of 2-ethyl hexyl acrylate (EHA). Related results are obtained with ultrathin films of 4-methyl styrene/EHA random copolymers. The special nature of the EHA comonomer is made evident by the fact that the elimination of the Tg-confinement effedt is not generalizable to n-alkyl acrylate comonomers, e.g., n-butyl acrylate and n-octyl acrylate. A study of the Tg-confinement effect in 98/2 mol% and 94/6 mol% S/EHA copolymers on both piranha-treated and dicholorosilane-treated silicon wafers indicates that hydrogen bonding plays no significant role in eliminating the effect. Instead, we find a strong correlation between Tg-confinement and fragility-confinement effects, indicating that the presence of the very low levels of EHA comonomer can substantially reduce fragility in bulk copolymer, which is correlated with packing efficiency of polymer chain segments. Our results indicate that the presence of as little as 2-6 mol% EHA comonomer can fundamentally alter chain packing efficiency and the effect of a free surface on the cooperativity of polymer segmental mobility. We hypothesize that the EHA units can interdigitate due to van der Waals interactions, thereby reducing bulk fragility and the fragility-confinement effect. Capitalizing on this, we will also discuss a very recently discovered interfacial behavior of EHA-containing copolymers that is of significant technological and commercial importance. Finally, a brief comment will be made on the long-standing diversity within the materials community.

9:30 AM *BI01.02.04
Intersecting Polymer Chemistry with Sustainability in Lignin-Derivable Macromolecular Systems Ty Christoff-Tempesta and Thomas Epps; University of Delaware, United States

The valorization of lignin-derivable (LD) small molecules to polymeric materials offers a promising avenue to reduce dependences on petrochemical feedstocks in material design. However, challenges in achieving semicrystallinity and material circularity of chain-growth, LD macromolecules have limited the practical application of lignin-based polymers. Here, we describe strategies to address these targets through considerations in LD monomer design. First, we demonstrate the development of LD vinyl monomers that can undergo living polymerizations to yield stereoregular, semicrystalline macromolecules. Tailored monomer design enabled polymerization under mild synthesis conditions and gave rise to desirable crystallinities and thermal properties in the resulting macromolecules. Then, we detail the development of advanced recycling methods to thermally deconstruct high-glass-transition temperature (> 100 °C) LD polymethacrylates to their constituent monomers in high yields and purities. Understandings of the thermodynamics and kinetics underlying depolymerization enabled bulk chemical recycling to monomers that were then upcycled to value-added polymers. The discoveries described herein offer pathways to broaden the application potential of LD macromolecules and design circular LD polymeric materials.

10:30 AM *BI01.02.05
Superconducting Thin-Films for Quantum Devices with Off-Line Quality Assessment Clara M. Barker, Finn Squires and Susannah C. Speller; University of Oxford, United Kingdom

Quantum computers are capable of high-speed calculations, far superior to modern supercomputers. The data of each strand of the calculation does not

need to be stored permanently, but challenges include maintaining the integrity of the data (coherence) for long enough for calculations to be performed with a low error rate. To increase coherence times to useful values for multi-qubit systems, research has focussed on the design of resonators and qubits, often overlooking the design of the materials used [1]. Smart materials selection and control of the chemistry and microstructure to optimise the Q-factor of the resonators (ratio of stored energy to input energy) and increase coherence times can help make superconductor-based quantum computers more viable. Most materials used in quantum circuitry are selected for ease and reliability of deposition of multi-layered JJ structures with reasonable superconducting properties. However, it is known that other materials may have better properties if they could be optimised. For example, control of deposition flux can affect the surface roughness of a material, a parameter that can increase surface resistance and reduce the Q-factor of a quantum resonator. The structure and chemistry of the material can also impact superconducting properties. For example, changes in crystal structure, degree of crystallinity, crystallographic texture and chemical composition can affect the critical temperature of the superconductor of the film. A systematic study of carefully controlled deposition properties, linking film growth and superconducting properties, would be invaluable for assessing alternative materials for quantum resonators.
In this presentation, the results of a thorough, systematic study of the growth of superconducting materials of merit for use in quantum circuits will be reported. This study links growth parameters, material properties and superconducting performance. Initially, metal thin films- specifically niobium and molybdenum - have been deposited using magnetron sputtering, with the aim of fully understanding the deposition window before moving on to more complex materials, such as alloys and nitrides. The thin films have been analysed using SEM, XRD, XPS and AFM to determine microstructural and crystallographic properties. Electrical transport measurements have been performed to determine room temperature resistivity, transition temperature and transition width, critical field and critical current. We also aim to present preliminary low temperature microwave measurements on resonator devices. Conditions for the growth of high-quality superconducting films will be identified and this presentation will explore any links between deposition properties and material properties, to assess whether high quality room temperature and low temperature properties can be used to predict ultra-low temperature performance of materials for quantum devices.

11:00 AM BI01.02.06
Modification of Perovskite Solar Cell Architecture to Increase Thermal and Mechanical Resilience Melissa Davis, Kelly Schutt, Duong Nguyen-Minh, Kaitlyn VanSant, Axel F. Palmstrom and Joseph Luther; National Renewable Energy Laboratory, United States

On the cusp of commercialization and market breakthrough, perovskite solar cells have emerged as a competitor to silicon technology. Their efficiency rivals commercial products and the decreased energy for production and overall cost give perovskite solar cells an edge. However, parts of this technology still require improvement, in particular addressing thier thermal and mechanical instability. These instabilities can give rise to device degradation. Comprehensive knowledge of these degradation mechanisms is required to address and solve these downfalls. In this research, we present the results of a myriad of tests, including water contact angle, kelvin probe, and double cantilever pull apart tests, designed to address these issues. As a result of the connection between instability and decreased performance, we have correspondingly altered the device architecture of standard p-i-n perovskite solar cells to improve performance. More specifically, thermal stability of devices was studied with the use of water contact angle and kelvin probe tests. Modified hole transport layers, or HTLs, were developed to ease delamination seen during tests due to thermal stress. The mechanical stability of devices was tested with double cantilever beam tests to determine mechanical weak layers. Additional modifications were added to the electron transport layers, or ETLs, to address the mechanical instability. With the adoption of these modifications within the HTL and ETL layers, this research introduces perovskite solar cells with improved thermal and mechanical resilience. These improvements will aid in this technology's path to commercialization.

11:15 AM BI01.02.07
Effects of Sulfonation Degree on Compatibility and Separation Performance of Polybenzimidazole (PBI)-Sulfonated Polyphenylenesulfone (sPPSU) Blend Membranes Siyum S. Beshahwored; National Taiwan University of Science and Technology, Taiwan

Industrial liquid waste is preferred to be recycled to sustain the ecosystem. Therefore, the development of polymer-blend nanofiltration membranes with good chemical resistance and molecular compatibility is crucial. In this presentation, the molecular compatibility between polybenzimidazole (PBI) and sulfonated polyphenylsulfone (sPPSU) and their blend membranes for herbicide removal in water reuse and for drug separation in organic solvent nanofiltration (OSN) has been investigated as a function of sulfonation degree in sPPSU. Flat sheet membranes cast from PBI-sPPSU blends with a mass ratio of 1:1 were prepared. At ambient temperature, portions of them were cross-linked using trimesoyl chloride (TMC). The blend made of PBI and 12.7 mol% sPPSU showed high compatibility based on the calculated enthalpy of mixing (ΔHm), measured dope viscosity, phase diagram, and single Tg. The TMC-modified membrane cast from this composition also exhibited higher chemical resistance, mechanical stability, narrower pore size and pore size distribution, a macrovoid-free structure, and better separation performance. All fabricated membranes were evaluated using feeds containing tetracycline (MW = 444 Da) as a model drug in ethanol and pendimethalin (MW = 281.3 Da) as a model herbicide in water. The cross-linked PBI-12.7 mol% sPPSU (12.7C) membrane exhibited rejections of >96% against low-molecular-weight pendimethalin from water and tetracycline from ethanol. It also has the capability to separate mixed solutes, even with small molecular weights. This study illustrates the effectiveness of highly compatible polymer blends with the aid of one-step cross-linking modifications for nanofiltration.

Keywords: Degree of sulfonation; Polymer blend compatibility; Single-step crosslinking; Drugs; Pesticides; Liquid nanofiltration

11:30 AM BI01.02.08
Teaching Density Functional Theory to Students of Art Conservation Joseph W. Bennett; University of Maryland Baltimore County, United States

As an assistant professor that identifies as LBGTQIA+ and is employed at a minority serving institution, I am well aware of the multitude of issues surrounding diversity, equity, inclusion at the university level. My chosen field in STEM is computational materials chemistry and an issue that plagues this field is diversity in students, specifically their identities and backgrounds. This is why I've spent 3 summers as an instructor for the Baltimore SCIART program, teaching computational methods to students interested in art conservation science. While many of the students in the program identify as LGBTQIA+, the majority of students that have learned to compute surface interactions are women. Funded by the Andrew W. Mellon Foundation, the Baltimore SCIART Consortium offers a 10-week summer research experience for undergraduate students at the interface between science and art and has been developed for students from Baltimore area academic institutions with a diverse background and strong interest in art conservation science and engineering. The development of density functional methods as a nondestructive probe to study works of art is still in its infancy and here, I will discuss aspects of our inclusive teaching pedagogy and our recent successes both computing surface interactions of objects important to cultural heritage and student outcomes.

SESSION BI01.03: Materials Research by the LGBTQIA+ Community and a Vision for Inclusivity III
Session Chairs: Ty Christoff-Tempesta and Alvaro Gallo Cordova
Wednesday Afternoon, April 24, 2024
Room 326, Level 3, Summit

1:30 PM BI01.03.01
A Tale from The Queer Resistance: Activism from with(in) Materials Science Jerry A. Yang and Eric Pop; Stanford University, United States

Broader sociopolitical movements toward inclusivity have brought attention to LGBTQIA+ issues in materials science, including the marginalization of LGBTQIA+ materials scientist professionals and students in the field. Previous work on LBGTQ+ students in engineering disciplines highlights the continued struggles for non-straight, non-cisgender people in STEM [1].

In this talk, I [JAY] present my current research in both materials science and engineering education while narrating my interdisciplinary journey straddling two vastly different fields of study. As a cisgender, gay, Asian-American man, my dual existence within both the materials science and engineering education research disciplines has given me unique insights into the nature of science and has substantially informed how I conceptualize equity and inclusivity in materials science.

My materials science work in two-dimensional (2D) semiconductors has shaped a large portion of my professional life. In my graduate studies at Stanford University, I currently study strain engineering 2D materials. With Prof. Eric Pop, my advisor, we have electrically and optically characterized the strain response of monolayer tungsten disulfide and molybdenum disulfide, demonstrating a ~2x improvement in electronic mobility for tungsten disulfide under ~0.3% biaxial tensile strain [2]. While my materials science work continues to satisfy me intellectually, my experimental work has often felt sterile compared to the complexities of my queer experience.

Engineering education research provides systems of thinking that enables me to deconstruct my experiences as an “outsider within” materials science [3]. In a recent study, I explored the experiences of LGBTQ+ undergraduate engineering students with a departmental survey (n = 854 students) and focus groups (n = 10). While the LGBTQ+ students in my study experienced tokenization, misgendering, and social ostracism, they found ways to actively combat these experiences and create their own supportive communities within engineering [4], [5]. With this work, I began to formulate my own understanding of inclusivity in materials science and leverage my position to advocate for queer issues. I continue my engineering education work alongside my materials science work through projects on queerness, race, and privilege in engineering education.

Before entering academia, I thought that my existences as a materials scientist, engineering education researcher, and resident gay were distinct, destined to never intersect. However, I have discovered that science is fundamentally a social endeavor, rife with the complexities of human social interaction. While using cleanroom tools may not directly summon my queerness, how I interact with my colleagues, how I present my work to my group, and how I communicate my work to the scientific community call for me to craft a professional image of myself – one that, for me, is fused with my gay identity.

I contribute my work and my story to argue for two key elements in a vision for inclusivity in materials science: first, to look beyond quantitative metrics for “diversity” and uplift the work that marginalized people are doing to resist systemic inequities, and second, to spark conversations with (queer) social justice scholars outside of materials science, who can provide valuable insight into the equity challenges facing the discipline. Inclusivity rests on recognizing both the existing climate and the agency that queer people hold in materials science and centering marginalized voices in materials science policy. I acknowledge support from the National Science Foundation Graduate Research Fellowship for this work.

1:45 PM BI01.03.02
Materials Science in The Anthropocene: Learning from Queer Advocacy William Livernois; University of Washington, United States

The Anthropocene [1], an epoch defined by human-driven planetary changes, beckons the materials science community to reconsider its role in shaping the world. [2] Although materials science offers potential sustainable solutions, the messages from both the scientific and activist communities are clear: the scale and timeline of a green transition must address the urgency of the climate crisis and the disproportionate impacts to frontline communities. [3] The queer community’s history of activism provides a blueprint of ways for materials scientists to engage in envisioning alternative futures, and the willingness to engage in transformative change. This talk will draw parallels between the messages of moral urgency from groups like Act Up during the AIDS crisis and messages of moral urgency from climate justice groups today. The theory of change of these groups will also be discussed, with the presenter drawing from personal experience as a queer scientist engaging in activism.

The "Materiality" of Sexual Orientation and Gender Identity to Materials Science: Exploring LGBTQ Participation in the Sciences Bryce E. Hughes; Montana State University, United States

In the realm of scientific pursuit, the prevailing notion often asserts that one's sexual orientation and gender identity are irrelevant—that the quality of scientific contributions is solely determined by an individual's skills and abilities. However, LGBTQ individuals exhibit a disproportionately higher attrition rate from the sciences when compared to their heterosexual and cisgender counterparts.
In this presentation, I will summarize my research on LGBTQ participation within undergraduate STEM (Science, Technology, Engineering, and Mathematics) majors. My research delves into various facets of this phenomenon, shedding light on how LGBTQ undergraduates find a sense of belonging within the heteronormative landscape of STEM disciplines. Additionally, my research investigates the influence of LGBTQ students' social networks on

their commitment to pursuing STEM majors as well as how identifying as LGBTQ shapes students' perceptions of future prospects within STEM careers. Collectively, these findings emphatically affirm that LGBTQ identities do, indeed, matter within the sphere of scientific endeavors. Moreover, this research underscores how the intricate interplay between different forms of privilege and oppression continues to structure participation in STEM fields in ways that impede the overarching goals of broadening participation in STEM. My talk will then conclude with concrete recommendations and take-aways to improve the climate within materials science as well as STEM broadly.

3:30 PM BI01.03.04
Designing Novel Materials for Energy Applications by Leading an Open-Minded and Diverse Research Group Edgardo Saucedo; Universitat Politècnica de Catalunya, Spain

The design of novel materials for energy applications, is a fascinating field that combines in equal parts knowledge in materials science, imagination, risk, and open mind to accept and adapt non-conventional ideas. In the first part of this work, a complete novel family of van der Waals materials based on pnictogen chalco-halides ((Sb,Bi)(S,Se)(Br,I)) will be presented, as an example of out-of-the-box compounds that in principle, does not fulfil the requisites to be excellent semiconductors for energy applications, but that in real are being revealed as very promising compounds. The most relevant non-standard properties of these materials will be presented for the first time, showing that non-conventional ideas can be widely accepted with the right approach. The versatility and adaptability of this family of materials will be described, as an example of how the diversity in materials science is very relevant for progressing in this field.
In the second part of this work, the development of these new family of materials will be compared, as an example, with my career in the materials science world, where being different has been always an extra motivation. I will explain how to be part of the LGBTQIA+ community has impacting in my research career from the very beginning, starting with my PhD, my postdoctoral experience abroad, and my consolidation as independent researcher, giving me an open mind character that I have also applied in my day-to-day work through the development of new materials. Currently, I'm leading a group of 20 very diverse scientists in Barcelona, working in the development of materials and devices for energy applications, from where I'm always very committed and proactive with the visibility of the LGBTQIA+ community, and where I have created a very safe space for the diversity. I will explain how I manage my visibility as LGBTQIA+ community member, considering that I have coordinated several big European Projects with consortiums including the most relevant academic institutions, and I'm granted with a European Research Council (ERC) Consolidator Grant, which has help me to consolidate my position as Group Leader. I will also explain my interaction with my students, my colleagues in my Institution, and with collaborators worldwide, and how I apply my commitment with the diversity and visibility of the LGBTQIA+ community in my life, helping me to progress as researcher, but more important, as human being.

* Invited Paper
+ JMR Distinguished Invited Speaker
^ MRS Communications Early Career Distinguished Presenter

SESSION BI02.01: Broadening Participation in Materials Research and STEM I
Session Chairs: Chartanay Bonner, Lisa Neshyba, Kristen Rahilly and Michael Scheibner
Thursday Morning, April 25, 2024
Room 326, Level 3, Summit

8:15 AM *BI02.01.01
Best Practices for Engaging HBCUs: Increasing URM Engagement in Materials Research Michael L. Curry[1] and Michael Schwartz[2]; [1]North Carolina Agricultural and Technical State University, United States; [2]University of Wisconsin–Madison, United States

Only 7.7% of Chemists and 4.4% of Engineers in the US are Black, even though greater workforce diversity drives innovation and contributes to America's economic power. This warrants the exploration of new partnerships and approaches to maintain our competitiveness in the marketplace. Since its inception, Historically Black Colleges and Universities (HBCUs) have contributed to the nation's scientific and technological dominance by producing exceptional talent and cutting-edge research. HBCUs have an unparalleled impact on the education and professional development of underrepresented minorities in

chemistry, engineering, and related fields. While African Americans comprise 9% of the STEM workforce, HBCUs produce more than 24% of Black STEM undergraduates & 30% of Black science/engineering doctorates. Hence, finding new and innovative ways to tap into the human potential of the nation's 101 Historically Black Colleges and Universities for mining and investment purposes is critical. In this discussion, we will explore best practices for partnering with HBCUs as a promising approach to increase broad participation in the Materials Research community.

8:45 AM BI02.01.02
When The University and City Hall Join Forces: The STEAM BSM_UPC Project Luis Carlos Pardo Soto[1], Artur Paz[1] and Alba Feria[2]; [1]Universitat Politècnica de Catalunya, Spain; [2]Barcelona de Serveis Municipals, Spain

Barcelona's iconic landmarks, including the Olympic Stadium, Gaudi's Park Güell, the Zoo, and the amusement park Tibidabo, serve as the backdrop for a series of STEAM activities that bring together 6,500 students from across the Barcelona metropolitan area every year. This ambitious project is made possible by the collaboration between the academic expertise of a public university like the Polytechnic University of Catalonia and the public enterprise B:SM, which oversees from Barcelona's parking system to the Zoo or the amusement park. During these events, students aged 10 to 18 engage in a range of experiments and scientific shows tailored to the unique characteristics of each location.

For example, at the Zoo, students explore life and the materials that constitute it, such as DNA and the energy-giving substances essential for life. At the Olympic Stadium, chemistry concepts are taught through an interactive show, and physics is demonstrated through a blend of a contemporary dance quartet and a scientist. In the amusement park, mobile phone sensors are utilized to investigate the movements and forces behind the rides. At the world-renowned Park Güell, we investigate how Gaudi used materials inspired by nature.

However, the project doesn't end with students. Every year, we organize training courses for teachers and public shows designed for a broader audience. These shows feature unique presentations, such as one conducted by a physicist and a violinist or a jazz band exploring the connection between music and mathematics.

Overall, this highly successful project is the result of researchers stepping out of their labs and engaging with a broad audience, and the willingness of the town hall to organize and support such impactful scientific activities.

9:00 AM BI02.01.03
Utilizing Cross-Program Collaboration to Sustain & Enhance STEM Outreach Portfolios Mark Licurse, Ashley Wallace and Eric A. Stach; University of Pennsylvania, United States

Effective management and growth of STEM outreach programs remains an ongoing challenge for many organizations and institutions. While the goals of broadening participation are clear and commonly shared, there is little established guidance on how to build and sustain a successful portfolio of programs. Newly funded initiatives, especially, face pressure to quickly establish programs to compete with more experienced organizations and centers but can often overwhelm limited staff. We have recently implemented an innovative model that engages participants as active contributors to improving and sustaining our portfolio of outreach programs. Rather than treating each program in isolation, this approach specifically utilizes the diverse experiences and skill sets of program participants to enhance the activities and objectives of other programs within the same portfolio. In doing so, we believe this allows for a more robust set of programs to be created and supported. We highlight how this model was implemented for three of our core programs: a summer research experience for undergraduates, a research experience for high school teachers, and a summer camp for high school students focused on materials science and engineering. The integration and exchange across programs provides benefits and extends beyond just the sharing of resources. It fosters an inclusive community in which participants contributions matter beyond just their own experience. While tested on materials research education and outreach programs, we believe this approach of utilizing participants' strengths to enhance a portfolio of programs could be applied to STEM outreach broadly across disciplines. Crucially, the model can be integrated into existing outreach efforts, leading to continuous improvement and increased impact over time.

9:15 AM BI02.01.04
The Emergence of Transdisciplinary Material Science in Diverse Applications: Towards The Development of Frameworks for Inclusive and Diverse Perspectives of Material Science Research and Education David Ryman[1], Saquib Ahmed[2,2] and Sankha Banerjee[1,3]; [1]California State University, Fresno, United States; [2]Buffalo State College, United States; [3]University of California, Davis, United States

The field of material science is undergoing a transformative shift towards transdisciplinary approaches, demonstrating its relevance in a variety of applications. This shift is paving the way for the creation of comprehensive frameworks that foster inclusivity and diverse perspectives in material science research and education. By embracing a transdisciplinary perspective, material science is adapting to the complex and interconnected challenges of our time, promoting innovation and sustainability in a broader range of applications. This abstract provides an overview of the evolving landscape of material science, highlighting the importance of inclusive and diverse frameworks to advance the field and meet the evolving demands of modern society.
The following work focuses on the transdisciplinary aspects of material science research and education in the areas spanning materials fabrication and their application in water treatment, biomedical devices, environmental impact, and economic assessment. It delves into the intersections of material science with these critical fields, emphasizing the need for a holistic understanding of materials' roles in addressing contemporary challenges. By examining materials science through the lenses of water treatment, biomedical devices, environmental sustainability, and economic evaluation, this work contributes to a more inclusive and diversified approach, fostering a more profound comprehension of the pivotal role materials play in our interconnected world. Moreover, this work extends its examination to the implementation of these approaches within the semiconductor industry. It sheds light on how these methodologies are being employed to enhance research, development, and education within this industry, ensuring the widespread dissemination of innovations and their potential to drive advancements in material science. By exploring the intersections of material science, using machine learning-based approaches, and diversity-related issues within the context of the semiconductor sector, this research contributes to a more inclusive, sustainable, and technologically advanced future.

9:30 AM BI02.01.05
How can TA Meetings Effectively Prepare TA Instruction? Eugenia S. Vasileiadou; Northwestern University, United States

A General Chemistry course consists of multiple components, amongst these are recitation and office hour sections. These sections are centered on enhancing students' conceptual understanding and honing their problem-solving skills. Even without the current realization of online teaching, these objectives require a skillful synthesis of technical and pedagogical planning. The goal of this project was to examine how teaching assistant (TA) meetings can effectively prepare TA instruction in General Chemistry discussion sections with inclusive practices, considering an online teaching environment. Firstly, the challenging areas of virtual TA instruction were probed. Subsequently, five quarterly objectives for the TA meetings were determined related to the pedagogical and learning needs TAs' reported. Accordingly, biweekly presentations serving the quarterly objectives were developed, containing pedagogical strategies and resources to aid TAs' preparation for effective and inclusive instruction. Following the biweekly presentations, TAs' completed

a reflection journal based on a survey format, where overall 4 journal entries were requested. The TA reflection journal inquired if TAs accomplished the learning objectives of the biweekly presentation, as well as it included space for TAs to generate prompts and questions for the next presentation. Importantly, the TA reflection journal incorporated demographic information of TAs, where no corresponding demographics of graduate students had been collected in our Chemistry department prior. Altogether, utilizing the collaborative and informative nature of the TA meetings to the highest extent, serves as a vehicle for the pedagogical development of TAs to make effective instructional decisions that result in enhancing student learning.

9:45 AM BREAK

10:15 AM ROUNDTABLE DISCUSSION

10:45 AM *BI02.01.06
Overcoming Technology Barriers and Incorporating Culturally Responsive Outreach in Materials Research Kyle Johnson[1,2] and Ngozi Ezeokeke[1]; [1]AVELA - A Vision for Engineering Literacy & Access, United States; [2]University of Washington, United States

In 2020, 11% of undergraduate students in the University of Washington's Materials Science and Engineering (MSE) department were from underrepresented minority (URM) backgrounds, with only 8% of graduate students in the department identifying as URM. In contrast, the URM population in Washington State was 21% in 2017, and 34% nationwide. High barriers of entry to the field of materials research limits who is learning about and gets involved in the field. For primary and secondary school students, these barriers include limited access to the expensive technologies required to perform materials research such as load frames, high magnification microscopes, and autoclaves. Not only is it difficult to have K-14 students engage with application or research-based material science lessons in primary or secondary school, but inequitable access to technology for Black and Latine communities are compounded by persistent economic challenges, social injustices, and human rights issues. We present sociotechnical access inequalities for Black and Latine urban communities, and our findings show that many students are hesitant to engage with already available technologies due to a lack of enticing support systems. We analyze the AVELA (A Vision for Engineering Literacy & Access) nonprofit's holistic student-led STEM engagement model leveraging near-peer mentorship, experiential learning, mentor embodied community representation, and culturally responsive lessons. Through 24 semi-structured interviews with college AVELA members, an analysis of 171 survey responses from AVELA's secondary school class participants, and an autoethnographic analysis we evaluate the model's impact on decreasing sociotechnical access inequalities. Using data from AVELA's 4 years of operation, where more than 200 university student instructors have taught to 2,500+ secondary school students in 110+ classrooms, we identify access barriers and provide principled recommendations for designing STEM education programs with a focus on materials science lessons and activities.

11:15 AM BI02.01.07
Experimenta con PREM: Outcomes and Best Practices from a Two-Decade Materials Research Summer Program for Underrepresented High School Students Idalia Ramos[1], Jose O. Sotero Esteva[1], Vibha Bansal[2], Francisco Bezares[3], Ezio Fasoli[1], Mark Licurse[4], Rolando Oyola[1], Nicholas Pinto[1], Juan Santana[2], Eric A. Stach[4] and Ashley Wallace[4]; [1]University of Puerto Rico at Humacao, United States; [2]University of Puerto Rico at Cayey, United States; [3]University of Puerto Rico at Mayaguez, United States; [4]University of Pennsylvania, United States

A long-standing partnership between the University of Puerto Rico (UPR) and the University of Pennsylvania (PENN) *Laboratory for Research on the Structure of Matter* aims at diversifying the materials research community by identifying and guiding students through a pathway from high school (and K-8) to STEM undergraduate programs, and then onto graduate school. The program is supported by the National Science Foundation *Partnerships for Research and Education in Materials* (PREM) program. The UPR-PENN PREM program targets women and students from disadvantaged backgrounds, such as low-income families, first-generation college students, and those living in geographically isolated areas in Puerto Rico, where the student population is approximately 99% Hispanic.
The *Experimenta con PREM* (ECP) summer program for high school (HS) students is a highlight of the UPR-PENN PREM. Since 2005, this two-week research experience has attracted talented students to materials research. The program started at the Humacao campus of UPR and extended to the Cayey campus in 2016. To date, approximately 400 students (68% women), from 34 towns and 59 schools in Puerto Rico have taken part in ECP. All of them graduated from high school, with 78% pursuing STEM fields.
ECP aims to foster scientific literacy and inquiry skills among students and inspire them to pursue research-oriented careers. The experience is expected to be like what they would face in a Research Experience for Undergraduates (REU), from the application process to presenting their findings. The program introduces materials science as a field that welcomes diverse interests and skills, such as materials characterization, devices, soft matter, crystals, and experimental and theoretical-computational methods. Nine UPR faculty mentors create laboratory experiences that are closely aligned with their own PREM research and that incorporate, within the time constraints, the relevant aspects of conducting research such as literature review, data collection and analysis, report, and final oral presentation. In the laboratories, HS students work in groups of up to 4 members with constant guidance from the faculty researcher and undergraduate PREM students.
Before the research experiences, the students participate in a series of workshops that help them develop soft skills that are essential for scientific research, such as diversity awareness, public communication, and laboratory safety. Additional training includes hands-on workshops on scientific writing, programming, and spreadsheet skills. The PENN partners actively contribute to the learning experience. Graduate students, post-docs and faculty members from PENN give talks, workshops and interact with the students on various topics related to materials science.
This presentation will cover the goals, components, and achievements of ECP, along with the challenges and lessons learned. We will discuss some of the best practices that emerged from our experience and how they can inform future initiatives in science education.

11:30 AM BI02.01.08
AfterSchool Academy and Teachers Camp for a Diverse Undergraduate Population Andre Schleife and Cecilia Leal; University of Illinois at Urbana-Champaign, United States

It is our goal to broaden participation in materials research starting from the undergraduate level and we particularly focus on increasing our number of students from all underrepresented groups. We find it challenging to accomplish this goal through traditional recruitment practices, including social media, email, and mail-based approaches. Our hypothesis is that we do not effectively reach our target population or reach them too late when they either have decided against college or for a different major. To mitigate this, we started pursuing a two-pronged approach reaching out to (i) high-school students directly through a newly established AfterSchool Academy and to (ii) high-school teachers by organizing a teacher's camp every summer, together with the ASM Materials Education Foundation. If successful, we envision to advertise materials research to a population of students that is still considering their college career and a population of high-school teachers that can inform students about materials research much earlier and more efficiently and deeply than mail or online campaigns. Our early success indicators are that participating students and teachers were very excited and engaged in the experimental activities and we envision to turn this into better, more diverse undergraduate enrollment over the next years. In this presentation details about both activities and their implementation from scratch will be discussed.

SESSION BI02.02: Broadening Participation in Materials Research and STEM II
Session Chairs: Chartanay Bonner, Lisa Neshyba, Kristen Rahilly and Michael Scheibner
Thursday Afternoon, April 25, 2024
Room 326, Level 3, Summit

1:30 PM BI02.02.01
Materials Science and Engineering Program Needs: Students! Thomas Stoebe; University of Washington, United States

Materials Science and Engineering is a multidisciplinary field that works between the physical and biological sciences, engineering and medicine. Engineering students sometimes have difficulty determining the difference between the many opportunities in MSE and the more well defined opportunities in other engineering areas. In particular, entering undergraduate students who see themselves focused on industrial jobs often choose other engineering departments over MSE because of perceived potential future jobs.
Materials engineering, which applies the principles of materials science to practical systems, devices and processes, is an area that Materials Science can be used to attract interest among students. This has been shown based on enhanced interest in both applied experiments and demonstrations used in high school classrooms, and in special programs and camp projects in many locales. These programs include
1. Technology education workshops for teachers
2. Science and technology curriculum development based on material science and engineering, and
3. After school activities such as designing and building a guitar
The National Resource Center for Materials Technology Education (MatEdU) has collected and developed resources that provided means for materials concepts to impact areas as diverse as electronics education and advanced manufacturing, energy and critical materials utilization. Such areas can be used to inform students of their prospects in MSE. These opportunities will be developed in this presentation. General reference www.materialseducation.org.

1:45 PM BI02.02.02
Design and Delivery of Low-Cost Science Laboratory Kits for Primary- and Secondary-Level Classrooms in Eastern Africa Jill Wenderott[1], Joyce Elisadiki[2], Julie Fornaciari[3], Danielle Butts[4], Cecilia China[5], Gloriana Monko[2] and Sossina M. Haile[6]; [1]Drexel University, United States; [2]University of Dodoma, Tanzania, United Republic of; [3]University of California, Berkeley, United States; [4]University of California, Los Angeles, United States; [5]Nelson Mandela African Institution of Science and Technology, Tanzania, United Republic of; [6]Northwestern University, United States

Only about 30% of women students in higher education globally select science, technology, engineering, and mathematics (STEM)-related subjects, with particularly low enrollment in engineering, manufacturing, and construction (8%) and in natural science, mathematics, and statistics (5%).[1] Improving this representation is a multi-faceted challenge. Women Supporting Women in the Sciences (WS2) has been focused on spurring K-12 girls' interests in STEM and promoting women scientists as mentors to younger students. With the support of a 2020 American Physical Society (APS) Innovation Fund,[2] WS2 spearheaded the Lab Kit Initiative during which low-cost materials science and physics laboratory kits for K-12 students were designed and distributed to schools in eastern Africa. During the design phase, seven international teams composed of 59 volunteers (over 70% women) created 3 lab kits for primary level students and 4 lab kits for secondary level students on the topics of food science, electrostatics, light and color, and energy transfer. A key feature of the lab kits is the use of easy-to-source supplies to ensure low-cost and wide accessibility. Working with eleven partners in Ethiopia, Kenya, Rwanda, Tanzania, and Uganda, WS2 provided lab kits that engaged over 5100 students at over 40 school sites in hands-on science learning, with 62% being girls. This talk will discuss the outcomes of the Lab Kit initiative which concluded in early 2023 and future endeavors in which WS2 has been involved that are broadening the reach of our lab kits.

Women Supporting Women in the Sciences (WS2)[3] is an international organization unifying and supporting graduate and professional-level women and allies in STEM.

2:00 PM BI02.02.03
More Inclusive Q&A Sessions Will Lead to Better Science Christopher Rom; National Renewable Energy Laboratory, United States

Traditional question and answer (Q&A) sessions are a sub-optimal use of conference time because they do not engage the full audience. Since 2017, several studies in a range of academic disciplines have identified that women are under-represented among question-askers after scientific talks. Insufficiently inclusive Q&As leave thought-provoking questions un-asked, meaning our communities miss out on ideas worth hearing. Throughout my PhD and into my postdoc, I have collected data on question asking behavior at the conference talks I attended (ceramics, materials, and solid-state chemistry, broadly speaking), revealing that this disparity is present in our community too. Fortunately, prior research shows that merely discussing this trend can help balance Q&A sessions. In this presentation, I will summarize existing research on gender equity in Q&A sessions, present my own data relevant to the MRS community, and describe preliminary results from possible alternative Q&A formats. This work will spark conversations around how to structure our scientific talks to better foster learning and collaboration, boosting our ability to conduct cutting edge science.

2:15 PM BI02.02.04
Computational Course-Based Undergraduate Research Experience (CURE) for Condensed Matter Physics David A. Strubbe[1] and Enrique Guerrero[1,2]; [1]University of California, Merced, United States; [2]California State Polytechnic University, Humboldt, United States

Course-based Undergraduate Research Experiences (CUREs) are a way of bringing the excitement of research into the classroom and potentially reaching more students and reaching them earlier in their studies than would happen with the typical summer research experience or senior thesis project. Key aspects are of a CURE are: students learn and use research methods, give input into the project, generate new research data, and analyze it to draw conclusions that are not known beforehand. I will show a paradigm for a computational CURE in an undergraduate/graduate condensed matter physics class at the University of California, Merced. It is based on computational studies with density functional theory, provided by a convenient GUI tool on nanoHUB (https://nanohub.org/tools/ucb_compnano) that we co-developed which requires minimal computational skills. After preparatory exercises, students calculated structures, energies, and Raman spectra of different structures and compositions of a monolayer alloy $MoS_{2x}Se_{2(1-x)}$. They followed a defined protocol to contribute to a novel class dataset which they analyzed, and also calculated an additional property of their choice in consultation with the instructor. Studies show that CUREs improve learning, foster a sense of belonging in the field, increase retention of students in science (including going on to do summer research), and are especially beneficial for minoritized/underrepresented students such as at a Hispanic Serving Institution like UC

Merced.

2:30 PM BREAK

3:00 PM BI02.02.05
Designing Inclusive Research Experiences for Undergraduates Rajan Kumar; Northwestern University, United States

Research Experiences for Undergraduates (REU) programs are a key driver for broadening participation in materials research. Every year, over 100 REU sites offer essential opportunities for students to gain hands-on exposure to materials research and develop technical skills that extend beyond the classroom. Furthermore, several of these programs aim to increase access to materials research for underrepresented students in order to help diversify academia and other research disciplines. But with increasing participation, how do we tailor REU programs to benefit students from all backgrounds? And how can we provide research opportunities that actually promote continued interest in STEM careers? In order for REU programs to have an ever greater impact, we need to focus on designing inclusive research experiences that support all students and foster a sense of belonging in materials science and engineering.

In this talk, I will introduce a template for designing inclusive undergraduate research experiences as demonstrated through the Stanford Materials Science and Engineering REU Program. Overall, our goal is to help undergraduates self-identify as materials scientists and engineers in order to encourage broader participation in STEM careers. Several important components of the REU Program will be described to identify best practices that promote positive outcomes in undergraduate research experiences, regardless of student background or preparation level. These components include program recruitment and selection, research project design, mentorship training, student programming, and program evaluation. Specific efforts related to research and communication skill development, career guidance, and community-based mentorship will also be discussed along with key outcomes from these initiatives.

3:15 PM *BI02.02.06
Empowering Diversity: Inclusive Strategies in STEM Education Debora Monego[1,2]; [1]Heidelberg Institute for Theoretical Studies, Germany; [2]Heidelberg University, Germany

In Materials Science and other STEM fields, the inclusion of diverse perspectives is more than just an added advantage, it is a necessity. Drawing from my experiences as a first-generation Latina teaching science at Columbia University, my talk will focus on fostering strategies for inclusive teaching, enhancing a sense of belonging, and empowering students to take agency in their STEM education. Practical tactics for curriculum design will be highlighted, along with discussions on challenges faced by students from underrepresented backgrounds. The goal is to craft a more inclusive environment that resonates with every student's unique journey in STEM.

3:45 PM ROUNDTABLE DISCUSSION

SESSION BI02.03: Poster Session: Broadening Participation in Materials Research and STEM
Session Chairs: Chartanay Bonner, Lisa Neshyba, Kristen Rahilly and Michael Scheibner
Thursday Afternoon, April 25, 2024
Flex Hall C, Level 2, Summit

5:00 PM BI02.03.01
Integrating Art in Materials Science Education: An Interdisciplinary STEAM Course on Metal Craft for Engineering Students In-Suk Choi and Bog-Ki Min; Seoul National University, Korea (the Republic of)

We introduced an innovative interdisciplinary STEAM course for undergraduates in collaboration with the College of Fine Arts, titled “Metal Craft for Engineering Students.” Designed for freshmen, this course enables students to create their own metal crafts under the guidance of Fine Arts professors. Although most participants were new to hands-on activities, they engaged in metal craftwork such as casting, hammering, and polishing, all while utilizing CAD/CAM programs for design. In conjunction with the practical craftwork, introductory lectures on physical metallurgy topics like hardening, annealing, and dislocation were delivered, contextualizing the applied theories. This hands-on approach allowed students to directly observe material thermodynamic and deformation phenomena. By melding fabrication techniques with scientific principles, the course offers a comprehensive understanding of materials science. Feedback has shown high student satisfaction, underscoring our belief that the course not only broadens perspectives but also ignites an interest in multidisciplinary research. Notably, it fills a critical void for materials science students who typically lack hands-on fabrication experience due to a curriculum predominantly focused on analysis, characterization, and theoretical modeling.

5:00 PM BI02.03.02
Broadening the Participation in Materials Research by Creating Science Identity using Near Peer Mentoring Mary Sajini Devadas, Jim Coombs and Ellen Hondrogiannis; Towson University, United States

Science/STEM identity” is the sense of who students are, what they believe they are capable of, and what they want to accomplish with respect to science by interacting with others in the field. This requires intervention to help the “socializers” (i.e., STEM faculty and UGs) better understand the value and purpose of science literacy themselves so as to encourage students to appreciate science, be aware of possible career options in science, and enjoy learning and doing science. The project involves building “*science identity*” via the active involvement of Towson University’s (TU) undergraduate student researchers (UG) in 1) engagement in research with the high school (HS) recruits through the apprenticeship model, 2) outreach activities in local high schools. This results in science identity among undergraduate and high school students as they assist in workshops and internships (where they carry out authentic research) involving synthesis and characterization of nanoparticles. Through surveys collected, we show that we have built science identity and broadened the participation in student participants and in the near-peer mentors. The retention of students in STEM using this method will be discussed.

5:00 PM BI02.03.03
Bridging the Gap: A Case Study to Broadening Participation in Materials Research through Community Outreach and Education Edgar Mejia[1], Tiara Torres-Flores[1], Zina Medina[2], Zhang Zhang[1] and Nancy R. Sottos[1]; [1]UIUC, United States; [2]University of Puerto Rico at Mayagüez, United States

In the pursuit of broadening participation (BP) in Materials Research (MR) and STEM, conventional methods have often been insufficient in creating a lasting impact. This poster presents an innovative, multifaceted outreach program targeting K-5 Spanish-speaking students. The program, titled "El Verdadero Valor del Plastico (The True Value of Plastic)," serves as a case study for sustainable and effective MR outreach.

In alignment with the symposium's goals, our initiative explores the intersectionality of MR and BP by:
■ Designing workshops and demonstrations centered on plastic recycling.
■ Evaluating the needs of underrepresented communities to bridge gaps in scientific exposure and representation.
■ Customizing workshop materials to suit diverse audiences.
■ Scaling the initiative by training additional facilitators to conduct similar workshops.

Our pedagogical approach combines hypothesis-driven lessons with interactive instruction and collaborative learning, all reinforced by scientific curiosity and family engagement. Drawing inspiration and collaborating with the "Cena y Ciencias" bilingual elementary program, we offered hands-on experiences, such as transforming plastic milk jugs into coasters.

The program successfully engaged the local Spanish-speaking community, increasing awareness of the plastic waste crisis. To gauge the comprehension levels of both children and their parents, we administered a questionnaire before and after the workshop was presented. Our initiative stands as a blueprint for the effective blend of MR and BP agendas, tackling the unequal distribution of opportunities for women and other minority groups. By disseminating our best practices, we aim to contribute to the symposium's overarching objective of fostering a collaborative network committed to broadening participation in the materials science field.

5:00 PM BI02.03.04
Elementary Arts Lab: Building a Community of Scientists, Artists and Educators to Impact Local Elementary Education Elizabeth K. Allan-Cole[1], Emma Antonio[1,1], Katarina Lott[1], Thomas P. Chaney[1], Lacey Roberts[1], Andrew J. Levin[1], Mary Powell[2] and Michael Toney[1]; [1]University of Colorado Boulder, United States; [2]Boulder Valley School District, United States

Elementary Arts Lab is a group of artists, scientists and educators who are passionate about cultivating enthusiasm and curiosity for how we explore and interact with the world around us. We work with K-12 schools to develop and deliver curriculum that integrates movement, art and music with the physical sciences. We aim to educate and inspire children and ourselves while challenging the stereotypes of scientists and artists. Our approach uses the concept of integrated learning, or the process of making connections between multiple concepts and topics and using experience-based learning [1]. Integrated learning plays on the idea that when you experience something you are more likely to internalize the concepts you were aiming to learn [1]. Our primary aim is to create a long-term network between educators, scientists, and artists and through this network create arts-based science resources for elementary school teachers and their students.

We began our journey in 2020 at the height of the pandemic, working virtually with University Hill Elementary School in Boulder. We started with eight CU Boulder graduate students, a post-doc, and two elementary school educators, an art and music teacher, in our first phase. Together, we built science lessons for third graders that we communicated through art, dance, and music. Our initial endeavor demonstrated that students were learning and starting to internalize the science concepts we were communicating [2]. Our first expansion included building off the fourth-grade curriculum in the Boulder Valley School District (BVSD) and implementing our work at a larger scale by making lesson plans that were available to all BVSD school teachers [2]. We also worked with a class at Heather Wood Elementary School during this time and doubled our CU Boulder student involvement as well as started to incorporate undergraduate students in both science and arts. Our current phase implements continuing education for current Denver Public Schools (DPS) elementary school teachers. We work directly with DPS teachers throughout a full school year in multidisciplinary diverse teams to build integrated learning lesson plans based on class curriculum. By supporting this approach and maintaining a long-term relationship with these teachers we can indirectly impact all the students that they teach throughout their career. We have worked with more than 10 DPS teachers and have now brought in more than 50 CU Boulder graduate and undergraduate students in arts, science, and education working as a network to impact more than 350 elementary school students to date in Colorado.

Beyond our direct impact, we also aim to combat the image of a scientist or engineer for these students. We aim to bring together a diverse community and show students on classroom visits that they, too, can become scientists.

Multimodal Core-Shell Nanocomposites for Biomedical Applications Munirah Ghariani[1,2,3], Caroline O'Sullivan[1] and Yurii K. Gun'ko[1,2,3]; [1]Trinity College Dublin, Ireland; [2]Advanced Materials and Bioengineering Research (AMBER), Ireland; [3]Science Foundation Ireland (SFI), Ireland

Multimodal nanomaterials are an important class of materials in the rapidly developing field of nanoscience. These nanomaterials have deserved a lot of attention due to their wide variety of applications including targeted cell drug delivery, biomedical imaging and cell labelling.[1] The main aim of this project was to develop new magnetic metal carbonate core-shell structures for potential biomedical applications. Calcium carbonate ($CaCO_3$) and magnetite (Fe_3O_4) were chosen as the functional materials for this research, thus combining the modalities of biocompatibility and magnetisation.[2,3]
Magnetic nanoparticles (NPs) have been prepared by a precipitation approach using both Fe^{2+} and Fe^{3+} salts as iron precursors in the presence of poly(sodium styrene sulfonate) (PSS). These stabilised NPs exhibited high monodispersity and stability making them ideal for further functionalization. For the very first time, the PSS-Fe_3O_4 NPs were encapsulated into $CaCO_3$ shell by a novel dry ice carbonation method resulting in distinctive morphological structures.
The new composites were loaded with a specific cationic dye as a model to investigate their potential drug uptake and release processes. The testing was monitored using UV-Vis spectroscopy.
This research opens up a route to new multimodal nanomaterials with unique properties making them of great interest.

Enhanced Immobilization of EDTA on Graphene Oxide Sponge by Siloxane Bridge for Multi-Pollutants Removal in Wastewater Yi-Ting Lai[1,1,1], Chen-Jie Liao[1], Dhanaprabhu Pattappan[1], Da-Wei Huang[1], Yu-Chin Liao[1], Yu-Hsuan Huang[1], Shu-Jun Lu[1], Po-Chun Hsu[2] and Ching-Lung Chen[1]; [1]Ming Chi University of Technology, Taiwan; [2]The University of Chicago, United States

This work developed an ethylenediaminetetraacetic acid (EDTA)-modified graphene oxide (GO) sponge to remove multi-pollutants in wastewater. During the grafting of the silicon-based EDTA (EDTA-Si) on the GO sponge, the abounded functional groups on the GO surface can interact with silane groups to form silane-bridging by removing water molecules. Thus, the silanol molecules can anchor EDTA-Si on the surface of GO, leading to stable adhesion toward the GO sponge. This proposed EDTA-Si/GO sponge can not only adsorb and chelate various heavy metals in wastewater but also degrade organic dyes by producing super radicals. This work provides a facile and eco-friendly strategy to remove heavy metals and organic pollutants in wastewater to achieve the availability and sustainable management of water with industrial applicability.

5:00 PM BI02.03.09
The Effects of Substrate Growth on VS_2 by Chemical Vapor Deposition Clara L. Jackson[1], Kedar Johnson[2], Elycia Wright[1], Selena Coye[1], Indika Matara Kankanamge[1] and Michael Williams[1]; [1]Clark Atlanta University, United States; [2]Morehouse College, United States

Vanadium disulfide (VS_2) has grown popular for its potential applications in energy storage and renewable energy due to its thin layered structure, metallic conductivity, and ability to form highly crystalline structures. Our research focuses on investigating the impact of vanadium disulfide growth on various substrates, such as sapphire, silicon oxide on silicon (SiO_2/Si), and gallium oxide (Ga_2O_3), using the chemical vapor deposition (CVD) technique. Furthermore, the research aims to identify the optimal growth parameters, including growth temperature, and carrier gas flow rate for each substrate to achieve a large coverage film. To achieve this, we use the carrier gases (Ar, Ar + H_2) while implementing the growth temperatures of VS_2 during the sample growth. We will measure the resulting materials using spectroscopic probes like photoluminescence, Raman, Fourier transform infrared (FTIR), and confocal laser optical microscopy to examine the surface morphology, structural quality, absorption, and reflection of materials.

5:00 PM BI02.03.10
Comparison of Seeding Promoters in Growth of Tungsten Disulfide by Chemical Vapor Disposition. Kedar Johnson[1,2], Clara L. Jackson[2], Elycia Wright[2], Selena Coye[2], Indika Matara Kankanamge[2] and Michael Williams[2]; [1]Morehouse College, United States; [2]Clark Atlanta University, United States

Seeding promoters have been utilized to facilitate the growth of transition metal dichalcogenides via chemical vapor deposition (CVD). The choice of seeding promoter can significantly impact the resulting film's properties, including its crystallization, growth area, phase, and composition. Our study will investigate the effects of different seeding promoters on tungsten disulfide (WS_2) growth on sapphire, which is known to be challenging to control in terms of layer area, quality, and thickness. The seeding promoters we will be using in our study are sodium chloride (NaCl), zinc oxide/zinc sulfate ($ZnO/ZnSO_4$), and sodium sulfate ($NaSO_4$). We will analyze the effect of each seeding promoter on the properties of WS_2 to determine their correlation and identify the best promoter for future growth. To analyze the properties of WS_2films, we will use confocal laser microscopy, photoluminescence spectroscopy (PL), Raman spectroscopy, Fourier transform infrared microscopy (FTIR), and x-ray photoemission spectroscopy (XPS). Our focus will be on studying these films' photoluminescence, absorption, layer thickness, impurity, optical phonon modes, and bandgap.

5:00 PM BI02.03.11
RAFT Iniferter Photopolymerization of PNIPAM based Block Copolymers Fabian Rodriguez; The University of Texas Rio Grande Valley, United States

Poly(N-isopropyl acrylamide) (PNIPAM) has been studied for various biomedical applications such as drug delivery, wound dressings, and, specifically, sensing via hydrogels due to a characteristic phase transition around 32°C. Previous work focused on the fabrication and characterization of PNIPAM based microfibers. The fibers were subsequently processed into a fibrous hydrogel to be used as biosensor. The fibrous structure was maintained as it functions as an avenue to improve the sensitivity of the biosensor by increasing the surface area. Current work focused on improving the viscoelastic behaviors of the hydrogel through the synthesis of block copolymers (BCPs) containing PNIPAM. These BCPs were synthesized using photo reversible addition-fragmentation chain transfer (RAFT). While RAFT is a commonly used controlled polymerization technique, photoinitiated RAFT can yield polymers with ultra-high molecular weights and can be performed under mild conditions. Therefore, photoinitiated RAFT is promising for synthesizing polymers ideal for ultra-thin fibers and hydrogels due to enhanced viscoelastic and mechanical properties. Alongside PNIPAM, the highly hydrophilic poly(N,N-dimethyl acrylamide) (PDMA) is a promising candidate as a stabilizing block since it improves the mechanical properties of hydrogels. A compact UV setup was implemented using a commercially available nail curing device, while also varying the distance between the reaction/light bulbs, and the light intensity through the number of said bulbs. The methodology was optimized using common lab equipment to enable widespread implementation. The physical setup was kept intentionally simple with the intent to allow small undergraduate institutions and even high schools to perform polymer synthesis, while maintaining a level of scientific refinement via the use of photo-iniferter RAFT. This project offers an avenue to broaden participation for young students and researchers to engage with and contribute to materials research by validating the potential of using commercially available equipment.

Photoinduced Modulation of an Excitonic Resonance Coupled to Coherent Optical Phonons and The Role of Dynamical Screening in a Layered Semiconductor Selene Mor[1,2], Valentina Gosetti[1,2], Alejandro Molina-Sanchez[3], Davide Sangalli[4], Simona Achilli[4] and Stefania Pagliara[1,2]; [1]Università Cattolica del Sacro Cuore, Italy; [2]Interdisciplinary Laboratories for Advanced Materials Physics (I-Lamp), Italy; [3]University of Valencia, Spain; [4]Università degli Studi di Milano, Italy

The ultrafast light-matter interactions in semiconductor materials are intensively studied due to their technological relevance in the field of, e.g., photovoltaics or data processing. The elementary photoexcitation of a semiconductor is the formation of an electron-hole pair, called exciton, as a result of the weak screening of the Coulomb interaction between the electron and the hole. The coupling of excitons with other excitations like, e.g., lattice vibrations (phonons) plays a pivotal role on the nonequilibrium optical properties of semiconductors, eventually governing their optoelectronic functionalities. However, how exciton-phonon coupling manifests in the time and energy domains has raised an active debate between experiment and theory in the last years [1]. Moreover, the effect of dynamical screening, i.e. of transient changes in the screening by the photoexcited quasi-free carriers, on the coupling of excitons to phonons has remained elusive. These open questions represent a forefront fundamental research challenge in semiconductor optics and an essential step toward the development of novel protocols for optoelectronic applications.
Layered semiconductors formed by van-der-Waals stacked atomic planes offer a great quantum materials platform for the study of coupled dynamics with accessible and technologically relevant energy and time scales. The quantum space confinement of mobile carriers reduces the dielectric screening, stabilizing the excitons and favoring their coupling to lattice vibrations [2].
In our work, by means of ultrafast broadband optical spectroscopy combined with ab-initio calculations of the layered semiconductor bismuth triiodide (BiI_3), we set the spectral fingerprints for the optical detection of exciton-phonon coupling in van-der-Waals layered semiconductors [2]. Our joint experimental and theoretical effort allows us to unravel the impact of exciton-phonon coupling by microscopically relating a photoinduced coherent energy modulation of the excitonic resonance to coherent optical phonons. This further enables us to track the extent of the photoinduced atomic displacement in real space with unprecedented subpicometer resolution. These findings eventually solve the debate between experiment and theory on the spectral evidences of exciton-phonon coupling, and establish the role of exciton-phonon coupling on the ultrafast exciton dynamics.
Further, we address the effect of dynamical screening on the exciton-phonon coupling in BiI_3 [3]. To this goal, we investigate the ultrafast broadband optical spectroscopy under excitation condition either resonant or off-resonance with the excitonic resonance in order to either exclude or enable the excitation of a population of quasi-free carriers. We find evidences that that the dynamical screening breaks the coupling of excitons to coherent optical phonons, thereby hindering the photoinduced modulation of the excitonic resonance.
Finally, these complementary works move a step forward in the detection of many-body couplings in layered materials by ultrafast optical spectroscopy, paving the way to optical control of an excitonic resonance on the picosecond timescale.

Temperature-Dependent Phonons and Photoluminescence of WS_2 Monolayer to Bulk rown by CVD. Selena Coye[1], Kedar Johnson[2], Indika Matara Kankanamge[1] and Michael Williams[1]; [1]Clark Atlanta University, United States; [2]Morehouse College, United States

WS_2 is a layered material with unique band gap properties, making it highly promising for developing advanced electronics and optical devices. While bulk WS_2 has an indirect band gap in the near-infrared, monolayer WS_2 has a direct band gap in the visible spectrum. The optical and bandgap characteristics of WS_2 can be temperature dependent. Understanding the temperature-dependent phonon properties of materials is crucial for managing heat in electronic devices, as they impact thermal properties and scattering effects. In addition, self-heating can alter the vibrational properties of WS_2 layers, and the way electrons and phonons interact. Further, understanding the temperature-dependent A and B excitonic peaks is significant in device applications. Temperature-dependent photoluminescence and Raman spectroscopy can be utilized to identify these materials' different optical transitions and phonon properties. In this study, we will present a systematic analysis of temperature-dependent bandgap, optical transitions (including A and B exciton), electron-phonon coupling, and strain effect of WS_2 grown by chemical vapor deposition. The layers will be analyzed using photoluminescence and Raman spectroscopy techniques.

10:50 AM BI02/MT01/QT01/QT04.04
Quantum Machine Learning for The Synthesis of Photocathodes by Epitaxial Growth Salil Bavdekar, Jason B. Gibson and Richard Hennig; University of Florida, United States

We present a high-throughput, material-agnostic strategy to study promising new photocathode materials for their epitaxial growth. Cs_3Sb films grown on 3C-SiC(100) substrates with molecular beam epitaxy (MBE) display lattice parameters intermediate to fully epitaxial layers and bulk structures, indicating partial relaxation at a thickness of only 38 Å. The surface phase diagrams and structures for monolayer thin films of epitaxial Cs-Sb photocathodes on SiC substrates have been predicted using a genetic algorithm (GA) coupled with density functional theory (DFT) calculations. This information helped identify the experimental growth conditions for uniform and stoichiometric films and possible surface reconstructions. However, the computational cost of DFT calculations limits the study to a single monolayer, and the nucleation and growth of these films cannot be studied with this method.

Hence, we employ machine learning accelerated GA simulations to predict complex surface structures with larger in-place unit cells and increasing film thickness to model the transition from monolayer to bulk. Following this, the growth of Cs-Sb layers on (100) and (001) 3C-SiC substrates is studied with exascale molecular dynamics (MD) simulations. Our atomistic modeling aims to elucidate the structural transition from potentially epitaxial monolayers to bulk structures and identify structures, nucleation mechanisms, and film growth processes on (100) and (001) 3C-SiC substrates. The GA and MD simulations are powered by machine-learned ultra-fast force fields (UF^3) trained on the data from the previous GA/DFT studies, greatly reducing the computational cost. The resulting structures obtained from the simulations are compared with experimental XRD and RHEED patterns, and the structural energies provide the basis for a thin-film phase diagram.

While the work here is presented for Cs-Sb films on a SiC substrate, the framework can be applied to any material system to create similar phase diagrams. These phase diagrams, along with kinetic information gleaned from the molecular-dynamics simulations, can help identify optimal experimental processing conditions during MBE growth and guide the selection of other materials systems.

11:05 AM BI02/MT01/QT01/QT04.05
Data-Driven Discovery of Dynamics from Time-Resolved Coherent Scattering Nina Andrejevic, Tao Zhou, Qingteng Zhang, Suresh Narayanan,

Mathew Cherukara and Maria K. Chan; Argonne National Laboratory, United States

Coherent X-ray scattering (CXS) techniques, including X-ray photon correlation spectroscopy (XPCS), play a critical role in the investigation of mesoscale phenomena evolving at time scales spanning several orders of magnitude. However, obtaining accurate theoretical descriptions of complex dynamics is often limited by one or more factors – the ability to visualize dynamics in real space, computational cost of high-fidelity simulations, and accuracy of approximate models. Here, we aim to bridge the gap between theory and experiments by extracting mechanistic models of dynamics directly from CXS data. To do so, we develop a data-driven framework which employs neural differential equations to parameterize unknown real-space dynamics and a computational scattering forward model to relate real-space predictions to reciprocal-space observations. This framework is shown to recover dynamics of several computational model systems, including domain synchronization, particle clustering, and source fluctuation, under various simulated conditions of measurement resolution and noise. We further demonstrate the practical application of this approach in the context of two proof-of-concept experiments. Our framework represents a general and versatile platform to discover dynamics from time-resolved CXS measurements without solving the phase reconstruction problem for a complete time series of diffraction patterns.

11:20 AM BI02/MT01/QT01/QT04.06
Pressure-Dependent Thermodynamics of Cubic Lu-H-N Solid Solutions by First-Principles Calculations and Graph Neural Networks Pinwen Guan, Matthew Witman, Catalin Spataru, Vitalie Stavila and Peter A. Sharma; Sandia National Laboratories, United States

Metal hydrides are an important class of materials with high scientific significance, finding applications in various fields such as hydrogen storage, batteries, gas sensors, nuclear reactions and high-temperature superconductivity. Pressure, among others, is an important variable to control their properties. Previous computational studies of metal hydrides under high pressures usually treat them as stoichiometric compounds, without lattice disorder considered. However, when pressure becomes more moderate, lattice disorder gets more significant, as shown in the recent claimed room-temperature superconductor at near-ambient pressures, N-doped Lu hydrides, where three constituents (hydrogen, nitrogen and vacancy) have disordered occupancies in the tetrahedral and octahedral interstitial sites in the fcc Lu lattice. To consider lattice disorder dependent on pressure, in addition to other variables including temperature and composition, first-principles calculations are computationally demanding. In this work, a model of the cubic Lu-H-N solid solutions is developed by combining first-principles calculations and lattice graph neural networks to learn pressure-dependent thermodynamic quantities in the configurational space, and composition-pressure-temperature phase diagrams are derived to describe the relationship between the synthesis conditions and the resulted phase equilibria. This work can improve the thermodynamic understanding of the Lu-H-N system and help rational synthesis of N-doped Lu hydrides, as well as demonstrate an efficient approach to model pressure-dependent thermodynamics of multi-component solid solutions.

Biodegradable Luminescent Porous Silicon Nanoparticles in Cancer Diagnosis and Therapy Liubov A. Osminkina[1,2]; [1]Lomonosov Moscow State University, Russian Federation; [2]Institute of Biological Instrumentation, Russian Academy of Sciences, Russian Federation

The development of new intelligent drug delivery systems to overcome unwanted side effects and maximize the therapeutic effectiveness of chemotherapy for cancer diseases is one of the main tasks of modern medicine. Active research is being conducted to explore various nanosized drug carriers (nanocarriers) for these purposes.
The use of porous silicon nanoparticles as the basis for nanocarriers is due to the unique properties of these solid-state nanomaterials, such as high biocompatibility [1] and complete biodegradability into non-toxic silicic acid [2]. The porous structure of the nanoparticles, with porosity values reaching up to 80% of their volume, provides a high drug-loading capacity for efficient drug delivery [3]. The simplicity of surface modification methods for the nanoparticles enables specific targeted delivery of various hydrophobic and hydrophilic drugs, radiopharmaceuticals, proteins, peptides, RNA, etc. into cells.
The presence of efficient luminescence in porous silicon nanoparticles allows their utilization as contrast agents for bioimaging of cells and tissues [5]. The properties of porous silicon nanoparticles, acting as photosensitizers [6], sensitizers of high-frequency electromagnetic fields [7] and therapeutic ultrasound [8], provide them with therapeutic functions and the potential for stimuli-triggered drug release from the nanopores of nanocarriers.
The research is supported by Russian Science Foundation Grant No. 24-45-20009.

Ultrasound-Guided STING Activation by Nucleotide Nanocomplex-Decorated Microbubbles for Cancer Immunotherapy Sina Khorsandi[1], Xuefeng Li[2], Yifan Wang[2], Kristin Huntoon[2], Adam Woodward[1], Nazia Hafeez[1], Katheryne Nguyen[1], Connor Endsley[1], Julien Santelli[1], Wen Jiang[2] and Jacques Lux[1]; [1]University of Texas Southwestern Medical Center, United States; [2]MD Anderson Cancer Center, United States

The recent success of immunotherapy for treatment-refractory metastatic melanoma, lung cancer and renal cell carcinoma has provided a new hope that immunotherapy can be generalized to a broader range of cancers. However, many cancers do not respond to immune checkpoint inhibitors, which has limited their use to a subset of patients. There is now greater recognition that to generate optimal antitumor immunity requires activation of both innate and adaptive immune systems in patients. Innate immune cells, including macrophages and dendritic cells (DCs), possess phagocytic and antigen presenting capabilities that enable the initial immune recognition of tumor cells and serve as a link between the innate and adaptive immune systems through antigen cross-presentation and subsequent priming of T cells. In order for these professional antigen-presenting cells (APCs) to perform these immune functions, several cellular processes must be activated, including the innate immune sensor cyclic GMP–AMP synthase–stimulator of interferon genes (cGAS-STING). Agents that target the innate immune regulators, such as STING agonists are now being investigated as potential therapeutics for a wide range of human cancers. However, because STING is a cytosolic innate immune sensor, the intracellular delivery of agonists such as the negatively charged 2'3'-cyclic-GMP-AMP (cGAMP) is very challenging. Equally important, non-specific global STING activation can cause systemic inflammatory responses and toxicity. Systemic administration of STING agonists leads to dose-dependent T cell death that facilitates tumor immune evasion, further hindering the translation of STING agonists into the clinic.

To address this technical challenge and meet the clinical need, we developed a technology termed MUSIC (Microbubble-assisted Ultrasound-guided Immunotherapy of Cancer) that utilizes gas-filled microbubbles (MBs) conjugated with APC-targeting antibodies, and cationic polymers to efficiently load cGAMP via formation of nanocomplexes on the MB surface.

Our preliminary results show that, upon exposure to US, MUSIC produces robust STING activation and type I interferon responses in APCs and more efficiently primes antigen-specific $CD4^+$ and $CD8^+$ T cells *in vitro*. These immune stimulatory effects of MUSIC directly translated into antitumor responses *in vivo*, where we showed that the MUSIC was able to generate antitumor effects against syngeneic orthotopic primary (EO771) and metastatic (4T1) murine breast cancer models. Both models showed dramatic antitumor responses following local treatment of the primary tumor. Specifically, 6 out of 10 EO771 tumor-bearing animals were tumor-free after 50 days while 4T1 tumor-bearing mice exhibited a significant decrease of the systemic disease burden including lung metastases. We also confirmed the establishment of systemic immune memory following MUSIC treatments as mice rejected tumor cells upon re-challenge. MUSIC was also evaluated in two syngeneic murine melanoma models (B16-F10 and D4M) with 100% of D4M-tumor bearing animals and 50% of B16-tumor-bearing animals achieving complete remission when treated with a combination of MUSIC and immune checkpoints inhibitors.

MUSIC showed efficient antitumor immune responses in localized and metastatic murine breast cancer models as well as in two melanoma models leading to the establishment of immune memory (*i.e., in situ* vaccination). This nanocomplex-conjugated microbubble platform enables more efficient loading and release of cGAMP and provides a new drug delivery vehicle for further functional modifications including for loading drug or gene delivery for cancer treatment and/or vaccines.

8:45 AM *BI02/SB01/SB03/SB05.03
Neuromorphic Thin-Film-Devices for Process-In-Sensor Applications Sung Kyu Park; Chung-Ang University, Korea (the Republic of)

These days, the development of sensory systems for observing the surrounding environment information is drawing a lot of attention in various fields such as self-driving, security, robotics, and internet of things (IoT). In order to efficiently convert and recognize an external stimulus into an electrical signal, the

high-performance sensory system is required. However, conventional sensor devices have been difficult to maintain and pre-process the transformed information due to their rapid recovery properties. In this regard, the human-like neuromorphic sensory systems that can efficiently recognize external information by sensing and memorizing the incoming stimulus signals is emerging. Nevertheless, to interpret incoming information, many electronic systems often need more complementary components, such as various filters or logically connected circuit structure. Such architectural complexity can limit the development of high-density and high-resolution system.
In this talk, neuromorphic sensory systems based on thin-film-devices such as amorphous indium-gallium-zinc-oxide (*a*-IGZO) and CNT thin-film-transistors(TFTs)/circuits are demonstrated by constructing hybrid heterojunction structure with various nanostructured materials as a sensing material. Specifically, through utilizing a quantum dot, nano-scaled materials, and metal chalcogenide layers integrated with *a*-IGZO TFTs exhibits evidently enhanced environmental detection ability with neuromorphic memory function. Furthermore, we will discuss a promising strategy for the facile artificial sensory systems such as neuromorphic olfactory, self-defensive, and auto controllable visual system that have low power and small size which are significant factors in neuromorphic applications.

9:15 AM BI02/SB01/SB03/SB05.04
Biomolecular Neuristors from Voltage-Activated Lipid Membranes Michelle Makhoul-Mansour and Stephen A. Sarles; The University of Tennessee, United States

Spiking neural networks (SNNs) show promise as energy-efficient and fast computing devices for adaptive spatiotemporal data processing and classification, which is critical for applications requiring efficient acquisition, and processing of time-dependent data. Taking inspiration from their biological counterparts, the artificial neuristors in SNN hardware systems have been typically designed to generate dynamic voltage spikes -i.e., *action potentials*- when a cumulative stream of received electrical inputs crosses a critical threshold. However, unlike biological neurons, action potential generation in man-made systems is achieved using complex circuitry of many solid-state devices that are often non biocompatible. Examples of artificial neurons, and *neuristor* circuits, include those based on threshold-switching memristors[1] and organic electrochemical transistors[2].

We recently demonstrated the use of voltage-activated lipid membranes as artificial synapses for neuromorphic computing. Advantages of this approach include the available diversity of functional biomolecules, the low voltage and power requirements, and the potential for greater biocompatibility and scalability. To-date, we have demonstrated that voltage-activated biomembranes can exhibit tunable memory resistance[3], memory capacitance[4], and various forms of activity-dependent plasticity that provide specific computational advantage[5].

Herein, we study the behaviors of biomolecular neuristors consisting of voltage-activated lipid membranes exposed to alamethicin (ALM), protamine and histidine peptides. Remarkably, two distinct types of action potentials—fast (~10 ms) and slow (~1s)—have been observed, with their characteristic speeds and spike shapes differing based on the composition of the device and the direction and amplitude of the applied current. We have conducted experiments at varying compositions and concentrations of species to identify the molecular mechanisms for spike generation and develop mathematical models able to capture these behaviors.

While earlier approaches depended on complex multi-device circuitry, a biomolecular neuristor achieves this within a single stimuli-responsive biomembrane. This simplifies the fabrication process by reducing complexity, material volume, and cost, all while maintaining its adaptability to various input types. Leveraging the characteristics of synthetic biomembranes, this work can help unlock the potential for creating compact, energy-efficient, and biocompatible neuristors, thus driving progress in the realm of neural interface technology and spiking neural networks (SNNs).

Single-Pulse Control of 'Trans-Memristor' Artificial Synapses Sander Smink, Renée Meijer, Lennart Cool and Hans Hilgenkamp; University of Twente, Netherlands

As field-effect transistors (FETs) form the backbone of contemporary digital electronics, artificial synapses form the backbone of various realizations of analog electronics. Inspired by the operation of the brain, these elements determine the degree to which other circuit elements are coupled to each other, the synaptic weight. This weight can be programmed at will or evolved using a training algorithm, typically as a non-volatile response to pulsed input. Among other characteristics, the ideal artificial synapse has an as large as possible number of deterministically programmable states; as low as possible energy costs and delay times for both programming/training and processing; robustness against repeated cycling and stable over time; and scalability to nanoscale dimensions.

Here, we investigate the long-foreseen application of FETs as artificial synapses [1], of which a proof-of-concept was recently demonstrated by various groups [2]. A pulse-controlled switching element – in the simplest realization, a second FET – is used to place charges on the gate electrode of a FET. The channel conductivity responds to the number of charges in a well-defined, analog manner, which allows defining a synaptic weight deterministically. Like digital electronics, both programming and readout can in principle be extremely fast (picosecond timescales) and scaling is straightforward.

We present experimental results on the temporal response of the so-realized 'trans-memristors' to the application of a few voltage pulses, and discuss the dependence of this response on pulse width (~$10 - 10^4$ ns), frequency (~$1 - 10^6$ Hz), and charging voltage (~ ±2V). We observe that charging obeys simple resistor-capacitor behavior, which allows us to control the associated characteristic time by introducing lump circuit elements such as a series resistor. The FETs under study are micrometer-sized Au-$LaAlO_3$-$SrTiO_3$ transistors [3], which have the advantages of a single-crystalline dielectric – boosting endurance – and a low room-temperature mobility of ~1 cm^2/Vs – lowering the conductance G to ~1 µS and thus readout power $P \sim U^2G$.

Our experimental results reveal various transient effects, which we identify to be related to characteristic RC times and the FET transit time. Some transients affect the final state of the synapse and must therefore be related to the charging behavior of the gate; other transients do not and must therefore be related to the response of the channel to this charging. These results establish experimental methods to study the dynamics of field-effect artificial synapses – and FETs themselves – in detail, which are key to developing design principles that will reveal the true potential of field-effect artificial synapses as building blocks for neuromorphic hardware.

Economical and Convenient Fabrication of Antifouling Hydrogels for Implantable Medical Devices Hasani G. Jayasinghe and Arunachalam Muthaiyan; The University of New Mexico - Gallup, United States

Hydrogels garnered special attention as a biomaterial because these soft materials can mimic the natural environment of human tissues and are compatible with the human body. Poly(2-hydroxyethyl methacrylate)-based [poly(HEMA)-based] hydrogels have been used for biomedical applications such as soft contact lenses for decades. Despite the versatile applications of poly(HEMA)-based hydrogels attributed to their excellent biological, chemical, and mechanical properties, they show poor cell attachment. The low cell attachment on this soft material is beneficial for fabricating antifouling materials. Thus, poly(HEMA)-based hydrogels have potential applications in the medical field to prevent the growth of biofilms on medical implants and devices that stay in the human body for prolonged times. When a device remains in the human body for a long time, bacteria attach to the substrate and grow into clusters of cells known as biofilms. Biofilms are thick cell masses and resistant to antibiotics, so treating biofilms-related infections is challenging. Consequently, the biofilms grown on an implant may cause detrimental issues to the patient or damage the medical device. Therefore, searching for materials that can prevent biofilms has a vital importance. This study investigates the fabrication of a HEMA-based hydrogel with antifouling properties. Surface charge and functional groups are the key factors controlling bacterial attachment to a substrate. Therefore, we synthesize copolymers by blending HEMA with monomers such as 2-(Dimethylamino)ethyl methacrylate (DMAEMA). We prepare the polymers by changing the composition of the monomers in the reaction mixture to optimize the chemical composition of the polymer. The polymer with the optimum chemical composition should restrict the attachment of bacteria while maintaining the desired chemical and mechanical properties. The crosslinked network structure of a hydrogel determines its mechanical properties and supports the mechanical integrity of the polymer. Crosslinks also allow the polymer to absorb water excessively, making high water retention a unique feature of a hydrogel. However, the number of crosslinks in the polymer regulates its water retention capacity. Therefore, we vary the number of crosslinks by changing the amount of crosslinking agent in the reaction mixture to obtain the polymer with desirable mechanical and water retention properties. Furthermore, we investigate the effect of surface charge on controlling the bacterial attachment by introducing ionic groups to vary the surface charge. Additionally, we look into the conditions that make the synthesis process more controllable. In this study, we use a thermal initiator to initiate the polymerization reaction. Since the thermal initiation does not require sophisticated instruments, our technique makes the synthesis process convenient, simple, and economical.

Biomaterials Research Mentoring for High School Students Andrew Ulaszek, John Peponis and Yawen Li; Lawrence Technological University, United States

As a primarily undergraduate institution (PUI), Lawrence Technological University (LTU) provides ample opportunities for students to participate in research. Over 50% of the undergraduates in the Biomedical Engineering (BME) Department have conducted at least one research project before they graduate. The most active research in the BME Department is on biomaterials, with strong student interest and facility support. Over the past five years, many high school students are also involved in semester-long biomaterials research with the BME faculty, staff and students.
One group of high school students are from the Bloomfield Hills High School (BHHS) Biomedical Pathway Program (BPP), the first and only Center for Advanced Professional Studies (CAPS) program in Michigan and a nationally recognized innovative high school program that partners with industry and post-secondary institutions to provide authentic immersive learning experience for students. BPP students spend two class periods each week in their junior and senior years to develop biomedical related knowledge and skills in an immersive project-based environment. In the first year, students take classes that provide formative skills in biomedical engineering with limited classroom exposure to research and career pathways. During the second year, they are placed in host organizations that fit their career interests. Built on partnership between the BPP program and the BME Department, BME students with ongoing research projects can choose to mentor and train BPP students in the second year. Students from other high schools participate in research in the BME department either through their school internship/externship programs or over the summer. Since Fall 2019, 19 high school students have conducted research with BME faculty, staff and students. 16 of these 19 students worked on biomaterials related projects, ranging from decellularized spinach leaves, metal 3D printing, to skin tissue engineering, and bioprinted wound dressing mesh.
We have developed a process to effectively mentor high school students on biomedical research. This includes targeted orientation and training of BME mentors and high school mentees, clear definition of the research scope and objectives, regular progress check and oversight of the faculty and staff, and periodic evaluation of the student learning. We report in this talk our high school research mentoring process, example projects, experience gained and lessons learned in our continuing effort to involved high school students in biomaterials research to produce high quality project outcomes with enhanced learning for all students involved.

SESSION SB01.01: Bioresponsive Nanotheranostics I

10:30 AM *SB01.01.01
Engineering Biofunctional Metal–Phenolic Materials via Supramolecular Assembly Frank Caruso; University of Melbourne, Australia

The development of rapid and versatile coating strategies for interface and materials engineering is of widespread interest. This presentation will focus on our studies on the formation of a versatile class of metal–organic materials, metal–phenolic networks (MPNs), which can be formed on various substrates by coordinating polyphenols and metal ions through self-assembly. This robust and modular assembly strategy is substrate independent (covering organic, inorganic, and biological substrates) and has been used for the preparation of various materials, including thin films, particles, superstructures and macroscopic assemblies. It will be shown that a range of polyphenols and a library of metal ions are suitable for forming MPNs and that by altering the type of metal ions, different functions can be incorporated in the MPN materials, ranging from fluorescence to MRI and catalytic capabilities. Furthermore, the use of polypeptides and proteins to form engineered films and particles for a range of biological applications will be highlighted. The ease and scalability of the assembly process, combined with the tuneable properties of MPNs, provide a new avenue for functional interface engineering and make MPNs potential candidates for biomedical, environmental, and advanced materials applications.

11:00 AM SB01.01.02

DNA Origami Directed Virus Capsid Polymorphism Iris Seitz and Mauri Kostiainen; Aalto University, Finland

Most known viruses protect their genome by encapsulating it inside a protein capsid. Viral capsids can adopt various geometries, most iconically characterized by icosahedral or helical symmetries. The assembly process of native capsids is highly cooperative and governed by the protein geometry, protein-protein as well as protein-nucleic acid interactions. Importantly, the high control over the size and shape of virus capsids would have advantages in the development of new vaccines and delivery systems. However, tools to direct the assembly process in a programmable manner are exceedingly elusive or strictly limited to specific structures. Here, we introduce a modular approach by demonstrating DNA origami directed polymorphism of single protein subunit capsids. We achieve control over the capsid shape, size, and topology by employing user-defined DNA origami nanostructures as binding and assembly platforms for the capsid proteins. Binding assays and single-particle cryo-electron microscopy reconstruction show that the DNA origami nanoshapes are efficiently encapsulated within the capsid. Further, we observe that helical arrangement of hexameric capsomers is the preferred mode of packing, while a negative curvature of the origami structure is not well tolerated. The capsid proteins assemble on DNA origami in single- or double-layer configurations depending on the applied stoichiometry. In addition, the obtained viral capsid coatings are able to efficiently shield the encapsulated DNA origami from nuclease degradation. Our approach is, moreover, not limited to a single type of virus capsomers and can also be applied to RNA–DNA origami structures. We have for example demonstrated folded mRNA structures and identified key folding strategies to enable protein translation, without a separate origami unfolding step. Therefore, these findings may in addition find direct implementations in next-generation cargo protection and targeting strategies.

11:15 AM SB01.01.03
Protein Cages as Responsive Tools for Nanomedicine Jeroen Cornelissen; University of Twente, Netherlands

Different types of protein cages are nowadays studied in the fields of nano- and materials science, because of their well-defined size and structure in the nanometer regime. Compared to more traditional polymer-based nanoparticles, these – often – virus-based materials are extremely uniform, and the position of functional groups is precisely defined. Encapsulins are protein cages found in bacteria that have interesting properties with respect to (thermal) stability and cargo loading. In the past we and others have studied the application of encapsulins, but so far, their preparation, durability and functionalization are restricted to fundamental studies.[1]
Recently, we reported the design of encapsulins from two different origins (e.g., *T. maritima* and *B. linens*) with functional loops on its surface.[2] This allows for future site specific genetic or chemical modification. We, furthermore, optimized the cages' production and showed that, under the selected conditions, these are stable over time periods of a least a year. Both the genetic and chemical manipulation of the encapsulin based protein cages allows for the introduciton of functional compounds, such as fluoresecent proteins for recognition of enzymes for therapeutic applications. Exciting new developments are the introduction of moieties that respond to an external trigger, where promising results are obtained with - amongst others - light responsiveness.
The research presented in the contribution, therefore, paves the way for further design, engineering and production of encapsulins, for instance for drug delivery, vaccine development or other theranostic applications.

Continuous Growth of Monodisperse Water-Dispersible Iron Oxide Nanoparticles for Potential Biomedical Applications Jing Qu[1], Joanna Wang[2], Jianghong Rao[2] and Yongfeng Zhao[1]; [1]Jackson State University, United States; [2]Stanford University, United States

A direct synthesis of highly water-dispersible magnetic nanoparticles has been of great interest for biomedicine, but systematic control over size has not been achieved. Here, we have developed a general method to synthesize monodisperse water-dispersible iron oxide nanoparticles with nanometer-scale size increments, ranging from 4 nm to 15 nm, in a single reaction. Precise size control was achieved by continuous growth in an amphiphilic solvent, diethylene glycol (DEG), where growth step was separated from nucleation step by sequential addition of reactant. There was only one reactant used in the synthesis, and no additional capping agents and reducing agents were required. This approach suggests the "living growth" character of the synthesis of iron oxide nanoparticles in an amphiphilic solvent. The synthetic method demonstrates high reproducibility. The as-prepared iron oxide nanoparticles are highly water dispersible without the need for any surface modification. Furthermore, the synthesized 9 nm iron oxide nanoparticles exhibit extremely high transversal and longitudinal relaxivities, as reported in the literature for sub-10 nm spherical nanoparticles. Additionally, the iron oxide nanoparticles were studied for magnetic particles imaging (MPI). The performance of MPI increases with the increase of nanoparticles size. This study will not only shed light on the continuous growth phenomenon of iron oxide nanoparticles in amphiphilic solvent but also stimulate the synthesis and application of iron oxide nanoparticles.

1:30 PM *SB01.02.01
Understanding Nanomaterial Behavior in a Physiological Environment Promotes their Translational Exploration Tianjiao Chu, Christy Maksoudian, Irati Perez Gilabert, Mukaddes Izci, Bella Manshian and Stefaan Soenen; KU Leuven, Belgium

The interest in the biomedical use of nanomaterials has been quite strong for several years, yet despite the excellent preclinical proof of concept data, the clinical translation of nanomedicines has remained somewhat low. One potential issue in this regard are the uncertainties related to the biodistribution and bio-effects that nanomaterials will have upon systemic administration. In the present contribution, we aim to provide an overview of some recent examples on how developments in imaging and analysis can help to overcome some of the hurdles currently associated with biomedical research involving nanomaterials.
This presentation itself will focus primarily on the role that non-invasive (optical) imaging can play in better determining the true therapeutic efficacy or potential toxicity of nanomaterials. Recent data will be discussed on the detailed characterization of tumor heterogeneity and how nanomaterials delivery to solid tumors can be improved through manipulating tumor physiology. These gained insights also led to recent advances in nanomaterial effects at the

tumor site, where we specifically look at the combined effects of nanomaterial chemistry and tumor parameters on the degree of metastases and how this can influence the choice of nanomaterials to be used. We also explore the use of engineered nanomaterials to promote anti-tumor immunity and lastly, demonstrate the ability to investigate the use of pDNA-loaded nanomaterials for therapeutic use. Together with examples of novel imaging modalities and the need for fully quantitative data, we
hope that this presentation will help any interested scientists in uncovering the full potential that
nanomedicines have to offer.

2:00 PM SB01.02.02
Core-Shell Semiconducting Polymer Nanoparticles for Detection and Photothermal Ablation of Breast Cancer Nicole Levi and Santu Sarkar; Wake Forest University School of Medicine, United States

Triple negative breast cancer (TNBC) is one of the deadliest among other subtypes of breast cancers due to its absence of standard biomarker expressions, and the aggressive nature of TNBC leads to low patient survival. Current treatment strategies include surgery, chemotherapy, and radiation therapy, although photothermal therapy is an evolving treatment strategy. It has recently been shown that breast cancer can harbor intracellular bacteria, which may impact therapeutic responses. Here we present the use of semiconducting theranostic polymer nanoparticles composed of a photothermal poly[4,4-bis(2-ethylhexyl)- cyclopenta[2,1-b;3,4-b′]-dithiophene-2,6-diyl-alt-2,1,3-benzoselenadiazole-4,7-diyl] (PCPDTBSe) core with a fluorescent poly[(9,9-dihexylfluorene)-co-2,1,3-benzothiadiazole-co-4,7-di(thiophen-2-yl)-2,1,3-benzothiadiazole (PFBTDBT10) shell for detection and treatment of TNBC cells harboring Staphylococcus aureus bacteria. These dual polymer core-shell nanoparticles (CSNPs) had absorption maxima at 450 nm and 740 nm corresponding to PCPDTBSe and DBT10 respectively. The quantum yield was 9.64% The core diameter was 83 nm and the CSNPs were 125 nm, both with negative zeta potential. Exposure of TNBC cells (MDA MB 231) to the CSNPs for 24 h resulted in a 50% reduction in viability, wheras non-tumorigenic breast epitherlial cells (MCF 10A) were not impacted at 250 ug/ml in the absence of infrared light. Exposure to 800 nm resulted in a temperature change of 15°C at 250 ug/ml of CSNPs exposed to 3W of 800 nm light for 60 s. This led to a 75% reduction in uninfected MCF 10A cells, but only a 60% reduction when this cell line was infected. Uninfected MDA MB 231 cells subjected to 250 ug/ml of CSNPs and 800 nm (3W for 60 s had a 40% reduction in viability, and the infected cells had a 70% reduction. Differences in cell response to PTT whether the cells were infected or not indicates that infected TNBC cells may be preferentially more sensitive to CSNP-induced PTT. The CSNPs could be imaged within the cells, setting the stage for using this CSNPs for detection of breast cancer and precision photothermal ablation.

2:15 PM SB01.02.03
Remote Stimuli-Responsive Nanomaterials for Regenerative and Cancer Therapy Heemin Kang, Yuri Kim, Hyunsik Hong, Nayeon Kang, Sungkyu Lee and Sunhong Min; Korea University, Korea (the Republic of)

Cells constantly interact with native nanostructured extracellular matrix at the molecular level. Nanomaterials responsive to tissue-penetrative remote stimuli can be designed to present bioactive ligands or deliver functional molecules as a nanomedicine to regulate or elucidate dynamic nanoscale cell-material interactions. In this talk, I will demonstrate the design of dynamic nanomaterials that can be remotely and spatiotemporally controlled via various remote stimuli, such as magnetic field, light, self-assembling molecules, or their combinations.

In particular, I will show that magnetic field can control the motion of magnetic nanomaterials, such as reversibly controlling RGD ligand nano-coupling, nano-blocking, nano-stretching, and nano-interconnectivity with graph theory-based analysis, which can regulate the focal adhesion-mediated mechanotransduction and resultant differentiation of stem cells. Near-infrared light can activate photonic nanomaterials to trigger photoisomerization, thereby mediating the swelling of liganded supramolecular self-assembly, which can be reversibly deswelled by visible light. Such photonic control enables *in vivo* stability imaging and spatiotemporally controlled molecular delivery to regulate the adhesion-dependent pro-inflammatory vs. pro-regenerative polarization of macrophages. Furthermore, molecules and ions can reversibly induce *in situ* self-assembly of biofunctional nanomaterials.

I will also introduce a couple of representative examples of recent cancer therapies and diagnostic imaging controllable by remote stimuli, such as magnetic field, light, and ultrasound, which utilize mechanical force, 1-D nanomaterials, in situ self-assembly, ferroptosis, and others. These strategies can present benefits for safe personalized precision therapies while minimizing drug resistance and side effects.

2:30 PM *SB01.02.04
Recent Progress on Phototherapy Juyoung Yoon; Ewha Womans University, Korea (the Republic of)

Switchable phototheranostic nanomaterials are of particular interest for specific biosensing, high-quality imaging, and targeted therapy in the field of precision nanomedicine. Here, we develop a “one-for-all” nanomaterial (NanoPcTBs) that self-assembles from flexible and versatile phthalocyanine building blocks. Fluorescence and reactive oxygen species (ROS) generation could be triggered depending on a targeted, protein-induced, partial disassembly mechanism, which creates opportunities for low-background fluorescence imaging and activatable photodynamic therapy (PDT). On the other hand, the *in vivo* specific binding between albumin and PcS, arising from the disassembly of injected NanoPcS, was recently confirmed using an inducible transgenic mouse system. In a recent investigation, we devised a novel molecular design approach to create heavy-atom-free photosensitizers for thionapthalimides and BODIPYs. The thionaphthalimides display dramatically enhanced quantum yields for photosensitized singlet oxygen formation. Photodynamic antibacterial therapy is also regarded as an innovative and promising antibacterial approach due to its minor side effects and lack of drug resistance. Recently, we suggested that reactive differences may pave a general way to design selective photodynamic agents for ablating Gram-positive bacteria-infected diseases.

3:30 PM SB01.02.06
Advanced Tissue Engineering Scaffolds Incorporated with Gold Nanoparticle-Based Theranostics for Postoperative Cancer Patients Lin Guo, Qilong Zhao, Li-wu Zheng and Min Wang; The University of Hong Kong, Hong Kong

Cancer causes millions of human deaths each year and surgery has been the most commonly used method for treating many types of cancers. After surgical removal of the tumor, new tissues need to be formed at the resection site for restoring body functions. Scaffold-based tissue engineering has emerged as a viable approach for regenerating tissues in the body. Another major issue for many cancer patients, such as suffers of gastrointestinal (GI) tract cancer, is the high cancer recurrence rate. Therefore, new strategies should be investigated to detect and treat recurrent cancer for patients after their initial cancer treatment. In nanomedicine, nanodevices that provide both diagnostic and therapeutic functions (the so-called “theranostics”) appear to be highly promising for the early detection and effective treatment of cancers. In the current study, a new concurrent electrospinning and co-axial electrospray technology was developed for fabricating advanced tissue engineering scaffolds incorporated with gold nanoparticle (AuNP)-based theranostics for treating cancer patients. Model scaffolds designed for GI tract cancer patients were made using this technology. It was shown that a controlled release of AuNP-based theranostics

could be achieved for the advanced scaffolds. The study using NIH/3T3 mouse fibroblasts indicated good biocompatibility of released theranostics. HeLa cells, which have a high-level of folate receptor (FR) expression, and MCF-7 cells, which have a low-level FR expression and thus could provide a negative control in the current study, were employed for investigating the designed functions of the theranostics. *In vitro* investigations showed that the theranostics released from scaffolds could provide both diagnostic and therapeutic functions, including strongly amplified Raman signals via the surface enhanced Raman scattering (SERS) effect, active targeting, cellular imaging and photothermal therapy for HeLa cells. Our other studies also showed the potential of these advanced scaffold for GI tract tissue regeneration. Altogether, these novel scaffolds are highly promising for offering the treatment for postoperative cancer patients.

3:45 PM *SB01.02.07
Structural Immunotherapy: Spherical Nucleic Acid (SNA) Immunotherapy for HPV-Associated Head and Neck Cancer Chad A. Mirkin[1,2] and Sergej Kudruk[1,2]; [1]Northwestern University, United States; [2]International Institute for Nanotechnology, United States

Squamous cell cancer of the head and neck (SCCHN), ranked 6th in global cancer mortality, is witnessing a transformative shift in its causation due to the escalating prevalence of human papillomavirus (HPV). Current HPV-SCCHN treatment options include surgery, chemotherapy, and radiation. Immunotherapy for HPV-SCCHN has so far been limited to commercially available immune checkpoint inhibitors targeting PD-1 or PDL-1 as a synergistic treatment to chemotherapy. However, even with these options, on average 50% of patients with SCCHN will experience a recurrence/metastasis which has a poor prognosis and a median overall survival <1 year. Therefore, there is a critical need for the development of new and improved treatment options for HPV-SCCHN. To that end, HPV oncoproteins E6 and E7 have emerged as promising targets for vaccine-based therapies. Here we employ chemically tunable spherical nucleic acid (SNA) nanostructures, consisting of a nanoparticle core densely functionalized with DNA, that incorporate selected HPV-SCCHN-specific antigens in a controlled orientation. Indeed, the three-dimensional presentation and overall structural design of SNAs enables effective entry into cells and perturbations to structural and compositional parameters can be altered to achieve a desired therapeutic outcome. Thus, SNAs for immunotherapy allows one to explore the implications of structural presentation of vaccine components in generating epitope-specific T cells. In this study, SNA-based therapeutic cancer vaccines are designed to efficiently deliver adjuvants and tumor-specific antigens, thus activating both innate and adaptive immune systems. We evaluated multiple HPV-16 antigens, with the goal of maximizing immune responses in tumor-burdened humanized murine models and patient-derived tumor spheroid samples. To identify the most potent antigen-SNA formulation, generation of antigen-specific CD8+ T-cells, cytokine production, and HPV cancer-specific cell killing are evaluated. Overall, this work highlights how the structure of SNAs is critical to designing effective therapeutics while providing insights into the molecular interactions between the immune system and cancer cells.

4:15 PM SB01.02.08
Spatiotemporally Delivery of Multiple Growth Factors from Electrospun Scaffolds through Photothermal Effect to Manipulate Skin Wound Regeneration Xindan Zhang and Jiajia Xue; Beijing University of Chemical Technology, China

Due to the increasing incidence of full-thickness skin injuries caused by mechanical trauma, burns, as well as conditions like diabetes and malignant tumors, the repair of skin wounds has become a major medical challenge in the field of wound healing. During the process of skin wound repair, different types of growth factors play specific roles at various stages, collectively promoting wound healing. In this study, we fabricated a nanofiber scaffold with surface topographical features using electrospinning. Furthermore, the scaffold was functionalized to provide the required microenvironment for skin wound repair by incorporating growth factors. To enable the spatiotemporal controlled release of these growth factors, we combined photothermal therapy with phase change materials and introduced a photomask strategy. Specifically, a three-layered sandwich-like photothermal scaffold was prepared by in conjunction with coaxial electrospraying, using polycaprolactone as the base material. The scaffold consisted of an inner layer of radially aligned nanofibers, an outer layer of random nanofibers, and an intermediate layer containing growth factors and photothermal agents in the form of phase change microspheres. By utilizing near-infrared light irradiation and the photomask strategy, the spatiotemporal controlled release of the growth factors was achieved. The multi-layered structure of the scaffold was confirmed by surface morphology analysis, and the modified surface was found to promote cell adhesion according to water contact angle measurements. Photothermal experiments and studies on growth factor release demonstrated that the scaffold could achieve spatiotemporal controlled release while maintaining photothermal stability, and the released growth factors retained their pro-angiogenic activities. *In vitro* experiments showed that the scaffold not only promoted cell proliferation but also facilitated cell migration through the combination of its topographical surface and the spatiotemporal controlled release of growth factors. Finally, an animal full-thickness skin wound model was employed to evaluate the wound healing effectiveness of the scaffold, revealing the regulatory patterns and effects of growth factors *in vivo* under programmable photothermal stimulation. In conclusion, the nanofiber scaffold with photothermal-triggered controlled release of growth factors effectively integrates the topographical structure of the nanofibers with the controllable release of growth factors. It provides a novel approach for the design of skin wound repair scaffolds and their combination with photothermal therapy to promote skin wound healing. This research holds significant potential in the fields of tissue regeneration and controlled release.

SESSION SB01.03: Poster Session: Bioresponsive Nanotheranostics

5:00 PM SB01.03.01
Programming Injectable DNA Hydrogels Yields Tumor Microenvironment-Activatable Chemo-Immunotherapy Yu Fan[1,2]; [1]DWI-Leibniz Institute for Interactive Materials, Germany; [2]RWTH Aachen University, Germany

Injectable hydrogels have been investigated extensively to incorporate with drugs for tumor treatment because those materials can simultaneously deliver multiple drugs to the target sites with rational ratios and minimal invasion, and elevate their tumor accumulation, blood stability, and half-lives. Importantly, the local treatment of hydrogel-encapsulated drugs showed superior tumor growth inhibition compared to the local or systemic delivery of non-encapsulated chemotherapeutics and immunomodulators. However, since current studies regarding injectable chemo-immunotherapeutic hydrogels are mainly based on the intratumoral gelation of soluble precursors, sol-gel transformation may be impeded by the complex physiological environment, resulting in the reduced cross-linking degree, abrupt drug leakage, and unpredictable pharmacokinetics. Besides, conventional polymers lack molecular, structural, and functional programmability, which results in significant challenges in tailoring the biofunctionalities of hydrogel scaffolds for intimately interacting with tumor tissue.
Here, we describe an unprecedented injectable DNA hydrogel in which the repeats of cytosine-phosphate-guanine oligodeoxynucleotide (CpG ODN) and adenosine triphosphate (ATP) aptamer are encoded on the ultralong DNA building blocks by RCA-mediated DNA polymerization. By sequentially

incorporating DNA hydrogel with immune checkpoint inhibitor anti-programmed cell death protein ligand 1 (aPDL1) and chemotherapeutic agent doxorubicin (DOX), a chemo-immunotherapeutic DNA hydrogel adjuvant (aPDL1/DOX@DNA Gel) is formed. Due to its super-soft property, this DNA hydrogel encoded with ATP aptamers can be readily injected into tumor tissues in which the overexpressed ATP binds to the corresponding aptamer. This results in the conformational change of aptamer and volume expansion of the gelmatrix to stimulate the distinct release kinetics of co-encapsulated therapeutics. DOX is first released to induce immunogenic cell death that intimately works together with the polymerized CpG ODN in gel scaffold for effectively recruiting and activating dendritic cells. While, the polymerized CpG ODN displayed very high tumor retention with a significant reduction of the systemic circulation, which is attributed to the restricted in vivo motility and metabolism of the polymerized CpG ODN, thereby reducing the adverse effects of CpG ODN while enhancing its tumor immunomodulatory efficacy. Furthermore, aPDL1 antibody was subsequently released from DNA hydrogel to block the immune inhibitory checkpoint molecules PD-L1 on the tumor cell surface, thus reversing the tumor microenvironment immunosuppression through potentiating T-cell mediated immune responses. The programmed aPDL1/DOX@DNA Gel demonstrated potent suppression of tumor growth and lung metastasis via the induced strong systemic immune response and immune memory effect. This work thus contributes to the first proof-of-concept demonstration of a programmable super-soft DNA hydrogel system that perfectly matching the sequence programmability to the synergistic therapeutic modalities based on chemotherapeutic toxicity, in situ vaccination, and immune checkpoint blockade. With the high programmability of design principle, we believe that our approach can be combined with DNA-protein conjugation chemistry, DNA nanotechnology, and microfluidic technique to develop a library of biomaterial systems in new biomedical applications beyond chemo-immunotherapy of tumors.

5:00 PM SB01.03.02
Nano Herbals for Effective Wound Healing Aarti Shastri[1], Arti Swami[1], Swarupa Hatolkar[2] and Sachin Bhusari[3]; [1]MIT World Peace University, India; [2]Mrbiologist LLP, India; [3]ICT Aurangabad, India

Background: The demand for Pharmacognostic-based compounds with diverse pharmaceutical activities has been escalating to combat challenges like drug resistance, emerging diseases, and the toxicity of currently used chemical compounds. The plant kingdom offers a plethora of bioactive compounds with unprecedented potential to address these difficulties, leading to a surge in novel solutions within the pharmaceutical industry. Ayurvedic formulations of Tobacco (Nicotiana tabacum) have emerged as a promising approach due to their established use in herbal medicine with multiple medicinal benefits.

Methods: This study aimed to explore the wound healing potential of the tobacco plant. Tobacco leaves were processed to create a traditional ayurvedic formulation, including Mashi formulations known as Anterdhum Padhati Mashi, Bahirdhum Padhati Mashi, and Muffle Furnace Mashi, following traditional ayurvedic practices. Additionally, aqueous, and alcoholic extracts of tobacco leaves were prepared. The wound healing efficacy of these formulations was assessed using an Excision model in mice.
Results: Comparative analysis revealed that the Bahirdhum Padhati Mashi with methanolic discharge exhibited significantly higher wound healing ability compared to a reference drug formulation.
Conclusion: In conclusion, the Bahirdhum Padhati Mashi derived from tobacco demonstrates promising wound healing potential and could serve as an effective wound healing agent. The findings from this experimental study support the exploration of ayurvedic formulations as potential candidates for addressing wound healing complications. Further investigations and

clinical trials are warranted to ascertain their safety, efficacy, and potential application in wound management.
Keywords: Nano particle, Nicotiana tabacum, wound healing, Anterdhum Padhati, Nano formulation, herbal nano formulation

Magneto-Responsive Textile modified by (Nano)Materials Arkadiusz Jozefczak[1], Rafal Bielas[1], Bassam M. Jameel[1], Ivo Safarik[2] and Peter Kopcansky[3]; [1]Adam Mickiewicz University, Poland; [2]Czech Academy of Sciences, Czechia; [3]Slovak Academy of Sciences, Slovakia

Textiles are materials made by interlocking bundles of yarns or threads The inherent flexibility of the textile materials opens the possibilities for their functionalization. The space between the single fibers and their surface can carry additives of different functionalities, such as magnetic nanoparticles and drug molecules. Magneto-responsive textiles have emerged lately as an important carrier in various applications, including those in biomedical fields such as drug delivery, tissue engineering, and regenerative medicine. We designed and characterized simple woven and non-woven textile materials with magnetic properties that can become potential candidates for a smart magnetic platform for hyperthermia treatments [1]. When heat was induced by magneto-responsive textiles under the influence of a high-frequency alternating magnetic field, the temperature increase in tissue-mimicking phantoms depended on several factors, such as the type of basic textile material, the type of materials used for textile surface modification (magnetic fluids, magnetic Pickering emulsion), and the number of layers covering the phantom. The values of temperature elevation, achieved with the use of magnetic textiles, are sufficient for potential application in magnetic hyperthermia therapies and as heating patches or bandages. Controlled release of substances and/or nano-sized objects from the textiles triggered by high-intensity ultrasound is also possible. This paves the way for the potential use of the proposed textile materials in the theranostics paradigm.
This work was supported by project no. 2019/35/O/ST3/00503 (PRELUDIUM BIS) of the Polish National Science Centre, and project no. APVV-22-0060 of the Slovak Research and Development Agency.

***In Vivo* Brain Tumor Response to Magnetothermal Effect of The Optimized Magnetic Particle Imaging (MPI) Contrast Agents** Maryam Golshahi and Hamed Arami; Arizona State University, United States

Magnetic Particle Imaging (MPI) has been recently developed for image-guided magnetothermal treatment of tumors in animal models. These therapies are designed based on rapid magnetization and de-magnetization of superparamagnetic nanoparticles in the presence of AC magnetic fields. This technique offers localized treatment of deep tissue and inoperable tumors due to the high tissue penetration rate of the electromagnetic fields. Also, unlike

chemotherapy approaches, which generally lead to whole-body biodistribution of the drugs, this method enables localized treatment of the tumors with minimal side-effect on other organs when intratumoral administration routes are used. Owing to their safety and tunable physiochemical properties, iron oxide nanoparticles are the optimal types of contrast agents for MPI. We have shown that since the magnetic properties of these nanoparticles are size-dependent, they play a key role in tuning the amount of heat and contrast they can generate in tumors in response to MPI magnetization. Here, we will discuss our most recent results for effective MPI imaging and magnetothermal treatment of GBM (the most deadly type of brain tumor) in mouse models. We will demonstrate the effectiveness of this technique for treatment of three types of intracranially implanted GBMs with different levels of invasiveness and growth patterns. Our survival and histological results indicated that GBM response to this treatment depends on GBM cell type, anatomical growth pattern of the tumors, and permeability of the nanoparticles within tissues. These results were used to further optimize our technique (i.e., improving the magnetization system and adjusting the nanoparticles' properties, such as core and hydrodynamic sizes and surface charges) for more effective magnetothermal treatment of different GBM models.

Highly Efficient Photothermal Therapy of Tumors Using Easily Prepared Nanoparticles Songyi Lee; Pukyong National University, Korea (the Republic of)

The simple molecular design of small molecule-based photothermal nano-agents with high photothermal conversion efficiencies (η) remains a highly challenging obstacle in the development of new anti-tumor drugs. Although several efficient small agents have been reported, they tend to contain bulky alkyl chains and/or aromatic rings, which were introduced to enhance the photothermal effect, but result in complicated preparation procedures. Herein, we report the preparation of nano-agents from commercial reagents using a one-step organic reaction with facile purification and a subsequent simple self-assembly process in water under a flow of air overnight. The obtained nano-agents exhibited high photothermal conversion efficiencies (η) of up to 92.5%. This photothermal effect originated mainly from twisted C=N bond-induced non-radiative decay with completely inhibited radiative decay and the intersystem crossing process. In addition, the photothermal effect was enhanced by synergistic twisted intramolecular charge transfer, strong donor–acceptor interactions, various intramolecular vibrations, and the presence of rotators. The obtained nano-agents efficiently inhibited tumor growth after 10 d of photothermal therapy, and they exhibited a good biocompatibility in a mouse tumor model. This simple approach can conveniently facilitate the further development and testing of such systems.

Design of One-For-All Near-Infrared Aggregation-Induced Emission Nanoaggregates for Boosting Theranostic Efficacy Huilin Xie and Ben Zhong Tang; The Hong Kong University of Science and Technology, Hong Kong

Fluorescence-guided phototherapy with integrated diagnostic and therapeutic functions has great potential in the field of precision medicine, as they fully utilize light for energy conversion or transduction, and have the advantages of multifunctionality, low cost, and convenient. From a diagnostic perspective, near-infrared fluorescence imaging (FLI) has lower interference from autofluorescence, improved imaging depth, and higher sensitivity compared to conventional imaging in the visible light region. On the other hand, photothermal therapy (PTT) and photodynamic therapy (PDT) have received great research attention due to their non-invasive, controllable, and low drug resistance characteristics. PTT uses non-radiative transitions of excited molecular states to convert light energy into heat for therapy, while PDT involves energy transfer processes of excited state molecules, producing highly reactive oxygen species, inducing cell damage and apoptosis. Combining PTT and PDT with fluorescence localization of lesions could lead to better diagnostic and therapeutic effects. However, the competitive energy relaxation pathways of molecules are difficult to regulate, and the fluorescence of many planar organic molecules is quenched upon aggregation, making it difficult to achieve efficient FLI, PTT, and PDT simultaneously. Aggregate science offers more opportunities to solve this problem, as the energy dissipation pathways of aggregates are more diverse, providing more possibilities for constructing "one-for-all" phototheranostic agents and realizing their multifunctionality. Based on this, this study reports a multifunctional diagnostic and therapeutic platform with near-infrared emission, high fluorescence quantum yield, reactive oxygen species generation efficiency, and photothermal conversion efficiency. *In vivo* studies show that the use of aggregation-induced emission (AIE) nanoaggregates in this platform can make mouse tumors show bright fluorescence, while exhibiting good photodynamic and photothermal therapy effects, ultimately completely eliminating the tumors. This study is of great significance for the rational design and synthesis of multifunctional near-infrared nanoaggregates with high energy dissipation utilization efficiency for precise diagnosis and effective treatment of tumors.

5:00 PM SB01.03.07
Design and Optimization of an Electrospraying System for Bioactive Compound Nanoencapsulation for Nasal Vaccines Sebastián León-Carvajal[1], Esteban Avendaño-Soto[2,2], Sebastián Zuñiga-Salazar[1] and Ricardo Starbird-Perez[1]; [1]Costa Rica Technological Institute, Costa Rica; [2]University of Costa Rica, Costa Rica

Controlled drug release systems are innovative techniques that offer advantages over traditional methods. They enable precise localization of bioactive payloads in specific regions and provide control over drug concentration within therapeutic ranges for extended periods. One example of a controlled drug release systems are nasal vaccines, where a bioactive compound (core) is encapsulated within a biopolymer matrix (shell) in the form of micro and nanoparticles. The size and morphology of the obtained particles facilitates the controlled diffusion of the bioactive payload, and the release of the bioactive compound occurs when ambient conditions favor shell dissolution or core diffusion to the medium. Several techniques are employed to synthesize encapsulated nanoparticles, including nano-spraydrying, electrostatic-spraydrying, and electrospraying. Electrospraying is particularly interesting for the development of drug release systems because it allows the synthesis of nanoparticles without the use of high temperatures, that could potentially damage the payload. In contrast, electrospraying achieves this by applying a high electric field to electrostatically atomize and deposit generated particles onto a collecting plate for recovery. In this research, we have developed an electrospraying device that is capable of synthesizing nanoparticles based on biocompatible biopolymers, such as zein, polyvinyl alcohol (PVA), and chitosan, as well as optimized the electrospraying parameters in order to obtain homogeneous particle distribution and morphology. These systems are capable of encapsulating bioactive materials for controlled release in nasal vaccines. The implementation of this technology has the potential to enhance the biological response and, consequently, the overall effectiveness of treatments.

5:00 PM SB01.03.08
Development and Evaluation of Brimonidine Tartrate Nanoparticulate Ocular Insert Shruti Kadam[1], Dipti Dhurat[1], Hrishikesh Khude[1], Amol Tagalpallewar[1], Akshay M. Baheti[1], Shrikant Joshi[2] and Anil Pawar[3]; [1]School of Health Sciences and Technology, Dr. Vishwanath Karad MIT World Peace University, India; [2]Maliba Pharmacy College, Uka Tarsadia University, India; [3]Dr. Vishwanath Karad MIT World Peace University, India

Glaucoma is the second leading cause of vision loss in the world after cataracts. It is estimated that the number of people with glaucoma will be nearly 79.6 million worldwide by 2023. This alarmingly high number of anticipated patients requires urgent improvement in the current therapeutic approaches adopted for the treatment of this disease. At present, Antiglaucoma agent brimonidine tartrate is commercially available in the form of eye drops and marketed under the name of Alphagan® (0.2%) or Alphagan® P (0.1% and 0.15%). For effective management of intraocular pressure, it needs to be administered 1 to 3 drops every 6 h. The drawbacks associated with the available eye drops are short pre-corneal retention time along with poor patient compliance. The present was conducted to formulate, optimize and evaluate a brimonidine tartrate nanoparticulate ocular insert to improve patient compliance.
Nanoparticulate ocular inserts were prepared in two steps initially ionic gelation for nanoparticles and solvent casting method for the ocular insert. Release studies showed that the prepared insert releases brimonidine tartrate by zero-order kinetic up to 8 h. The inserts were evaluated for several parameters like drug-excipient interaction, thermal studies, the thickness of the insert, swelling index, and moisture studies, Furthermore, the in-vivo evaluation showed that the ocular insert has good therapeutic activity and fewer side effects as compared to other marketed formulations.

5:00 PM SB01.03.09
Confirmation of The Effect of Gold Nanoparticles on Macrophages by PEG and Analysis of Gene Expression Profiles on The Cellular Response of Macrophages Young-Hwa Kim and Kyung Hyun Min; Jeonbuk National University, Korea (the Republic of)

Purpose: Recently, understanding the relationship between immune cells and nanoparticles has played an important role in its biomedical applications. However, biological responses by nanoparticles are not clear. We investigated the effects of cellular and immune responses related to gene expression and *in vivo* behavior in murine macrophages by the gold nanoparticles (AuNPs).
Materials and Methods: To evaluate the effects of cellular responses of the hydrophilic reagent, PEG (polyethylene glycol), murine macrophage cell lines (RAW264.7) were treated with unmodified 50 nm-sized AuNPs and PEGylated 50 nm-sized AuNPs. Cytotoxicity test was performed using CCK-8 assay for 72 hrs. Morphology and intracellular localization of the AuNPs were observed by transmission electron microscopy (TEM). To analyze the modified gene expressions, total RNA was extracted from AuNPs-treated cells and whole-genome cDNA microarray analysis was performed. The uptake and clearance of ^{125}I-unmodified AuNPs and ^{125}I-PEGylated AuNPs were evaluated by serial SPECT/CT studies from 0 hr to 4 hrs after i.v injection of 11.1 MBq ^{125}I-AuNPs in nude mice.
Results: In Dynamic Light Scattering (DLS) analysis, the hydrodynamic size of unmodified AuNPs and PEGylated AuNPs was 49.8 ± 7.4 nm, 65.4 ± 9.2 nm, respectively. The viability of RAW264.7 cells were observed in more than 80% with 0.02 ~ 0.2 mg/mL AuNPs treatments. TEM images showed that unmodified AuNPs and PEGylated AuNPs were trapped in vesicles inside the cytoplasm of RAW264.7 cells with aggregation and separation, respectively. In the microarray analysis, significant effects were observed on gene regulations involved with immune response, oxidative stress and cell death between the unmodified AuNPs and the PEGylated AuNPs. In *in vivo* imaging, unmodified AuNPs-treated mice were observed in the liver and the spleen up to 4 hrs, however, PEGylated AuNPs were well circulated in the whole blood up to 4 hrs.
Conclusion: In this study, we investigated to understand the interaction between immune cells and gold nanoparticles, and to respond the biological mechanisms. This information would help to develop various kinds of nanoparticles with improved safety and efficacy.

5:00 PM SB01.03.10
Continuous Metal-Organic Framework Thin Films for High-Resolution X-Ray Imaging Jianxin Wang and Omar F Mohammed; King Abdullah University of Science and Technology, Saudi Arabia

In the realm of scintillator material science, the significance of scintillator screens lies in their ability to enhance imaging resolution and X-ray sensitivity.1,2 These two factors are of utmost importance for achieving accurate medical diagnoses and treatments, improving safety inspections, and enabling comprehensive examinations of industrial equipment.3 Presently, the dominant methods employed for creating scintillator screens primarily involve high-temperature sintering, crystal growth, and polymer doping techniques. However, these methods come with stringent synthesis requirements and grapple with challenges related to achieving uniform and extensive growth across large surfaces while minimizing light scattering.4 The in-situ electrochemical synthesis of continuous metal-organic framework (MOF) thin films offer a solution that increases material density, reduces light dispersion, and ensures long-lasting durability. The tightly interconnected and precisely oriented growth structure of continuous MOF thin films results in a significant reduction in light scattering.5 Consequently, the inherent characteristic of diminished light dispersion holds great promise for enhancing spatial imaging resolution in X-ray scintillators.
Herein, we present a versatile approach rooted in in-situ electrochemical-directed assembly, dedicated to crafting MOF thin films tailored for exceptional X-ray imaging capabilities. Through this electrochemical process, a series of coherent MOF thin films have been successfully synthesized, employing interconnected lanthanide metals and terephthalic acid linkers. This specific MOF thin film emerges as a standout contender, enabling high-resolution X-ray imaging while retaining X-ray sensitivity. This achievement is attributed to its superior material density, reduced light scattering, and simplified manufacturing procedure. Notably, this particular MOF thin film surpasses the majority of documented organic and traditional inorganic scintillators, achieving an X-ray imaging resolution exceeding 32 line pairs per millimeter (lp/mm). This research has the potential to elevate MOFs as highly efficient scintillators for X-ray imaging, opening up exciting opportunities in the fields of radiology and security screening applications.

Bacterial Cellulose based Modulated Drug Carriers for Transdermal Skin Patches with Diclofenac Sodium and Simvastatin: Role of Differently Soluble Drugs, Drug-Matrix Interaction and Matrix Morphology Peddapapannagari Kalyani and Mudrika Khandelwal; Indian Institute of Technology, Hyderabad, India

Bacterial cellulose (BC) is a type of nanofibrous, highly crystalline cellulose that is being used as a drug carrier for two differently soluble drugs of Diclofenac sodium and Simvastatin as a model drug for likely water soluble and water insoluble drugs. One of the benefits of using BC is that it is hydrophilic and highly swellable, which means that it offers a burst release of water-soluble drugs and a limited release of hydrophobic drugs. We have modified the matrix of BC using in-situ techniques to modulate its morphological and structural properties. To achieve this, we used biopolymers of Agar and Chitosan as a modifying agent during culture, which affects density and microstructure. Chitosan also imparts additional functional groups that can modulate interaction with drugs. These polymer-modulated BCs were further modulated by varying drying conditions such as freeze drying and air drying to obtain bacterial cellulose-based modulated drug carriers as transdermal skin patches. To understand the characteristics of these drug carriers for skin

patches, conducted a range of characterization studies using SEM, FT-IR, XRD, BET analysis, water swelling and uptake studies, and drug release studies. Mathematical modeling was also fitted by use of Zero order, First order, Higuchi and Korsmayer peppas model fitting to understand the release mechanism and the factors that govern the release. The results showed that the simple modulated BC (M-BC) can release them through a swelling and diffusion-controlled first order quasi-fickian mechanism, irrespective of the drug load. The modulated Agar-BC (A-MBC) releases both drugs through swelling and Erosion driven non fickian first order diffusion kinetics. But the release in A-MBC was sustained for 3 days in water insoluble drug due to its Curley oriented denser fiber assembly making some time to release of ensnare drug molecules. On the other hand, for Chitosan-modulated BC (C-MBC), the release is greatly sustained over 14 days for water-insoluble drug (Simvastatin) through swelling, polymer relaxation and erosion following zero order- case II release through drug-matrix interaction. It seems that non-fickian release mechanism was taken place in the M-BC and A-MBC skin patches with the irrespective of the drug used. The Drug release mechanism in the C-MBC skin patch was changes from non-fickian first order diffusion kinetics for likely water-soluble drug to case II transport with zero order diffusion kinetics for water insoluble drug. This research implies the various transdermal skin patches applications like immediate potential application to sustain chronic disease management such as Vaccines, Acne, hypertension, hormonal management, thyroid treatment, cardiovascular disease, central nervous diseases, cigarette cessation, motion sickness, arthritis, diabetics, hyperlipidemia etc.

5:00 PM SB01.03.12
Brimonidine Nanoparticulate Ocular Inserts for Glaucoma Shruti Kadam[1], Dipti Dhurat[1], Hrishikesh Khude[1], Amol Tagalpallewar[1], Akshay M. Baheti[1], Shrikant Joshi[2] and Anil Pawar[1]; [1]Dr. Vishwanath Karad MIT World Peace University, India; [2]Maliba Pharmacy College, Uka Tarsadia University, India

Ocular drug delivery is challenging due to the unique anatomical and physiological barriers of the eye that limit drug absorption. Conventional eye drops often have low bioavailability and short residence time on the ocular surface, requiring frequent dosing that leads to poor patient compliance. Antiglaucoma agent brimonidine is commercially available in the form of eye drops that need to be administered 1 to 3 drops every 6 h. We developed and evaluated a brimonidine tartrate nanoparticulate ocular insert to improve patient compliance. Nanoparticulate ocular inserts were prepared in two steps involving ionic gelation for the synthesis of nanoparticles and solvent casting method for the fabrication of ocular insert. The inserts were evaluated for several parameters including in-vitro release profile and in-vivo efficacy in rabbits. An in-vitro study showed the release of brimonidine from the ocular inserts by zero-order kinetic up to 8 h. The in-vivo study further validated the efficacy of these inserts in decreasing intraocular pressure. It is concluded that the brimonidine nanoparticulate ocular inserts can serve as a potential treatment option for glaucoma patients.

5:00 PM SB01.03.13
Poloxamer-Based Thin Film Ocussert for Long-Term Sustained Delivery of Dorzolamide Aishwarya V. Patil[1], Shrikant Joshi[2], Akshay M. Baheti[1], Amol Tagalpallewar[1] and Anil Pawar[1]; [1]Dr. Vishwanath Karad MIT World Peace University, India; [2]Maliba Pharmacy College, Uka Tarsadia University, India

Ocular drug delivery is challenging due to the unique anatomical and physiological barriers of the eye that limit drug absorption. Conventional eye drops often have low bioavailability and short residence time on the ocular surface, requiring frequent dosing that leads to poor patient compliance. Ocular inserts or Ocussert offer a promising solution to these issues by providing controlled drug release and sustained therapeutic effects. We developed ocular inserts of dorzolamide using polymers namely polyvinyl alcohol and propylene glycol and poloxamer 407 P. The formulated dorzolamide ocular inserts were studied for in-vitro drug-release profile, ex-vivo transcorneal permeation and in-vivo efficacy in rabbits. An in-vitro study showed sustained release of dorzolamide from the ocular inserts for seven hours. Ex-vivo transcorneal permeability study demonstrated gradual transcorneal permeation of dorzolamide indicating extended-release characteristics. The in-vivo study further validated the efficacy of these inserts in decreasing intraocular pressure. It is concluded that the dorzolamide ocular inserts exhibit a controlled release profile and can serve as a potential treatment option for glaucoma patients.

5:00 PM SB01.03.14
Advanced Breast Cancer Therapy: Thermosensitive Hybrid Hydrogel (PLGA-PEG-PLGA) with Metallic Nanoparticles Enhancing Withaferin-A Release Mythili Srinivasan; School of Health Sciences and Technology, Dr. Vishwanath Karad MIT-World Peace University, India

Background: Drug-delivering copolymers respond to temperature through sol-to-gel transitions. Lower transitions involve micellar growth, while upper transitions bring about micellar structure breakage. The fine-tuned PLGA-PEG-PLGA hydrogel, embedding silver or zinc nanoparticles, achieved a prolonged release of Withaferin-A.
Aim: This study sought to develop a hybrid hydrogel with in situ gel-forming for sustained release, utilizing the PLGA-PEG-PLGA copolymer and incorporating silver and zinc nanoparticles entrapped with Withaferin-A to address breast cancer.
Materials and Methods: PLGA (75:25) to PEG copolymer (3:1 ratio) formulated as *in situ* gel-forming hybrid hydrogel. Characterization involved 1H NMR, dynamic light scattering, and rheology. Silver and zinc nanoparticles were green synthesized using Camillia sinensis extract, and the characteristics of the prepared nanoparticles were analyzed through FTIR, Zeta potential, XRD, TEM, and FE-SEM. Subsequent to the drug entrapment into a hybrid hydrogel, *in vitro* drug release studies were conducted using a trans-diffusion cell apparatus. In vitro cell line studies using MCF-7 and MDA-MB-231 were conducted.
Results: Silver and zinc nanoparticles exhibited a particle size of 255 nm and 128.5 nm, respectively, with zeta potentials of -17.5 mV and -12.9 mV. XRD analysis confirmed 2-theta (deg) values of 56.20 and 56.64 for silver and zinc nanoparticles, respectively. FE-SEM and TEM reports displayed spherical-shaped silver nanoparticles and cylindrical-shaped zinc nanoparticles. Hydrogels demonstrated controlled release of Withaferin-A over 39 to 43 days based on polymer concentration. Effective internalization and antiproliferative impact in MCF-7 and MDA-MB-231 breast malignancy cell lines with negligible hemolytic effects. Zinc Nps induce selective cytotoxicity and apoptosis. Silver NPs exhibited dose-dependent cytotoxicity, inducing cell death and cell cycle hindrance in breast carcinoma cells.
Conclusion: The temperature-responsive PLGA-PEG-PLGA copolymer-based hybrid hydrogel, developed by incorporating silver and zinc nanoparticles, facilitated the sustained and controlled release of Withaferin-A. The formulation exhibits potential for efficient drug delivery in breast cancer therapy, with promising physicochemical properties and drug release kinetics.

5:00 PM SB01.03.15
Advancing Glioblastoma Treatment: Aptamer-Mediated, Long-Circulating, Cationic, PEGylated Hybrid Liposomes with Bavachalcone Ashwini Y. Chandane; Abhinav Education Society's, College of Pharmacy, India

Background: Glioblastoma, a formidable brain tumor, poses a significant therapeutic challenge. Current treatments face limitations due to the infiltrative nature and resistance of glioblastoma cells.
Aim: To explore the brain-targeting efficacy of cationic, long-circulating, targeting PEGylated liposomes incorporating transferrin, folate vitamins, and cationic albumin as aptamers (hybrid-liposomes). These liposomes are entrapped with poly (lactic-co-glycolic acid) (PLGA) nanoparticles containing the anticancer ligand Bavachalcone (BCN), with the goal of advancing therapeutic strategies for glioblastoma.

Materials and Methods: PLGA nanoparticles were formulated to encapsulate Bavachalcone. Characterization involved TEM, FE-SEM, FT-IR, XRD, particle size, and zeta potential analysis, confirming successful formulation. Liposomes were prepared via the ethanol-injection method and characterized using a particle size analyzer, zeta potential, TEM, and CSM. In silico studies encompassed network pharmacology, docking, and simulation for efficacy assessment. In vitro cell line studies utilized U87MG, LN-229, and T98G to evaluate cytotoxic effects.
Results: In silico studies unveiled the potential inhibitory effects of BCN on glioblastoma growth. Prepared NPs exhibited a particle size of 187 ± 0.5 nm, zeta potential of -33 mV, and drug entrapment efficiency of 89.33 ± 0.5%. Liposomes displayed a favorable particle size of 175.5 ± 0.29 nm with a positive surface charge of 8.72 ± 0.53 mV. Encapsulation efficacy was measured at 77.8 ± 0.61% for BCN. In vitro drug release studies demonstrated significantly higher cumulative release rates of BCN over 82 h. Hybrid liposomes exhibited superior cytotoxicity and accelerated apoptosis in glioblastoma cell lines (U87MG, LN-229, and T98G) through MTT assays. Cellular uptake studies confirmed enhanced internalization in glioblastoma cells. Cell viability assays demonstrated improved cytotoxic effects on glioblastoma cells.
Conclusion: Bavachalcone exhibited promise against glioblastoma, supported by in silico and in vitro studies. Hybrid liposomes offer an innovative approach for enhanced drug delivery, addressing BBB challenges. This approach sheds light on the potential of natural compounds and nanotechnology for enhanced glioblastoma treatment.

5:00 PM SB01.03.16
Chitosan Modified Hydrophobic Bacterial Cellulose as Skin Patches: Role of Simvastatin as a Model Drug in The Novel Drug Delivery Applications Peddapapannagari Kalyani and Mudrika Khandelwal; Indian Institute of Technology Hyderabad, India

Bacterial cellulose (BC) is nanofibrous with ultra-fine network, and hydrophilic in nature is being used as a drug carrier for immediate drug release applications. On of the benefits of using BC is that it offers a burst release of water-soluble drugs and limited to release of hydrophobic drugs for longer period. In our research, we modified BC with chitosan solution and without solution under ultrasonication by means of ex-situ modification and air dried. We achieved a water contact angle greater than 95, obtained hydrophobic modified BC as skin patches with the dimensions of 2*2 cm (about 0.79 in). To understand the characteristics of hydrophobic BC based skin patches, we conducted characterization studies by using FT-IR, DSC, BET, SEM, contact angle, swelling studies. Drug release studies were conducted by using Simvastatin as model drug for hydrophobic drug for two different concentrations. To know the drug release kinetics and mechanism of drug release, applied the various mathematical model fitting by applying Zero order, First order, Higuchi model, Korsmeyer Peppas model. The results showed that simple processed airdried BC is able to release the maximum amount of hydrophobic drug over 15 days (about 2 weeks) but chitosan modified BC has taken 40 days (about 1 and a half months) to get release maximum amount of drug. In this research, we achieved the sustain release of hydrophobic drug through effortless processes of ultrasonication and drying, but we further extend the release of hydrophobic drug by using hydrophobic modified BC. The goodness of fitting changes from first order to zero order and mechanism of drug release also changes from quasi-fickian to non-fickian for unmodified BC and hydrophobic BC respectively. Hence, we taken Simvastatin as a model drug for hydrophobic drug and maintains the drug profile over 40 days. Also, one can understands that hydrophobic modification to the BC matrix could find advantages over solubility issues of hydrophobic drugs, entrapment into the matrix, good skin permeation, good mechanical properties, long durability etc. However, BC has the emerging drug matrix for skin patches but achieving hydrophobicity with good barrier properties led to challenging outbreak for sustained release transdermal drug carrier especially long-term skin patches. . The obtained chitosan modified BC skin patches most useful in the monthly basis hormonal pills for birth control and thyroid management due to missing dose may hamper the regular activity of specific glands and also maintains constant therapeutic dose over period of time. Hence, most of the marketed drugs are in the form of hydrophobic in nature, the hydrophobic BC matrix could explore the novel drug delivery applications of sustained release novel drug delivery for hormonal management, thyroid treatment, cardiovascular disease, central nervous diseases, cigarette cessation, motion sickness, arthritis, diabetics, hyperlipidemia etc.

5:00 PM SB01.03.17
Thermosusceptible Nitric-Oxide- Releasing Nitrogel for Strengthening Antitumor Immune Responses with Tumor Collagen Diminution and Deep Tissue Delivery during NIR Laser- Assisted Photoimmunotherapy In-Kyu Park[1] and Yong-Kyu Lee[2]; [1]Chonnam National University, Korea (the Republic of); [2]Korea National University of Transportation, Korea (the Republic of)

Combined cancer immunotherapy has demonstrated promising potential with an amplified antitumor response and immunosuppressive tumor microenvironment (TME) modulation. However, one of the main issues that cause treatment failure is the poor diffusion and insufficient penetration of therapeutic and immunomodulatory agents in solid tumors. Herein, a cancer treatment approach that combines photothermal therapy (PTT) and nitric oxide (NO) gas therapy for tumor extracellular matrix (ECM) degradation, along with NLG919, an indoleamine 2,3-dioxygenase (IDO) inhibitor that reduces tryptophan catabolism to kynurenine, and DMXAA, a stimulator of interferon gene (STING) agonist that stimulates antigen cross-presentation, is proposed to overcome this issue. Upon NIR (808 nm) laser irradiation, NO-GEL achieved the desired thermal ablation by releasing sufficient tumor antigens through immunogenic cell death (ICD). NO delivery triggered local diffusion of excess NO gas for effectively degrading tumor collagen in the ECM, homogeneously delivered NLG919 throughout the tumor tissue, inhibited IDO expression that was upregulated by PTT, and reduced the immune suppressive activities. The sustained release of DMXAA prolonged dendritic cell maturation and $CD8^+$ T cell activation against the tumor. In summary, NO-GEL therapeutics offer a significant tumor regression with PTT and STING agonist combination that stimulates a durable antitumor immune response. Additional unification of IDO inhibition during PTT supplements the immunotherapy by reducing the T cell apoptosis and immune suppressive cell infiltration to TME. NO-GEL with the STING agonist and IDO inhibitor is an effective therapeutic combination to counter possible limitations during solid tumor immunotherapy.

5:00 PM SB01.03.18
Sodium Chloride Nanoparticles as Radiosensitizers Xinning Lai; University of Georgia, United States

Previous studies have demonstrated that SCNPs can enter cells through endocytosis and disrupt osmotic balance by releasing sodium and chloride ions. This process leads to cancer cell death. It's speculated that the SCNPs might affect the levels of other ions in the cells and have a significant impact on the redox balance. The research suggests that combining SCNPs with radiation therapy could enhance the effectiveness of the treatment. Radiation therapy works by ionizing molecules, especially water, to produce radicals that damage biomolecules like DNA. SCNPs might enhance this effect by promoting the production of reactive oxygen species (ROS).

In particular, we are interested in exploring SCNPs as a radiosensitizer for head and neck squamous cell carcinoma (HNSCC). HNSCC, a significant and increasingly common malignancy, often requires treatment through surgery or radiotherapy. However, these treatments have limitations, including toxicity and a high risk of recurrence. Combining chemotherapy with radiotherapy increases efficacy but also the risk of systemic toxicities. SCNPs are considered as a potential new treatment modality that could improve efficacy without adding toxicity.

In this study, we synthesized and characterized folate-conjugated sodium chloride nanoparticles (SCNPs@folate) and explored their potential as radiation sensitizers in HNSCC. Our results showed that the nanoparticles exhibited proficient cellular uptake and increased intracellular levels of sodium and chloride. Interestingly, the increase in sodium levels also causes calcium influx through the NCX, triggering an increase in ROS. We found that the ROS-

promoting effect works in tandem with IR, leading to GSH depletion, resulting in DNA and lipid damage, and ultimately cell death. Our in vitro results showed that there is a synergistic effect between SCNPs@folate and IR. In vivo studies showed that intratumorally injection of SCNPs@folate combined with irradiation resulted in a significant improvement in tumor growth inhibition compared to IR alone and a higher percentage of tumor-free mice. Taken together, our studies suggest a great potential of SCNPs@folate as a radiosensitizer in HNSCC.

SESSION SB01.04: Bioresponsive Nanotheranostics III
Session Chairs: Ruirui Qiao and Hao Song
Wednesday Morning, April 24, 2024
Room 428, Level 4, Summit

8:15 AM SB01.04.01
Multi-Pronged Approach for Targeting Oral Biofilms Keuna Jeon, Nesha Andoy and Ruby Sullan; University of Toronto, Canada

The oral microbiome is a complex system consisting of numerous bacterial species that plays host to both beneficial and harmful organisms. Among the pathogenic species in the oral cavity is *Streptococcus mutans* (*S. mutans*), the primary agent responsible for dental caries. Different antimicrobial-based strategies have been developed to tackle this problem, but the rise of antibiotic resistance among microorganisms necessitated the development of new and effective therapeutics. One such solution is the *de novo* antimicrobial peptide (AMP), GH12, which has showed potency against cariogenic bacteria. GH12 has a high content of α-helical structures that facilitate pore formation on bacterial membranes. Quorum sensing molecules such as competence stimulating peptides (CSP) have been identified as communicator molecules in bacterial species that are used to monitor not only their own but other species in their surroundings. Recently, polyserotonin (PSe) has emerged as a photothermally active nanomaterial that shows promise towards biomedical applications. In this work, I made a cocktail combining all three of the aforementioned components—AMP for bacterial killing, CSP for targeting, and PSe for localized heating—to develop a multi-pronged approach aimed to increase antibiofilm efficacy. My findings indicate that the presence of both peptides, membrane damaging and competence stimulating, in conjunction with the photothermally active PSe, effectively inhibited the growth of *S. mutans* in both planktonic and biofilm states. Overall, these results reinforced that the strategic use of multi-pronged therapeutic approaches could reduce cariogenic bacteria within the oral microbiome.

8:30 AM *SB01.04.02
Developing MRI-Based Therapeutic and Diagnostic Tools: From Cancer to Chemical Weapons Gemma-Louise Davies; University of Birmingham, United Kingdom

Magnetic resonance imaging (MRI) is a powerful non-invasive technique which becomes considerably more potent when contrast agents (CAs) are introduced. Molecular contrast agents based on Gd-chelates (e.g. Dotarem®) are regularly used in the clinic, however these usually lack specificity for selective disease or biomarker diagnostics, and can also suffer from poor signal-to-noise and blood circulation half-life, which can limit their clinical utility. Carefully designed contrast agents, and contrast agents based on nanomaterials have the potential to overcome these issues. In this talk, I will introduce our approaches to the careful design and development of MRI contrast agents tuned for different applications. I will describe nanostructured composites capable of reporting on drug release in a unique non-invasive way, of use for the pharmacokinetic mapping of drug release towards personalised medicine. I will also discuss recent advances in the diagnosis of chemical weapon poisoning using molecular contrast agents.

9:00 AM SB01.04.03
Precision in Colorimetric Sweat Sensing through Machine Learning Lijun Zhou, Minqin Zhang and Mohammad H. Malakooti; University of Washington, United States

Sweat contains diverse biochemicals that can serve as a source for detecting biomarkers, particularly in individuals with chronic conditions like diabetes. Non-invasive sweat sensors have gained popularity in various applications, promoting personalized healthcare and daily convenience. Different methods, including electrochemical, fluorescence, and colorimetric approaches, have been employed for real-time sweat analysis. Among these methods, colorimetric sensors stand out for their accuracy, stability, and portability in addition to their scalability in production processes. However, the main challenge in colorimetric sweat sensing currently lies in two areas: the need for improved sensor accuracy and the precise detection of color changes resulting from sweat exposure.
In this presentation, we will showcase the development of our sensors, offering real-time, stable, and rapid monitoring of glucose concentration and pH value without causing discomfort. The detection process takes approximately five minutes. Most notably, we address the challenge of detecting subtle color changes, which are virtually imperceptible to the naked eye, by leveraging artificial intelligence. We will discuss how the utilization of a breathable, bio-compatible, acid-base-balanced cotton substrate is the key to achieving higher color differences. In a series of experiments, we cover the fabrication and testing of two generations of pH sensors and two types of glucose sensors. We will then demonstrate the application of machine learning to our sensors and how it significantly enhances prediction accuracy. Three machine learning algorithms, namely Linear Discriminant Analysis (LDA), Support Vector Machine (SVM), and Convolutional Neural Network (CNN) are applied, demonstrating stable and excellent prediction accuracy of 90% for the test results. Finally, we will showcase the practical application of our combined pH and glucose sensors within a single substrate. This work contributes to the advancement of sensor preparation techniques and underscores the critical role of accurate machine-learning algorithms in the successful utilization of sweat sensors across various domains.

9:15 AM SB01.04.04
Collectively Interacting Colloidal Magnetic Nanoparticles with Strong AC Field Response for Remote Imaging and Thermometry Adam Biacchi, Thinh Bui, Frank Abel, Eduardo Correa, Samuel Oberdick, Curt Richter, Cindi Dennis, Solomon Woods and Angela R. Hight Walker; National Institute of Standards and Technology, United States

Colloidal magnetic nanoparticles (MNPs) are an important class of nanomaterials being investigated for use in a host of therapeutic and diagnostic modalities such as medical imaging, remote sensing, drug delivery, and hyperthermia.[1] These applications exploit the very soft ferrimagnetic magnetic behavior found in certain materials, often ferrites, when they are confined to tens of nanometers in diameter or less. Such nanomagnets can produce a strong collective response to applied alternating current (AC) magnetic fields, while simultaneously remaining dispersed in liquid media.

Recently, remote magnetic imaging of temperature has been identified as an exciting potential diagnostic application of colloidal MNPs. This thermometry measurement employs dispersed particles to construct a 3D visual representation of temperature throughout a volume. The technique, which is a variation

on the magnetic particle imaging (MPI) modality, is based on the temperature-dependent response of MNPs to an applied AC magnetic field. Additionally, when applying high-frequency magnetic fields, these MNPs can also generate localized heating, thus allowing them to function as nanotheranostics. However, significant challenges remain in the development of this technology, including a need to finely engineer MNPs to increase both their magnetic thermosensitivity and magnitude of AC response.

Here, we report on our development of MNPs, both as liquid dispersions and solid assemblies, specifically designed with a robust response to applied AC magnetic fields for imaging, thermometry, and temperature control. A series of colloidal nanocrystals based on ferrites were synthesized *via* highly tailorable and commercializable solution chemistry routes.[2] Careful selection of the synthetic reagents and precursor thermal decomposition kinetics allow for control of the resultant MNP composition (Fe, Co, Zn, V ratios) and size (5-80 nm). These MNPs were then investigated using solid- and liquid-phase AC and DC field magnetometry measurements. A home-built arbitrary-wave magnetic particle spectrometer was employed to perform relaxometry and measure magnetic AC susceptibility, allowing for a rigorous analysis of the temperature- and frequency-dependent AC response from 1 Hz to 30 MHz. The results were cross-correlated with detailed structural characterization including X-ray diffraction, light scattering, optical spectroscopy, and high-resolution electron microscopy to develop a set of structure-property relationships.

Finally, we tune these parameters to optimize spatial imaging of MNP magnetic response and a robust thermosensitive AC magnetic signal using magnetic particle imaging and thermometry instrumentation specifically developed for these applications.[3] We find particle size and compositional doping act as levers to optimize the AC response through the manipulation of interparticle and intraparticle magnetic spin interactions. Using these guidelines, we find the set of structural parameters that produce the most robust thermosensitive magnetic response and conduct imaging experiments whereby spatial reconstructions of colloidal MNP magnetic response are generated. The key to this improved performance, in both liquid and solid media, is the field-induced linear alignment of strongly interacting MNPs, resulting in a substantially augmented magnetic anisotropy. Collectively, these studies illuminate the complex behavior of MNPs under AC driving fields, reveal extensive correlations between nanoscale structure and magnetic response, and provide guidelines for the design of MNPs used in magnetic imaging, thermal sensing, and therapeutic applications.

Dynamic Nano-Assemblies for Biological Sensing, Imaging and Therapy Dai S. Ling; Shanghai Jiao Tong University, China

Inspired by the living systems that constantly undergo dynamic processes to maintain metabolic homeostasis, the Dynamic Nano-Assemblies have been developed to tackle complicated diseased environment for various biomedical applications. The materials composing the nanoparticles produce fascinating and diverse functionalities. The controllable assembly mediated by a multitude of different ligands would lead to the flexible modulation of nanomaterials' fate in vivo, endowing the nanoplatform with targeted delivery and accumulation to disease lesions. The clever combination of different functional components via the ligands directed co-assemblies would lead to the development of multifunctional nano-biomedical platforms for ion selective imaging, targeted delivery, fast diagnosis, biological regulation and efficient therapy. Furthermore, the ingenious control over the assembly/disassembly process based on small-sized functional nanoparticles could achieve both in vivo targeted delivery and stimuli-responsive disassembly for efficient disease therapy and bioelimination. Overall, dynamic nano-assemblies based biomaterials and drug delivery systems can achieve the improved diagnostic accuracy and therapeutic efficacy in many diseases including cancer, infection and neurodegenerative diseases.

Curcumin Derived Nanoscale Coordination Polymers for Modulating Stress Response in Plants Xin Zhang[1], Kangkang Feng[2], Yiyang Cong[2], Binqing Tao[1] and Hao Hong[2]; [1]Jiangsu Academy of Agriculture Sciences, China; [2]Nanjing University, China

Aim/Introduction:
Different stressing factors (e.g. drought, viral infection, insects, etc.) can impose significant survival threats to plants, especially in agricultural scenarios. Strategies to alleviate these stress burdens are able to improve plant physiology and adapt them to more "unfriendly" environment. Nanotechnology is a rising star to ameliorate plant stress situation. The goal of this study is to develop a curcumin-metal coordination nanoplatform with intrinsic protecting capacity against various stressing factors in chosen plants (Arabidopsis thaliana and wheat selected as the patients), and it can simultaneously deliver therapeutic cargos to further improve plants survival against various stressing factors.

Materials and Methods:
Curcumin (Cur) was reacted with manganese acetate or zinc acetate by a solvothermal method to form porous nanostructures. X-ray diffraction analysis revealed the crystal structures from both Cur-Mn and Cur-Zn. The morphology, stability, and other physical properties from Cur-Mn and Cur-Zn were also evaluated. The biocompatibility of Cur-Mn/Cur-Zn was tested in Arabidopsis thaliana and wheat cells and plants. Subsequently, the biological impacts of Cur-Mn/Cur-Zn along with their distribution profiles in these plants were measured post the spay of a suspension of 50 μg/mL. The cargo accommodating and releasing capacity was tested for fludioxonil, a broad-spectrum bacteria and fungi killing molecule. Finally, the molecular mechanisms of Cur-Mn/Cur-Zn for stress resistance in these two plants were also explored.

Results:
Cur-Mn and Cur-Zn had a size range of 60-90 nm (measured by TEM) with good dispersity and production yields. In their structures, curcumin was coordinated with manganese/zinc to form framework structures. Cur-Mn and Cur-Zn could be internalized into Arabidopsis thaliana and wheat cells with no noticeable toxicity. Once applied in the plant leaves, these materials could be absorbed quickly and transported via vessels inside plant stem, and reached the roots and other plant parts in a timely manner. Pure Cur-Mn and Cur-Zn could add the drought resistance capacity to these plants, and the molecular mechanisms were clarified by RNA-seq techniques. Moreover, Cur-Zn could accommodate more than 40%w/w of fludioxonil, and protect it from UV degradation. Once applied in the field of wheat, fludioxonil@Cur-Zn could protect wheat plants from fusarium blight in a more persistent manner.

Conclusion:
As a natural compound from the plant, curcumin can coordinate with different metals to form nanosized materials, and our findings revealed that this "from plant, to plant" strategy could be an efficient tool to protect plants from multiple critical stress factors, broadly applicable in plant rescue.

11:00 AM SB01.04.07
Understanding Structure and Stability for The Development of Novel Artificial Oxygen Carriers Martin A. Schroer[1], Jan-Eric Sydow[2], Fabian Nocke[2], Ozan Karaman[2] and Katja B. Ferenz[2,1]; [1]University of Duisburg-Essen, Germany; [2]University Hospital Essen / University of Duisburg-Essen, Germany

Red blood cell concentrates (RBC) are an indispensable tool in various clinical scenarios; however, the available quantity is already highly limited, which will become an even more severe problem in the future. To overcome these peculiarities and limitations of RBCs, we developed albumin-derived perfluorocarbon-based artificial oxygen carriers (A-AOCs), that are comprised of a perfluorodecalin (PFD) nano-emulsion core and an albumin shell, and have already successfully supplied oxygen in extra-corporally perfused hearts and various animal models **[1]**.

The structure and stability of A-AOCs is sensitive to changes of the carrier solution, so we need to learn more about the structure and structural changes on the nanoscale. Conventional characterization techniques lack the spatial resolution (*e.g.* light scattering) or need dried and consequently non-physiological samples (*e.g.* SEM, TEM), and thus yield limited information on A-AOC structure in solution. We therefore use X-ray scattering techniques to study A-AOCs, which do not have such limitations and allow also to study dense, opaque suspensions.

In this contribution, we present recent results of X-ray scattering measurements on A-AOCs covering a wide, clinical-relevant concentration and temperature range. We investigate A-AOCs from different synthesis approaches, using ultra-sound **[2]** and microfluidizing techniques, which reveal different sizes and stabilities. Based on these findings, it is now possible to optimize the synthesis parameters, in order to yield stable A-AOCs of desired size and dispersity.

This study demonstrates the huge potential of X-ray scattering for the study of pharmaceutical and medical-relevant samples **[3]**, with direct implications for the development of new formulations.

11:15 AM SB01.04.08
Versatile Application of Nanoscale Metal-Organic Frameworks for Intratumoral Delivery Eunseo Choi and Conroy Sun; Oregon State University, United States

Recent preclinical and clinical studies have highlighted the improved outcomes of combination radiotherapy and immunotherapy. Concurrently, the development of high atomic number (high-Z) metallic nanoparticles as radiation dose enhancers has been explored to widen the therapeutic window of radiotherapy and potentially enhance immune activation. Due to their high X-ray attenuation and high density, metal-based nanoparticles also have the potential to serve as imaging agents. Exploiting high-Z metal nanoparticles would provide clinical advantages for image-guided radiotherapy for targeted cancer treatment.
Despite the numerous advances in the field of drug delivery, there are still unmet needs that could lead to the development of a therapeutic molecule delivery carrier. In this study, we seek intraturmoral delivery of metal-organic frameworks to induce a robust stimulation of anticancer immunity for a systemic and long-lasting therapeutic benefit. By utilizing hafnium and iron-based metal-organic frameworks, we target immune cells with other targeted cancer therapies for synergistic advantages. We employ this nanomaterial as a pharmaceutical carrier system for the delivery of a wide range of materials, from small molecules to macromolecules. Radiotherapy-induced local tissue damage and inflammation have the potential to generate tumor antigen and release danger-associated molecular patterns. Nanoscale metal-organic frameworks are a versatile platform for combination radiotherapy. In addition to serving as drug carriers, our high-Z metal-organic frameworks are attractive nanomaterials that serve as contrast agents in biomedical imaging. We conducted phantom studies *in vitro* and *in vivo*, using microCT for real-time monitoring, which will facilitate advanced analysis of tumor cells and their responses to therapy. Intratumoral immunotherapy provides the capacity to manipulate the tumor microenvironment by targeting cells within the tumor microenvironment, making it an attractive therapeutic approach.

11:30 AM *SB01.04.09
Understanding Biological Processes Using Responsive Polymers and Bio-Orthogonal Chemistries Kristofer J. Thurecht, Nicholas Fletcher, Gayathri Ediriweera and Craig Bell; The University of Queensland, Australia

The evolution of therapeutic systems for cancer therapy has offered the opportunity to treat more complex and refractory disease. However, there still remains key challenges around quantitatively determining the tissue specific drug release profile of therapies. It is crucial, then, for materials to be precisely engineered to allow direct assessment of their behaviour in biological systems, as well as provide feedback on biological responses. Central to this thinking is the development of theranostics, which are materials that are able to provide both spatial and temporal information about therapeutic delivery and efficacy.
Our research explores a number of avenues related to materials engineering that can provide unique insights into therapeutic efficacy of nanomedicines, where biological cues can be utilised to give realtime feedback of drug effects. Alternatively, exogenous stimuli can also be applied resulting in material changes to the delivery system. Such stimuli can be administered as applied radiation (often in the form of visible/near infrared radiation), or through chemical stimuli that take advantage of the bio-orthogonality of defined covalent reactions. Bio-orthogonal reactions that take advantage of pre-targeting, allow diagnostic and therapeutic probes to be administered with greater site-specificity to diseased tissue.

In this presentation, I will present our work exploring novel approaches to utilise the pre-targeting strategy and bio-orthogonal reactions to improve therapeutic delivery to tumours while provided realtime readout of therapeutic activity. By exploiting the multivalency and multimodality of polymeric nanomaterials, the true advantages of theranostics can be realised in nanomaterial systems.

Wednesday Afternoon, April 24, 2024
Room 428, Level 4, Summit

1:45 PM *SB01.05.01
Biomaterials to Boost Cancer Immunotherapy Zhuang Liu; Soochow University, China

Cancer immunotherapy has attracted tremendous attention in recent years. In our recent studies, by employing rationally designed biomaterials as well as nanoscale delivery systems, we are able to enhance cancer immunotherapy via developing novel nano-vaccines, modulating tumor microenvironment, and achieving combinational immunotherapy, as evidenced by various animal model experiments. In this presentation, I would introduce our latest efforts in this exciting research direction. In particular, we have tried to combine various types of local tumor treatment methods with immunotherapy using biomaterials as the bridge. Stimulated by the tumor antigens released after local tumor ablation, the triggered immunological responses if in combination with immune checkpoint blockade (ICB) therapy could result in effective inhibition of tumor cells remaining in the body, promising for treatment of cancer metastasis. A strong immune-memory effect could also be observed after such treatment. Beyond that, we are also working on biomaterials that are capable of modulating tumor microenvironment for enhanced immunotherapy. A start-up company has been founded based on the technologies from our laboratory. Several pipelines are now being tested in clinical trials.

2:15 PM SB01.05.02
Lactate Oxidase Nanocapsules Boost T Cell Immunity and Efficacy of Cancer Immunotherapy Zheng Cao[1,1], Duo Xu[1], Wenting Chen[1], Yunfeng Lu[2,1] and Jing Wen[1,1]; [1]University of California, Los Angeles, United States; [2]Beijing University of Chemical Technology, China

Cancer immunotherapy has reshaped the landscape of cancer treatment, but its effectiveness in solid tumors is limited by the overproduction of lactate by cancer cells. Extensive trials are being conducted to reduce lactate concentrations through inhibiting lactate dehydrogenase. However, such inhibitors often disrupt the metabolism of healthy cells and cause non-specific toxicity. In contrast to those strategies, we target lactate itself with an enzyme, lactate oxidase, which effectively reduces lactate concentrations and releases hydrogen peroxide, an immunostimulatory molecule, in the tumor microenvironment. However, recombinant lactate oxidase from microorganisms possesses short circulating half-life, low enzyme activity, and potential immunogenicity. To circumvent this limitation, we report herein a nano-encapsulating strategy to encapsulate lactate oxidase molecules within a thin polymer shell through in-situ polymerization, affording the synthesis of nanocapsules. The nanocapsules stabilize lactate oxidase and prevent it from proteolysis and denature, minimize the immunogenicity, prolong the circulating half-life, enabling their use as a potent therapeutic for cancer immunotherapy. Lactate oxidase nanocapsules can promote the proliferation and activation of effector T cells and suppress tumor-resident regulatory T cells *in vitro*. As further demonstrated in a murine melanoma model and a humanized mouse model of triple-negative breast cancer, nanocapsules avert tumor immunosuppression and enhance anti-tumor T cell immunity by upregulating gene expression for T cell recruitment and activation, as confirmed by single-cell RNA sequencing. Such multifunctional lactate oxidase nanocapsules lead to improved efficacy of immunotherapies for solid tumors.

3:30 PM *SB01.05.03
Electrospun Nanofibers for Tissue Repair and Regeneration Jiajia Xue; Beijing University of Chemical Technology, China

Electrospun nanofibers have been widely applied for tissue repair and regeneration because of their advantages of mimicking the structure and composition of extracellular matrix to a certain extent. We have developed a series of scaffolds based on electrospun nanofibers to promote the repair and regeneration of peripheral nerve, bone, and skin. To improve the repair efficacy of peripheral nerve injury, we have constructed a nerve guidance conduit based on electrospun nanofibers in a bionic design to simulate the microenvironment required for nerve repair. Nerve growth factor and indocyanine green were loaded in phase change material particles and then deposited between two layers of electrospun nanofiber membranes to obtain a photothermal responsive scaffold. Upon the irradiation of a near-infrared laser, nerve growth factor was triggered to be released from the scaffold, promoting the axon extension. In addition, we deposited a density gradient of bioactive nanoparticles on the surface of uniaxially aligned fibers to guide the axon extension and accelerate cell migration along the direction of increasing the density of the nanoparticles. We further constructed degradable hydrogels in the lumen and regulated the degradation rate of the hydrogel to be increased from the proximal to distal position, allowing for the long-term delivery of growth factor loaded in the hydrogel and promoting the regeneration of sciatic nerve in rat. Additionally, we conducted large animal experiments in sheep to explore the effects of multi-channel nanofibrous nerve conduit on sheep nerve injury repair. For the repair of skin wounds, according to the demand of various growth factors in each stage of repair period, we constructed a multi-layered nanofibrous scaffold with a radially aligned nanofibrous inner surface. The scaffold effectively integrated multiple induced signals such as topography, bioactive factors and photothermal response to achieve spatiotemporally controlled delivery and accelerated wound healing. Combined with photothermal effects, we constructed a multifunctional bone repair scaffold to recruit stem cells and induce their osteogenic differentiation to improve the repair of bone defects. We also developed gradient self-assembled activated fiber scaffolds to induce osteogenic differentiation of stem cells. In summary, electrospun nanofibers can be applied to construct multifunctional tissue repair materials to promote tissue injury repair and regeneration.

4:00 PM SB01.05.04
Effects of Sequential Ultrasound Irradiation in The KHz and MHz Bands on Transdermal Administration of Biopolymeric Drugs Kengo Matsubara and Yuta Kurashina; Tokyo University of Agriculture and Technology, Japan

Introduction
Biopolymeric drugs are expected to have high efficacy and minimal side effects due to their specificity. Meanwhile, a minimally invasive method of administering these drugs is difficult to establish. As one of the attracting methods, sonophoresis is a method of drug-administering by disrupting the stratum corneum layer through the collapse of cavitation bubbles and drug infusion by the microjets induced by the bubbles (N. Deagicevic, *et al.*, ***Springer*** 2017). However, the amount of drugs administered by conventional techniques is limited, since the randomness of the microjets generated from cavitation bubbles makes stable drug infusion difficult. This is because the position of the bubble nucleus for the generation of cavitation bubbles is unstable and not directional.
Here, we propose an ultrasound irradiation method with multiband to achieve efficient transdermal administration of biopolymeric drugs. Especially, the synergistic effect of cavitation induced by low-frequency and acoustic streaming induced by high-frequency on drug administration is demonstrated by sequentially irradiating in the kHz and MHz bands with fluorescence-modified ovalbumin (OVA, for nano-sized drug model).

Materials and methods
Transdermal administration experiments with fluorescence-modified OVA to porcine skin irradiated by ultrasound (US) were carried out on the effectiveness of acoustic streaming by sequential irradiation in the kHz and MHz bands. Here, the irradiation distance of the acoustic streaming on the drug

dosage was evaluated. Ultrasound irradiation was experimented under the following four conditions. As a conventional method (i), US in the kHz band was applied for 10 min (control). (ii)-(iv) As the method proposed, US in the kHz band and MHz band was sequentially applied for 5 min., respectively. The MHz band was irradiated at a distance of (ii) 1 mm, (iii) 2 mm, and (iv) 3 mm. After irradiation of multiband US, the skin from each condition was lysed, and the fluorescence intensity of cyanine 5 modified OVA was measured by a spectrofluorometer to evaluate the dose of the nano-drug model quantitatively.

Results and discussion
In order to investigate the effect of acoustic streaming on the proposed method, the ultrasonic irradiation device was constructed using two types of transducers. A Langevin transducer with a resonance frequency of 45.9 kHz was used for kHz band irradiation (X. Xie, *et. al.*, ***J Drug Deliv Sci Technol*** 2022), and a piezoelectric device with a resonance frequency of 1.97 MHz was utilized for MHz band irradiation. The velocity of acoustic streaming is expressed as a function that depends on the distance from the irradiation source (J. Friend *et. al*, ***Lab Chip*** 2019). The results obtained from the function suggest that under the conditions of this study, the flow velocity rises with increasing irradiation distance in the MHz band. This calculated outcome shows that the drug dosage increases in the range of 1 mm to 3 mm. The results of fluorescence intensity measurements for each condition suggested that the highest drug dose was obtained when the US in the MHz band was irradiated at an irradiation distance of 3 mm after irradiation of the US in the kHz band. Furthermore, as with the theoretical value, the drug dose significantly rose with increasing irradiation distance ((i) vs (iv): $*p<0.05$, (ii) vs (iv): $**p<0.01$, Student's *t*-test). These results suggest that sequential irradiation of the kHz and MHz bands is more effective than conventional irradiation of only the kHz band. Therefore, the acoustic streaming induced by the MHz band contributes to the improvement of drug dosage for sonophoresis.
The development of the multiband US administration method enables us to propose minimally invasive biomacromolecule drug administration as an alternative to injection. Therefore, this method is expected to contribute to the development of research on biopolymeric drug materials.

4:15 PM SB01.05.05
Magnetic Liquid Marbles as Thermo-Responsive Materials under Alternating Magnetic Fields Rafal Bielas[1], Tomasz Kubiak[1], Matus Molcan[2], Ivo Safarik[3] and Arkadiusz Jozefczak[1]; [1]Faculty of Physics, Adam Mickiewicz University in Poznan, Poland; [2]Institute of Experimental Physics, Slovak Academy of Sciences, Slovakia; [3]Biology Centre, ISB, Czech Academy of Sciences, Czechia

Responsive materials are essential in modern scientific and industrial fields. Within this context, the potential to control these materials using external stimuli, such as magnetic fields, is of great interest. Magnetic liquid marbles—airborne droplets surrounded by particles—are emerging as suitable candidates for such purposes. For example, their ability to open and close on-demand using static magnetic fields makes them ideal for specialized tasks, such as testing fragile entrapped species [1].

When exposed to alternating magnetic fields, the internal temperature of liquid marbles rises, a phenomenon attributed to magnetic energy dissipation due to magnetic relaxation and hysteresis processes. Elevated temperature can be employed for functions like amplifying DNA contained within the particle shell of these marbles [2]. Building on this, we propose utilizing magnetic heating to modulate thermo-responsive liquid marbles.

In our experiments, we prepared liquid marbles with a ferrofluid, which included agar powder and either maghemite nanoparticles or magnetosomes (nanoparticles from magnetotactic bacteria). The droplets were coated with either polymer or bio-particles and then exposed to an alternating magnetic field with a kHz frequency. The resulting temperature increase inside the liquid marbles initiated varied reactions depending on their particle coating. With polymer particles, a combination of partial particle fusion and enhanced evaporation led to the creation of rigid magnetic shell residuals, which could be seen as precursors to a new generation of liquid marbles [3]. On the other hand, for non-thermo-responsive particle coatings, such as *lycopodium* shell, the liquid core underwent partial disintegration driven by reversal process of gelation. The diverse structures observed after the magnetic heating procedure may provide new way for developing materials suitable for applications like smart lotions or creating new types of capsules for theranostic procedures.

The work was supported by Polish National Science Center through the project no. 2019/35/N/ST5/00402.

Radiation-Activated Ferroptosis with Liposome Nanoparticles Encapsulating 7-Dehydrocholesterol Enhancing Antitumor Immune Responses Jianwen Li, Zhizi Feng, Xinning Lai, Wei Yang, Shuyue Zhan and Jin Xie; University of Georgia, United States

In this project, we explore an approach that triggers ferroptosis and enhances antitumor immune responses by external radiation. The key component of this technology is 7-dehydrocholesterol (7DHC), a natural biosynthetic precursor of cholesterol. This zoosterol can react with radiation-induced reactive oxygen species (ROS), initiating a radical chain reaction between 7DHC and polyunsaturated fatty acids (PUFAs) in cell membranes. We show that this interaction leads to direct lipid peroxidation, culminating in cell death *via* ferroptosis. In terms of delivery, we show that 7DHC, similar to cholesterol, can be incorporated into the lipid layer of liposomes. To improve targeting, we incorporated NTS_{mut}, a ligand for NTSR1 that is overexpressed in multiple malignancies, into liposomal nanoparticles. Our tests show that these NTS_{mut}-incorporated and 7DHC-loaded liposomal nanoparticles are minimally toxic, but significantly enhance the efficacy of radiation by activating ferroptosis in cancer cells. As a highly immunogenic cell death (ICD) pathway, ferroptosis induced by our treatment further triggers the increased secretion of danger-associated molecular patterns (DAMPs) and elevated surface exposure of “eat-me” signals such as ATP, IFN-β and calreticulin. These patterns are then sensed by antigen-presenting cells such as dendritic cells (DCs), in turn boosting T cell driven adaptive immunity. Such a strategy of controlled activation of ferroptosis offers a favorable therapeutic index and opens avenues for clinical application.

Advancing Targeted Drug Delivery via Optimization of Drug-Loaded Polymeric Nanoparticles and Red Blood Cell-Mediated Approaches Hermon P. Girmatsion[1,2,2], Vincent Lenders[1,2,2], Bella Manshian[1,2,2] and Guy Van den Mooter[1,2]; [1]KU Leuven University, Belgium; [2]KU Leuven, Belgium

Bronchopulmonary Dysplasia (BPD) represents a complex pathophysiological challenge in neonatal care, predominantly affecting preterm infants. Current interventions, such as mechanical ventilation and supplemental oxygen, often yield suboptimal outcomes, necessitating the exploration of novel therapeutic modalities. The administration of Dexamethasone (DEX), while effective in reducing mechanical ventilation dependency, is hindered by its severe long-term neurodevelopmental impacts and crystalline structure leading to poor solubility.

In response, our study pioneers an advanced drug delivery system involving the encapsulation of DEX within poly(lactic-co-glycolic acid) (PLGA) nanoparticles (NPs), subsequently coupled to red blood cells (RBCs). This approach aims to produce a polymer-matrix-stabilized amorphous form of DEX, ensuring sustained and localized pulmonary release. By leveraging these DEX-loaded NPs (DEX-NPs) in combination with RBCs, we aim to optimize drug circulation time, biodistribution, and targeted lung delivery, thereby attenuating systemic adverse effects of DEX.

We employed the nanoprecipitation method to synthesize drug-free and DEX-loaded NPs, thoroughly characterizing their size, polydispersity index, zeta potential, encapsulation efficiency, and DEX stabilization capability. Our results demonstrate that these polymeric NPs effectively encapsulate and stabilize DEX up to 3 mg, with higher amounts leading to crystallinity. Solvent, polymer, and drug compatibility studies indicated that PLGA stabilizes about 15% of its weight in DEX (~3 mg) with acetone or acetone: DMSO as solvents. Notably, acetone and DMSO blend markedly improved encapsulation efficiency and drug stability in PLGA nanoparticles.
In addition to these findings, we successfully coupled various types of NPs to mouse RBCs, examining the efficiency of this coupling and the biocompatibility of the resultant constructs. This element of our research was critical in assessing the feasibility and safety of the NP-RBC conjugates for *in vivo* applications. Our *in vitro* toxicity assessments across various cell lines revealed that while plain NPs exhibited limited toxicity, DEX-NPs showed higher cytotoxicity at concentrations above 0.05 mg/mL. *In vivo* studies on term-born neonate CD-1 mouse pups highlighted the superior lung targeting of NP-hitchhiked RBCs compared to free NPs.

This study emphasizes the potential of DEX-PLGA NP-RBC conjugates in revolutionizing BPD treatment. Our findings not only advocate for the targeted pulmonary delivery of therapeutics but also set a foundation for subsequent investigations into the efficacy and safety of this novel approach in the context of neonatal lung diseases.

SESSION SB01.06: Bioresponsive Nanotheranostics V
Session Chairs: Jessica Hsu and Bella Manshian
Thursday Morning, April 25, 2024
Room 428, Level 4, Summit

8:30 AM *SB01.06.01
Biomimetic Nanoparticles for Drug Delivery Chunxia Zhao; The University of Adelaide, Australia

Nanotechnology holds great promise for cancer diagnosis and treatment. A wide range of nanoparticles have been developed ranging from polymer particles to lipids, proteins and other synthetic compounds for cancer drug delivery. However, only a handful cancer nanomedicines have been approved by the FDA (such as Doxil, and Abraxane). This demonstrates the huge gap between laboratory research and clinical translation of cancer nanomedicines, mainly due to several key barriers: (1) challenges in large-scale production of nanomedicine with good reproducibility and well-controlled properties; (2) incomplete understanding of the interactions between nanoparticles and biological systems; (3) targeted delivery. To address these fundamental issues, my group has been focusing on the development of platform technologies for producing nanoparticle libraries with reproducible and systematically varied properties (liposomes, polymer nanoparticles and nanocapsules) with high drug loading. We also developed different strategies for improving targeted delivery. Particularly, we developed a bioinspired nanotechnology integrating naturally derived cell membranes for enhanced biointerfacing capabilities and nanoparticles for incorporation of various payloads for targeted delivery, which provides a revolutionising strategy for fabricating nanoscale artificial cells. We have also developed biomimicking chips (Tumor-on-a-Chip, Tumor-Vasculature-on-a-Chip) to fundamentally understand nanoparticle extravasation and their tumor accumulation.

9:00 AM SB01.06.02
Soybean Oil-Derived Lipids for Efficient mRNA Delivery Jessica Hsu, Zhongmin Tang and Weibo Cai; University of Wisconsin-Madison, United States

Lipids have been extensively utilized as a delivery platform for mRNA. Lipids consist of an N element-based head group with hydrophobic tails of varying composition and different length. Currently, most lipid materials are either positively charged or ionizable in nature, which allows for the formation of nanoparticles through electrostatic interactions with negatively charged mRNA. This not only serves to safeguard mRNA from enzymatic degradation but also facilitates endosomal escape, thereby ensuring mRNA expression and functions. In addition to core lipids, the delivery platform comprises helper lipids, cholesterol, and PEG lipids. Varying compositions, surface modifications, charges, and pKa values can impact mRNA expression and allow organ-specific targeting for disease treatment. Hence, continued investigation of novel lipid materials and formulations will further advance our understanding and techniques in optimizing mRNA delivery.

The ideal synthesis of lipids involves adhering to key principles, such as operating under solvent-free conditions, employing a straightforward reaction process, and eliminating the need for purification steps. These criteria aim to enhance product purity and streamline production, thereby increasing the likelihood for clinical translation. Current lipid synthesis methods involve Michael addition, epoxide ring-opening, reductive amination, and thiol-ene reactions. Furthermore, an effective lipid should encapsulate a high mRNA payload for improved expression *in vivo* and exhibit favorable biosafety without significant adverse effects. Notably, a common soybean oil derivative, rich in epoxy groups, can readily undergo ring-opening reactions with amino-containing compounds. Since soybean oil is FDA-approved and has excellent biocompatibility, it may give rise to a new class of synthetic lipid materials with the potential for mRNA delivery applications.

In our system, epoxidized soybean oil and amino-containing compounds with varying carbon chain lengths, structures, and numbers of N were the sole reactants. Lipids were synthesized via epoxide ring-opening reactions and subsequently purified through heating and rotary evaporation, all without the use of solvents. We found that the majority of lipids derived from soybean oil showed high mRNA loading capacity, thereby enhancing mRNA expression both in vitro and in vivo, all the while demonstrating excellent biosafety. In our *in vivo* studies of Luc mRNA delivery, we observed that certain lipids could enhance mRNA expression in the spleen, while others could achieve high expression in the lungs or liver. This highlights the potential utility of these lipids for precise and tunable organ targeting in the treatment of relevant diseases. In addition, soybean oil-derived lipids displayed exceptional performance in delivering Cre mRNA for gene editing. Encouraged by these results, we anticipate that soybean oil-derived lipid materials can assume a more prominent role in the realm of mRNA delivery for a diverse range of bioapplications. The synthesis of novel lipids utilizing FDA-approved substances remains a promising domain yet to be fully explored.

9:15 AM SB01.06.03
Nature-Inspired Nanoparticles for Therapeutics and Vaccine Delivery Hao Song[1,2]; [1]The University of Queensland, Australia; [2]Massachusetts Institute of Technology, United States

Recent advances in nanotechnology have greatly boosted the development of novel delivery systems for therapeutic and vaccine applications, in particular highlighting the great success of lipid nanoparticle-based mRNA vaccines fast responding to the COVID-19 outbreak. To lead a successful nanomedicine technology, the key lies in the rational design and fabrication of safe and efficient nano-carries, while the delivery performance could be maximized by custom-designed nanoparticles considering the unique bio-interface configurations towards both cargo biomolecules and cell/tissue surfaces. Mimicking the spiky morphology of pollen and virus, which allowed enhanced interactions at bio-interfaces, here, we showcase our recent progress in the development of spiky nanoparticle-based smart theranostics.[1-4] Through a simple sol-gel synthesis approach, colloidal nanoparticles with an intrinsic spiky surface are fabricated and characterized by the advanced microscopy techniques of electron tomography.[5] We demonstrated the precise control over the delicate nanotopography of spiky nanoparticles, engineering the surface chemistry,[6] hollow interior,[7] and asymmetry of the particles.[8] We explored the interactions of these nature-inspired unique spiky nano-features towards both biomolecules and cells, gaining new understandings of the bio-nano-interfaces. Our findings underpinned the development of 1) a bacterial-adhesive antimicrobial nano-agent,[1, 9-11] featuring an antibiotic-free approach to address the drug-resistance issue of infections; 2) a nano-burr hooking the rope-like DNA/mRNA molecules for efficient intracellular delivery,[12] which allowed sufficient enzymatic protection of gene molecules and enabled of upregulated translation[2]; 3) a pathogen mimetic adjuvant that boosts the vaccine delivery performance, [3] including our most recent study in developing DNA and subunit (RBD) spiky nano-vaccines for SARS-Cov-2.
From bench to market, this spiky nanoparticle-based delivery platform is on the translation collaborated with industrial partners toward novel nanomedicine. Our journey from fundamental research to the launching of 'NUVEC®' will also be shared in this talk.

Hydrogen Medicine and Nanomedicines Qianjun He; Shanghai Jiao Tong University, China

Hydrogen molecule has broad-spectrum anti-oxidation and anti-inflammation effects, and has exhibited clear therapeutic functions against many inflammation-related diseases and relatively high biosafety. Therefore, hydrogen therapy is an emerging and promising therapeutic strategy. But hydrogen medicine is currently facing three major issues, including (1) what is the fundamental principle of hydrogen therapy; (2) how to detect hydrogen molecules in vivo; (3) how to deliver hydrogen molecules to the focus in vivo. Aiming to these three issues, our research group has obtained a cascade of important research achievements in principle exploration, tool development, and materials application, mainly including (1) the discovery of the biological target of hydrogen molecule and the disclosure of the fundamental principle of its anti-inflammation, anti-cancer and anti-senescence functions; (2) the development of the first bioprobe of hydrogen molecule and the verification of the high biological barriers-crossing capability of hydrogen molecule; (3) the development of a series of novel biomedical materials for hydrogen delivery to enhance the efficiency of hydrogen delivery and their applications for the treatment of many major diseases. This lecture will deliver our recent research advances in these aspects.[1-10]

Nanozymes and Polymers for Nitric Oxide Delivery from Prodrugs Rona Chandrawati; University of New South Wales, Australia

Nitric oxide (NO) is a potent biological molecule that contributes to a wide spectrum of physiological systems, including the cardiovascular, immune, and central nervous systems. However, NO therapeutic delivery technology remains severely limited due to the physiological properties of NO: 1) NO has a short half-life in human tissues (seconds); 2) NO can only diffuse over short distances (~100 μm), thus limiting its action to only areas near the source of delivery; and 3) NO can exert protective or deleterious effects depending on its concentration. Current strategies for NO delivery focus on encapsulation of NO donors into pre-fabricated scaffolds or an enzyme-prodrug therapy approach. The former is limited by the finite pool of NO donors available, while the latter is challenged by the inherent low stability of natural enzymes. Enzyme mimics are attractive substitutes for their natural counterparts in diverse biomedical applications because they have excellent stability against biological degradation compared with natural enzymes. In this work, we present nanoparticles and polymers that can catalytically decompose natural (endogenous) and synthetic (exogenous) *S*-nitrosothiols NO donors to generate NO at physiological conditions. With this approach, we envision that sustained NO delivery could be achieved by relying on life-long pools of endogenous NO donors, and when needed, on-demand NO delivery at the desired levels of NO could be realized by externally administered exogenous NO prodrugs. By tuning the concentrations of particles/polymers and NO prodrugs, physiologically relevant NO levels were generated. These materials preserved their catalytic property to generate NO for at least 6 months. The nanoparticles and polymers were immobilized in biomaterials and on surfaces, and we demonstrated the therapeutic activity of NO to inhibit cancer cell proliferation and disperse bacterial biofilms.

11:00 AM SB01.06.06
Ultrasound-Induced Cascade Amplification in Mechanoluminescent Nanotransducer for Sono-Optogenetic Deep Brain Stimulation Huiliang Wang; The University of Texas at Austin, United States

Remote and minimally invasive neuromodulation is a promising approach in the advent of clinical applications. Ultrasound-triggered mechanoluminescent technology offers a promising approach for achieving remote brain modulation. However, its application has thus far been limited to shallow brain depths due to challenges related to low sonochemical reaction efficiency and restricted photon yields. Here we report a self-amplifying mechanoluminescent nanotransducer based on cascade reactions in liposomes to achieve efficient light emission upon ultrasound stimulation. As a result, blue light was generated under ultrasound stimulation with subsecond response latency. Leveraging the high energy transfer efficiency of focused ultrasound in brain tissue and the high sensitivity to ultrasound of these mechanoluminescent nanotransducers, we are able to show efficient photon delivery and activation of ChR2 expressing neurons in both the superficial motor cortex and deep ventral tegmental area (VTA). Our novel liposome nanotransducers enable minimally invasive deep brain stimulation for behavioral control in animals via a flexible, mechanoluminescent sono-optogenetic system.

11:15 AM SB01.06.07
Development of *In-Situ* Gel Containing Brinzolamide loaded Nano Structured Lipid Carrier and Its Evaluation Dipti Dhurat, Anil Pawar, Shrikant Joshi, Amol Tagalpallewar and Akshay M. Baheti; School of Health Sciences and Technology Dr Vishwanath Karad MIT World Peace University Pune, India

Ocular drug delivery system is most challenging and complicated to deliver drugs at the target site with its therapeutic dose. Intraocular bioavailability is only 5 to10 % of total eye drop administered. In past few decades, researchers have attracted to nanotechnology based drug delivery system in which lipid based Nanostructured lipid carriers (NLC) appear as effective ophthalmic drug delivery system, which have, higher drug loading, stability and biocompatibility as compare to other lipid carried due to use of physiologically biodegradable lipid. The Nanostructure carrier provides more retention time, better permeation, targeted delivery, improve bioavailability, Non-toxic. Now a days, the conventional eye drops replace by Polymeric eye drop i.e. *in-situ gel*, they are liquid in nature after instillation it undergoes gelation to form viscoelastic gels triggered by stimulation such as temperature, pH and ion activation. Consequently, gel formed increases residence time, extended drug release, enhances bioavailability, reduce dosing frequency and patient compliance.The aim of this work to develop and evaluate *in-situ* gel containing Brinzolamide loaded Nano structured lipid carrier to increase its retention time, Bioavailability, Corneal permeation, reduce dose and dosing frequency.
The saturation solubility study was used to select liquid lipid. The solubility of Brinzolamide was determined in several solid lipids such as Bees wax, Stearic acid, Gelucure50/13, Palmitic acid, Glyceryl mono stearate (GMS), Precirol ATO, Compritol ATO 888, cetyl palmitate. Compatibility between selected lipids was examine by preparing mixture of solid lipid and liquid lipid in a ratios of 9:1, 8:2, 7:3, 6:4, 5:5, 4:6, 3:7, 2:8 and 1:9. Only one single phase Mixtures were selected for further study. High speed homogenization method was used to prepare Brinzolamide loaded NLCs. A three-factor, three-level Box–Behnken design experimental design (BBD) was applied for evaluation of critical experimental conditions to maximize experimental efficiency and minimize experiments to optimize The particle size and particle dispersity index (PDI) of the NLCs was determined using the dynamic light scattering (DLS) at a fixed angle of 90 degree at 25 degree C using Nanophox, Sympatech, Germany .The ZP of BRZ-NLC was determined by using zeta sizer (Delsa Nano C, USA) to check electrostatic mobility and stability of formulaton. The entrapment efficiency (% EE) of BEZ in NLC formulation was determined The physical state of BRZ-loaded nanostructured lipid carriers demonstrated by DSC characterization technique. BRZ-loaded NLC *in situ* gel was prepared by the cold method. The drug content was determined by HPLC. In vitro release of BRZ-loaded NLC *in situ* gel was studied on Franz diffusion cell. Transcorneal permeation studies were carried out on freshly excised goat cornea. HET CAM (Hen's egg chorioallantoic membrane) study is an alternative to the Draize *in-vivo* rabbit eye test for the recognition of ocular irritations. Therapeutic activity study was conducted with albino rabbits (1.5–2 kg) under the permission of Institutional Animal Ethics Committee (IAEC).
From solubility data Gelucire 50/13 and Oleic acid were selected as the solid and liquid lipid for NLC preparation. Amongst various ratios of solid and liquid lipid 9:1, 8:2, 7:3, 6:4, and 5:5 no phase separation and homogenous mixture was observed for 8:2 ratio, this were selected as lipids mixture. The SEM analysis reveals that spherical and smooth surface of NLC with uniform distribution of particles. BRZ content in formulated *in situ* gel was determined and found to be in range of 99.34-98.58%.BRZ-NLC shows rapid release of drug (68.33%) within 4 h and within 7 h it completely releases (94.33%) drug.This initial raid release of drug due to the unentrapped drug which release from NLC) Whereas, BRZ-NLC *in situ* have extended and slow release of drug (96.44%) up to 15 h.

A Hitchhiker's and Backpacker's Guide to Drug Delivery Samir Mitragotri[1,2]; [1]Harvard University, United States; [2]Wyss Institute, United States

Nanoparticle-based drug delivery systems are widely explored to improve the biological outcome of chemo and immunotherapy. However, poor vascular circulation, limited targeting and the inability to negotiate many biological barriers are key hurdles in their clinical translation. Biology has provided many examples of successful “carriers” in the form of cells, which routinely overcome the hurdles faced by synthetic nanoparticle systems. We are exploring hitchhiking and backpacking approaches which involve combining synthetic particles with cells to drastically alter the in vivo fate of the particles as well as the cells. I will provide an overview of the principles and examples of hitchhiking and backpacking approaches for drug and cell therapy.

Ultrathin Nanosheets for Catalytic Cancer Therapy Sophia Gu; University of New South Wales, Australia

Nanotechnology has emerged as a promising approach for precision treatment of cancers. Two-dimensional nanoparticle-based therapeutic agents have been developed for safe and efficient treatment of cancers.[1] In this talk, I will present our recent work on development of nanosheets for catalytic cancer therapy. We have developed a sustainable method to synthesize ultrathin layered double hydroxide nanosheets via a polymer-assisted bottom-up approach,[2] and demonstrated high catalytic activity to disproportionate hydrogen peroxide in tumors and in-situ generated hydroxyl radicals efficiently to kill tumor cells.[3] Without any drug loading, the nanosheet exhibited highly selective and specific anti-tumor effect. The hydroxyl radical generation-induced anti-tumor effect was further enhanced by cascade catalytic reactions triggered by photocatalysis.[4] We also showed that the nanosheet generated oxygen bubbles and promoted the long-distance and directional movement toward the tumour microenvironment, thus achieving targeted delivery of therapeutic nanomedicine without traditional surface ligand modification.[5]

10:30 AM *CH01.01.01
An *In Situ* look at Interfacial Structure and Dynamics during Nucleation and Self-Assembly James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Interfaces play a critical role in nucleation and growth from solutions by altering the distribution of water and ions from that of the bulk, introducing an interfacial free energy that largely determines the free energy barrier to nucleation, and creating an entropic repulsion that acts as a volume exclusion force to drive colloidal assembly. The origin and characteristic length scales of these phenomena are inherently atomic-to-molecular but are manifest in ensemble dynamics and outcomes. Moreover, processes like nucleation and self-assembly arise from fluctuations, making the events that must be probed transient in nature. Consequently, in situ imaging techniques that can capture structure and its evolution, particularly at high speed and atomic-to-nm resolution, are required to build a quantitative picture of such processes. Here I use examples from and *in situ* TEM, high-speed AFM, and fast force mapping studies of interfacial structure, nucleation, and particle assembly to elucidate the mechanisms by which interfaces direct these processes, leading to unique pathways, materials, and morphologies. The results reveal the importance of surface charge, chemical gradients, and solvent organization near interfaces in determining how ordered materials emerge from the solution.

11:00 AM CH01.01.02
***In Situ* Characterization of Calcium Carbonate Crystallization on Nano-Textured Surfaces** Tobias Armstrong[1], Julian Schmid[1], Janne-Petteri Niemelä[2], Ivo Utke[2] and Thomas Schutzius[1,3]; [1]ETH Zurich, Switzerland; [2]Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]UC Berkeley, United States

Natural and technological interfaces influence the crystal nucleation and growth of calcium carbonate, including the crystallization pathways, the thermodynamic/kinetic barriers, and the crystal orientation. Predictions show that the heterogeneous nucleation rate on functionalized surfaces of the calcium carbonate polymorph calcite are 20 orders of magnitude higher compared to homogeneous nucleation. Hence, the crystallization pathway can be redirected from complex free energy landscapes towards the classical nucleation theory, allowing to compare different functionalized surface. This is exemplified by higher nucleation rates of calcite for carboxyl groups on surfaces than for thiol groups on surfaces under the same conditions. While smooth functionalized surfaces have been studied, the effect of nano-textured surfaces on calcium carbonate crystallization is unknown. Based on research for other phase change materials, it can be either: promoting or inhibiting. If calcium carbonate crystallization is promoted or inhibited by nano-textured surfaces is relevant to the understanding of calcium carbonate crystallization and facilitates rationally designed interfaces.
Here we show the effect of nano-textured functionalized surfaces on calcium carbonate crystallization. We fabricated and quantified a rationally designed nano-textured surfaces using blockcopolymer lithography, ensuring a significant amount of surface curvature features in an order of magnitude to the critical nucleus size for calcite. The fabricated nano-textured surfaces are functionalized with carboxyl groups and compared to smooth functionalized surfaces to isolate the effect of the nano-texture onto the crystallization. The investigation of the crystallization at different supersaturation conditions provides a holistic understanding of the effect on the thermodynamic as well as the kinetic barrier. *In situ* optical transmittion microscopy coupled with digital holographic microscopy characterize the nucleation and single-crystal growth rates in a microfluidic cell with controlled calcium carbonate supersaturation through mixing. The analysis of the acquired microscopy images is using trained instance segmentation algorithms for accurate crystal detection.
This work shows that nano-textured surfaces promote the calcium carbonate nucleation by more than one order of magnitude compared to a smooth surface at the same supersaturation. This difference can be described by the classical nucleation theory, explaining an increasing kinetic barrier of nucleation and a decreasing thermodynamic barrier. For the tested supersaturations and nano-textures, the decreasing thermodynamic barrier outperforms the increasing kinetic barrier. While the increasing kinetic barrier is affected by a decreased monomer collision probability in the confined volumes of the nano-texture pits, the thermodynamic barrier is lowered by surface curvatures in the pits within an order of magnitude to the critical nucleus size. Besides higher nucleation rates, calcium carbonate crystallization on nano-textured surfaces shows lower induction times, higher site densities, and lower single-crystal volume growth rates. We expect that this work will provide guidance for the design of interfaces, which are needed to advance technologies relying on the understanding of the crystallization behavior of calcium carbonate and other inorganic minerals.
This project has received funding from the European Research Council (ERC), Starting Grant, under the European Union's Horizon 2020 research and innovation programme (Grant agreement No. 853257).

11:15 AM CH01.01.03
Autonomous Flow Synthesis of On-Demand Hybrid Perovskite Quantum Dots based on a Closed-Loop Feedback Control System Hoang Khang Bui and Tae Seok Seo; Kyung Hee University, Korea (the Republic of)

Nanostructured hybrid organic–inorganic lead halide perovskites quantum dots (QDs) have gained enormous attention and hold the potential to surpass traditional semiconductor nanocrystals as versatile photonic sources for displays, lighting, light-emitting diodes (LED) as well as light harvesters for photodetector devices, and solar cell. Moreover, due to the unique quantum-size effects, their optical bandgap and emission wavelength can be finely tailored by the ease of compositional control between halide ratio and adjusting the stoichiometry leading to the production of visible electromagnetic spectrum QDs. Currently, conventional flask-based synthetic platforms encounter a range of challenges from unwanted batch-to-bath variations such as precursor stability, temperature fluctuations, macro-environment kinetics.
A promising alternative is the use of continuous flow technology for the auto-production of perovskite QDs. The flow reactive chemistry in microfluidics has demonstrated rapid heat and mass transfer to speed up the chemical reaction time, precise control of the reagent volume, and reaction kinetics to produce uniform nanomaterials. Microfluidic synthesis can be integrated with an in-situ detection module so that the synthetic nanomaterials could be analyzed in real-time, which is inaccessible to the traditional flask-based methods. Moreover, all steps of microfluidic synthesis and product characterization can be software-controlled, thus ensuring time- and labor-effective QDs synthesis with high reproducibility.
One of the strategies for accelerating the identification of the most effective reaction conditions relies on automation. Automating synthesis enables quicker and more accurate procedures, including reagent loading, mixing, heating, and in-process product characterization. Furthermore, implementing an electronic feedback control module allows for the automatic optimization of reaction conditions, helping to generate the target nanomaterials with low cost and high speed. Developing a convenient and novel intelligent algorithm capable of data acquisition and analysis for resetting the reaction conditions could accelerate the transition from a manual synthetic batch process in an ordinary laboratory to a fully automatic continuous synthetic platform.
In the current work, we report an autonomous platform for self-control synthesis of desired perovskites QDs, which utilizes familiar yet efficient Proportional-Integral-Derivative (PID) algorithm. The PID controller have been used in industrial control applications for a long time since it minimizes overshoot in steady state response and lesser settling time. The PID controller has three tuning parameters: the controller gain (P term), the integral time constant (I term), and the derivative time constant (D term). The Internal Model Control methodology is a model based PID tuning techniques that has gained significant attention since it only requires one tuning parameter, namely the closed loop time constant. In conjunction with microfluidic synthesis, the PID drives an optimization in precursors regulations to rapidly return accurate specifying reaction conditions which leads to precise on-demand optical properties. To demonstrate the feasibility and efficiency of our proposed method, we have synthesized MAPbBrxI3-x perovskite QDs with controlled fluorescence emission spectra in various P, I, D parameters to apparently indicate the effect of controlling to the outputs. The self-driving PID-based QDs synthesis strategy is a trade-off between target reaching time and stability, which are showcased clearly in this studies. Finally, we successfully produced two representative candidates for red-shift QDs at 650 nm and blue-shift QDs at 550 nm. This study further guides the production in large scale with simple, adaptable PID algorithm for not only lab bench synthesis but also industrial manufacturing.

11:30 AM CH01.01.04
Epitaxial Si on Epitaxial-Gd_2O_3/Si(111) Virtual Substrate Using Low-Cost RF Sputtering for Silicon on Insulator (SOI) Application Shubham Patil[1], Adityanarayan Pandey[1], Swagata Bhunia[1], Sandip Lashkare[2], Apurba Laha[1], Veeresh Deshpande[1] and Udayan Ganguly[1]; [1]IIndian Institute of Technology Bombay, India; [2]Indian Institute of Technology Gandhinagar, India

There is an ever-growing need for 5G communication technology and the Internet of Things to achieve better-performing systems in speed and power consumption. Research has shown SOI technology to be very promising among different technologies (it offers low voltage and high-frequency operation capability) [1]. However, the costly smart-cut method for manufacturing SOI wafers is a challenge. Alternatively, the notion of using epitaxial rare earth (RE) oxides onto Si followed by epi-Si growth is a potential alternative to enable cheaper and high-volume manufacturing (HVM) of SOI wafers. Gd_2O_3 oxide is the most promising among all rare oxides due to its large bandgap, sufficient band offsets, stable oxidation state, and low lattice mismatch with Si(111). In this context, our group patented a methodology to produce semiconductors on an insulator substrate using an HVM-friendly RF magnetron

sputter system [2,3].
In the work, we demonstrate epitaxial-Si on epitaxial-Gd_2O_3/Si(111) substrate by RF magnetron sputtering for SOI application. The fabricated heterostructure is characterized through XPS, HRXRD, cross-sectional HRTEM, and EDS analyses, providing compelling evidence for the formation of the epi-Si(111) layer on the epi-Gd_2O_3 surface.
The cap-Gd_2O_3/Top-Si/BOX-Gd_2O_3 (capping layer (cap)/channel (Top-Si)/Buried-oxide (BOX)) stack is deposited on Si(111) substrate using RF sputtering. The box layer is deposited at 750 ^oC with 20 W RF power (~0.12nm/min) for 100 min, followed by intrinsic-Si deposition (~0.3 nm/min) at 100 ^oC temperature. The Gd_2O_3 capping layer is deposited at a higher temperature (750 ^oC) to crystallize the channel layer. The heterostructure is subsequently annealed at 850 ^oC to study the impact of rapid thermal annealing. The heterostructure thickness is 12 nm/15 nm/16 nm, confirmed using HRTEM. The capping layer is etched using an H_2SO_4: DI water wet etch, O_2 plasma ashing, followed by BHF etch. The conformal etching is verified by analyzing the XPS spectra. The absence of a Gadolinium (Gd3d and Gd4d) signature and a strong Si2p peak of bulk-Si confirms that the capping layer is properly etched. Next, HRXRD is employed to determine the structural nature of the BOX-Gd_2O_3.
The full range Φ measurements at fixed $X = 70.5^o$ and $2\theta = 28.44^o$ show two sets of peaks 120^o apart correspond to the Si(-111) and c-Gd_2O_3(-222) planes. This observation indicates a 3-fold symmetrical nature of the peaks, establishing that the (222) planes of Gd_2O_3 are grown epitaxially onto the Si(111) substrate. The Si peaks are found to be rotated by 60^o relative to Gd_2O_3, suggesting the presence of an A/B twinning relationship between Si and Gd_2O_3. The epitaxial quality of the BOX is further validated using a skew-symmetric ω-2θ scan.
The HRTEM analysis demonstrates three key findings: (a) the formation of an atomically sharp interface at the BOX-Gd_2O_3/Si(111) interface, (b) the epitaxial nature of the BOX-$Gd_2O_3$and Top-Si layers, and (c) confirmation of the A/B/A stacking arrangement of Top-Si/BOX-Gd_2O_3/Si(111). The EDS analysis further confirms the formation of a flat and homogenous interface without significant Si(Gd) out-diffusion.
In conclusion, we have developed a low-cost, high-volume, manufacturable state-of-the-art epitaxial Si-Gd_2O_3 on Si (111) substrate (SOXI) by RF sputtering. The epitaxial nature of the heterostructure is confirmed through HRXRD and HRTEM analyses. In the near future, a SOXI MOSFET demonstration should be done.

Iodine-Passivation Facilitates On-Surface Synthesis of Robust Regular Conjugated Two-Dimensional Organogold Networks on Au(111) Arash Badami Behjat[1,2], Gianluca Galeotti[1,2] and Markus Lackinger[1,2]; [1]Technical University of Munich, Germany; [2]Deutsches Museum, Germany

Dehalogenative Ullmann-type couplings are recognized as the basis for on-surface synthesis, producing extended covalent nanostructures on metal surfaces.[1] While one-dimensional (1D) structures are typically derived from ditopic precursor molecules, two-dimensional (2D) networks like polymers can be synthesized from precursors with more than two halogen substituents. In this study, we present evidence for the debrominative coupling of a tetra-bromine-substituted thiophene-rich monomer on an iodine-passivated Au (111) surface, affording well-ordered 2D organogold networks.
Previous studies have investigated the on-surface polymerization of the 2,5,9,12-tetrabromoanthra[1,2-b:4,3-b′:5,6-b″:8,7-b‴]tetrathiophene (TBATT) precursor on both silver (Ag) and copper (Cu) surfaces. [2, 3] These studies revealed a notable challenge arising from kinetic competition between binding motifs during the irreversible phase. As a result, the resulting networks tended to be predominantly irregular, with only small areas exhibiting regular patterns. To advance the fundamental understanding, we study the debrominative coupling of TBATT directly on pristine Au(111). When the sample is annealed at temperatures between 200 °C and 220 °C, debromination is activated, resulting in predominantly irregular networks. Interestingly, the measured intermolecular distances agree with the DFT calculated values of organometallic carbon-Au-carbon bonds instead of direct carbon-carbon bonds. Subsequently, TBATT was deposited on iodine passivated Au(111) (I-Au(111)), where we observed intact molecules either forming organized supramolecular structures or existing as dispersed single entities. Subjecting these samples to annealing temperatures of 200 °C to 220 °C induced a significant structural transformation, shifting from densely packed to a porous grid-like network.
The remarkable stability of the TBATT-derived organogold networks as evidenced by high temperature annealing, is attributed to the π-conjugation. This motivated further investigation of the network's electronic properties. The calculated electronic band structure revealed a surprisingly narrow band gap of 0.71 eV, together with dispersive bands. To confirm these DFT calculations experimentally, Scanning-Tunneling-Spectroscopy (STS) experiments were performed. The differential conductance dI/dV versus voltage V spectra indicate an electronic band gap of the order of 1.0 eV.
In conclusion, our study has demonstrated the feasibility of using I-Au(111) surfaces as effective substrates for the on-surface synthesis of covalent 2D networks through debrominative couplings. In particular, when using the TBATT precursor on I-Au(111), we achieved highly regular organogold networks, in contrast to the poor structural order observed when synthesized on pristine Au(111).
Although the domains are still relatively small, they contain a sufficient number of repeat units to allow the anthra-tetrathiophene network to develop an electronic band structure. This convergence is partly due to the 2D topology, which allows a faster evolution of electronic properties compared to 1D structures, mainly because more intermolecular bonds are formed per monomer. The influence of the iodine monolayer on the formation of highly regular organogold networks is twofold: On the one hand, iodine induces reversibility of the robust carbon-Au-carbon bonds, facilitating dynamic error correction, as confirmed by experiments where the organogold networks disintegrated when annealed in an iodine atmosphere. On the other hand, the presence of the iodine monolayer does not impose spatial constraints but instead supports the formation of exceptionally regular networks.

SESSION CH01.02: Crystal Growth II

Multi-Phasic Growth Mechanism of Colloidal Nanoparticles by Statistical Liquid Phase TEM Jungwon Park; Seoul National University, Korea (the Republic of)

Nanoparticle nucleation and growth have long been of great interest in science and industry. Despite impressive advances in nanotechnology, the thermodynamic origin of nanocluster nucleation is still a mystery, and there is no quantitative understanding of nanoparticle growth dynamics. It is because of the complexity that intrinsically exists in nanoparticle growth pathways. A comprehensive understanding of the growth mechanism requires experimental investigation of nanoparticle growth from two different aspects: individual growth trajectories and kinetics in ensemble average. To address this issue, we monitor hundreds of individual trajectories of growing nanoparticles using liquid-phase transmission-electron-microscopy. Statistical analysis of ensemble growth trajectories reveals that the growth of nanoparticles can be classified into multiple distinct types and stages. We present a

microscopic model and statistical mechanical theory that provide unified, quantitative understanding of the time-dependent mean, variance, and distribution of nanoparticle size at all stages of the nanoparticle growth processes observed. We find that strongly-nonextensive free energy originating from a nanoparticle's edge interaction, motion, and conformational degeneracy, which has received little attention so far, plays an essential role in the nanocluster nucleation and non-classical growth dynamics.

2:00 PM CH01.02.02
Emergence of a Novel BCT Phase in Eutectic High Entropy Alloys during Laser Powder Bed Fusion Bingbing Zhao[1], Qingsong Shu[1], Ming Chen[2] and Lanting Zhang[1]; [1]Shanghai Jiao Tong University, China; [2]Northwestern University, United States

High entropy alloys, composed of a minimum of four principal elements, exhibit exceptional combinations of strength and ductility, along with impressive corrosion resistance and microstructural adaptability. Recent strides in eutectic high-entropy alloys (EHEAs), a subset within this category, reveal multi-phase structures and uniform microstructures in their as-cast state. Traditional metallurgical processing of EHEAs leads to limited improvements in strength and ductility due to the formation of a coarse lamellar structure. Additive manufacturing, particularly laser powder bed fusion (L-PBF), enables the construction of intricate three-dimensional structures by incrementally adding thin layers, overcoming geometric constraints. However, the phase transition process of EHEAs from liquid to as-deposited state is constrained, particularly during the rapid heating and cooling inherent in the L-PBF process. This can induce metastable phases under these non-equilibrium conditions, significantly affecting the properties of the printed EHEA. The implementation of an operando X-ray diffraction device at a synchrotron beamline, harnessing the high brilliance and swift detectors available, serves as the vital bridge to numerical methods. Our pre-alloyed powder, with a nominal composition of $Ni_{30}Co_{30}Fe_{11}Cr_{11}Al_{18}$, exhibits a lamellar structure consisting of B2 and FCC phases as predicted by thermodynamic phase equilibrium calculations. During the L-PBF process, a novel BCT phase emerges during solidification. Operando X-ray diffraction, employed during L-PBF, provides a real-time measurement of phase transitions and structural evolution in EHEA. This study not only establishes the relationship between processing and phase constitution but also illuminates how kinetics influence morphology and property control.

2:15 PM CH01.02.03
Understanding Graphene Inception and Growing by Investigating Early-Stage Particle Formation Ornel Padilla[1], Kyle J. Daun[2], Hartmut Wiggers[1] and Christof Schulz[1]; [1]IVG, Institute for Energy and Materials Processes – Reactive Fluids, and CENIDE, Center for Nanointegration Duisburg Essen, University of Duisburg-Essen, Germany; [2]University of Waterloo, Canada

Microwave-assisted plasma synthesis is a promising pathway for large-scale production of few-layer graphene flakes. One of the challenges associated to the advancement of this process, is to develop a better understanding of the stages of inception and growth of graphene, as well as of the connection between the synthesis conditions, the reaction conditions in the gas phase, and the quality of the material obtained.
In a microwave-assisted plasma reactor, the carbon-bearing precursor enters the plasma region and gets decomposed into smaller reactive fragments, such as C, H, H_2, C_2, C_2H_2, and CO. These reactive fragments then leave the plasma region, where they form nuclei that rapidly grow into graphene[1]. The literature suggests connections between the type of structure formed and the temperature gradient, residence time, and carbon concentration in the nucleation and growing zones[2]. Further, the use of low precursor content is common to prevent or reduce soot formation.
In this work, ethanol and ethylene are used as precursor to study graphene formation. The first one is a common precursor used in the literature, and the second one is a known key intermediate species during graphene formation. Key species formed during precursor decomposition which later become building blocks for graphene formation downstream have been analyzed in situ and through exhaust gas sampling.
Optical emission spectrometry (OES) has been performed at different heights above the nozzle of the reactor, and light collection with a plano-convex lens was used to provide good spatial resolution. Following the approach described in Ref. [3], several wavelength regions of key species light emission were selected, and for each wavelength region the measurement conditions were fixed for proper comparison of signals at different heights above the nozzle (HAN). Spectra corresponding to C and C_2 appeared at higher HAN. When increasing HAN, light emission corresponding to CH first increases and then decreases in intensity for both precursors. Emission from the H_β Balmer, important for determination the electron density, could be well distinguished from background radiation. With ethylene as precursor, C, CH, C_2, and H emissions were stronger than with ethanol. Analysis of collected material by TEM show characteristic folded layers of graphene. With ethylene as precursor graphene and soot were formed in parallel, while ethanol led to the formation of graphene only. FTIR, light scattering, and thermophoretic sampling from the post-plasma region will provide further information about particle nucleation and growth.

***In Situ* Observation of (Trans-) Formation of Oxide Nanoparticles during Chemical Vapor Synthesis** Shradha R. Joshi, Martin A. Schroer, Maximilian Stepponat and Markus Winterer; Universität Duisburg-Essen, Germany

Characteristics of nanoparticles (NPs) such as microstructure and morphology determine their physicochemical properties and thereby their application potential. Particle characteristics and correlated properties may be optimized by tuning relevant process parameters [1].
Chemical vapor synthesis (CVS) is a dynamic gas phase synthesis to generate NPs where the formation and transformation of NPs is mainly governed by the time-temperature *T(t)* profile in the reactor [2]. Usually, the synthesized NPs are collected and characterized ex situ to determine various characteristics. This often leads to the loss of information due to artifacts during particle collection, oxidation, hydration, surface reactions or ageing of NPs. Ex situ methods also limit insight into intermediate species. Reliable information about the dynamic processes in CVS and related particle characteristics is only accessible via in situ observation.
Here, we present results on CVS of tin oxide (SnO_2) and iron oxide (FeO_x) NPs investigated in situ using high energy X-rays at synchrotron beamlines [3]. The key challenge in these experiments is the low number density of the particles generated in the gas phase process which is about three orders of magnitude smaller than in corresponding bulk systems [4]. However, due to high intensity X-ray sources at contemporary synchrotron radiation facilities and modern X-ray detectors it is nevertheless possible to obtain scattering and spectroscopy data.
A novel mobile CVS reactor is designed for these experiments which enables control of process parameters, especially the time-temperature *T(t)* profile and oxygen partial pressure $p(O_2)$ to produce oxide NPs. In situ small and wide-angle X-ray scattering (SAXS and WAXS) are used to study microstructure, morphology, phase composition and crystal structure. X-ray absorption spectroscopy (XAS) is performed to study electronic and local structure.

Synthesizing Well-Defined Pre-Catalysts for Multi-Modal Studies of Electrocatalysts under Reaction Conditions See Wee Chee; Fritz Haber Institute of the Max Planck Society, Germany

Chemical conversion through renewable energy-powered electrocatalysis is a crucial technology in our green energy strategy. However, we still lack the fundamental understanding of working catalytic structures under reaction conditions needed to enable the rational design of optimal catalysts for such applications. Even though *operando* studies can be used to investigate catalysts during reaction, no single *operando* technique provides complete information about an electrocatalyst under reaction conditions because the relevant catalytic processes span several orders of magnitude in length and time scales. Hence, multiple techniques are usually needed for such studies. Ensuring that we are looking at catalysts under self-consistent reaction conditions in the different tools is not easy. The starting point towards addressing this challenge is the ability to make the samples in a controllable and reproducible manner. In this talk, I will discuss my group's work using different methods to synthesize model pre-catalysts with well-controlled characteristics for *operando* microscopy studies. Using such transferable synthesis protocols, we further bridge the gap between various techniques with targeted measurements that correlate the structure and the properties of catalysts during reaction.

3:45 PM CH01.02.07
***In-Situ* Synchrotron Light Studies of Cobalt Ferrite and Cobalt(II) Oxide Synthesis via The Polyol Method: Uncovering Intermediate Phases through *In-Situ* XRD and SAXS Monitoring** Miran Baricic[1,2], Roxana Mirshahi[2], Youssef Snoussi[1], Jasper Plaisier[3], Lara Gigli[3], Alessandro Mariani[3], Barbara Sartori[3], Sophie Nowak[1], Paolo Centomo[4], Davide Peddis[5], Souad Ammar[1] and Carlo Meneghini[2]; [1]Universtié Paris Cité, France; [2]Università degli Studi di Roma TRE, Italy; [3]Elettra Sincrotrone Trieste SCpA, Area Science Park, Italy; [4]Università degli Studi di Padova, Italy; [5]Università degli Studi di Genova, Italy

The synthesis of cobalt ferrite (CFO) and cobalt (II) oxide (CO) nanoparticles (NP-CFO, NP-CO) through the polyol method has garnered considerable interest due to their promising applicative potential in fields such as catalysis, electronics, biomedical engineering, and magnetic materials science. Detailed knowledge of the processes taking place during synthesis is crucial information for the precise adjustment of synthesis parameters. We have used synchrotron radiation X-ray diffraction (SR-XRD) and small-angle X-ray scattering (SR-SAXS) at the Elettra synchrotron radiation facility, to monitor in situ the formation of NP-CFO and NP-CO during polyol synthesis. The analysis of time-resolved XRD and SAXS patterns provides insight into the evolving crystallographic structure and morphological changes during synthesis.
Our findings reveal curious and original insights into the evolution of the reactant during the synthesis, such as the presence of intermediates (e.g., layered hydroxide salts, LHS) and the appearance of sub-nanometre-sized precursor phases likely acting as pre-nucleation clusters of NP-CFO/CO phases. The in-situ monitoring allowed us to capture the dynamic evolution of these intermediates, providing valuable information on their formation pathways and growth kinetics, which significantly affect the nucleation and growth processes of the cobalt-based nanoparticles. The unambiguous identification of these intermediates sheds light on the intricate mechanisms governing the process and represents a crucial step towards optimising the polyol synthesis and improving the purity and crystallinity of the final products.
The understanding of the synthesis dynamics and mechanistic insights gained from this in-situ study advance tailored synthesis strategies for producing high-quality NP-CFO and NP-CO materials. This also provides relevant details for better interpretation of the magnetic properties of antiferromagnetic materials such as CO, which is critical to avoid ambiguities given its relatively low magnetic signal.

4:00 PM CH01.02.08
Multiscale Insights into Amalgamation Synthesis of Intermetallic Nanocrystals via *In Situ* X-Ray Scattering Florian Schenk[1], Christian Prehal[2] and Maksym Yarema[1]; [1]ETH Zurich, Switzerland; [2]University of Salzburg, Austria

Bimetallic nanocrystals are a family of materials with over > 20 000 potential members with a multitude of applications in catalysis, energy conversion and- storage, plasmonics and magnetics.[1] Recently, a general synthetic approach for colloidal intermetallics via amalgamation was presented,[2] unlocking up to 1 000 potential new intermetallic nanocrystals. Combining pre-synthesized metal seeds with a liquid metal, the intermetallic compound is formed via fast diffusion dynamics. This overcomes challenges of combining two dissimilar metals at the nanoscale, such as contrasting oxidation potentials or epitaxial constraints. With accurate and predictive control over the size and composition, this synthesis provides access to a wide range of tailor-made intermetallic nanocrystals. Further optimization and expansion of the amalgamation synthesis, however, requires understanding of the process on the atomic as well as on the particle scale.
Here, we turn to in situ small- and wide-angle X-ray scattering as an ideal tool for observing size and size dispersion, as well as crystallinity and phase-dynamics in colloidal systems.[3–6]. We track multiscale reaction dynamics of colloidal intermetallics (Au-, Ag- and Pd-based alloys) in real time using a tailor-made reactor and reveal unprecedented reaction mechanisms in the formation of intermetallics. Furthermore, we also provide a toolbox for in situ studies of nearly every nanocrystal synthesis since the combination of reactor and in situ scattering can be applied to highly air- and moisture-sensitive protocols at temperatures up to 330 °C and down to millisecond timescales.

4:15 PM CH01.02.09
Controlled Synthesis of Self-Reduced CoO Decorated Co_3O_4 Yi-Wen Lin, Sin-Pei Wang, Yen-Ling Wang, Karan Giri, Chun-Hua Chen, Chia-Yin Cheng, Shang-Jung Wu, Wen-Chieh Hsieh and Hung-Shuo Chang; National Yang Ming Chiao Tung University, Taiwan

Nitrogen dioxide (NO_2) is a common toxic gas in automobile and locomotive emissions, industrial combustion, and power generation. Long-term exposure to nitrogen dioxide will not only cause photochemical smog and acid rain to pollute water, soil, and air but cause harm to human health, such as respiratory distress, heart failure, and pulmonary edema. Precise detection and emission control of nitrogen dioxide are thus critical.
In this study, Co_3O_4 nano-assemblies with different morphologies, including sphere, pillow-shape, and star-shape, were successfully produced via the polyol method at different reaction temperatures. The appropriate operating temperature of these three nano-assemblies for having the highest gas responses were then evaluated under 1000 ppm NO_2, and were then found to be 130 °C. The observed highest response approaching 207% was found for the pillow-shaped nano-assembly. The spherical Co_3O_4 nano-assembly was selected for the subsequent self-reduction study due to its relatively regular morphology among these three nano-assemblies. The spherical Co_3O_4 nano-assembly was then reduced in a mixture of 95% nitrogen and 5% hydrogen with various controlled temperatures and time for having a nanocomposite comprising coexisted multiple cobalt oxides. The Rietveld, x-ray photoelectron spectroscopy (XPS), and energy-dispersive x- ray spectroscopy (EDX) were mainly performed to identify the phase fraction and chemical composition. It was found that after reduction at 250 ℃ for 120 minutes, a heterogeneous nanocomposite comprising CoO (Co^{2+}) (43 wt%) and Co_3O_4 (Co^{2+}/Co^{3+})(57 wt%) can be successfully obtained. The XPS analysis confirmed that the amount of the surface adsorbed oxygen (Oc) and the oxygen vacancy (Ov) associated with O_2-ions in oxygen-deficient regions within the matrix of Co_3O_4 increase with the increase of Co^{2+} ions newly formed via the reduction procedure from Co_3O_4 to CoO, which is considered to be beneficial for improving gas sensing performance. The sensing response at 400 ppm NO_2 at 130 °C increases from 61% of the unreduced Co_3O_4 nano-assembly to 91% of the self-reduced CoO / Co_3O_4 one. Compared with CH_4, C_2H6, C_3H8, C_2H_5OH, and CO, the self-reduced CoO / Co_3O_4 nano-assembly exhibits excellent selectivity to NO_2. The response of NO_2 is four times higher than that of other gases. Based on the dynamic recovery test, the self-reduced CoO / Co_3O_4 nano-assembly shows a reproducible response.

Keywords: gas sensor, nitrogen dioxide sensing, Co_3O_4, reduction, selectivity, nano-assembly.

Characterizations of Force-Induced Mineralization Processes for Self-Adaptive Materials Sung Hoon Kang; Johns Hopkins University, United States

Adaptability is one of the hallmarks of living systems that provide resilience to survive and flourish in a dynamically changing environment. I will present self-adaptive materials that can change their mechanical properties depending on loading conditions by the coupling between stress and material synthesis. Nature produces outstanding materials for structural applications, such as bone and wood, that can adapt to their surrounding environment. For instance, bone regulates mineral quantity proportional to the amount of stress. It becomes stronger in locations subjected to higher mechanical loads. This capability leads to the formation of mechanically efficient structures for optimal biomechanical and energy-efficient performance. However, it has been challenging for synthetic materials to change and adapt their structures and properties to address the changing loading condition. To address the challenge, we are inspired by the findings that bones are formed by mineralizing ions from blood onto collagen matrices.

I will present our characterization results of a material system that triggers proportional mineral deposition from electrolytes on piezoelectric matrices upon mechanical loadings so that it can self-adapt to mechanical loadings. For example, the mineralization rate could be modulated by controlling the loading condition, and a 30-180% increase in the modulus of the material was observed upon cyclic loadings whose range and rate of the property change could be modulated by varying the loading condition. Moreover, the material system showed improved fatigue resistance from its damage mitigation mechanism with one order of magnitude slower crack propagation speed. Based on our characterization data, we developed a model to elucidate the underlying mechanism.

Our findings can contribute to new strategies for making resilient and sustainable materials for dynamically changing mechanical environments, with potential applications including healthcare, infrastructure, and vehicle.

SESSION CH01.03: Crystal Growth III

Dissolution Enables Dolomite Crystal Growth near Ambient Conditions Joonsoo Kim[1], Yuki Kimura[2], Brian Puchala[1], Tomoya Yamazaki[2], Udo Becker[1] and Wenhao Sun[1]; [1]University of Michigan–Ann Arbor, United States; [2]Hokkaido University, Japan

Crystals grow under supersaturated solutions. A mysterious counterexample is dolomite $CaMg(CO_3)_2$, an abundant sedimentary mineral that apparently cannot grow at ambient conditions, not even under highly supersaturated solutions. Using atomistic simulations, we show that dolomite initially precipitates a cation-disordered surface, where high surface strains inhibit further crystal growth. However, mild undersaturation will preferentially dissolve these disordered regions, enabling increased order upon reprecipitation. Our simulations predict that frequent cycling of a solution between supersaturated and undersaturated can accelerate dolomite growth by up to seven orders of magnitude. We validate our theory with in situ liquid cell TEM—directly observing bulk dolomite growth under supersaturation cycles. This mechanism explains why modern dolomite is primarily found in natural environments with *p*H or salinity fluctuations. More generally, it reveals that the growth and ripening of defect-free crystals can be facilitated by deliberate periods of mild dissolution.

Unveiling Multiple Transient States in Cerium Oxalate Crystallization and their Impact on Nucleation Rates Jade Raimbault[1], Maxime Durelle[2], David Carriere[1], Corinne Chevallard[1], Frederic Gobeaux[1], Mark Levenstein[1], Fabienne Testard[1], Florent Mallogi[1], Ovidiu Ersen[3] and Dris Ihiawakrim[3]; [1]CEA de Saclay, France; [2]University of Leeds, United Kingdom; [3]Institut de Physique et Chimie des Matériaux de Strasbourg, France

Crystallization from solution can occur through a “nonclassical” route where amorphous or liquid transient species are formed prior to final crystals[1]. These intermediates, often ignored in theoretical modeling, can however have a significant impact on crystallization mechanisms and therefore on

nucleation rates. Most industrial processes still rely on single step Classical Nucleation Theory (CNT) and then overlook cases where these routes are followed.

Cerium oxalate, a well-known surrogate for plutonium oxalate in nuclear waste recycling, shows evidence of a transient amorphous structure prior to crystallization[2]. However, we revealed that not one, but two non-crystalline transient species are involved: amorphous nanoparticles and dense liquid droplets. Formed in less than a minute, they may also coexist depending on the chemical conditions[3]. It challenges not only their characterization but also their theoretical description, making the validation of a nucleation model even more delicate.

We used in situ X-ray scattering at synchrotron and liquid cell TEM to characterize cerium oxalate precipitation down to the millisecond reaction times and the nanometer scale. In addition to their identification, we confirmed the amorphous and liquid nature of these intermediates. Their impact on experimental nucleation rates was also assessed and revealed a drastic increase when liquid droplets are formed, far from the values expected by a single step model. Finally, we determined the different phase transition mechanisms involved depending on the nature of the transient structure, which gives us a hint on compatible nucleation theories.

Formation of Highly Branched Nanocubes through Multi-Stage Oriented Attachment of Pt Nanoparticles Yuna Bae, James J. De Yoreo and Dongsheng Li; Pacific Northwest National Laboratory, United States

Crystals grow through various pathways, such as monomer-by-monomer addition and attachment processes among ions, amorphous or crystalline particles, and clusters. Oriented attachment is a common path for crystal growth. The process of particle attachment is determined by the interplay between particles, i.e. interparticle forces, including vdW attraction, hydration repulsion, steric hindrance, and electrostatic interactions, which depend on the liquid-solid interfacial structures at particle surfaces. Herein, we investigate the formation process of branched Pt nanocubes via oriented aggregation of nanoparticles using a combination of cryo TEM, liquid-phase TEM, and simulations. Initially, primary nanoparticles of 2 to 3 nm in size are generated and then agglomerated to form a cluster. This cluster will further grow through nanoparticle and cluster aggregation. The nanoparticles within the cluster are spatially separated at early stage and continuously rearrange their alignment via oriented attachments, leading to clusters with core/shell structures. The inner particles in the cluster begin to attach on the (100) plane forming the cube-shaped core. At later growth stage, nanoparticles attach along the (111) plane, forming branched rods on top of the cube as the shell. The core/shell structure finally evolves into a branched cubic mesocrystal through the gradual ordering. Low pH and high chloride ions can induce changes in the surface structure and charge between clusters and nanoparticles, leading to the nanoparticles preferentially attaching along (100) at the early stage and (111) at the later stage. Simulations based on molecular dynamics and density functional theory will be also performed to examine the influence of HCl and formates on Pt (100) and (111) surfaces, elucidating their relationship with (100) and (111) attachments at different chloride ions.

Inline Spectroscopic Investigation of Metal Patch Growth on Spherical Nanoparticles in Continuous Flow Julia S. Seifert, Andreas Voelkl and Robin N. Klupp Taylor; Institute of Particle Technology, Germany

Plasmon resonant nanoparticles have been extensively investigated over the last decades due to their promise in a wide range of applications (e.g. theranostics, pigments, sensors, photocatalysts). As the tunability of the resonant frequency of isotropic plasmonic nanoparticles (NPs) is limited, anisotropic particles can be used to expand the available property space. One example of anisotropic plasmonic NPs are patchy particles, where noble metal patches with controlled size and morphology are deposited onto a dielectric core particle. We have demonstrated these particles to have a wide optical tunability and scalable production in a continuous flow process. However, there is still a lack of predictive models for patch formation, hindering further process optimization. To obtain the kinetic parameters for such models, in situ characterization of the growing patches is required. Addressing this, the present contribution will give details of a purpose-built inline spectroscopic setup and the results obtained with it.
Inline measurements to understand the continuous flow growth of various types of nanoparticles have been reported in the literature. In the case of noble metal nanoparticles, a change in size and morphology can be detected via a change in the optical spectrum. Consequently, inline extinction spectroscopy offers an easily accessible tool to follow the particles' structural evolution in time.
To investigate the patch growth under well-mixed conditions, we use a continuous inline spectroscopy setup which consists of a polyamide T-mixer connected to a rectangular borosilicate glass tube. The latter is mounted on a linear stage on an optical pegboard. Via an automated protocol, the glass tube is moved through a fixed measurement position of a fiber spectrometer. Thus, each position along the glass tube corresponds to a specific reaction time. An adjustable spacer tube can be used to obtain data at later residence times.
Using measurements at different reaction conditions, we collect kinetic data for model development. To validate our measurements, we utilize a quenching approach which freezes the metal patches at various growth stages and thus enables them to be investigated via ex situ characterization techniques. Correlating in situ and ex situ data, we show that a kinetic model for the formation of patchy particles valid for a wide range of reaction conditions can be established, paving the way for further process optimization and automation.

In Situ Liquid Phase TEM of Chemical Reactions and Materials Transformations Haimei Zheng; Lawrence Berkeley National Laboratory, United States

The recent development of liquid phase transmission electron microscopy (TEM) have enabled break-throughs in characterizing various chemical reactions and materials transformations. It has unveiled many materials transformation dynamics, and the structure and bonding evolution in situ/in operando with high spatial resolution. Since the electron beam for imaging can also induce perturbation to the chemical processes, it has been a concern that the observed phenomena in a liquid cell may deviate from the real-world processes. Strategies have been developed to overcome the electron-beam induced issues, and to connect the observation with the real-world chemical reactions. Here, I will discuss various strategies in using liquid cell TEM to study nucleation, growth, and self-assembly in solution, where electron beam is often used to initiate the reactions. Due to the complexity of the liquid cell TEM experiments, strategies are often employed simultaneously, for example, low dose imaging, advanced electron microscopy techniques, carefully designed

control experiments, multimodal characterization, and so on. The multidisciplinary research has opened many new opportunities by merging different expertise and approaches together stimulating innovations and fostering novel discoveries.

10:30 AM CH01.03.06
Early-Stage Nucleation Behavior of GaAs Nanowires on Si Substrate based on *In-Situ* TEM Chen Wei[1,2], Jean-Christophe Harmand[2] and Federico Panciera[2]; [1]Université Paris-Saclay, France; [2]Centre National de la Recherche Scientifique, France

To take advantage of the unique physical properties of nanowires (NWs), it is crucial to accurately control their geometry, crystal structure, and doping level. This goal will ultimately be achieved by a deeper understanding of the growth mechanisms.

Meanwhile, the initial stages of the growth process are the least understood and have been investigated almost exclusively by ex-situ techniques. Here, we present real-time observations of the nucleation and growth of self-catalyzed GaAs nanowires using a transmission electron microscope (TEM) equipped with molecular-beam-epitaxy (MBE) sources. Custom-made floating substrates, in the form of electron-transparent <111>-oriented Si membranes, were fabricated using MEMS (Micro-electromechanical Systems) technology. A combination of finite-element simulations and Raman spectroscopy was used to accurately calibrate the sample temperature and optimize its design. The results were in good agreement and further verified by the dimension and distribution of pre-deposited Ga droplets.

Nanowires were grown directly on the membrane inside the microscope via a vapor-liquid-solid mechanism as a practical MBE configuration and the process was monitored *in situ* and in real-time with high spatial and temporal resolution. On the base of our direct observations, the main steps of this dynamic process, from Ga droplet deposition to crystal nucleation at the interface as well as the vertical growth of nanowires will be discussed.

10:45 AM CH01.03.07
Multiscale Mechanisms of Twisted Carbon Nanotube Yarns Probed *In Situ* by Soft X-Rays during Tensile Loading Philip M. Jean-Remy[1], Daniel Malone[1], Alec Schwartz[1], Cheng Wang[2], Adam Golder[1], Eric Meshot[3] and Xavier Lepro Chavez[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Atomic Machines, United States

Resonant soft x-ray scattering (R-SoXS) can help realize the promise of data driven research in hierarchical materials whose structure spans multiple length-scales, such as carbon nanotube (CNT) assemblies. Our prior work demonstrated the wealth of high-resolution and statistical data R-SoXS provides about chemical and structural morphologies across different length scales in CNT materials [1]. CNTs are known as the strongest 1D material due to their covalent sp2 carbon bonds, hexagonal lattice, and cylindrical shape. However, piecing together CNTs into assemblies has proven to be so far a failed strategy to achieve the same elite performance metrics as individual CNTs. This highlights a critical deficiency in understanding the effects that the processing of individual nanostructures has on the performance of their derived macroscale assemblies, thereby hindering the development of a process-structure- performance map for these materials.

In this work, we propose a new method to decouple the distribution orientation of nanoscale tortuosity and the macroscale twist of CNT dry-spun yarns under applied loads via in- situ R-SoXS probing at high energy (1200 eV) and low energy (280 eV), respectively. With this decoupling enabled by in-situ R-SoXS, we gain new insights on the deformation mechanisms of these yarns which have been structurally reinforced with a novel vapor-phase polymer that is subsequently self-crosslinking [2]. Further, we examine how both the distribution orientation of the nanoscale tortuosity of CNT bundles and the macroscale twist of the yarns evolve as a function of applied load for different processing conditions, including yarns with plasma-enhanced surface reactivity prior to the polymer reinforcement. Better understanding of the multiscale structural behavior of CNT yarns as a function of processing will allow advances for the manufacture at large scale of products based on ultra-strong, flexible, conductive fibers for aerospace, defense, communications, wearables, and biomedical industries.

11:00 AM CH01.03.08
Synthesizing New Ternary Nitrides with Guidance from *In Situ* X-Ray Diffraction Christopher Rom[1], Shaun O'Donnell[1,2], Kayla Huang[1,3], Rebecca Smaha[1] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado State University, United States; [3]University of Illinois at Urbana-Champaign, United States

Ternary nitrides are an important class of functional solids, most famous for underpinning high-efficiency light emitting diodes. These materials are composed of nitrogen along with two other elements (e.g., $In_xGa_{1-x}N$ for those light emitting diodes). However, making these materials is challenging, in part owing to the low reactivity of elemental nitrogen gas (N_2), and the propensity for nitrogen-containing solids to decompose at elevated temperatures (releasing N_2). Metathesis reactions (also known as ion exchange reactions) can help us overcome these challenges and keep nitrogen in the solid state to synthesize new ternary nitrides. For example, we have recently discovered that starting from lithium-containing precursors (e.g., Li_6WN_4), we can conduct metathesis reactions with ZnX_2 salts (X = F, Cl, Br) to synthesize new Zn ternary nitrides (e.g., Zn_3WN_4). This presentation will focus on our recent work studying these kinds of metathesis reactions using *in situ* X-ray diffraction, with an eye towards generalizing this synthesis approach to accelerate materials discovery.

11:15 AM CH01.03.09
Formation of Quasi-2D Perovskites using *In Situ* Multimodal Spin Coater with Grazing Incidence X-Ray Scattering Aidan Coffey[1,2] and Chenhui Zhu[1]; [1]Lawrence Berkeley National Lab, United States; [2]University of Houston, United States

Hybrid perovskites are a class of ideal absorbing materials for solar cells that suffer from moisture and temperature instability. Single junction PVs using the hybrid perovskites $MAPbI_3$ and $FAPbI_3$ (MA= H_3CNH_3, FA= NH_2CHNH_2) have achieved a certified power conversion efficiency (PCE) over 25%, which is very close to the premier silicon PVs. To combat the instability of hybrid perovskites, 2D perovskites that feature large organic ligands that replace MA^+ or FA^+ in the 3D structure. Introducing electronically insulating moieties into perovskites makes crystal orientation critical to device efficiency. Nucleation and crystallization mechanisms for large organic ligands remains unknown and can be investigated thoroughly by in situ GIWAXS/SAXS and are vital to the development of stable perovskite solar cells.

The exploration of incorporating ligands into 2D perovskites is allows another tunability parameter to control the mechanical and optoelectronic properties of perovskite materials. While incorporating organic ligands improves moisture stability, it also introduces electronically inactive components, making crystal orientation critical to photovoltaic power conversion efficiency. There have been several efforts to vertically align 2D perovskites by changing thermodynamic procedure conditions, precursor concentration, and precursor type. While there have been efforts to characterize the crystallization dynamics with the 3D perovskites (e.g.$MAPbI_3$), the dynamics of 2D crystallization are not well understood. To study the formation of quasi-2D films, we have fabricated a custom-made in situ multimodal spin coater system with an integrated heating stage that can be programmed with spinning and heating recipes and coupled with synchrotron-based grazing-incidence WAXS and SAXS (GI-WAXS/GI-SAXS).

Studying the crystallization of quasi-2D perovskite films using synchrotron radiation allows for reduced exposure times, ensuring high time-resolution data that is paired with in situ photoluminescence to understand how the choice of ligand affects film crystallization kinetics, crystallinity, and orientation – all of which are crucial to increasing efficiency. Using the new stage, we have studied the formation of various bithiophene-based (2T) organic ligands at a variety of n-numbers (3, 5, and 10) and compared them to the well-established butylammonium (BA) ligand. In addition, the new stage allows us to control the temperature of the substrate, allowing for the elucidation of how thermal effects can be used to leverage the formation kinetics, thus paving the way for more stable, high efficiency perovskite solar cell materials.

11:30 AM CH01.03.10
Distinguishing Classical from Non-Classical Nanoparticle Growth Mechanisms by *In-Situ* X-Ray Diffraction Stephan Foerster, Manuel Wilke, Sascha Ehlert and Martin Dulle; Forschungszentrum Jülich, Germany

Hot-injection and heat-up synthesis routes are very commonly used for the controlled synthesis of nanoparticles with narrow size distribution and high crystallinity. These synthesis routes can proceed via classical or different non-classical nucleation and growth pathways, the latter often involving pre-nucleation clusters or oriented attachment. For synthetic control is important to have knowledge about the reaction pathways. To obtain fundamental insights into the nanoparticle nucleation and growth kinetics for these reactions is particularly demanding, because these synthesis routes typically involve heating to temperatures above 200°C which is challenging for many in-situ experimental techniques.

We designed glass flask reactors to perform *in situ* X-ray diffraction (SAXS/WAXS) experiments to investigate the nucleation and growth kinetics of noble metal, semiconductor and oxidic nanoparticles during heat-up synthesis up to 340°C. The analysis of the growth curves for varying heating rates, precursor/ligand ratios and plateau temperatures shows that the kinetics proceeds *via* non-classical reaction paths involving the formation of amorphous prenucleation clusters, nucleation, oriented attachment and final growth by monomer consumption. [1,2] Although these pathways are more complicated compared to classical nucleation and growth, one can identify kinetic phases of induction, nucleation and growth that are typically transected during the synthesis.

For a quantitative analysis of the growth curves we extended classical nucleation and growth theory to account for amorphous transient or precursor states and particle aggregation e.g. by oriented attachment during the nucleation and growth phases. We find that this non-classical model is able to quantitatively describe all experimental growth curves. The model provides fundamental insights into the underlying kinetic processes especially in the nucleation and growths phases with the occurrence of a transient amorphous state, the nucleation of crystalline primary particles, particle growth and particle aggregation, all proceeding on overlapping time scales.
The described *in situ* X-ray scattering experiments together with the extension of the classical nucleation and growth model quantitatively describe the two most important mechanisms of non-classical nucleation and growth routes, *i.e.* the formation of intermediate or transient species, and the particle aggregation processes.

3D Structure of DNA-Protein 2D Lattice by Cryo-Electron Tomography Jianfang Liu; Lawrence Berkeley National Laboratory, United States

Programmable and self-assembled two-dimensional (2D) protein lattices hold tremendous potential in the realms of biological crystalline devices and nanoscale catalysis, signifying a pivotal advancement from the fundamental building blocks towards intricate three-dimensional (3D) crystal structures. However, the creation of high-order lattices remains challenging, partly due to the lack of a tool to precisely analyze the 3D structure of each building block within short-range-ordered crystals without averaging. In this study, we leveraged advances in cryogenic electron tomography (cryo-ET) and the individual-particle electron tomography (IPET) technique to determine the 3D structure of each individual building block within short-range-ordered 2D protein-DNA origami lattices. The building block features a DNA origami octahedral cage, composed of 12 DNA helical bundles, and encapsulates ferritin molecules. Our quantitative analysis of the variations of conformations and orientational of these distinctive and asymmetric building blocks showed that ferritin loading exerted a negligible influence on the lattice unit-cell parameters. However, the flexibility of the blocks themselves and their connectors significantly affected lattice fluctuations. These findings were further validated by molecular dynamics (MD) simulations and juxtaposed with small-angle scattering (SAXS) data. This research offers an innovative approach to troubleshooting high-order crystallization by evaluating the crystal structure through the lens of the 3D structure of each unit cell.

1:45 PM CH01.04.02
Direct Observation of Key Aluminum Hydroxide Oligomers for Gibbsite Crystallization in Bayer Liquor by ToF-SIMS Juejing Liu[1,2], Carolyn Pearce[1], Xiaofeng Guo[2], Kevin Rosso[1], Zihua Zhu[1] and Xin Zhang[1]; [1]Pacific Northwest National Laboratory, United States; [2]Washington State University, United States

The Bayer process, discovered over a century ago, is still not fully understood with regards to the mechanism of crystallization of γ-aluminum hydroxide (γ-Al(OH)3, gibbsite) from the Bayer liquor. In order to gain a better understanding of this process, we utilized liquid ToF-SIMS to directly observe the

evolution of Al oligomers in a sodium aluminate solution simulating Bayer liquor. Our results were then validated through in-situ Raman, SAM-NMR, and DFT simulation. By comparing the change in the relative concentration of Al oligomers with +1 and -1 charge in environments favoring the crystallization of gibbsite and solid sodium aluminate, we were able to identify three major Al oligomer candidates: iso-tetramers, iso-pentamers, and cyclic hexamers. Our in-situ Raman results demonstrated that the relative concentration of iso-tetramers and iso-pentamers saturated when crystallized gibbsite appeared, while cyclic hexamers saturated before the appearance of gibbsite. Liquid SAM-NMR and DFT simulation provided evidence that the Al oligomers were inherent in the solution, rather than fragments from bigger molecules or crystals. We believe that the iso-pentamers and iso-tetramers exhibit a higher contribution than cyclic hexamers in terms of the crystallization of gibbsite. Our study expands knowledge of gibbsite crystallization in Bayer liquor, which is crucial for optimizing Al metal production and cleaning up liquid radioactive waste at the Hanford site.

2:00 PM CH01.04.03
N Content and Stoichiometry Impact on Crystallization Kinetics of Ge-Rich GeSbTe Alloys Oumaima Daoudi[1], Yann Mazel[1], Maxime Dupraz[2], Hervé Roussel[3], Mélanie Dartois[1], Magali Tessaire[1], Névine Rochat[1], Nicolas Bernier[1], Fréderic Fillot[1], Van-hoan Le[1], Hubert Renevier[3], Emmanuel Nolot[1] and Gabriele Navarro[1]; [1]University Grenoble Alpes, CEA, Leti, France; [2]University Grenoble Alpes, CNRS, France; [3]University Grenoble Alpes, CNRS, Grenoble-INP, LMGP, France

Phase–Change Memory (PCM) is a mature technology based on chalcogenide alloys, which has proven its suitability for next generation of non–volatile memory, in particular targeting embedded applications [1]. This result was achieved thanks to the intrinsic features of PCM in terms of scalability, fast programming and high endurance. Enrichment of GeSbTe (GST) alloys by Ge (GGST) and the introduction of light elements demonstrated to be a successful solution to enhance the data retention in PCM. This opens the possibility for this technology to target automotive applications, featuring strict specifications in terms of stability in high temperature environment [2-4]. The optimized combination of N introduction and increased Ge content delayed phase separation and crystallization processes of Ge and GST phases. This delay can be attributed to the reduced mobility of Ge atoms caused by the formation of Ge-N bonds [4, 5].
In this work, we performed *in situ* X-ray diffraction to assess how N and stoichiometry influence GGST materials during thermal annealing. Thus, the need for a beam with high energy and rapid measurements were necessary for following the amorphous-to-crystalline transition effectively.
These experiments took place at BM2-D2AM Beamline of the ESRF in November 2022. A monochromatic beam with energy of 10.9 keV and a 2D detector were used to record the scattered intensity. The result patterns were subsequently corrected and integrated to derive 1D diffraction patterns for analyses and interpretation. The diffraction peaks were fitted with Lorentzian function to extract different parameters (area, height and full width at half maximum) giving information about the crystallization evolution. In the present work, we performed annealing with different heating ramp ups for recovering activation energy by using Kissinger law [6], and then quantifying the impact of N in the different compositions.
These measurements allowed us to observe the following phenomena:
N increases the energy barrier for the crystallization of Ge cubic phase in all the GGST systems studied, while a limited impact is observed on the crystallization kinetic of the GST phase;
- The growth rate of the Ge phase is confirmed to be really high but likely limited at the interface of GeSbTe grains (i.e. where the heterogeneous nucleation of Ge takes place), i.e. the Ge grains size reaches very fast a plateau, and starts to slowly increase again only at temperatures higher than 450 °C;
- The GST phase shows a linear evolution (with respect to Ge phase), with dependent growth rate on the initial stoichiometry of the deposited alloy.
- The evolution of the parameters extracted from our measurements (i.e. crystallization temperatures, crystals sizes etc.) will be presented comparing different GGST compositions. These results will be supported with *ex situ* Raman and IR spectroscopies as well as TEM-EDX analyses.
These results bear new insights for a better understanding of the crystallization process in Ge-rich GST and the impact of N introduction in such alloys.

***In Situ* Near Edge X-Ray Absorption Fine Structures Spectroscopy for The Characterization of Deploymerization Rate during Polymer Recycling** Zhengxing Peng, Mutian Hua, Rishabh D. Guha, Kristin A. Persson, Brett A. Helms and Cheng Wang; Lawrence Berkeley National Laboratory, United States

The circular polydiketoenamine (PDK) elastomers cover a broad range of thermo-mechanical properties to meet various application demands, and they can be fully deconstructed back to monomers through acid mediated hydrolysis. It is found that the deconstruction rates can be controlled by tuning the anions in the acidic media, i.e., the deconstruction rate is accelerated when switching from a hydrogen sulfate anion to a bromide anion. To quantitatively quantify the deconstruction rate, we developed an in-situ NEXAFS method combining with time dependent density function theory (TD-DFT) predictions to investigate the deconstruction of the PDK elastomers, which produced chemo-specific spectrums that are subsequently interpreted with specific assignment to functional groups. Briefly, we sealed a PDK403 thin film with a layer of acid in a sandwiched SiNx membrane windows as the in-situ liquid cell for the collection of NEXAFS spectrum. With careful manupulation of X-ray flux to avoid radiation damage, we consistenly observed an increasing peak at 289.4 eV and a decreasing peak at 286.6 eV over time, indicating the progression of chemical transformation. With accurate peak assignemnt from DFT calculations, the increases at 289.4 eV is ascribed to the release of solvated T-403. The progressively increase in the peak intenisty works for the quantification of depolymerization rate of PDK403. This is the first time to in situ characterize the deconstruction of crosslinked polymers as a solid that do not dissovle in a solvent enviorment. This methodology opens up the possibility to characterize the chemical transformations in various crosslinked vitrimers and elastomers.

3:30 PM CH01.04.05
A Hard X-Ray Laboratory XES and XAFS Spectrometer Implementing Asymmetric Bragg Diffractions for High-Resolution *Operando* Measurements of Ni_2P Nanoparticle Electrocatalysts Anthony J. Gironda, Ricardo Rivera-Maldonado, Jared Abramson, Dawson Dean-Hill, Gerald Seidler and Brandi M. Cossairt; University of Washington, United States

X-ray spectroscopy techniques typically reserved for synchrotrons, namely x-ray absorption fine structure (XAFS) and x-ray emission spectroscopy (XES), have been undergoing a renaissance in the laboratory over the past decade. Advancements in detector technologies and Bragg optic manufacture has enabled high resolution (~1 eV) XAFS and XES spectrometers to be built in the lab. Spherically bent crystal analyzers (SBCAs) are the dominant high-

resolution hard x-ray optic both in the ongoing rebirth of laboratory-based and in synchrotron hard x-ray photon-in/photon-out methods. In almost all cases, SBCAs are implemented in a 'symmetric' configuration on the Rowland circle, wherein the diffracting crystal plane is nominally coincident with the analyzer wafer surface. The laboratory spectrometer described is a powerful characterization tool capable of *in situ* and *operando* measurements across many disciplines while implementing asymmetric Rowland geometries with many benefits.

This work details the following. First, the construction and operation of a laboratory spectrometer specialized in operating with asymmetric Rowland geometries, wherein the diffracting crystal plane is not coincident with the optical surface of the analyzer. Results indicate several benefits of such an instrument, demonstrating increased energy resolution compared to the symmetric counterpart and a massively extended energy range of a single SBCA, enabling a technique we refer to as '*hkl* hopping'. Second, the design and implementation of a low-absorption electrolytic cell optimized for transmission XAFS measurements. This cell enables *operando* x-ray measurements of catalytic materials in the laboratory due to a clear line of sight to the sample window and very thin low-Z materials to minimize unwanted x-ray absorption outside the sample. Third, the use of such a cell and the laboratory spectrometer for *operando* measurements of a Ni_2P nanoparticle electrocatalyst. Ni_2P is an earth-abundant material proposed for use as an electrocatalyst for hydrogen evolution, nitrate reduction, CO_2 reduction, and alcohol oxidation. However, Ni_2P is susceptible to oxidation. Several studies on the material and operating cell were conducted with the laboratory spectrometer, measuring the XAFS of the Ni K-edge to monitor changes in oxidation state with respect to changes in pH, air exposure, and applied potential as the cell operates and is measured simultaneously. Measured in the laboratory, synchrotron quality data of nanoparticle stability and assessment of cell performance is made possible, and through a sweeping series of experiments controlling pHs and applied potentials, a pseudo-Pourbaix diagram of nanoparticle Ni_2P can be constructed.

3:45 PM CH01.04.06
Ultrasound and Rheological Study of Oil-In-Oil Magnetic Pickering Emulsions Bassam M. Jameel, Rafal Bielas and Arkadiusz Józefczak; Faculty of Physics, Adam Mickiewicz University in Poznan, Poland

Magnetic Pickering emulsion is a type of heterogeneous system consisting of stabilized immiscible liquid droplets stabilized with insoluble solid particles, such as magnetic nanoparticles. The control of the formation process and stability of such a three-phase system material is important from the application point of view. Moreover, due to its possible biocompatibility and high cargo-loading capacity, magnetic Pickering emulsions hold significant promise in biomedical and pharmaceutical applications, including therapeutic delivery and bioseparation.
This research primarily focused on characterizing magnetic Pickering emulsion stabilized using various volume concentrations of magnetic nanoparticles and with two distinct formation processes involving ultrasound homogenization and electric field. Ultrasound scattering theory, based on a so-called core-shell model, was employed to analyze ultrasound propagation through such a magnetic three-phase system. Additionally, rheological properties were measured to examine changes in the internal structure when subjected to a static magnetic field. The Herschel-Bulkley model was applied to determine the yield stress based on magnetorheology measurements. Optical microscopy was employed to verify optical changes in the system resulting from different formation processes.
The ultrasound spectroscopy results demonstrated variations in attenuation associated with different magnetic shell thicknesses, core radii, and concentrations. Fitting experimental data to the core-shell model revealed the relationship between volume concentrations and both core and shell sizes. Higher particle concentrations were found to result in a greater number of particles at the droplet interface [1], directly affecting the radius of magnetic Pickering droplets, aligning with the findings of another study [2]. Furthermore, higher volume ratios of magnetic nanoparticles exhibited a more pronounced magnetoviscous effect. Additionally, the formation process involving an electric field yielded higher dynamic yield stress [3].
This work was supported by project no. 2019/35/O/ST3/00503 (PRELUDIUM BIS) of the Polish National Science Centre.

SiO_2 Particles prepared from PDMS Foam/Sponge with Potential use as a Viscosity Enhancer Yogendra Yadawa and Amit Ranjan; Rajiv Gandhi Institute of Petroliam Technology, India

In this work we report a simple technique to produce SiO_2 particles with completely different morphologies, starting from the commercially available PDMS (Sylgard 184, Dow Chemicals). The process consists of first preparing a PDMS sponge by taking a solution of PDMS and cross-linkers in THF with suitable concentration and subjecting it to heating. The cross-linking reaction simultaneously occurring with the bubble formation due to boiling of the THF results in the formation of sponge-like PDMS. Subsequently, the sponge pieces are kept under two different thermal environment conditions which yield SiO_2 with entirely different morphologies in the resulting material. In the first case when the sponge is subject to slow heating to 550 ºC and slow cooling, a very soft powder of SiO_2 nanoparticles is obtained. In the second case, fast heating and fast cooling of the same sponge wrapped inside an aluminum foil yields a brittle solid. The formation of amorphous SiO_2 in both the cases is confirmed from XRD and FT-IR. The SEM imaging of the soft powder shows particles of nearly spherical shape with size ranging from 100 nm to 500 nm whereas the brittle solid when crushed and ground, shows much larger particles with planar faces. The BET surface area was found to be 4.36 m^2/g for the soft powders which increased considerably to 192 m^2/g for the brittle solid.
We further studied the rheological alterations due to soft powder samples. A mixture of PDMS-THF solution with 1.25 wt% soft and brittle SiO_2 particles enhances the viscosity nearly 1.5 and 2 times respectively at low shear rate (1 s^{-1}). This mixture was found to homogeneously incorporate water up to a certain extent (nearly 30 wt%) beyond which the mixture was found to phase separate. The viscosity of the PDMS-THF-particle mixture with 30 wt% DI water was found to further increase by a factor of nearly 10 for soft and 20 for brittle SiO_2 particles as compared to the mixture without any water. Our formulation which is completely based on a commercially available product, will be explored towards enhancing the rheological properties of the mixture PDMS-THF-particle solutions.
Keywords: SiO_2 nanoparticles, polydimethylsiloxane (PDMS), THF, zero shear viscosity.

***In Situ* X-Ray Imaging of Droplet Drying with Dense Particle Suspensions: Exploring the Mechanism of Coffee Ring Formation** Yuanyuan Liu, Wajira Mirihanage and Brian Derby; University of Manchester, United Kingdom

Droplet deposition and drying is a key process in many manufacturing processes including: the spray deposition of paints and coatings, inkjet printing, and the manufacture of large area electronics. During the drying of droplets that contain small particles in suspension, it is well known that, under certain

experimental conditions, the dried residue does not form a uniform deposit related to the shape of the initial liquid drop but instead a migration of particles to the pinned contact line of the drop leads to a characteristic ring deposit or *coffee stain.* In dilute particle suspensions this phenomenon is believed to be initiated by contact line pinning during evaporation, which leads to a radial outward fluid flow along the base of the drop increasing the local particle concentration at the contact line because evaporation removes the solvent. The precise conditions that trigger the formation of a coffee ring are still a topic of investigation but are believed to be associated with the mechanisms that lead to contact line pinning before the receding contact angle is reached during drying.
There has been considerable experimental study of the drop drying process and in situ imaging of dilute particular suspensions using optical microscopy and individual particle tracking experiments has prove valuable for studying the dynamics of the coffee ring and fluid flow during droplet drying. However, many of the real-world applications of droplet-based manufacture use dense particulate suspensions as the fluid or ink and, although it is known that such dense suspensions can form a coffee ring, study of droplet drying in these cases has been limited to observing the change in drop shape.
Here, we present an *in situ* study of the drying of dense suspensions of sub-micron ZrO_2 particles in aqueous suspension using a synchrotron X-Ray source to track changes in drop volume and shape during drying at 20, 45 and 60 °C on glass, silicon and Kapton substrates that show different contact angles of 24°, 36° and 73° respectively. We show that if the drop retains radial symmetry during the drying process, the signal intensity across the drop image can be transformed to determine the local density of the suspension and from this a semi-quantitative measure of the particle concentration in the liquid as a function of vertical and radial position in the drop. Hence, we can track the relative densification of the particle suspension as a function of position during the drying of the drop.
Coffee rings are found to form more easily on the lower contact angle surfaces and at higher drying temperatures where evaporation is more rapid. Our results show that the density profile across drying drop is significantly different between drops that show uniform drying and those where a coffee ring forms. In the absence of a coffee ring, densification commences across the surface of the drop in a uniform manner and there is evidence for a possible surface crust during drying. However, under the conditions that lead to a coffee ring, initial densification is also more intense at the upper surface but is now much stronger towards the contact line. It is unclear whether the surface crust formation suppresses coffee ring formation or is a consequence of its absence.

Continuous EELS Spectrum Imaging of Nano-Droplet Crystallization Heterogeneity Benjamin Miller, Liam Spillane and Cory Czarnik; Gatan, Inc., United States

Electron energy loss spectroscopy (EELS) is a powerful technique for characterizing nanomaterials. A number of materials properties can be extracted from the information-rich spectra. One application is nano-thermometry, where the local temperature of individual metal nanoparticles can be measured by a precise determination of the plasmon peak position. As thermal expansion increases a particle's volume, the density of electrons decreases, and the energy loss of the plasmon peak shifts to lower energies. This same approach can be used to detect melting and crystallization, which result in much larger changes in the electron density. Continuous acquisition of EELS data enables precise determination of the melting and crystallization temperatures. Using the new in-situ EELS spectrum imaging features of the Continuum GIF, a continuous series of drift-corrected spectrum images can be acquired over an ensemble of particles, and the melting and crystallization behavior monitored.

In this work, we show how a series of EELS spectrum images can be acquired and processed along with the temperature data from a MEMS-based heating holder. With modern fast detectors and spectrometers, spectrum images with thousands of spectra can be acquired in less than a second, making continuous in-situ spectrum imaging feasible. The holder temperature data is automatically synchronized and correlated with EELS spectrum image data. We also show how the entire series of in-situ EELS spectrum images can be rapidly fit using the built-in NLLS tools in DigitalMicrograph, yielding series of synchronized fit maps. After summing over a single nanoparticle, plots of the peak position over time can be generated, and even plotted against the nominal temperature from the holder in scatterplots.

This new in-situ EELS spectrum imaging capability has been applied to a Sn nanoparticle sample which was oscillated above and below its melting temperature. Watching the maps of plasmon position over time reveals that while all the Sn particles crystallize during most cycles, and most particles crystallized during every observed cycle, some particles occasionally did not crystallize even though surrounding particles did. This heterogeneous and stochastic behavior at the nanoscale can only be observed with high spatial and temporal resolution. In-situ electron microscopy, and specifically in-situ EELS spectrum imaging is an excellent technique for exploring these dynamics.

Solid Nanoparticles and Liquid Droplets on The Path to Crystallization in Solution: Some Fundamental Questions on Nucleation Addressed with Synchrotron X-Ray Scattering Methods. David Carriere; CEA, France

Crystallization from solution often involves transient, non-crystalline states like reactant-rich liquid droplets and amorphous particles [1]. This state of affairs not only challenges the chemical engineering models used to rationalize laboratory- and industrial-scale processes, but also motivates deep experimental tests of the multistep nucleation theory proposed as an alternative to the well-known classical nucleation theory of Becker and Doering [2]. However, testing both engineering and physical models requires challenging quantification of the structures and phases (sizes, volume fractions, crystallinity, compositions), down to the millisecond reaction times and sub-nanometer characteristic lengths.

Here, I will illustrate how coupling synchrotron X-ray methods and electron microscopy can tackle challenging scientific questions in the crystallization of oxide nanoparticles, vanadates and rare-earth oxalates through: 1) providing evidence of transient structures, and sometimes multiple transient structures, together with growing crystals [3–6] 2) assessing the impact of these transient phases on the final product, in particular when it consists of nanometer-sized aggregates of nanocrystals [5] 3) providing evidence of an evolution in the chemical composition of the transient phases [6] and 4) assessing the impact of the transient phases on chemical engineering models [7].

Atomic Scale Imaging of Defects in Solution Grown Tin Disulfide Naveen Goyal, Rajeev Kumar Rai and N. Ravishankar; Indian Institute of Science, India

Tin disulfide (SnS_2), a layered material, has gained substantial attention in recent years due to its applications in various fields, including broadband photodetection spanning from UV to NIR regions, selective room-temperature gas-sensing of NO_2, serving as an anode material in sodium-ion batteries, and application in supercapacitors.[1] These applications arise are a result of a synergistic interplay between SnS_2's inherent properties and the precise engineering of defects, such as vacancies, dislocations, and grain boundaries.[2] Along with these, other defects such as ripplocations are also present exclusively in layered materials.[3] The control of such new defects and their influence on the properties and applications of layered materials is currently a wide subject of study.
In this study, we utilized the solution chemistry method to synthesize nanocrystals of SnS_2. The phase purity of these nanocrystals was confirmed through powder X-ray diffraction, and their uniform nanosheet morphology was evident from SEM images. We have conducted a comprehensive analysis of defects using advanced microscopic techniques, specifically using aberration-corrected scanning transmission electron microscope. By directly imaging the layers of SnS_2 along [100] zone axis, we identified the presence of various defects at the core of nanocrystal, including line and screw dislocations, voids and warping of layers. While dislocations and voids are well-documented in various materials, the ripplocations appears to be a unique characteristic of van der materials like SnS_2. These defects are believed to result from local variations in supersaturation during the nucleation and growth of the crystnnal. This type of investigation is expected to yield valuable insights for tailoring the properties of layered materials.

Frequency-Guided Photoreactions: A Case Study on 1,3-Dimethoxybenzene Trifluoromethylation Katsuyuki Morii[1,2] and Mayaka Maeno[2]; [1]Nippon Shokubai Co Ltd, Japan; [2]Osaka University, Japan

We propose a new method for controlling photochemical reactions using the frequency of the light as a parameter. The 21st century is called the century of light, and photoreaction are being actively researched. Furthermore, research is active in fields that try to apply light, such as beauty, medicine and plant cultivation. Recently, in several fields, it has been reported that time-controlled light, that is, pulsed light, has an effect beyond expectations. Therefore, in order to clarify its origin, we investigated the relationship between optical parameters of pulsed light and results with photoreactions. In this study, we conducted a pulsed-light–induced trifluoromethylation reaction under simple reaction conditions wherein we combined 1,3-dimethoxybenzene, anthraquinone, and CF_3SO_2Na without any other additives, oxidants, or reductants, and exposed the mixture to both conventional and pulsed light.
The photoreaction was carried out at a temperature of 15 degree C for 20 hours. All conditions were the same except for frequency modulation, and photoreactions were performed using (a) continuous light and (b) pulsed light at 10^5Hz and duty 0.1. Comparing entry (a) and (b), entry (a) achieves the same yield as entry (b), even though it uses only 10% of the light exposure. In addition, the amount of bis-trifluoromethylated products were decreased by half compared to entry (a). We considered it important that this result was achieved using only frequency modulation. Compared to conventional light, pulsed light yielded higher efficiency and regioselectivity, while also suppressing undesirablereactions. Even more interestingly, it was found that both reaction yield and chemoselectivity varied with the frequency of the pulsed light in the range from 1.4×10^{-5} Hz to 10^5 Hz. Notably, the total irradiation time was kept constant at 7200 s.
Our findings suggest that pulsed light offers a promising avenue for controlling photochemical reactions, and beyond traditional parameters like reagents, solution concentration, and temperature, the method of light irradiation emerges as a critical factor in photochemical processes.
Furthermore, the reaction characteristics within the frequency modulation of more than 10 orders of magnitude are thought to indicate the behavior of some intermediates, substrates, and catalysts on various time scales, and it is expected that this method will be useful for evaluating the dynamics of photoreactions.
We demonstrated, for the first time, a pulsed-light–induced trifluoromethylation reaction conducted under simple reaction conditions, wherein the frequency of the pulsed source was used as an adjustable control parameter. We found that pulsed-light irradiation improved the yield and regioselectivity of the reaction. This showed that varying the parameters of the light source could be an important factor in controlling the reaction. The effect of frequency, which corresponds to the ON/OFF time ratio of the pulsed light, may be related to the lifetime of the active species and the concentration of the photocatalyst or reaction intermediates. Elucidation of the full mechanism behind the frequency-controlled photochemical reactions is expected to establish new methods for reaction control and will contribute toward the development of new reactions.

Synthesizing Nanomaterials with Optimal Properties using Closed Loop Optimization Brenden Pelkie, Abdul Moeez and Lilo D. Pozzo; University of Washington, United States

Many nanomaterial synthesis procedures require the selection of several experimental parameters to control the properties of the material that is produced. While this can provide detailed control over material properties, navigating this high dimensional parameter space to select values that enable desired outcomes can be an intractable process. While the applications of laboratory automation makes the systematic testing of parameter combinations more accessible, complete combinatorial explorations can still be inefficient or impossible for large systems. Closed loop optimization methods like Bayesian optimization provide a method to autonomously select experimental parameter values to test, on-the-fly during an ongoing experiment. These approaches use machine learning methods to select parameters that are likely to improve a material's performance, as defined by a researcher-defined metric.

Implementation of fully closed loop experiments requires capabilities for automated sample synthesis, characterization, and data processing. We are developing infrastructure to enable closed loop optimization for nanoparticle systems. To enable automated synthesis, we have developed an open-hardware robotic motion platform to enable flexible lab automation for advanced synthetic capabilities and automated flow synthesis tools for nanoparticle synthesis. Online characterization is enabled by an autosampler and automated data processing workflow for lab-scale x-ray scattering. These capabilities are applied to gain morphological control of various nanoparticle synthesis processes.

5:00 PM CH01.05.04
A Parametric Study Regarding The Influence of Fabrication Methods on The Explosive Characteristics of Porous Silicon Nathan Heavner, Max Krauss, Greer Miller and Jeff Jessing; Fort Lewis College, United States

Over the past decade, extensive research has explored the reactive properties of porous silicon (PSi) when combined with chemical oxidizers. PSi detonations, capable of precise and reproducible thrust, have the potential to be utilized for advanced micro-thruster applications. By adjusting fabrication and oxidation parameters, it is possible to enhance the reactivity of chemically oxidized PSi. Changing these parameters can also provide valuable insights into the energetic yield of PSi, thus allowing optimization of propulsion characteristics. This parametric study focuses on performing the electrochemical anodization of bulk silicon (Si), using a 3:1 ratio of 49% hydrofluoric acid to ethanol (HF:EtOH) with varying current densities and anodization times to fabricate PSi. A 3.2Mol sodium perchlorate methanol solution is then applied to the PSi substrate as an oxidizer. The samples are subsequently dried using one of three methods: atmospheric drying, vacuum drying and drying in a nitrogen box. Variable drying times for each method are also reviewed. Finally, a bomb calorimeter is employed to analyze the combustive properties of the PSi samples. The results of this analysis are used to identify the optimal fabrication parameters for achieving maximum energy yield from a PSi detonation.

5:00 PM CH01.05.05
The Operando SAXS Characterization of The Binary Mixing of F127/L121 Pluronic Biomedical Hydrogels in The Self-Assembly Tz-Feng Lin and Wei-Chieh Wang; Feng Chia University, Taiwan

Pluronic biomedical hydrogels (PBHs) was proposed to study the structural changes in the self-assembly of binary mixing copolymers. PBHs are served as a microenvironment and a as a targeted drug delivery system offering many attractive benefits such as intrinsic biocompatibility and controllable prolonged drug delivery.Small angle X-ray scattering (SAXS) was used to discover the self-assembled structures of the PBHs in real time with respect to the temperature variations. According to the SAXS results, structural changes of the micelle and the lamellar affected the mixing behavior of hydrophilic segments and hydrophobic segments. Thus, the transformation between the flat lamellar amphiphilic boundary and the hydrophobic core was studied. Results show that the diffusion of the amphiphilic segments in the PBHs will affect a lot across the interface between the hydrophilic corona and the hydrophobic core. Evidence are observed for the self-assembly of PBHs at the temperatures from 25 to 45 °C simultaneously.

5:00 PM CH01.05.06
Real-Time Etch End Point Detection for Silicon Biomembranes in Lung-On-A-Chip Applications Leif Gislason, Sahra G. Genc, Sally Thompson and Jeff Jessing; Fort Lewis College, United States

Wet-etched thinned silicon membranes are common in the microelectromechanical system (MEMS) industry, with accuracy in dimensions, specifically thickness, being a crucial aspect to the functionality of these devices. Our research focuses on producing biomembranes for lung-on-a-chip applications. The current fabrication process of these membranes uses a heated aqueous solution of potassium hydroxide (KOH) to thin double-side polished, (100), p-type silicon wafers to sub-5 µm. Previously, our work has relied on a procedure that involves removing the membrane midway from the KOH bath, measuring with a micrometer, calculating an etch rate, and then finishing the etch based on this etch rate. This damages the silicon and ultimately compromises the quality of the resultant membrane. We propose an optical-based method to determine in real-time the thickness of the membrane as it is being etched with KOH. The setup of this experiment involves a custom fabricated enclosure for the thinned sample with apertures on both sides, with one having a light source and the other, a photodetector. Various light sources and detection wavelengths are used to investigate the optimization of light transmission through the thinning membrane so that a correlation of transmission to membrane thickness can be determined. Using scanning electron microscopy for accurate thickness determination we present a model that provides correlation with light transmission through the membrane. Our ultimate goal is to be able to determine the thickness in real-time during an etch, which will entail significant research considering it must pass through multiple media, including two glass beakers, water, and an aqueous solution of KOH and water which introduces multiple scattering events.

SESSION CH01.06: Crystal Assembly and Transformation

In and Out-Of-Equilibrium Assembly Dynamics of Nanoparticles Qian Chen; University of Illinois at Urbana-Champaign, United States

In this talk, I will discuss our recent efforts on utilizing liquid-phase TEM imaging and associated machine-learning or computational simulation methods to understand the fundamental colloidal forces in both equilibrium and out-of-equilibrium assemblies of nanoparticles. Anisotropic gold nanoparticles are our model systems, with intriguing plasmonic properties and directional interactions. We study their nucleation pathway and growth habits in real-time in solution at the nanometer resolution, where colloidal interactions balance with mass transport to ultimately determine the size, shape and surface morphology of assembled superlattice. We study the phononic relaxation of the superlattices, where complex colloidal interactions act effectively as nanoscale springs to determine the collective structural reconfiguration. Going beyond equilibrium dynamics, we also study the external field driven assembly of nanoparticles, where hydrodynamic effects drive the nanoparticles into active “swarms” with rapidly-changing patterns. We will show new structural control and new functional relevance in these particulate systems, when we consider both the colloidal interactions and all the other factors such as diffusivity, many-body effects, and ionic flows.

11:00 AM CH01.06.02
Multiphase Silk Assembly for Two-Dimensional Bio-Crystal Film Chenyang Shi and James J. De Yoreo; Pacific Northwest National Laboratory, United States

Early insights into native silk fibroin (SF) architecture suggested that its unique structures and properties are determined by its multiscale assembly and the evolution of its secondary structure. Yet the pathways of assembly and the relationship to that evolution are poorly understood. Here we investigate SF self-assembly using in situ AFM and liquid phase infrared nanospectroscopy (nano-FTIR) and molecular dynamics. To do so, we assemble the silk at the interface between water and highly ordered pyrolytic graphite (HOPG). We find that SF grows heteroepitaxially on HOPG into highly ordered, monolayer-thick 2D nanocrystals consisting of 1D lamellae that exhibit β-sheet secondary structure and lie along the armchair direction of HOPG. Molecular dynamics simulations show that the armchair orientation is indeed energetically favored, as is polar packing to form a bilayer. As the SF concentration increases, SF assembles into multi-layers via two pathways that can occur concomitantly. One is a non-classical pathway by which a disordered metastable film forms on top of the lamellae of the first monolayer and gradually converts into the lamellar structure. The second is a classical layer-by-layer pathway by which new lamellae grow homoepitaxially on the underlying 2D lamellae nanocrystals without any evidence of an intermediate state. Appling synchrotron based tip-enhanced nano-IR to SF assembly for the first time, we demonstrate that the β-sheet conformation is adopted from largely unstructured SF in solution as the lamellae advance along the classical pathway or during the process of film transformation along the non-classical pathway. These new findings fill in the missing pieces of the puzzle showing how SF structure evolves at the liquid-solid interface and provides inspiration for the design of heterogeneous 2D SF bio-crystal film.

11:15 AM CH01.06.03
Microfluidics for Programmable Self-Assembly of Gold Nanorods Pandillapally Rama; Indian Institute of Technology Hyderabad, India

Self-assembly of nanomaterials is an effective tool for developing functional assemblies and nano devices that can be used for a multitude of electrical, biomedical, and mechanical applications to name a few. We focus on the self-assembly of anisotropic gold nanomaterials, gold nanorods (GNR) in our work, since gold nanorods possess unique optical properties that can be tailored based on their aspect ratios. The side-to-side, end-to-end and self-assembly of GNRs have been a topic of intense research due to both the challenges involved in achieving such assemblies and their application in surface enhanced Raman spectra (SERS) signal enhancements. Several studies show the assembly of GNR using solvents (Ethylene diamine tetra acetic acid (EDTA), tetra hydrofuran (THF), dimethyl formamide (DMF)), pH, temperature, surfactants, co-polymers and other conditions. However, a systematic analysis and thereby understanding of the mechanism of assembly/dis-assembly and the resultant influence of several contributing parameters is a limitation in these studies. The lack of reproducibility and kinetic control over the reaction make such analysis challenging in the methods used in the studies.
In the current work, we use droplet microfluidics to analyze the solvent based (EDTA) self-assembly of GNR. The GNR are encased in a 'micro-vessel' droplet within which reaction with EDTA happens is automated and proceeds reproducibly and controllably. We vary the concentrations of EDTA, change the drop size and also the ratio of aqueous to continuous flows and look at the shift in the resonance spectral wavelength of the clusters hence formed. The spectral shifts in these studies show the individual interaction of GNR with EDTA with respect to the aspect ratio of the GNR, size and shape of the individual particles. The study also shows the effect of mixing, leading to different results in each scenario. We performed a systematic analysis of the interaction and are currently working on programming and optimizing a general assembly strategy for GNR.

11:30 AM CH01.06.04
Unraveling Self-Assembly with Liquid Resonant Soft X-Ray Scattering for *In Situ* Measurement of Mesoscale Structure with Chemical Specificity Peter Beaucage, Lucas Flagg and Dean M. DeLongchamp; National Institute of Standards and Technology, United States

Resonant soft x-ray scattering (RSoXS) is a new characterization technique that offers insights into mesoscale structure with chemical specificity and the ability to probe molecular orientation. It does this by performing conventional small-angle x-ray scattering at a series of low photon energies (285 eV at the carbon K-alpha edge) as in x-ray spectroscopy. RSoXS was originally developed around and has been applied to great effect in morphological characterization thin films of organic semiconductors. Recently, our team has developed the first quantitative fitting engine for RSoXS data using GPU-accelerated forward simulation of real-space morphologies and applied this software to measure the orientation distribution in polymer-grafted nanoparticles, reverse osmosis water membranes, and several other families of industrial materials.
The promise of RSoXS as a label-free alternative to SANS has not been fully realized, however, largely due to great difficulties in the study of liquid samples, or indeed practically any sample without significant structure factor contributions. This limitation arises because of the very feature that makes RSoXS unique: at the low photon energies used for organic molecules, a typical absorption length is about 500 nm. RSoXS measurements are, therefore, overwhelmingly conducted on thin films and typically on highly concentrated samples due to the extremely small probe volume. The design of the NIST RSoXS beamline at the National Synchrotron Light Source-II addresses this issue by incorporating a TEM port holder in the chamber; the sample thicknesses required for electron beam transparency are similar to those required for soft x-rays. We have procured a commercial TEM liquid cell capable of encapsulating a 500 nm film of flowing liquid between two thin silicon nitride membranes.
This talk will discuss the commissioning of the cell, our first RSoXS measurements of dilute biomolecules in solution, and our recent efforts to combine solution RSoXS with solution SANS measurements to obtain a greater-than-sum-of-the-parts characterization of self-assembly processes and mechanisms in bioformulations. We will discuss the future extension of the liquid RSoXS technique to the *in situ* study of electrochemically active thin films in the hydrated state, and how measurements of pure form factor scattering enabled by the liquid sample environment and combined SANS-RSoXS experiments will enable quantitative understanding of the localization of additives during complex self-assembly processes.

SESSION CH01.07: Crystal Assembly and Transformation II

1:30 PM *CH01.07.01
Filming Photoinduced Ultrafast Phase Transformation of Vanadium Dioxide at The Single Nanoparticle Level Oh-Hoon Kwon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Visualizing structural rearrangements at the atomic/molecular level is essential in understanding the functions of matter. Once isolated, a molecule's intermediate and transitional structures during a chemical reaction may be routinely determined via ultrafast spectroscopy with femtosecond temporal precision. When the structural degrees of freedom increase, e.g., condensed matter comprising countless atoms or organized molecular units, local nanoscale structural defects become prevalent, and thus, the physical processes of each singularity do not proceed as those in bulk and even diverge. If controlled, these structural defects may yield functional benefits and be exploited to overcome the current technological challenges ranging from catalysis to quantum computing. Because the ensemble natures of spectroscopic measurements do not reveal the characteristic transition of each nanoscopic structure, simultaneous spatiotemporal imaging is required to resolve complex processes, hierarchically spanning small-amplitude, ultrafast atomic

displacements to collective structural rearrangements at expanded spatiotemporal scales. As an energy filter in transmission electron microscopy has improved the precision of structural determination by filtering out inelastic imaging electrons, introducing the energy filter to ultrafast electron microscopy (UEM) can advance the time resolution to the domain of atomic motion. Imaging transient structures with femtosecond temporal precision was made possible by gating imaging electrons of narrow energy distribution from dense chirped photoelectron packets, thus typically posing picosecond duration. Presented are the concept and proof-of-principle demonstration of the energy-filtered UEM achieving the temporal resolution limited by the briefness of an optical excitation pulse, i.e., 500 fs in this study, filming ultrafast insulator-to-metal phase transition of vanadium dioxide (VO_2), a representative strongly correlated system. In this study, the heterogeneous phase transformations of VO_2 nanoparticles were revealed and attributed to the emergence of a transient, low-symmetry metallic phase caused by different local strains. Our approach leads the access of electron microscopy to the timescale of elementary nuclear motions, visualizing the onset of structural dynamics of matter at nanoscales.

2:00 PM CH01.07.02
Characterization of Structural Transformations in Flash Annealed HZO Thin Films via Dynamic and Static Synchrotron Grazing Incidence X-Ray Scattering Cristian Ruano Arens[1], Valene Tjong[2], Balreen Saini[1], Jonathan Hartanto[1], Fei Huang[1], Chanyoung Yoo[2,1] and Paul C. McIntyre[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

In order to extend computational power beyond the era of conventional area scaling of semiconductor circuits, back-end-of-line (BEOL) integration is a promising pathway towards 3D integration of non-volatile memory with logic, to increase integration density and reduce latency and energy consumption associated with data transfer. With improved properties over perovskite-structure ferroelectrics, HfO_2-ZrO_2 (HZO) alloys are promising candidates for future nonvolatile memories because of their CMOS compatibility, sub-nanosecond switching speed, and scalability of ferroelectric properties to the nanoscale. However, synthesis of ferroelectric HZO typically requires rapid high temperature heating to form the ferroelectric phase. Flash lamp annealing (FLA) is a viable method for thermal processing of BEOL components in which sub-ms pulses of light potentially allow localization of steep temperature rises to the top layers of the device stack, and protect underlying interconnect and front-end-of-line (FEOL) structures while crystallizing higher level materials. However, the short time scales and non-equilibrium nature of the annealing technique complicates determining thermal gradients and has led groups to rely on model predictions, measurement of the underside temperature of the substrate, or comparison between the performance of devices processed using rapid thermal anneal (RTA) or FLA to estimate the temperature rise of the surface layers. Because of the strict thermal budget imposed on BEOL processing, it is vital to determine the time-temperature profile associated with non-equilibrium FLA processing.
Our work uses static and time-resolved synchrotron glancing incidence X-ray diffraction (GIXRD) for in-situ, quantitative temperature metrology to understand the temperature rise during FLA processing of TiN/HZO/TiN metal-ferroelectric-metal (MFM) capacitors. Time-resolved GIXRD was performed during FLA processing to observe, in real-time, the emergence of the ferroelectric orthorhombic phase, thermal expansion of the crystal lattice, and changes in diffraction intensity due to the Debye-Waller effect under various annealing conditions. Static GIXRD was subsequently performed to carefully monitor the changes in lattice parameter and diffraction intensity at discrete elevated temperatures. After careful calibration, we were able to compare the changes in both of these parameters and quantitatively determine the temperature rise associated with various FLA conditions.
Using a sequential learning Gaussian Process, we have explored the process manifold to fabricate MFM capacitors with good remnant polarization ($P_r \sim 20$ $\mu C/cm^2$) and low coercive fields ($E_c \sim 1.2$ MV/cm) while being cognizant of the thermal budget necessary to achieve devices of this performance. Thus, careful calibration has enabled exploration of the FLA processing space in effort to yield optimal ferroelectric device performance within the strict thermal budget set by BEOL processing requirements. This study has advanced in-situ temperature metrology to explore temperature transients and FLA processing effects in BEOL device stacks.

Investigating The Dynamics of Photo-Reversible Polymer Hydrogels using *In Situ* Shear Rheology Michael C. Burroughs, Eleanor L. Quirk, Brendan M. Wirtz, Tracy Schloemer, Dan Congreve and Danielle J. Mai; Stanford University, United States

Polymeric materials are often designed to be permanent, such that single-use convenience supersedes considerations of recyclability. For hydrogels, this approach has resulted in materials comprising many components such as polymer precursors, crosslinking agents, and photoinitiators; such complex formulations preclude the chemical recovery of the original constituents. To simplify the formulation of and encode recyclability into hydrogel materials, we report photo-reversible, network-forming polymers that are crosslinked and un-crosslinked using different wavelengths of light. Light-driven un-crosslinking has potential as a low-cost, low-energy, on-demand recycling technology. Photo-reversible polymer hydrogels comprise multi-arm star polyethylene glycol with terminal anthracene groups (PEG-anthracene). PEG-anthracene undergoes photo-crosslinking upon irradiation with ultraviolet light (UV, 365 nm) and un-crosslinking upon irradiation with deeper UV light (265 nm). The photo-reversibility of PEG-anthracene with 3, 4, 6, or 8 arms (5 kg/mol per arm) was compared using UV-vis absorbance spectroscopy and *in situ* dynamic rheology. Upon 365 nm UV exposure, PEG-anthracene solutions exhibited rapid gel formation indicated by crossovers from liquid-like to solid-like behavior during *in situ* small-amplitude oscillatory shear rheology. During photo-crosslinking, more arms generally led to the quicker formation of stiffer materials. In contrast, polymers with fewer arms underwent un-crosslinking more readily, indicated by changes from solid-like to liquid-like rheological responses. PEG-anthracene with fewer arms demonstrated liquid-like “recycling windows” that allow for facile polymer solution handling prior to re-crosslinking. These findings demonstrate opportunities for on-demand recycling of photo-reversible polymers, as well as polymer structure-dependent tradeoffs between crosslinking and reversibility. Further understanding of the interplay between polymer structure, material composition, and dynamic processing will advance the use of these materials in optoelectronics, biotechnology, and sustainable additive manufacturing.

2:30 PM CH01.07.05
Synthesis of V2O5-Co3O4 Nanoassemblied Spheres for Gas Sensing Applications Chia-Yin Cheng, Yi-Chen Chen, Chun-Hua Chen, Wen-Chieh Hsieh, Shang-Jung Wu, Yi-Wen Lin, Hung-Shuo Chang, Karan Giri and Yan-Lin Wang; National Yang Ming Chiao Tung University, Taiwan

Under the development of high industrialization, the excess of greenhouse gases has caused a global climate crisis, and thermal power generation is one of the primary sources of greenhouse gas emissions. With the rising awareness of energy conservation and carbon reduction in major industrial countries in recent years, the energy transition has become an important issue. At present, hydrogen energy is a potential sustainable energy source. The most significant advantage of using hydrogen (H_2) fuel to generate electricity is that it significantly reduces carbon dioxide emissions. However, the combustion of H_2 will still form nitrogen dioxide (NO_2), and exposure to NO_2 will cause damage to the human respiratory tract, lungs, and kidney functions. To reduce the risk of hydrogen leakage, explosion, and nitrogen dioxide harm to the human body, developing highly-sensitive gas sensing materials for detecting hydrogen and nitrogen dioxide has become an essential goal with great forward-looking and industrial application potential.
In this study, vanadium pentoxide (V_2O_5) and cobalt tetroxide (Co_3O_4) nanoassemblies with different morphologies were respectively successfully synthesized by the polyol method at different reaction temperatures. The synthesized V_2O_5 nanoassemblies can exhibit high-performance H_2 sensing properties at room temperature without catalyst modification. The Co_3O_4 nanoassemblies showed the highest response to NO_2 at an operating temperature of 130 °C. In addition, in the later stage of Co_3O_4 synthesis, vanadium acetylacetonate V(acac)$_3$ was introduced to form Co_3O_4-V_2O_5 nano-mixed particles. Finally, a novel heterogeneous core-shell nanoassembly structure comprised a Co_3O_4 core and Co_3O_4- V_2O_5 mixed nanoparticle shell. When V_2O_5, an n-type oxide, is assembled with Co_3O_4, a p-type oxide, the formed p-n junction will result in a depletion region. The electrical charge increases when the

target gases are adsorbed and desorbed, improving the sensing sensitivity. The specific surface area of the V_2O_5-modified Co_3O_4 nano-assembled spheres is 3.2 times that of the Co_3O_4 nano-assembled spheres. At 130 °C, the sensitivity to 400 ppm NO_2 increased from 247 % to 421 %. The gas-sensing responses of the synthesized nano-assemblies are all reproducible through cyclic measurements. Compared with CH_4, C_2H_6, C_3H_8, CO, NO gases, V_2O_5 and V_2O_5 modified Co_3O_4 nanoassembles showed excellent selectivity for H_2 and NO_2, respectively.

Thermodynamics and Kinetics of The Crystallization of Phase Change Materials from *In Situ* Microscopy and Nanocalorimetry Isak McGieson[1], Tamara D. Koledin[1], Jim Ciston[2], Feng Yi[3], David A. LaVan[3] and Melissa K. Santala[1]; [1]Oregon State University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]National Institute of Standards and Technology, United States

The thermodynamics and kinetics of crystallization are key to understanding the stability of glass-forming materials, including poor glass formers such as phase change materials (PCMs). PCMs are semi-conducting alloys with distinct optical and electrical properties in the amorphous and crystalline phases that make them useful for memory applications. In memory devices, amorphous bits are crystallized in nanoseconds by either laser or Joule heating, but the amorphous phase must also be stable against crystallization for long-term data retention. Crystal growth rates relevant to memory devices span orders of magnitude and fundamental questions regarding PCM crystallization mechanisms remain open, partly due to the difficulty in measuring crystallization kinetics in certain temperature regimes.

The crystal growth rate, *u*, has been directly measured from the glass transition, T_g, to the melting temperature for good glass formers owing to their low *u*. In contrast, *u* in PCMs can exceed 10 m/s. Thus, it is challenging to measure *u* directly with microscopic methods, because the small grain sizes demand high spatial resolution and the grains impinge rapidly. This has led to the use of indirect methods to study PCM crystallization such as differential scanning calorimetry (DSC). In this work nanocalorimetry with high-frame-rate transmission electron microscopy (TEM) imaging was used to investigate the thermodynamics and kinetics of the crystallization of $Ag_3In_4Sb_{76}Te_{17}$ and GeTe above T_g. The PCMs were deposited on individually-calibrated nanocalorimeters designed to be operated in a TEM. Direct electron detectors capture the crystal growth in the milliseconds before impingement enabling direct measurement of *u*. The enthalpies of crystallization are calculated from nanocalorimetry measurements. Classical models for nucleation and growth are fit against these data and models that predict the growth rate solely from DSC data are compared to the direct growth rate measurements.

3:30 PM CH01.07.07
Controlled Stepwise Wet Etching of Polycrystalline Mo Nanowires Khakimjon Saidov[1], Ivan Erofeev[1], Zainul Aabdin[2], Antoine Pacco[3], Harold Philipsen[3], Antony W. Hartanto[1], Yifan Chen[1], Hongwei Yan[1], Weng W. Tjiu[2], Frank Holsteyns[3] and Utkur Mirsaidov[1]; [1]National University of Singapore, Singapore; [2]Institute of Materials Research and Engineering (IMRE), Agency for Science, Technology and Research (A*STAR), Singapore; [3]IMEC, Belgium

With the persistent downscaling of integrated circuits, molybdenum (Mo) is currently considered a potential replacement for copper (Cu) as a material for metal interconnects. However, fabricating metal nanostructures with critical dimensions of the order of 10 nm and below is challenging. This is because the very high density of grain boundaries (GBs) results in highly non-uniform surface profiles during direct wet etching. Here, utilizing in-situ liquid phase transmission electron microscopy (LP-TEM), we track the etching of polycrystalline Mo nanowires (NWs) with a hydrogen peroxide solution in real-time [1]. Moreover, wet etching of Mo with conventional aqueous solutions is problematic, as products of Mo oxidation have different solubility in water, which leads to increased surface roughness. Next, we show a process for achieving a stable and uniform soluble surface layer of Mo oxide by wet oxidation with H_2O_2 dissolved in IPA at -20 °C. The oxide layer is then selectively dissolved, and by repeating the oxidation and dissolution multiple times, we demonstrate a uniform etch profile with a fine control over the metal recess. Ultimately, this presents a method of precise and uniform wet etching for Mo and other metals needed to fabricate complex nanostructures that are critical in developing next-generation electronic devices.

3:45 PM CH01.07.08
Force Spectroscopy and Quantitative Imaging of Hard and Soft Materials Vasileios Koutsos; Univ of Edinburgh, United Kingdom

New modes of atomic force microscopy (AFM) such as Quantitative Imaging (QI) use force spectroscopy at a high rate with direct force control and allow the high-resolution topography imaging of material surfaces while collecting simultaneously high-resolution images of adhesion, stiffness, and moduli. We applied the force spectroscopy and in particular, QI mode in different systems showing its potential to reveal unprecedented information on local material properties. We mapped the local (surface) elastic modulus of engineering polymer blends and we compared it to the bulk modulus derived from macroscopic tensile testing. The results show a remarkable agreement. We also studied the interactions of natural rubber latex films with carbon black particles (attached to the AFM tip) in aqueous solutions of ultrapure water and ultrapure water with 0.7% Ammonia. We show that in the basic 0.7% ammonia ultra-pure water solution, hydrogen ions are drawn from the surfaces leading to significantly larger negative surface charges, and therefore resulting in repulsion between the carbon black and natural rubber latex films upon the tip approach. Furthermore, we have used the superior control of the applied forces (which can be very low at the range <10 pN) of the QI mode to image and interrogate mechanically biomedical phospholipid-based microbubbles. The results demonstrate the controlled collapse of the microbubbles revealing their mechanical properties and internal structure.

4:00 PM CH01.07.09
Revealing The Kinetic Phase Behavior of Block Copolymer Complexes Using *In Situ* Solvent Vapor Isotherms Boyce Chang; Iowa State University, United States

Controlling the self-assembled morphologies in block copolymers heavily depends on their molecular architecture and processing conditions. Solvent vapor annealing is a versatile processive pathway to obtain highly periodic self-assemblies from high chi (χ) block copolymers (BCP) and supramolecular BCP complexes. Despite the importance of navigating the energy landscape, controlled SVA has not been investigated in BCP complexes, partly due to its intricate multicomponent nature. We introduce in situ measurements of characteristic absorption-desorption solvent vapor isotherms as an effective way to understand swelling and morphological evolution of BCP complexes. Using the sorption isotherms, we identify the glass transition points, polymer-solvent interaction parameters, and bulk modulus. These parameters indicate that complexation completely screens the polymer interchain interactions. Furthermore, we establish that the sorption isotherm of the homopolymer blocks serves to deconvolute the intricacy of BCP complexes. We applied our findings by developing annealing pathways for grain coarsening while preventing macroscopic film dewetting under SVA. Here, grain coarsening obeyed a power law, and the growth exponent revealed a kinetic transition point for rapid self-assembly. Overall, SVA-based sorption isotherms emerge as a critical method for understanding and developing annealing pathways for BCP complexes.

4:15 PM CH01.07.10
Mechanism Underlying Alloy Formation and Phase Segregation in Colloidal Synthesis of Multielement Nanoparticles Azadeh Amiri[1], Vitaliy Yurkiv[2], Abhijit Phakatkar[1] and Reza Shahbazian-Yassar[1]; [1]University of Illinois Chicago, United States; [2]The University of Arizona, United States

Understanding the nucleation and growth of colloidal multielement alloys remains pivotal in determining the resulting entropy-stabilized or chemically segregated nanoparticles' size, shape, and properties. Nevertheless, comprehending the complex mechanisms guiding the formation of these alloy nanoparticles or high phase segregation is incomplete. This is due to the involvement of multiple elements with distinct properties and the challenging limitations of materials characterization methods. In this study, we employed in-situ liquid cell transmission electron microscopy (TEM) technique to record the real-time colloidal synthesis of multielement nanoparticles from a precursor solution containing mixed metal salts.
The observations revealed two distinct pathways for nanoparticle formation and growth resulting in two separate sets of particles occurring within a multi-metal salt solution comprising Au, Pt, Ir, Cu, and Ni elements. Primary particles formed were 10-30 nm Au-Cu bimetallic alloy nanoparticles, while secondary particles were 1-4 nm Pt-Cu-Ir-Ni multielement alloy nanoparticles. Au-Cu bimetallic alloy nanoparticles were initially nucleated in solution, rapidly growing up to 5-10 nm. DFT calculations suggested a spontaneous reduction of Au and Cu ions on the nanoparticles' surfaces, facilitating their swift enlargement dominantly through autocatalytic surface growth. Coalescence events then merged them into larger particles, ultimately reaching sizes of 10-30 nm. In contrast, Pt-Cu-Ir-Ni multielement nanoparticles nucleated more slowly and exhibited a non-classical nucleation pathway. Starting with intermediate atomic clusters, they evolved into crystalline nanoparticles upon surpassing 2 nm. However, the surface growth of these multielement alloys through autocatalytic reduction was notably sluggish, resulting in minimal size increase for the detected small clusters or nanoparticles.
Furthermore, the surfaces of these nanoparticles were likely covered with adsorbed charged ion complexes, leading to agglomerated nanoparticles with amorphous interfaces. This hindered further growth by coalescence, as electrostatic interactions on charged surfaces limited direct nanoparticle surface-to-surface contact. Slow interatomic diffusion associated with the multielement structure might have contributed to hindering intraparticle ripening, merging, and recrystallization. The findings suggest that metal ion characteristics, particularly reduction rates and valence numbers, significantly impact particle composition during early formation stages. Differences in nanoparticle composition and surface properties, validated by DFT simulations, collectively influenced unique growth behaviors in each nanoparticle set.
This study provides valuable insights into the mechanisms underlying multielement nanoparticle formation and growth. Additionally, it illuminates the factors responsible for chemical phase segregation and emphasizes the effects of composition, surface energies, and element miscibility on the final size and structure of nanoparticles.

Evaluation of Oxidation Processes in $Ti_3C_2T_x$ MXene using *In Situ* Electrochemical Raman Spectroscopy Kateryna Shevchuk, Ruocun Wang and Yury Gogotsi; Drexel University, United States

MXenes, a large family of two-dimensional materials, have attracted a lot of interest due to their large chemistry space and diverse chemical, electrical, mechanical, and optical properties. MXenes follow the general formula $M_{n+1}X_nT_x$ (n = 1, 2, 3, or 4) with M representing an early transition metal, X - carbon and/or nitrogen, and T - surface terminations (=O, –OH, and –F). In particular, MXenes' metallic conductivities and redox-active surfaces make them attractive for electrochemical energy storage. Recently, we demonstrated that partial oxidization of $Ti_3C_2T_x$ MXene by cycling the material at 1.2 V vs. Ag wire led to enhanced pseudocapacitance in water-in-salt electrolytes. However, there is a fine line between partial oxidation of $Ti_3C_2T_x$ MXene and complete oxidation that leads to the formation of titania and carbon. The extent of oxidation is difficult to measure with conventional X-ray and electron-based techniques. This work focuses on using in situ electrochemical Raman spectroscopy to analyze the oxidation processes in $Ti_3C_2T_x$ MXenes at the high anodic potential. Raman spectroscopy has proven to be a powerful technique for detecting the natural oxidation of $Ti_3C_2T_x$ MXenes. The ability to perform Raman spectroscopy in situ during electrochemical reactions will allow us to expand our knowledge of MXene electrochemistry and its partial oxidation. The findings will help achieve higher energy density in MXene-based energy storage devices.

5:00 PM CH01.08.02
Microstructure, Texture and Tensile Properties of The 50% Hot-Rolled and Subsequent Heat Treated Ti6Al4V-5Cu Alloy Solomon K. Yeshanew; Dire Dawa University, Institute of Technology, School of Mechanical and Industrial Engineering, Ethiopia

In order to investigate the influence of 50% hot-rolling on the microstructure, textural evolution, and tensile properties in Ti6Al4V-5Cu alloy, an electron backscattered diffraction (EBSD) was used. To obtain a reduced textural influence behavior on the alloy, dual heat treatment schedule was specially designed. The results show that hot-rolling at high temperature significantly promote the transformation of phases to a fully α-phase structure and lamellar microstructure with different grains structure starting from elongated to coarsened appearance was produced. Hot-rolling deformation contributed for increasing the alloy texture intensity, whereas the heat treatment is important for weakening textural intensity, however, the coarsening of grains are prominent. Deformation and heat treatment temperature, therefore, an important factor affecting the texture and grain size. Using tensile testing experiment by considering 0.02 strain offset method, the yield strength of the alloy were estimated. During tensile testing process, studying strength of a material is the primary concern. Material strength could be measured in terms of either the stress essential to cause noticeable plastic deformation or the maximum stress that material can withstand. The tensile testing also provides information on the material's ductility behavior to measure how much the alloy can be deformed before fractured. Using specimen sectioned in rolling direction (90°), the true stress-strain curve revealed that the strength at which the alloy has significant plastic deformation under 0.02 offset yield strength method. The alloy revealed 35 MPa yield strength at 800 °C and its area reduction reached 168.5%, and elongation reached up to 83%.

5:00 PM CH01.08.03
Effect of Phase Composition in TiAlSiN Hard Coatings on The Behavior of Microstructure and Mechanical Properties Bum Soon Park[1,2], Min-Hyeok Yang[1,2], Jeong-Han Lee[1] and Hyun-Kuk Park[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Chonnam National University, Korea (the Republic of)

The aim of this study is to investigate the structural evolution and mechanical properties of TiAlSiN coating when processed by the arc ion plating method.

The nominal compositions of the ternary alloys were designed to be $Ti_{50}Al_{45}Si_5$, $Ti_{45}Al_{45}Si_{10}$, and $Ti_{40}Al_{45}Si_{15}$ (wt.%) and mechanically alloyed by planetary ball milling to form a hard coating. The powders were densely compacted during a rapid sintering process into a ternary system coating. The evolution of the structural phase from a powder to a compact material is dominated considerably by phase states such as a solid solution or intermetallic compounds. The relationship between the physical and chemical properties during the coating process is considered to be the dominant factor controlling the orientation and morphology of that zone. The TiAlSiN coating layer was found to have hardness above 45 GPa and an adhesion above 100 N. In other words, understanding the evolution and structure of TiAlSiN helped us to produce a material with excellent properties that can be used as a bard coating. Specifically, these properties were induced by a grain refinement of the nano-crystallite structure that corresponds to an increase in the silicon nitride contents.

5:00 PM CH01.08.04
Effect of Particle Shape on Microstructure and Thermal Conductivity of Al/Graphite Materials by Spark Plasma Sintering Bum Soon Park[1,2], Min-Hyeok Yang[1,2], Yu-Gyun Park[1,2] and Hyun-Kuk Park[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Chonnam National University, Korea (the Republic of)

The Al particle shapes which are spherical, irregular and flake shape were mixed with flake type graphite. The Al–50 vol.% Gr. powders, mixed by shaking mixer, were sintered under the following process conditions; sintering temperature of 550ºC, sintering pressure of 60 MPa and duration of 2 minutes at the temperature of 550ºC. The relative density of the sintered body reached its highest value of 99% when the shape of the Al particles was irregular. On the other hand, the lowest value was 92% when Al particle were flake-shaped. Pores were formed due to the wettability at the Al and Gr interface, which varied with the shape of the Al powder, thereby affecting the relative density. The hardness of the Al-Gr sintered body were investigated by vickers hardness analysis depending on the Al particle type. The results showed that the hardness value increased as the relative density became higher. The propagation of micro-cracks was further extended by the pores, which are assumed to have influenced the hardness. Moreover, the results of thermal conductivity as a function of the particle type, the most important indicator of this study, demonstrated the importance of porosity and the orientation of graphite.

5:00 PM CH01.08.05
***In-Situ* Synchrotron Imaging of Dendrite Growth During Rapid Solidification of Ni-Base Alloys** Won Sang Shin, Jun-Pyo Park and Yoon-jun Kim; Inha University, Korea (the Republic of)

An *in-situ* observation of metallic solidification using a conventional optical microscopy has been limited due to high solidification temperatures and opacity of solid metal. Hence, this study was initiated from developing an *in-situ* imaging technique using a white X-ray source generated from the synchrotron beam line operated by the Pohang Accelerator Laboratory, Pohang, Korea. Since high X-ray energies affect the scintillator, the generated synchrotron X-rays were suppressed from 15 keV to 40 keV through a Si attenuator with a sensor size of 3 mm. Then, the penetrated X-ray signals were converted to visible light by a scintillator to observe dendrite formation behaviors using an optical microscope and to record the *in-situ* optical images. The recorded images were post processed to remove noise and to make video which provides entire formation and growth behaviors of dendritic structure. Ni-base alloys were prepared by the vacuum induction melting method and machined into coupons with a dimension of 10 x 10 x 0.25 (thickness) mm. To load and hold each coupon in the furnace, two boron nitride (BN) covers wrap around a coupon like a sandwich. The sapphire glasses in the middle of the two BN covers are exposed to allow X-rays to pass through each coupon. Temperature and vacuum inside furnace were set at 1600 °C and 10^{-3} torr, respectively. Solidification commenced right after sample coupon was fully melted. Cooling rates were controlled by setting current on carbon heaters, -0.2, -0.5, and -0.8 A/min, respectively. Dendritic structure such as tip radius, arm spacing, and mushy zone under different solidification variables such as thickness of specimen and cooling rates were measured directly from *in-situ* optical images. The microstructural properties were further analyzed by optical and electron microscopies, and atom probe tomography to correlate the dendrite growth behavior, microstructure, and material properties.

5:00 PM CH01.08.06
Fabrication and Quantitative Performance Analysis of a High-Throughput CNT-DNA-Based Biosensor Bo Liu; Arizona State University, United States

The quest for highly efficient probes in the precise detection of single biomarkers has emerged as a compelling research field crucial for biological and biochemical studies. Over recent decades, this pursuit has been seen in not only small chemical probe molecules but also biomacromolecules such as enzymes, antibodies, and nucleic acids in the construction of biosensor platforms, enabling highly specific and efficient biomarker detection. Despite significant progress, there remains a pressing need to enhance biosensor performance, particularly for high-throughput clinical applications.

Among the tools contributing to single nucleotide detection, DNA-based biosensors stand out for their versatility. Their notable attributes, including good stability, high specificity, and excellent biocompatibility, make them valuable in both in vitro and in vivo applications. Here, we present a new DNA-modified CNT LoC sensor for small nucleic acid detection. Together with the probing platform, our novel biosensor platform excels in measuring the electrical signals of DNA with single-molecule precision while also enabling prolonged high-throughput measurements and the efficient screening of valuable data.

We anticipate that this platform will prove beneficial to individuals interested not only in biosensor technology but also in the broader realm of single-molecular detection.

SESSION CH01.09: Electrochemical Reactions

Room 442, Level 4, Summit

8:30 AM *CH01.09.01
***In Situ* Liquid Cell Electron Microscopy for Characterization of Dynamic Processes** Shu Fen Tan; Nanyang Technological University, Singapore

Many important reactions take place in liquids, but these processes are particularly difficult to study. Liquid cell electron microscopy provides opportunities for visualizing processes in liquids with good spatial and temporal resolution. The combination of imaging and electrochemical quantification have proved especially useful in studies of crystal growth, corrosion processes and battery materials. However, it has been a significant challenge to

improve the quality and quantification of liquid cell data due to the limitation in liquid cell equipment, control of local conditions and understanding of beam effects. In this seminar, I will discuss how I use *in situ* liquid phase electron microscopy to uncover the mechanisms of chemical transformation of catalytic nanoparticles under realistic reaction conditions. I will also talk about my recent work where I (1) developed a temperature-controlled electrochemical liquid cell for understanding the detailed mechanisms by which typical catalysts change their structures under electrochemical control in liquid electrolytes; and (2) incorporated 2D materials into the electrochemical liquid cell design to improve its achievable spatial resolution and electrochemical stability. My work lays the foundation for visualizing the nanoelectrochemical structure-function relationship in the electrochemical processes, which will open new opportunities for investigating a range of problems in energy storage and electrocatalysis.

9:00 AM CH01.09.02
From Bulk-To-Nano: Advances Towards Optimization of Electrochemical Studies for Liquid-Phase Transmission Electron Microscopy Madeline Dukes, Tim Eldred, Yaofeng Guo and Katherine Marusak; Protochips, Inc., United States

Liquid-phase transmission electron microscopy (LPTEM) has advanced considerably, evolving from rudimentary static cells [1] to advanced commercial systems capable of performing a variety of functions from temperature control to electrochemistry [2]. A core limitation of any TEM study is the assumption that the limited spatial area and sampling size inherent to TEM specimen preparation accurately represents the bulk state of the material [3]. This limitation is felt even more strongly for in-situ TEM studies, where the researcher must not only contend with determining if the sample itself is representative of its bulk state, but if that sample's environment and its operando behavior remain consistent with its bulk processes and mechanisms.

Here we describe recent advancements in hardware, MEMs chip designs, and software with the end goal of improving the accuracy of replicating bulk scale results in-situ. First, integration of an external, standard reference electrode (SRE) via a "metal bridge" enables integration of conventional Ag/AgCl reference electrodes. Employing an SRE eliminates the shifting potentials introduced by on-chip pseudo-reference electrodes, such as platinum, without introducing a significant ohmic drop [4], and enables more accurate comparisons between bulk and in-situ results.

Second, it is well understood that the narrow gap between chips necessary to maintain thin enough liquid layers for good resolution in LPTEM experiments, introduces a myriad of potential artifacts due to confinement, including incomplete mixing, slow exchange of liquids and ion depletion [5]. Recently, we developed a new E-chip configuration designed to balance both thin liquid layer required for optimal resolution and a deeper flow channel to improve liquid flow characteristics. This design utilizes a 10 micron channel etched into the silicon substrate of the E-chip. The viewing region, containing the amorphous silicon nitride membrane, is isolated within the center of the E-chip on an island type structure, such that the deep flow channel surrounds it like a moat and does not interfere with the gap between the top and bottom membranes. This significantly reduces the distance over which the liquid must diffuse to reach the narrow gap between the viewing windows from >1 mm to a few tens of microns, significantly improving liquid exchange within the critical region [6].

Finally, comprehensive analysis of the electron dose during in-situ studies is necessary to disentangle beam-induced changes and behavior from a samples' inherent chemical or electrochemical behavior. We utilize a state-of-the-art machine vision software, AXON Dose, to calibrate and accurately track electron dose exposure throughout an experiment to create a record of both the electron flux, and the samples' cumulative dose exposure, on a pixel-by-pixel basis [7]. Taken in concert, these new features bring us closer to achieving the goal of accurately replicating, measuring, and observing bulk electrochemical processes at the nanoscale.

***In-Situ/Operando* Electrochemical Investigation of Reduced Graphene Oxide in Aqueous Solution** Maria del Pilar Bernicola Garcia[1], Jose A. Garrido[1,2] and Elena del Corro[1]; [1]Catalan Institute of Nanoscience and Nanotechnology, (ICN2), CSIC and BIST, Spain; [2]ICREA, Spain

The development of new carbon nano-porous materials with increased capacitance, high conductivity and electrochemical stability is of high interest for a variety of applications. It is reported an anomalous increase of the specific capacitance in nano-porous materials with a pore size below of 1 nm[1]. However, the fundamental understanding of the mechanisms that involve these phenomena is still under study. Reduced graphene oxide (rGO) has gained significant attention due to its remarkable physicochemical properties such a high structural stability, large specific surface area, low cost, and availability. In the case of healthcare applications, highly porous rGO films have been widely studied because of their biocompatibility and biochemical sensing capabilities[2]. A proper understanding of electrokinetic phenomena such as potential-controlled ionic diffusion within the nano-porous and reduction of functional groups during electrochemical operation is necessary to improve the ultimate performance of rGO-based electrodes. Also, for these applications, it is key to investigate the chemical and structural changes happening in the rGO electrodes during their electrochemical operation.

In this work, we combine different *in-situ*/operando spectroscopic techniques to understand the dynamics and irreversible/reversible chemical and structural changes within rGO-nanoporous electrodes. The high electrochemical performance of the nanoporous rGO films can be explained by different phenomena such as ionic diffusion, ionic adsorption/desorption processes, protonation mechanisms and chemical and structural changes like those induced by defects or vacancies. The electrochemical performance of the rGO-nanoporous material, in terms of specific capacitance, potential windows and impedance, is studied by cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS). To have a deeper understanding of the fundamental phenomena that boost the electrochemical performance, we focus on the structural and chemical changes induced by the electrode-electrolyte interaction in

the nano-porous electrode. To study the structural changes that take place due to the electrode-electrolyte interaction, we have developed different custom-made electrochemical cells to couple to spectroscopic techniques like X-ray diffraction (XRD) and Raman spectroscopy. *In-situ* XRD measurements experiments give information about the impact on the rGO structure of the electrochemical operation, such irreversible/reversible changes on the interlayer distance induced by the applied potential. Operando Raman spectroscopy is used to study the structural properties of such defects, disorder and reduction degree induced by the applied potential. In this study we are able to evaluate the nature of the defects generated during electrochemical operation that impacts on the electrochemical performance[3]. Combined with analysis of CV coupled with electrochemical quartz crystal microbalance (EQCM), our results provide detailed information about ionic adsorption and charge transfer processes at the electrode-electrolyte. This work aims at expanding the current understanding of the properties of rGO-based nanoporous electrodes for their use as electrode material in healthcare applications.

Corrosion Propensity of Polyester-Chromium Nitrate Coated Al7xxx Alloy in Humid Environment Joseph B. Agboola, Chiamaka M. Uzuegbu and Olatunde I. Sekunowo; University Of Lagos, Nigeria

Aircraft propeller blades are exposed to various weather and climatic conditions, such as humidity, cold, high temperatures, and wind, which over time weaken the aluminium 7xxx that they are made of due to corrosion. The present work aims to evaluate chromium nitrate's effect on corrosion resistance of Polyester-Chromium Nitrate composite coated Al7xxx alloy in a humid environment. Polyester (PE) was synthesized by condensation polymerising symmetrical 1,3,4-oxadiazole and pimelic acid using sodium lauryl sulfate as a surfactant. Polyester-chromium nitrate composite was prepared by ultrasonication method. The prepared composite was applied on the surface of Al7xxx through the dipping method and cured at room temperature for 24 hours. Scanning electron microscopy (SEM/EDS) and X-ray Diffractometry (XRD) were carried out to compare the surface structure and the morphology of the coating. The results of the electrochemical measurement showed that the 60/40% composite-coated sample exhibited better corrosion resistance compared with the uncoated and pure polyester-coated samples. Polyester chromium nitrate coated samples had a longer controlled sacrificial anodic protection on Al7xxx substrate, a lower corrosion current density(i_{corr}) and a higher corrosion potential (e_{corr}).

10:15 AM CH01.09.05
Solid-State Reaction Heterogeneity during Calcination of Lithium-Ion Battery Cathode Sugeun Jo[1], Sungjae Seo[1], Subin Choi[1], Yijin Liu[2], Il Sohn[3], Keeyoung Jung[4] and Jongwoo Lim[1]; [1]Seoul National University, Korea (the Republic of); [2]SLAC National Accelerator Laboratory, United States; [3]Yonsei University, Korea (the Republic of); [4]Reseach Institute of Industrical Science & Technology, Korea (the Republic of)

Li-ion batteries, nickel-rich cathodes, synthesis during calcination, phase transitions with solid-state reaction, spatial distribution of local chemical compositions within the particles. During solid-state calcination, with increasing temperature, materials undergo complex phase transitions with heterogeneous solid-state reactions and mass transport. Precise control of the calcination chemistry is therefore crucial for synthesizing state-of-the-art Ni-rich layered oxides (LiNi1−x−yCoxMnyO2, NRNCM) as cathode materials for lithium-ion batteries. Although the battery performance depends on the chemical heterogeneity during NRNCM calcination, it has not yet been elucidated. Herein, through synchrotron-based in-situ structural analyses, gas analysis, X-ray microscopy, mass spectrometry microscopy, we provide a reaction map for Ni-rich layered oxides (LiNi1−x−yCoxMnyO2, NRNCM) cathodes during their calcination, which includes dehydration of the precursors, the insertion of ambient oxygen, and the insertion of solid-state Li+2-O2− after Li2CO3 thermal decomposition. The temperature-dependent reaction kinetics, the diffusivity of solid-state lithium sources, and the ambient oxygen determine the favorable aerobic decomposition of particle shell maintaining layered structure while the anaerobic decomposition of the particle core to lithium-blocking Ni-O rocksalt. Additionally, we found that the variations in the reducing power of the transition metals (i.e., Ni, Co, and Mn) determine the local structures at the nanoscale. The investigation of the reaction mechanism via imaging analysis provides valuable information for tuning the calcination chemistry and developing high-energy/power density lithium-ion batteries.

10:30 AM CH01.09.06
Revealing CaH_2-Driven Metal Oxide Reduction Kinetics with *In-Situ* Transport Measurements Jiayue Wang[1,2], Yijun Yu[1,2], Yi Cui[2,1] and Harold Y. Hwang[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Metal hydrides, such as CaH_2, have recently emerged as highly promising reducing agents for facilitating the low-temperature reduction of metal oxides. One unique advantage of hydride reduction is its capability to synthesize metastable materials that are inaccessible through conventional high-temperature reactions. Notably, researchers have harnessed hydride reduction techniques to create unusual NiO_4 square-planar coordination in nickelates to host superconductivity [1]. Beyond the realm of novel materials discovery, metal hydrides also hold substantial potential in applied engineering. For instance, previous studies have shown that CaH_2 can lower the temperature required for gas-phase H_2 reduction of iron oxide, which can benefit clean hydrogen-based ironmaking [2]. Given these promising features, there is a compelling motivation to delve deeper into the mechanics of the hydride reduction process.

In this study, we investigate the CaH_2-induced reduction kinetics of metal oxides using epitaxial α-Fe_2O_3 thin films as a model system. To elucidate the intrinsic reducing capability of CaH_2, we seal the iron oxide thin-film samples along with CaH_2 in an evacuated quartz tube and analyze the reduction behavior of iron oxide within this closed system. In particular, we have developed an experimental platform that enables real-time monitoring of the CaH_2 reduction process through transport measurements. Using this setup, we have successfully quantified the phase transformation kinetics from iron oxide to metallic iron by continuously tracking the evolution of electrical resistivity in the thin-film sample. Our results demonstrate that CaH_2 alone can effectively reduce α-Fe_2O_3 into metallic iron within a one-hour reduction treatment at 400 °C, whereas 5% H_2/Ar (99.999% purity) failed to reduce the sample at identical conditions. These findings can advance our fundamental understanding of the hydride reduction process, opening new avenues to harness this phenomenon for the exploration of emergent materials properties and the development of environmentally friendly engineering applications.

The Scanning Transmission Electron Microscope as a Platform for Atomic Scale Synthesis Ondrej Dyck, Andrew R. Lupini, Christopher T. Nelson, Mina Yoon and Stephen Jesse; Oak Ridge National Laboratory, United States

The scanning transmission electron microscope (STEM), a workhorse instrument in materials characterization, can not only be used to observe dynamic processes with atomic resolution, but also *drive and control synthesis with atomic precision*. Through custom control of the electron beam position that actively feeds back on image, spectroscopy, and other data streams, it's possible to use focused beam energy to precisely initiate and interrupt desired transformations. This can be used for generating point defects, drilling and milling materials, changing phase, modifying bond coordination, and positioning dopants. Furthermore, control over the local environment through custom MEMS devices for heating and biasing, *in situ* evaporators, and laser irradiation, provides means to dose the sample with thermal energy, optical excitation, and reactant or dopant materials to provide the proper conditions for reactions and transformations to occur. Finally, to close the loop, the STEM can then be used in its more traditional characterization modes to image transformation processes as they occur and assess if new functional properties emerge. Presented here are recent results highlighting advancements towards such a "synthescope"[1] including new insights gained by studying the generation and temperature dependent diffusion of beam-generated single vacancies in suspended 2D materials [4,5], strategies to restrict vacancy diffusion so they can serve as sites for dopant insertion, demonstration of patterning of arrays of dopants [3], and the delivery of dopant atoms to the sample, in situ [2]. Development of this combination of experimental methods provides a window into the dynamic synthesis processes at fundamental length scales and a path towards fabricating materials and devices with atomically precise components for potential quantum information science applications.

This work was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division, and was performed at the Center for Nanophase Materials Sciences (CNMS), a U.S. Department of Energy, Office of Science User Facility.

Fabrication Processes of Next-Gen Integrated Circuits through The Lens of *In Situ* Transmission Electron Microscopy Utkur Mirsaidov; National University of Singapore, Singapore

Understanding the nanoscale details of chemical and physical processes used in semiconductor manufacturing is critical for scaling and improving the performance of future integrated circuits. Here, I will review the major challenges associated with device scaling and describe how in situ TEM can help in the development of these processes. I will describe how direct imaging of such processes can speed up the implementation of new materials and device architectures to further enable the miniaturization of transistor footprints and improve their performance. Specifically, I will focus on etching and annealing processes used in the fabrication of both transistors and interconnects that link billions of these transistors together and to a power supply.
Our studies highlight the importance of direct nanoscale dynamic visualization of chemical and physical processes for advancing the fabrication processes of integrated circuits.

SESSION CH01.10: Characterization of Catalytic Materials
Session Chairs: Miaofang Chi and Dongsheng Li
Friday Afternoon, April 26, 2024
Room 442, Level 4, Summit

1:30 PM *CH01.10.01
Unraveling Sintering Mechanisms of Precious Metal Catalysts in Diverse Gas Environments Miaofang Chi; Oak Ridge National Laboratory, United States

Heterogeneous precious metal catalysts offer the highest selectivity and activity in chemical production and combustion by-product reduction reactions. However, their efficiency is hindered by sintering, particularly in high-temperature oxidizing environments such as automotive emissions control. To address this issue, we investigate the sintering mechanisms of platinum on alumina support in various exhaust gas environments at different temperatures using *in situ* environmental scanning transmission electron microscopy (STEM). We observe that the presence of both oxygen and water vapor significantly accelerates sintering, while water vapor alone has minimal impact. Our study unveils transient nanoparticle shape instability, indicating rapid particle migration, in an oxygen and water vapor environment, contrasting with stability in a vacuum. This underscores the complex interactions between platinum, the alumina substrate, and gases, providing essential insights for the design of improved catalysts for industrial applications.

2:00 PM CH01.10.02
Effects of Crystal Lattice Deformation on Catalytic Activities Dongsheng Li; Pacific Northwest National Laboratory, United States

Deformations of hierarchical structures at the atomic scale, especially long-range ones, can significantly enhance their functional behavior, such as catalytic activity. Metastable states or grain boundaries during the synthesis and processing of nanomaterials can introduce and control deformations (strains) in crystal lattices. We design the deformations in the crystal lattice to enhance the catalytic functionality of catalysts, such as TiO_2 and platinum-group-based metals, by controlling their synthesis processes of phase transformation and particle aggregation. For example, TiO_2 polymorphs have distinct properties that have been widely employed in various applications. It is well known that these polymorphs can transform into more stable phases, such as from TiO_2-B to anatase. Here, based on results from semi-in-situ transmission electron microscopy, X-ray atomic pair distribution function, and density functional

theory, we will investigate the effects of lattice deformation in crystals on the catalytic activities and their controlling factors. We seek to control deformations in supporting materials and their effect on catalytic materials to uniquely tailor functionalities. These findings suggest that lattice deformations can be designed to advance new functions.

2:15 PM CH01.10.03
Strong Metal-Support Interaction makes Durable Catalysts Ji Yang, David Prendergast and Ji Su; Lawrence Berkeley National Laboratory, United States

Liquid organic hydrogen carrier (LOHC) technology is a promising method for hydrogen storage and transportation by using a reversible hydrogenation–dehydrogenation cycle between aromatic compounds and naphthene, such as toluene and methylcyclohexane (MCH). A key issue in this technology is to improve the lifetime of the catalyst for MCH dehydrogenation. Here, we developed a TiO_2-supported Pt catalyst (Pt@TiO_2) by engineering a unique strong metal-support interaction (SMSI). For the first time, the monometallic Pt@TiO_2 catalyst delivers durable MCH dehydrogenation at 350 ^oC, without any deactivation observed within 500 h. MCH conversion of 94% and toluene selectivity of ~100% are achieved. Detailed electron microscopic and spectroscopic studies, supported by theoretical calculations, reveal that the excellent MCH dehydrogenation performance over Pt@TiO_2 is attributed to in-situ generated TiO_x-$Pt^{\delta+}$ interface induced by optimal SMSI, which immobilizes Pt nanoparticle (NP) onto TiO_2 surface and modulates electronic properties of Pt NP. MCH can be thus efficiently dehydrogenated and toluene is easily desorbed on the Pt NP surface. Our results expand the concept of classical SMSI and provide new insights into the rational design of durable supported metal catalysts based on unconventional SMSI.

2:30 PM BREAK

3:00 PM CH01.10.04
Analysis of Defects in Electrocatalysts using Variable Temperature Raman Spectroscopic Analysis of Phase Transition Mechanisms Rodney Smith; University of Waterloo, Canada

Defects within solid state materials can dramatically alter material properties, but direct analysis of such defects is particularly challenging. Such analysis is impeded by the low concentrations of defects relative to bulk sites, potential co-existence of multiple defect types in any given material, possibility of dynamic changes during catalysis, and fundamental limitations inherent in every characterization technique. We analyze distortions and defects in solids through indirect analysis, where changes in structural data for series of samples are monitored as a function of some perturbation. This talk will demonstrate how we have applied variable temperature Raman spectroscopy under controlled environments to analyze phase transitions in solid state materials commonly employed as (photo)electrocatalysts, with particular interest in how defects affect features such as the presence of phase transitions and the temperature at which they occur. Discussion will be focused on the analysis of protons trapped within hematite, a commonly employed photoelectrocatalyst for the oxygen evolution reaction, and the formation of disordered carbonate-containing overlayers on a family of perovskite electrocatalysts.

3:15 PM CH01.10.05
***In Situ* Environmental TEM Observation of Cu/Cu_2O Interface-Modulated Methanol Reaction Dynamics** Meng Li[1,2], Matt Curnan[3], Hao Chi[1], Stephen House[1,4], Jimmy G. McEver[1], Dmitri N. Zakharov[2], Wissam Saidi[1,5], Goetz Veser[1] and Judith C. Yang[1,2]; [1]University of Pittsburgh, United States; [2]Brookhaven National Laboratory, United States; [3]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [4]Sandia National Laboratories, United States; [5]National Energy Technology Laboratory, United States

Cu-based catalysts are the most widely used commercial catalysts in methanol chemistry due to their cost-effectiveness and high reactivity with methanol. Recent studies on Cu catalyst oxidation states indicate that during the Partial Oxidation of Methanol (POM), Cu catalysts are partially oxidized, producing reactivity and selectivity changes in pertinent reactions. These changes dynamically form metal/metal-oxide (M/MO) interfaces featuring short-lived and high-energy sites, which likely contribute to measured reactivity increases near phase boundaries. However, previous studies on these reaction mechanisms have primarily focused on pure Cu or Cu_2O surfaces, rather than investigating impacts on M/MO interfaces.

In this work, using *in situ* environmental transmission electron microscopy (ETEM) with machine-learning enhanced advanced data analysis and correlated DFT simulations, we investigated the influence of Cu_2O/Cu interfacial structures on methanol reduction dynamics. The atomic-resolution reaction dynamics are observed using *in situ* ETEM under 1 Pa methanol vapor at 300 C on heteroepitaxial Cu_2O/Cu model catalysts. Our observations reveal two-stage reduction dynamics modulated by the structures of Cu||Cu_2O junctions: when the Cu||Cu_2O interface at a junction is oriented along (100), an anisotropic layer-by-layer reduction occurs at the side facets of the Cu_2O island, followed by a Cu_2O-to-Cu interfacial transformation along (100). When the Cu||Cu_2O interface is oriented along (110), isotropic reduction at both top and side facets of Cu_2O islands is observed. Using machine-learning enhanced advanced data analysis, atomic-level size evolution kinetics are extracted. Stochastic trend analysis on island size kinetics suggests two distinct kinetic stages caused by different reaction mechanisms. Using correlated density functional theory (DFT) simulations of MeOH dissociative absorption, we found that MeOH adsorption energetics favor defect sites at Cu||Cu_2O(100) junctions, as opposed to fully coordinated sites on Cu_2O(110) surface steps or near Cu||Cu_2O(110) junctions. As the Cu||Cu_2O interface changes during the anisotropic-to-isotropic stage transition, active sites correspondingly relocate from Cu||Cu_2O(100) junctions to Cu_2O(110) surface steps. Our results emphasize the importance of M/MO interfacial dynamics during catalytic reactions, and provide new insights towards catalyst design and interface engineering.

The Effect Local Residual Stress States on The Internal Pore Growth in Laser-Welded Ti6Al4V Wei Sun and Xingrui Jiang; Xi'an Jiaotong-Liverpool University, China

The micron scale local residual stress states in laser-welded Ti6Al4V were characterized with focused ion beam ring-core milling coupled with digital image correlation (FIB-DIC), and its effect on the growth of welding porosity under external loading was investigated by *in-situ* tension under X-ray computerized tomography (CT). The internal pores were found to preferentially distribute along the fusion zone boundary and the weld centerline. FIB-DIC and X-ray diffraction indicated high-level tension in the vicinity of the fusion zone, balanced by the long-range compression in the base metal. Comparison with stress-free counterparts showed the residual stress significantly prepone the growth of the pores, whose aspect ratio and volume exhibited observable increments at low applied stresses. On the contrary, the pores without residual tension remained nearly undeformed until the yield point, and the relative tensile strain across the fusion zone showed a similar trend. The results demonstrated that the response of internal welding defects towards external load strongly correlates to the local residual stress states, and highlights the importance of precise measurements of the residual stress states in characteristic regions for applicational titanium laser welds.

8:05 AM CH01/CH03.02
***In-Situ* Study of Deformation Mechanisms in a Bi-Layered Bronze/Steel Sheet** Xingrui Jiang[1], Wei Sun[1], Li Rengeng[2], Min Chen[1] and Guohua Fan[2]; [1]Xi'an Jiaotong-Liverpool University, China; [2]Nanjing Tech University, China

Enhancing ductility is a crucial concern within metal matrix composites. Cu-Pb bronze alloy is a commonly utilized copper-based bearing alloy, and it demands superior mechanical properties and service safety. While copper and lead exhibit excellent ductility, Cu-Pb bronze alloys experience a substantial reduction in ductility due to plastic deformation being concentrated within the low-strength Pb phase. To address this issue, we employed the solid-liquid continuous casting (SLC) method to overlay the Cu-Pb alloy onto a mild steel substrate, significantly enhancing overall ductility. We conducted an in-situ tensile test using a scanning electron microscope (SEM) in conjunction with Digital Image Correlation (DIC) and Electron Back-scattered Diffraction (EBSD) to elucidate the underlying mechanisms. Localized strain is distributed uniformly in the steel layer but concentrated in the Pb phase within the bronze layer. However, this localization is effectively mitigated by the layered structure, as evidenced by the high compressive strain observed in the affected zone at the bronze/steel interface. Larger misorientation angles near the copper grain boundaries indicate that the deformation of copper grains is influenced by the localized strain within the lead phase. The layered structure effectively reduces strain concentration throughout the material and accommodates the deformation incompatibility inherent in Cu-Pb bronze alloys.

8:20 AM *CH01/CH03.03
***In-Situ* TEM Study of Microstructure Evolution in Ferroelectric/ferroelastic Materials under Stress** Yifeng Ren, Jiayi Li, Zhentao Pang, Jie Wu, Shaojie Fu, Meiyu Wang and Yu Deng; Nanjing University, China

In ferroelastic-ferroelectrics (FMs), stress-induced microstructure such as phase and domain can effectively enhance properties significantly. We prepared free-standing single-crystal $BaTiO_3$ sub-micrometer pillar as a model system to investigate microstructural evolutions in FMs under high stress loading. We directly observed and quantitatively analyzed in situ in a transmission electron microscope with 4D-STEM the microstructural evolutions in the pillar under various strain loading (different intensity, direction, and rate). We found that dozens of slow compression cycles (strain rate of 10^-2/s, at 520 MPa) can induce multiple-nanodomain and multiple-phase coexistence in $BaTiO_3$. After unloading, the pinned boundaries and domain walls by mobile point defects can stabilize these microstructures, including metastable ones, therefore improve both functional and mechanical performance of FMs. The "brittle" FMs can in fact withstand GPa level stress without fracture, resulting in large strain (higher than 5% in $BaTiO_3$) under the specially designed loading ways. Our work elucidates the complex multiscale (from micrometer to unit cell scale) evolution of phase, domain microstructures and their interactions in FMs, as well as the corresponding improvement in properties under the large strain loading. Based on this, we propose a novel method for domain engineering in FMs.

8:50 AM *CH01/CH03.04
Polymers Behaviour under Ionizing Radiations: *In-Situ* Characterization of Macromolecular Defects and Outgassing Yvette Ngono, Emmanuel Balanzat and Jean-Marc Ramillon; CIMAP, France

Polymers are made of long chains of repeating units linked *via* covalent bonds. Those chains are organized in function of the chemical structure of their repeating units; leading to different levels of organization. Due to these organization levels, polymers have different transition and relaxation temperatures and are more often than not semi-cristalline. Crystallites are embedded in amorphous phases and radicals created under ionizing radiations, that are the reactive species in polymers, can be trapped therein and react long after irradiation either with the oxygen or with humidity from the air.
Polymer are subjected to gas permeation and diffusion. Therefore, any analysis performed off-line, after irradiation is susceptible to represent not the state of the sample freshly irradiated but its state after subsequent post-irradiation evolution.
In order to make sure to actually study the effect of radiations, we have, at CIMAP, developed set-ups enabling to studying polymers under various temperatures and atmospheres and under different ionizing radiations be them ion or electron beams. Polymers are submitted to radiolysis and studying radiation-induced gas-emission is of great interest in assessing their ageing mechanisms, as gaseous products are the parallel of defects created in the polymer chains.
I will present not only experimental set-ups for online study of polymers but also beams available at GANIL for these studies and some results on polymers of interest.

9:20 AM CH01/CH03.05
Raman Spectroscopy: A Versatile Tool for The Studies on The Back-End of The Nuclear Fuel Cycle Laura J. Bonales, Jone M. Elorrieta Baigorri, Abel Milena Pérez, Iván Sánchez García, Nieves Rodríguez Villagra and Hitos Galán Montano; CIEMAT, Spain

In recent years, Raman spectroscopy has proven to be a highly versatile characterization technique for nuclear materials research. This sensitive technique possesses, among others, two relevant features that comply with the safety conditions required when handling nuclear materials: its flexibility allows for remote, *in situ* and *ex situ* analysis, and its relative ease of use implies small sample quantities and limited effort for sample preparation. In this work, we demonstrate the usefulness of taking into consideration Raman spectroscopy for research studies on the back-end of the nuclear fuel cycle. In particular, we show some of the valuable results that can be obtained when applying this technique to: 1) the advanced characterization of nuclear fuels, 2) the evaluation of the spent nuclear fuel behavior under different storage conditions, and 3) the development and monitoring of hydrometallurgical separation processes.

9:35 AM *CH01/CH03.06

Variable-Temperature Electron Spectromicroscopy Techniques for Investigating Metal/Insulator Transitions in V2O3 Systems Laura Bocher[1], Ibrahim Koita[1], Tizei Luiz H. G.[1], Jean-Denis Blazit[1], Xiaoyan Li[1], Benoît Corraze[2], Julien Tranchant[2], Marcel Tencé[1], Laurent Cario[2], Etienne Janod[2] and Odile Stephan[1]; [1]Université Paris-Saclay, France; [2]Université de Nantes, France

Taming abrupt resistive transitions in functional oxides is a promising approach for developing advanced information processing and storage systems. V_2O_3 is considered a prototypical system of metal-to-insulator transitions (MITs) where they can be activated under external stimuli such as temperature (T), pressure, or chemical doping [1] but hardly technologically feasible. Recent demonstrations from electric pulses yield MIT in $(V_{1-x}Cr_x)_2O_3$ systems with real potential capabilities for non-volatile memories and neuromorphic applications [2]. Hence, understanding the V_2O_3 electronic phase separation and its local mechanisms governing the insulator/metallic (I/M) domain dynamics across the IMTs remains of interest. However, all these electronic transitions rely on their relationship between structural and electronic degrees of freedom. For instance, when cooled below 160 K, V_2O_3 presents a symmetry breaking, associated with a large volume change (+1.4%) and an MIT yielding a resistivity change of 7 orders of magnitude. This T-activated MIT has been extensively studied at the macroscopic scale [1] and remains still a perfect arena to probe *in situ* the V_2O_3 structural and electronic evolutions at a very local scale. Recently, the microscopic electronic coexistence of I/M domains has been mapped in $(V_{1-x}Cr_x)_2O_3$ by *in situ* scanning photoemission spectroscopy [3], PEEM [4] and nano-IR [5] with 25nm spatial resolution at best. In addition, combined micro-XRD and nano-IR experiments have highlighted competitive mechanisms between structural and electronic contributions during this MIT [6]. These latest investigations also demonstrate the cautions and possible experimental limitations when it comes to accurately mapping the dynamics of mechanisms within regions of interest of a few tens of nm by combining different instruments, hence the need to perform structural and electronic experiments within the same instrument.

Advanced monochromated electron spectromicroscopy emerged this last decade as real game-changers for nanomaterials characterization. Here we performed *in situ* monochromated STEM/EELS experiments on the NION CHROMATEM 200 MC with variable-T options under cryo-conditions thanks to a double-tilt HennyZ cryo-holder using MEMS to vary continuously the temperature conditions across the IMTs. For each probed temperature, we associated mapping of relevant spectroscopic electronic excitations (from IR to soft X-ray) with an ultra-high EELS resolution at the nm scale and the local structural features (symmetry and lattice parameters) determined by 4D STEM nano- and microdiffraction. During low-T thermal cycling through the resistive transition, EELS spectra acquired in the low-loss regime present a characteristic signature at 1.1eV only in the metallic phase. Upon cooling, the abrupt MIT was monitored while the coexistence of I/M nanodomains was evidenced upon heating over a few degrees yielding the propagation of the electronic I/M domain wall. 4DSTEM nanodiffraction experiments reveal the local distribution of monoclinic/rhombohedral phases coexisting in the insulating domains. The observation of the low-T insulating hexagonal phase suggests an analogous paramagnetic insulating (PI) phase of large volume, as confirmed by the jumps in lattice parameters observed at the transition. These PI-like phases emerge also at the I/M domain wall, as a precursor of the metallic phase.

Advanced *In Situ* (S)TEM for Grain Boundary Phenomena in Oxides Yuichi Ikuhara[1,2,3]; [1]The University of Tokyo, Japan; [2]Japan Fine Ceramics Center, Japan; [3]Tohoku University, Japan

Oxides have been widely used for structural applications because of their superior mechanical properties. It has been known that the behavior of GB properties is strongly dependent on the GB characters such as misorientation angle between two adjacent crystals and GB plane, however, such effect has not been clarified yet. In addition, this effect is much influenced by the dopant segregation at GBs in oxides. In this study, in order to clarify the GB atomic structures in oxides such as Al_2O_3, ZrO_2, $SrTiO_3$, their bicrystals including various types of GBs with and without dopants were systematically fabricated. Then, the atomic structures and chemistry in thus fabricated GBs were characterized by aberration corrected STEM (scanning transmission electron microscopy), atom-resolved EDS and EELS, and the relationship between GB characters, segregated dopants and the properties for such ceramics will be discussed.
GB dynamics such as fracture and migration also play an important role in considering the sintering behavior and the properties. However, it has been still unclear as to how the GB fractures and migration proceeds at atomic scale. In this study, GB fracture and deformation are dynamically observed by TEM in-situ straining experiments using nano-indentation and newly developed MEMS straining holder. It was found that GB fracture occurs along the special crystal plane and dislocations are emitted from the crack front. Recently, we have proposed that GB migration behavior in ceramics can be precisely controlled by the aid of the high-energy electron beam irradiation. This electron beam technique was applied to directly visualize the atomistic GB migration. It was revealed that the GB migration is processed by a cooperative shuffling of atoms in GB ledges along specific routes. As a result, the GB passed through several different GB structures with low formation energies during GB migration.

Atomic Mapping of Polar Topologies in Oxide Superlattices Yinlian Zhu[1], Yunlong Tang[2] and Yujia Wang[2]; [1]Songshan Lake Materials Laboratory, China; [2]Institute of Metal Research, Chinese Academy of Sciences, China

Since the discovery of full flux-closure domains in PbTiO3/SrTiO3 multilayers grown on GdScO3 substrates[1], various polar topological domain structures such as vortices, skyrmions, merons and polar waves etc. were subsequently discovered in the ferroelectric films and superlattices. These polar topological structures are nanoscale objects and have potential applications in high-density non-volatile memory devices. The topological protection makes them very stable under small external stimuli and the cross-talk can be effectively avoided. Besides the industrial potential, they also possess rich emerging physical properties, such as negative capacitance, enhanced conductivity, electrocaloric effect, and so on. We choose and introduce some recent observations of polar topologies in ferroelectric films. It is pointed out that the PbTiO3/SrTiO3 system is becoming hot in modulating polar topologies these days. Both misfit strains and insulating layers play important roles in tuning the topologies. We expect more investigations to be carried out for unveiling the mask of complex structures in oxide films, multilayers and superlattices with perovskite structure.

Cryogenic-Monochromated STEM-EELS Analysis of Symmetry Breaking and Local Ferroelectricity in $SrTiO_3$ Based-Heterostructures Aravind Raji[1,2], Guillaume Krieger[3], Xiaoyan Li[1], Yves Auad[1], Daniele Preziosi[3], Manuel Bibes[4], Jean-Pascal Rueff[2,5] and Alexandre Gloter[1]; [1]Laboratoire de Physique des Solides Orsay, France; [2]Synchrotron SOLEIL, France; [3]IPCMS UMR 7504, CNRS, Université de Strasbourg, France; [4]Unité Mixte de Physique CNRS, Thales, Université Paris-Saclay, France; [5]LCPMR, Sorbonne Université, CNRS, France

The growth of oxide-based electronics is in a good pace, and the apt material knowledge obtained by advanced characterization techniques leverages the complexity in designing devices with intriguing properties. Knowledge of the atomic level arrangements in a material system enables us to make atomic level manipulations, thereby tweaking the electronics. This is made possible by one of the most advanced characterization techniques such as the Scanning Transmission Electron Microscopy (STEM). In this, in addition to obtaining a high-resolution image with good atomic phase contrast, one can have spectroscopic information representative of their electronic states through electron energy loss spectroscopy (EELS). Combining this with controllable external stimuli (Temperature, Photons, etc.) one can study a vast range of electronic and structural states in a chosen material. Some prototypical examples include temperature dependent metal-to-insulator transitions [1], photoinduced superconducting transitions [2], etc.
Here we will be focusing on $SrTiO_3$ (STO) based heterostructures exhibiting incipient ferroelectricity as a result of broken symmetry near the interface [3]. Some examples are the Al/STO [4], and Ca-doped STO [5], and even $NdNiO_3$/STO system that have a metal to insulator transition range spanning 150-200K [6]. Understanding the electronic origins of it is of paramount importance, and so is studying its variation with external stimuli. STO is an intriguing system that undergoes a cubic to tetragonal antiferrodistortive phase transition below 105K, and undergoes another transition to become a quantum paraelectric below 37K [7,8]. The influence of these transitions on the interface properties are of significant interest, and a spectro-microscopic study spanning the range of these transitions is much appreciated. In this regard, we carry out RT and cryogenic (~110K) STEM-EELS measurements in a monochromated Nion CHROMATEM microscope equipped with a hybrid pixel direct electron detector Medipix3 [9].
Our experiments in an $NdNiO_2$/STO demonstrated significant fine structure variations at the Ti-$L_{2,3}$ edge, on going from RT to ~110K. It has been previously reported that the cubic to tetragonal antiferrodistortive transition in STO occurs inhomogeneously, that the surface unit cells begin this transition at around ~150K, which possibly spans to the whole STO by ~105K [10]. Hence, the fine structure variations we see at around ~110K near the interface could be representative of this transition, thereby altering the interface properties. Characterizing such variations is enabled by high-energy resolution monochromated EELS, in combination with a cryogenic system. The resolution significantly overpasses previous studies reported in this direction, where, in addition a real space mapping of the fine structure variation couldn't be done [11, 12]. An investigation in this direction paves the way to better understanding the interesting phenomena such as superconductivity and ferromagnetism that emerges at these interfaces.

11:45 AM CH02.01.04
Unraveling Metal-To-Metal Hydride Phase Transformation using *In-Situ* S/TEM Techniques Gopi Krishnan[1], Lars Bannenberg[2], Herman Schreuders[2] and Joerg Jinschek[1]; [1]Technical University of Denmark, Denmark; [2]Delft University of Technology, Netherlands

In our relentless pursuit of solutions to advance the decarbonization of our society and economy, hydrogen stands out for its exceptional qualities as a zero-emission fuel, energy storage medium, and chemical feedstock. Nevertheless, the challenge of compact hydrogen storage remains a daunting one in both science and technology. Safe storage of hydrogen, particularly in solid forms such as metal hydrides, offers numerous compelling benefits.
However, further improving its storage properties requires a comprehensive understanding of nucleation and growth of metal-to-metal hydride phase transformation at the atomic scale. In this context, real-time visualization of the various steps of the transformation process is essential for a precise and quantitative understanding. For instance, for interpreting the hydrogen sorption property of materials, it is crucial to reveal the effect of stress/strain, the role of defects, and intermediate phase evolution during metal-to-metal hydride phase transformation.
In this study, we use MgTi thin films as a model system to study metal-to-metal hydride phase transformation using in-situ Scanning/Transmission Electron microscopy (S/TEM). The phase transition from hexagonal to face-centered cubic in Mg to $MgTiH_X$ is tracked through crystal structure changes observed by electron diffraction (ED) and in bulk plasmon resonance detected by electron energy loss spectroscopy (EELS). We also apply in-situ 4D STEM to investigate local structural displacements and strain developed during the process. Moreover, integrated differential phase contrast (iDPC) imaging aids in pinpointing hydrogen atom positions within the lattice. By combining these methods, we gain insights into the hydrogenation process and its effects on hydrogen storage properties.

SESSION CH02.02: Exploration of Complex Oxide Heterostructures and Microelectronics Devices via *In-Situ* Electron Microscopy II

In-situ Cryogenic and Biasing STEM and EELS for Quantum Materials Shelly Michele Conroy; Imperial College London, United Kingdom

Understanding how the emergent phases of quantum materials form and behave during operation at the atomic scale is crucial to future quantum technology design. Cryogenic Scanning Transmission Electron Microscopy (STEM) and Electron Energy Loss Spectroscopy (EELS) have emerged as powerful tools, enabling scientists to explore quantum materials under extreme conditions of ultra-low temperatures, vacuum condictions and applied stimiulus such as bias. This cutting-edge combination of techniques integrates the high-resolution imaging and diffraction capabilities of STEM with cryogenic technology and the analytical capabilities of EELS, allowing for the investigation of materials at these low temperature exotic emergent phases, while simultaneously probing their electronic structure.
In this presentation firstly the multiple ferroic phases below room temperture of Fe,I Boracite are investigated using a cryogenic STEM holder with temperature control. We investigate the change in strain, polarisation and domain configuration via 4D-STEM during temperature cycling and thus changing ferroic phases. By switching from 4D-STEM to EELS we can also collect changes in band gap and crystal field splitting. The dyamics of the domain wall topologies within these materials were investiagted using in-situ biasing at these various tempertaures and phases.
Secondly, this presentation will detail how cryogenic vacuum transfer STEM can be used to probe the superconducting phase of a doped Fe(Se,Te) system. Here we show the emergence of nanoscale superconducting puddles by complementary low temperature conducting atomic force microscopy. We could pick out these region using focsued ion beam and with a vacuum transfer system we can do all sample preparation and analysis under vacuum and cryogenic conditions. We reveal the clear changes in physical structure and band gap between the superconducting and high temperature phase using controlled in-situ heating from liquid nitrogen to room temperature.

In-*Operando* Optical Tracking of Vacancy Induced Phase Change in Few-nm Thick Ferroelectric HZO Atif Jan and Giuliana Di Martino; University of Cambridge, United Kingdom

Ferroelectric random-access memories (FeRAM) switching is achieved by ferroelectric switching of dipoles. FeRAMs offer low-energy and faster switching as compared to conventional memory circuitry. They excel in power consumption and low-voltage operation when stacked against current-driven contenders. Unfortunately, FeRAMs have been restricted to niche markets due to their limited CMOS compatibility and severe scaling issues of the complex ferroelectric perovskite systems. However, the discovery of ferroelectricity in binary oxides gave an impetus for developing a universal memory concept, which may lead to a significant breakthrough in the development of memory devices. Binary oxides generally do not suffer from a “dead layer effect”, which makes non-binary oxides, such as perovskites, ineffective for thin film technology. Moreover, high coercive fields inside binary oxides give them considerable resilience toward internal depolarization of the ferroelectricity, crucial to achieving scalability and overcoming the widespread reliability disadvantages of FE material. The underlying reasons for the stable ferroelectricity and distinct switching of FE domains inside binary oxides at an atomic level are poorly understood. Moreover, non-idealities seen upon continuous electronic switching cycles like wake-up and fatigue introduce uncertainties in device performance and endurance. In this work, we present the first proof of the underlying reasons for these non-idealities with cycle-to-cycle tracking of morphology changes in few-nm thick binary oxide ferroelectric ultra-thin films.
This work presents the first proof of the underlying reasons for these non-idealities with cycle-to-cycle tracking morphology changes in few-nm thick binary oxide ferroelectric ultra-thin films. With our Nanoparticle-on-Mirror (NPoM) geometry, we capture for the first time both migration of <1% oxygen ions and material phase change in just 5nm-thick binary oxide ferroelectric films when under continuous electronic switching and therefore track in real-time and in-operando the nanoscale kinetics of wake-up and fatigue in ferroelectric ultrathin memories. We use in-situ electrical and optical characterizations like darkfield scattering, photoluminescence and Raman spectroscopy to understand the nano-kinetics of the atomic level switching. The tracking of vacancy migration and phase change with the above-mentioned techniques combined with density functional theory (DFT) and finite-difference time-domain (FDTD) simulations provide the first insights into the morphological changes in ultra-thin binary oxide films [1].

2:45 PM CH02.02.04

Unveiling Texture Transfer in Dielectric Thin Films via *In Situ* Electron Microscopy Robert Winkler[1], Alexander Zintler[2], Oscar Recalde[1], Déspina Nasiou[1], Lambert Alff[1] and Leopoldo Molina-Luna[1]; [1]TU Darmstadt, Germany; [2]University of Antwerp, Belgium

Transition metal oxide (TMO) dielectric layers are pivotal for applications like field-effect transistors, supercapacitors, and emerging memories such as resistive random access memory (RRAM) [1]. Careful selection of the thin film layer materials and growth techniques in an RRAM device is essential to engineering the desired microstructure via texture transfer to improve performance and reliability [2], [3].
Usually, texture transfer is achieved via epitaxial growth at elevated temperatures, which, in the case of RRAM, might be more challenging to integrate in current complementary metal oxide semiconductor (CMOS) back-end-of-line (BEOL) processes. Therefore, a question arises if texture transfer is also possible when annealing amorphous HfO_2 thin films grown via reactive molecular beam epitaxy (RMBE) on highly textured (111) thin films. Here, we have employed in situ electron microscopy to precisely determine the minimum required temperature and the origin of grain growth.
Crystallization of amorphous HfO_2 starts at 180 °C, non-adjacent to an interface. The developing grains, as shown by automated crystal orientation mapping (ACOM) in ASTAR of the 4D-STEM data set, are nanocrystalline or amorphous until reaching an adjacent textured layer. The resulting (11-1+010) monoclinic phase of the annealed HfO_2 thin films indicates that texture transfer is possible, which is also represented in the improvement of the RRAM device's performance.
To summarize, the presented findings in our study are not only relevant in the field of dielectric thin films by connecting microstructural changes to device fabrication and performance but are generally useful when tracking the origins of grain growth with nanometer precision by analyzing 4D STEM via automated crystal orientation mapping (ACOM).

3:30 PM *CH02.02.05
Design interface and domain structure in doped $BaTiO_3$ systems for enhanced relaxor ferroelectric behavior and energy storage Aiping Chen[1], Di Zhang[1], Nicholas Cucciniello[1,2], Alessandro Mazza[1], Quanxi Jia[2], Michael Zachman[3], Rod McCabe[1] and James M. LeBeau[4]; [1]Los Alamos National Laboratory, United States; [2]University at Buffalo, The State University of New York, United States; [3]Oak Ridge National Laboratory, United States; [4]Massachusetts Institute of Technology, United States

Dielectric materials, holding charges as capacitors, are vital energy storage components of electronics and power systems. Dielectric capacitors distinguish themselves in features of ultrafast charging/discharging rates, high voltage endurance, and good reliability. Enhancing the relatively low energy densities of dielectric capacitors is essential for their applications in pulsed power equipment. Relaxor ferroelectrics are promising candidates for applications in energy storage. Therefore, considerable effort has been devoted to enhancing the energy storage via composition optimization, defect engineering, and architectural design.
In this talk, I will discuss the strategies of designing interface and domain structure in doped $BaTiO_3$ to achieve relaxor ferroelectrics. In the first part, I will discuss the design of $(Ba_{0.7}Ca_{0.3})TiO_3$ (BCT) and $Ba(Ti_{0.8}Zr_{0.2})O_3$ (BZT) superlattices via a high-throughput combinatorial approach. Well-controlled compositional gradient, superlattice geometry and domain size are explored by scanning transmission electron microscopy (STEM). Ferroelectric and dielectric properties identified the "optimal property point" achieved near the morphotropic phase boundary. Our results have found that relaxor-like ferroelectric behavior enhances and the leakage slightly increases with reducing the superlattice periodicity (or with more interfaces). In the second part of the talk, I will discuss strategies to further optimize domain structures and suppress the leakage current in BZT-BCT films via a machine learning approach. Sn has been identified as an ideal dopant to maintain the rhombohedral /tetragonal phase boundary, reduce leakage current and reduce the domain size below 10 nm for BZT-BCT systems and greatly enhanced relaxor ferroelectric behavior has been achieved. The large polarization and the delayed polarization saturation lead to greatly enhanced energy density of 80 J/cm^3 and transfer efficiency of 85% over a wide temperature range. Such a data-driven design recipe for a slush-like polar state is generally applicable to quickly optimize functionalities of ferroelectric materials.

4:00 PM CH02.02.06
Defect Induced Memristive Switching in Off-Stoichiometric $SrTiO_3$ and $CaTiO_3$ studied by *In Situ* Transmission Electron Mircroscopy
Changming Liu[1], Wahib Aggoune[2], Mohamed Abdeldayem[1], Alexander Meledin[3], Houari Amari[1], Izaz-Ali Shah[1], Thilo Remmele[1], Tobias Schulz[1], Andreas Fiedler[1], Jutta Schwarzkopf[1], Matthias Scheffler[2] and Martin Albrecht[1]; [1]Leibniz Institut fuer Kristallzuechtung, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]Thermo Fisher Scientific, Netherlands

In the quest for neuromorphic computing systems that emulate the intricacies of the human brain, the transition of digital memory to an analog state is paramount. A central scientific question revolves around directing materials to incorporate synaptic plasticity. Among the most promising and technologically advanced strategies for achieving this are resistive random access memory (ReRAM) devices. Traditional ReRAMs operate through the stochastic formation and breakage of conductive filaments within an insulator storage medium, making control challenging. This paper presents a novel approach to memristive devices, focusing on single crystalline SrTiO3 and CaTiO3 thin films. By deliberately introducing an A cation deficiency of up to about 16% through metal organic vapor phase epitaxy (MOVPE), we have successfully realized resistive switching without the need for filament formation, achieving on/off ratios as high as 10^3. Our investigation integrates various techniques, including electrical measurements, transmission electron microscopy (TEM), and in-situ X-ray studies at a synchrotron, to provide insights into the underlying mechanisms.

Our results suggest that the resistive switching phenomenon in off-stoichiometric films can be attributed to trap-assisted tunneling through Ti antisite defects, which induce a switchable polarization. Crucial parameters such as on/off ratio and retention time depend on the extent of off-stoichiometry. This study presents a comprehensive TEM analysis of these materials, including high-resolution scanning transmission electron microscopy (S-TEM), electron energy loss spectroscopy (EELS), and dynamic in-situ TEM measurements with electrical bias and heating. Our results show that approximately 50% of the V_{sr} sites are occupied by Ti and that these antisite defects are responsible for inducing ferroelectric polarization. Differential phase contrast measurements reveal the polarization of these domains. Preliminary in-situ TEM experiments confirm the resistive switching behavior observed in ex-situ electrical measurements. Furthermore, our in-situ studies suggest that these polar defects combine under bias to form nanopolar domains that are statistically distributed throughout the film. This is visually confirmed by contrast inversion in dark-field images using forbidden reflections, consistent with macroscopic observations in synchrotron experiments. We attribute this contrast inversion to the alignment of off-centered polar defects induced by the applied electric field. Reducing the voltage to 0 V results in a stable state, albeit with the polarization erased, returning the local film to a high-

resistance state. These preliminary in-situ I-V measurements confirm our recent findings that resistive switching in Sr-deficient SrTiO3 thin films occurs at significantly lower voltages than those required for filament formation, offering promising prospects for future neuromorphic computing applications.

4:15 PM CH02.02.07
Advanced Phase Plate Fabrication and Thin Film Characterization for TEM Imaging of Biological Samples Marcus F. Hufe[1], Mads S. Larsen[1], Stephan S. Keller[1], Marco Beleggia[2,1] and Paul J. Kempen[1]; [1]Technical University of Denmark, Denmark; [2]University of Modena and Reggio Emilia, Italy

Phase plates (PPs) for transmission electron microscopy (TEM) have been a research field since 2001 [1] and are of continuing interest to enhance contrast and increase resolution when imaging biological samples [2]. The most promising PPs for soft-matter imaging are thin-film-based [3]. These include Volta-, Zernike-, and Hilbert-type PPs. Thin-film PPs are generally fabricated by hand using sputtering tools in a single-device process [4]. These PPs suffer from several limitations that plague their widespread implementation. These challenges include contamination, ease of installation and use, lack of reproducibility, and lack of full understanding and control of the induced phase shift. In this work we are using cleanroom processes to fabricate PPs that are reproducible with known parameters. In this manner we can both know and control the induced phase shift. We present the fabrication of both Zernike-type phase plate devices (ZPPs), with an ideal phase shift of $\Delta\varphi = \pi/2$, and Hilbert-type PP devices (HPPs), for which $\Delta\varphi = \pi$.

In order to achieve this, it is necessary to know the accurate mean inner potential (MIP) of the materials involved. For our work, the most promising thin film materials are silicon nitride and amorphous carbon. MIP values for these materials in the literature vary widely, making it difficult to fabricate a device with the ideal phase shift. The phase shift is related to the mean inner potential V_0 and the film thickness t (via an electron constant C_E) in the following way [5]: $\Delta\varphi = C_E V_0 t$. We use ellipsometry and AFM techniques to determine and verify the thicknesses of the thin films. We use electron holography (EH) [6] to measure the phase shift of our devices. Using the thickness and phase shift values we can then accurately determine the MIP of our thin films. We can further use this to optimize our devices for optimal phase shift.

In addition to our material characterization, we installed the PPs in the back-focal plane of a *TF Tecnai TEM* using the existing objective aperture mechanism. We will demonstrate the functionality of our phase plate devices via contrast enhancement, using both a test sample made from thin carbon structures on a standard carbon-film TEM grid, and biological samples at cryogenic temperatures.

***In-Situ* STEM Studies of Ferroelectric Domains in Free-Standing Thin Films** Tamsin I. O'Reilly[1], Kristina Holsgrove[1], Xinqiao Zhang[2], John J. Scott[1], Iaro Gaponenko[3], Praveen Kumar[1,4], Patrycja Paruch[3], Joshua Agar[2] and Miryam Arredondo[1]; [1]Queen's University Belfast, United Kingdom; [2]Drexel University, United States; [3]University of Geneva,, Switzerland; [4]School of Mines,, United States

Ferroelectrics are polar materials known for their spontaneous polarization, which can be reversibly switched by applying an external field. As these materials are cooled below their Curie temperature (T_C), the resulting domain structure and switching dynamics are driven by boundary their conditions, aiming to minimize electrostatic and elastic energy in the system.
A particularly interesting aspect of ferroelectrics is the effect that surface chemical species have on the screening mechanism, and its resulting domain structure, and vice versa, how domains affect the surface chemistry. The latter could be exploited to tailor surface reactivity for electrochemical, catalytical,[1-6] and other energy harvesting applications.[2, 7-9]

This study focuses on investigating the thermally induced behavior of ferroelectric-ferroelastic domains in free-standing thin films under different chemical environments using in-situ scanning transmission electron microscopy (STEM) techniques. The similarities and differences between these environments are discussed, along with the associated challenges.

To the best of our knowledge, this is the first time in-situ heating under controlled gas environments has been employed to study ferroelectric-ferroelastic domains. Our findings provide valuable insights into the intricate relationship between important ferroelectric characteristics such as (T_C, domain size, etc) and the chemical environment. Furthermore, this work highlights the application of in-situ gas as a powerful technique for dynamically exploring the effects of other external variables such as pressure on polar materials.

High-Resolution Scalar/Vector-Field Electron Tomography Unveiling 3D Topological Spin Textures Xiuzhen Yu[1], Nobuto Nakanishi[1,2], Yi-Ling Chiew[1], Naoya Kanazawa[3], Kosuke Karube[1], Yasujiro Taguchi[1] and Yoshinori Tokura[1,3]; [1]RIKEN, Japan; [2]Thermo Fisher Scientific, Japan; [3]The University of Tokyo, Japan

The emergence of 2D topological spin textures, such as magnetic skyrmions in helimagnets, has garnered significant attention in the field of condensed matter physics and spintronics[1-2]. However, our understanding of nontrivial 3D spin textures remains limited, primarily due to the absence of a high-resolution 3D magnetic imaging technique, especially at lower temperatures below room temperature (RT). While some progress has been made in imaging magnetic twisted structures in 3D through nanotomography[3], challenges persist in accurately mapping 3D vector fields and achieving the necessary spatial resolution. These obstacles hinder our ability to comprehensively map 3D exotic spin textures in magnets with topological precision over a broad temperature range. The objective of this study is to develop a high-resolution scalar/vector-field electron tomography microscopy technique that covers a wide temperature range from 95 K to RT, enabling real-space observations of various 3D topological spin textures.
In this study, I will introduce scalar/vector-field electron tomography using 3D integrated differential-phase-contrast microscopy and discuss its applications. Specifically, I will show vortex pairs on the surface of elliptical skyrmions in an antiskyrmion-hosting magnet at RT and the formation of 'football'-like skyrmions and their heavy deformations around sample surfaces with varying temperatures in a helimagnet FeGe. This groundbreaking 3D magnetic imaging technique reveals hybrid topological spin textures, including surface spin textures such as vortices and monopoles, providing valuable insights into the topological aspects of various spin textures emerging in topological materials.

Investigating the Resistive Switching Mechanisms of Oxide and Nitride-Based Memristor Devices via *In Situ* STEM and EELS Di Zhang[1], Rohan Dhall[2], Matt Schneider[1], Chengyu Song[2], Sundar Kunwar[1], Nicholas Cucciniello[1], Hongyi Dou[3], Jim Ciston[2], John Watt[1], Winson Kuo[1], Michael T. Pettes[1], Haiyan Wang[3], Rod McCabe[1] and Aiping Chen[1]; [1]Los Alamos National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Purdue University, United States

The resistive-switching (RS) phenomenon observed in a variety of transitional metal oxides is of great research interest since it opens enormous opportunities for the next-generation electronic devices such as nonvolatile memory and neuromorphic computing units, etc. However, the RS mechanisms for many oxide- and nitride- based memristor devices are still unclear. In this project, we use *in situ* transmission electron microscopy (TEM) and Electron Energy Loss Spectroscopy (EELS) to investigate the RS mechanisms of different types of memristor devices. The high resolution STEM images captured during the *in situ* biasing experiment revealed the potential phase transition processes and polarized cations displacements, and the core EELS spectra confirmed the cations valene states change and the oxygen stoichiometry modulation during the RS processes. This study has shined great light on clarifying the RS mechanisms of different types memristor devices, which can be applied to the development of next-generation nanoelectronic devices towards advanced memory and neuromorphic computing units etc.

Breaking Barriers in Oxide Nanoelectronics: Advancements in *In Situ* TEM Studies Oscar Recalde[1], Tianshu Jiang[1], Robert Winkler[1], Alexander Zintler[1], Esmaeil Adabifiroozjaei[1], Yevheniy Pivak[2], Hector H. Perez-Garza[2] and Leopoldo Molina-Luna[1]; [1]TU Darmstadt, Germany; [2]DENSsolutions, Netherlands

In today's microelectronic industry, oxide nanoelectronics are at its core. To gain insights into the dynamic processes within these nano electronic devices at the nano and sub-nanometer scale, in situ/operando transmission electron microscopy (TEM) has become a vital research avenue. Recent advancements in the integration of microelectromechanical systems (MEMS) within electron microscopes have made it possible to apply various stimuli to samples directly inside the microscope, including electrical biasing.

However, achieving reliable sample preparation for these experiments using focused ion beam (FIB) techniques has been an intricate challenge. Conventional FIB methods have often led to the inadvertent creation of short circuits along the MEMS platforms and TEM devices during sample attachment and electrical contacting. This has obscured the true performance of these devices.

In this study, our innovative FIB sample preparation protocol overcomes these challenges, allowing for the dependable operation of two-terminal oxide devices within the TEM. We have investigated structural changes in materials like SrTiO3-based memristors, Nb-doped lead zirconate titanate (PNZT) piezoelectric, and BaSrTiO3 ferroelectric, directly correlating these observations with the simultaneous acquisition of current-voltage (I-V) curves. This has facilitated meaningful comparisons with their macroscopic counterparts.

Furthermore, our investigations encompass multi-stimuli experiments, introducing gas nano cells into the equation. Interestingly, we have observed the impact of device oxidation induced by electron beam irradiation that alters the electrical response of a SrTiO3-x and BaSrTiO3-x (BST) tunable dielectric device when subjected to an oxygen-rich environment.

Moreover, a suppression of leakage current in TEM lamella devices exposed to Ar/O2 plasma cleaning has also been investigated. Additionally, the effects of electron beam irradiation on the electrical properties of oxide devices, employing them as a tool for checking sample connectivity through STEM (SE)EBIC techniques, have also been explored. These findings collectively contribute to a more comprehensive understanding of oxide nanoelectronics and their behavior at micro and sub-nanometer scales.

In conclusion, our innovative FIB-based sample preparation technique not only enables the study of nano electronic devices under various stimuli conditions within a TEM environment but also facilitates the direct correlation of electrical properties with structural changes. Moreover, we have introduced the use of gas nano cells for multi-stimuli experiments, further enhancing our ability to probe sample connectivity and uncover microstructural factors influencing current-driven mechanisms.

9:30 AM *CH02.03.04
Quantum Monochromated Electron Microscopy: Combining High Spatial and Spectral Resolution to Observe Emergent Electronic and Vibrational Proprties in Nanosctructured Quantum Materials Jordan A. Hachtel[1], Eric R. Hoglund[1], Harrison Walker[2], De Liang Bao[2], Geemin Kim[3], Mahmut Sami Kavrik[4], Matt Law[3] and Sokrates Pantelides[2]; [1]Oak Ridge National Laboratory, United States; [2]Vanderbilt University, United States; [3]University of California, Irvine, United States; [4]Lawrence Berkeley National Laboratory, United States

Over the last 5-10 years, the scanning transmission electron microscope (STEM) has been turned to quantum materials more and more due to the ability to correlate the subtle structural signatures of quantum phase transitions with atomistic imaging and compositional analysis. Over this same time period, monochromation for electron energy-loss spectroscopy (EELS) in the STEM has also seen a resurgence. With typical energy resolutions improving by two orders of magnitude to enable a whole host of new experiments at the high spatial resolution of the STEM. The combination of the two is truly a new opportunity for quantum materials, as it allows the ability to probe the novel quasiparticles and shallow electronic structure that mediate emergent phenomena directly at the length scales over which they occur.

In this talk, I will discuss the application of monochromated STEM-EELS to quantum nanostructured superlattices. In $SrTiO_3$-$CaTiO_3$ (STO-CTO) superlattices, where the superlattice is in the growth direction with alternating layers of STO and CTO at different unit-cell thicknesses. In this system, the period of the superlattice dominates the macroscopic properties of the material through changing the number of interfaces between the STO and CTO. However, in short period superlattices, an emergent phonon response causes the interface-density-dependency to reverse and as the material takes a new property based off of the interface octahedral tilts. I will also discuss PbSe quantum dot superlattices, where the superlattice concerns lateral, self-assembled, epitaxially-connected quantum dots that form a network analog to a cubic crystal structure. Here the electronic states delocalize across the epitaxially connected QDs to create emergent electronic structure not present in the individual quantum dots. In both cases the combination of spatial and spectral information reveal emergent spectroscopic repsonses in the nanostructured superlattice.

10:30 AM *CH02.03.05
Investigating The Structure of Spin Qubits Using Electron Ptychography James M. LeBeau; Massachusetts Institute of Technology, United States

Divacancy and vacancy-transition metal (v-TM) complexes in silicon carbide (SiC) can form the basis for optically addressable single photon emitters. The convergence of SiC's technological maturity and the compatibility of these qubits with traditional semiconductors has thus sparked considerable interest in these defects. For example, recent quantum coherence measurements of v-TM complex spin states in SiC have underscored the potential of this platform in quantum computing applications. To validate theoretical frameworks and glean insights pertinent to emitter synthesis and stability, atomic resolution electron microscopy offers direct access to their structure and interactions within their local environment.

This presentation will explore the direct observation of individual defects in a SiC film using scanning transmission electron microscopy (STEM) imaging and multislice electron ptychography. We will show how the capabilities afforded by multislice electron ptychography enable us to characterize these defects at a localized level and in 3D without the need for tomography or through-focus methods. Moreover, we will show that conventional methods, such as high-angle annular dark field STEM, can be severely limited for this type of study due to noise and are frequently obscured by surface contamination, damage, and roughness. We will demonstrate that ptychographic reconstructions can directly quantify single defects and defect complexes on a slice-by-slice basis, imparting direct 3D information. This will be explored using simulated ptychographic datasets encompassing an array of defects in various positional configurations. Finally, we will discuss the limitations of capturing three-dimensional structures and the ability to capture small displacements arising from substitution and the formation of v-TM complexes.

11:00 AM *CH02.03.06
Towards *In-Situ* Electromagnetic Field Imaging in Materials by Scanning Transmission Electron Microscopy Naoya Shibata; The University of Tokyo, Japan

Differential phase contrast scanning transmission electron microscopy (DPC STEM) is a powerful technique for directly characterizing local electromagnetic field distribution inside materials and devices. In combination with tilt-scan averaging system [1,2] for suppressing diffraction contrasts, DPC STEM can be applicable to local electromagnetic field imaging even in the vicinity of crystalline defects such as heterointerfaces and grain boundaries [3,4]. The next step is to apply this technique for materials under various external conditions from low temperatures to high temperatures, electromagnetic biasing, mechanical loading and so on. In this talk, some resent developments and applications along this direction will be discussed.

Revealing Strain Engineering and Polar Structures for Oxides Yunlong Tang; Institute of Metal Research, Chinese Academy of Sciences, China

The ability to fabricate high-quality oxide films has created a vast playground to explore emergent phenomena and exotic phases which arise from the interplay of spin, charge, orbital, and lattice degrees of freedom. Several recent progresses on the finding of new types of polar topologies in ferroelectric films will be introduced, including the observation of a periodic array of flux-closure quadrants in strained ferroelectric $PbTiO_3$ films [1], the observation of room-temperature polar vortices and skyrmion lattice in $PbTiO_3$ related superlattices [2]. Moreover, we have proposed a practical way to prepare $REScO_3$ ultrathin films by a combination of precision pulsed laser deposition (PLD) and controlled post-annealing, which shows the same strain engineering effects on preparing ferroelectric polar topologies [3]. In addition, strain engineering also indicates an intermediate ferrielectric-like phase during the antiferroelectric to ferroelectric transformation within the $PBZrO_3$ films, as revealed by atomic scale scanning transmission electron microcopy [4]. These new results indicating that designing oxide films on the atomic scale may facilitate the formation of new phase components, topologies and exploration of novel physical properties of oxide films for future electronic nano-devices.

SESSION CH02.04: Exploration of Catalysts and 2D materials Dynamics via *In-Situ*/Cryogenic Electron Microscopy
Session Chairs: Yaobin Xu and Di Zhang
Wednesday Afternoon, April 24, 2024
Room 440, Level 4, Summit

1:30 PM *CH02.04.01
Atomic Resolution Scanning Transmission Electron Microscope Imaging of The *In Situ* Synthesis of Nanoparticle Catalysts Sarah J. Haigh[1], Yichi Wang[1], Nick Clark[1], Matthew Lindley[1], Thomas Slater[2] and Roman Gorbachev[1]; [1]University of Manchester, United Kingdom; [2]Cardiff University, United Kingdom

The shape and size of metallic nanoparticle catalysts have been shown to control the activity and selectivity for many chemical reactions. Most industrial catalysts are produced by wet impregnation and calcination, due to the scalable nature of this synthesis technique. However, a greater control of the composition, size and shape of the resulting nanoparticles is highly desirable. Understanding the interactions of metal ions with the surfaces in the wet impregnation solution, as well as better understanding of the drying behavior in hydrogen at elevated temperature would be highly desirable to support the production of the improved industrial catalysts needed to address the current energy emergency.
Our group have been developing in situ 2D heterostructure cells for atomic resolution transmission electron microscopy (TEM) imaging and analysis, using a combination of graphene, hexagonal boron nitride and MoS2 layers to trap liquid and gas pockets and enable new functionality such as liquid-liquid mixing [1]. We have used these 2D heterostructure liquid cells to investigate the dynamic processes that occur at a solid-liquid interfaces as metal ions from solution interact with a solid support at atomic resolution.[2] For example to demonstrate the use of liquid phase imaging to probe the preferred resting sites for platinum atoms on molybdenum disulfide.[2]
We have also used in situ gas cell TEM to investigate how the morphology is determined by the wet impregnation synthesis parameters, as well as how the starting structure and composition determines the evolution of industrial supported nanoparticle catalysts during activation heat treatment.[3]
In situ TEM studies are often limited to 2D imaging, especially for highly active nanoparticle systems like PtNi, where the particle composition and morphology can be used tune the performance for the oxygen reduction reaction.[4] We have shown that the single particle reconstruction method, which is widely used in cryogenic TEM imaging of proteins, is a valuable means to probe the three dimensional structural evolution of inorganic nanoparticles.[5] This approach averages over particles present in the image with different orientation to build up a tomographic reconstruction at much lower radiation dose than is required for conventional tilt series tomography.[5] We have shown that this opens up the single particle reconstruction technique to allow 3D visualization at different time points during in a synthesis process or catalytic reaction.[6] This approach could be brought to the atomic scale through harnessing the improved imaging performance achievable with new in situ cell designs.

Advanced Transmission Electron Microscopy Application in Non-Noble Catalyst Materials for CO2 Hydrogenation Qianqian Li; Shanghai University, China

Transmission electron microscopy (TEM) now has become one of the most influential techniques in nanoscience and nanoengineering characterization fields, which can be used to study the structure, component or valence at sub-angstrom scale. We involved the advanced Cs-corrected S/TEM to reveal the microstructural evolution of the non-noble catalyst for carbon dioxide hydrogenation. Firstly, we designed a porous Co@C catalysts derived from a novel layered metal-organic framework (MOF) with tunable pore sizes for CO_2 hydrogenation. Pointing out the dependence of the durability on the pore size. Secondly, we find the partial loss of catalytic activity of non-noble CoFe alloy catalysts, as exposed to oxygen, can be attributed to the migration of Co element from the core region of CoFe alloy to the surface. The adsorption energy of H for $CoFe_2O_4$ shell is stronger than Fe_3O_4 shell, so it is harder to fully desorb for H in the follow reaction process. Lastly, we revealed the non-noble catalyst structure stability optimization strategies and mechanisms in long-term reaction process for CO_2 hydrogenation. The studies above provide a new viewpoint to design high-performance catalyst and modify their structures.

2:15 PM CH02.04.03
Potential Synergism Between Sub-Nanometer Pd-Clusters and Adjacent NiO_x Domains Underneath for High-Performance CO_2 Methanation: An Ambient Pressure X-Ray Photoelectron Spectroscopy Study Amisha Beniwal and Tsan-Yao Chen; National Tsing Hua University, Taiwan

Carbon dioxide (CO_2) methanation serves as a critical process not only for the reduction of excessive CO_2 emissions but also for addressing the challenges linked to the storage and transportation of low-grade energy sources. Nevertheless, the presence of the competitive reverse water gas shift (RWGS) reaction significantly impedes the efficient production of methane (CH_4). To this end, a bimetallic nanocatalyst (NC) comprising sub-nanometer Pd clusters on Ni-oxide support (henceforth denoted as Pd@NiOx) has been successfully synthesized through a sequential control of metal ion adsorption followed by wet chemical reduction. As prepared material achieved an impressive CH_4 production yield of about 1900 umol/g at an operating temperature of 300ºC. This remarkable performance represents a more than 10-fold improvement compared to bare Pd nanoparticles. The results of in-situ ambient pressure X-ray photoelectron spectroscopy (APXPS) unveil that the exceptional catalytic activity of Pd@NiOx NC originates from the potential collaboration between surface-anchored sub-nanometer Pd clusters and adjacent NiOx domains at the heterogeneous interface, where the CO_2 activation takes place. On the other hand, the NiOx domains promote the H_2 splitting. More importantly, to the best of our knowledge, the Pd@NiOx NC with its unique structure exhibit the highest CH_4 production yield among existing catalysts with identical loading, composition, and geometric configurations. This achievement underscores the significance of this innovative bimetallic nanocatalyst in the field of catalysis.

2:30 PM BREAK

3:30 PM *CH02.04.04
Unveiling Phase Transitions in 2D Layered Materials via Atomic-Scale Cryogenic STEM Miaofang Chi, Haoyang Ni and Hsin-Yun Chao; Oak Ridge National Laboratory, United States

Quantum materials exhibit unique phenomena and functionalities beyond classical physics. The use of 2D sheets, heterogeneous interfaces, and moiré structures has emerged as a promising method to induce exotic quantum effects. However, studying these materials using cryogenic scanning transmission electron microscopy (STEM) has been limited by stage instability. Achieving stable atomic-scale imaging at cryogenic temperatures, particularly in techniques like atomic-scale 4D-STEM imaging and monochromated electron energy loss spectroscopy (EELS), is expected to provide valuable information for probing key parameters in quantum materials. Recent improvements in stage designs and machine learning-assisted acquisition and analysis algorithms offer opportunities for related research. In this presentation, I'll discuss our on-going research using cryogenic STEM and EELS to study lattice-spin-charge coupling in 2D van der Waals materials for spintronics applications, with a specific focus on our findings regarding layer-dependent atomic structural transitions and magnetic behavior alterations for spintronics applications. Additionally, we'll cover local temperature calibration methods for cryogenic STEM and the application of machine learning for data acquisition and analysis in achieving multi-dimensional STEM mappings at cryogenic temperatures, including atomic-resolution 4D-STEM imaging and spectroscopy.

4:00 PM *CH02.04.05
***In Situ* Cryo 4D STEM of CDW Phase Transitions in Layered Materials** Judy Cha, James Hart and Saif Siddique; Cornell University, United States

Many quantum materials possess complex electronic phase diagrams where correlated electronic phases, such as superconductivity, magnetic ordering, and charge density waves (CDWs), exist near each other. The proximity of these phases suggests that phase transitions must be understood to establish the microscopic origin for these correlated phases and to use them for applications. These phase transitions have mostly been studied using ensemble-average techniques, lacking real space information of nucleation and growth of these often-competing electronic phases. Nevertheless, such real-space information is essential for applications of quantum materials, which will be at the nanoscale where reduced dimensionality, confinement, local heterogeneities, interfaces, and defects will greatly modify the phase transitions.

In this talk, I will discuss our group's efforts on combining cryogenic scanning transmission electron microscopy (cryo STEM) and *in situ* cryo 4D STEM with *in situ* transport measurements to study the phase transition of TaS_2 in real-space with nanometer resolution as it undergoes a transition from the commensurate CDW (insulating phase) to the nearly commensurate CDW (metallic phase). We directly visualize the nucleation and growth of the NC-CDW phase out of the C-CDW phase and correlate this to the changing transport data. We establish that the phase transition starts at extended defects present in TaS_2. We also examine the pulse-induced CDW phase transition in TaS_2 and reveal the role of defects and the transition mechanism. Our findings are extended to CDWs in rare-earth tri-tellurides (RTe_3) and other layered materials.

4:30 PM CH02.04.06
STEM Imaging of AC Electric Field Driven Non-Centrosymmetric Atomic Displacements in The 2D TMD WSe_2 Christopher T. Nelson[1], Ondrej Dyck[1], Mina Yoon[1], Jawaher Almutlaq[2], Dirk Englund[2] and Stephen Jesse[1]; [1]Oak Ridge National Laboratory, United States; [2]Massachusetts Institute of Technology, United States

Simultaneous characterization by (S)TEM and application of electrical bias is a powerful platform to study the real-space dynamic electronic couplings at nanoscales: the length scale of interest for many electronic, quantum, and electrochemical materials and processes. Minimum acquisition times across all STEM modes favor in situ electrical bias experiments that are quasi-static for a good signal/noise. Exploring dynamic responses at faster time scales necessitates multi-cycle summation to overcome the shot-noise limits for a coherent source. In this work we utilize this approach to characterize moderate frequency (25kHz) AC electric-field induced response on the atomic structure of a 2D semiconductor WSe_2.

As tunable 2D direct-gap semiconductors, WSe_2 and similar Transition Metal Dichalcogenides show promise for applications in nano- and opto-electronics. Their potential lies in part with a wide library of 2D materials, TMD and otherwise, and a correspondingly large design-space for heterogenous multi-layer engineering. Here we applied an in-plane electric field across a free-standing monolayer WSe_2 by biasing across a gap in an overlaid graphene layer. Rolling series short-dwell HAADF images were collected with a custom scan coil controller[1] while an AC 25kHZ sinusoidal bias was applied. Atomic structure fluctuations vs applied voltage were determined form a workflow of phase-detection -> averaging -> binning -> and atom position finding using a machine-learning model *AtomAI*[2]. Collective atomic motion was removed, observed to be ~0.5 Å/V, owing to beam deflection by long range stray-fields. We observe a small but robust centrosymmetry breaking counter-motion between the W and Se atoms. This displacement has a total delta of ~0.5pm/V up to 4 volts (maximum applied) and can be attributed to field-induced electrical polarization. Notably, this effect was only observed for datasets collected within the electrode gap and not within the graphene electrode itself. The nominal field concentration within the former and absent in the latter strongly supports this is direct real-space observation of local field induced dynamics, specifically a fixed-frequency optical-phonon type dielectric response.

Endotaxial Polytype Engineering: Enhancement of Incommensurate Charge Density Waves in TaS_2 Suk Hyun Sung[1,2], Pat Kezer[2], Nishkarsh Agarwal[2], Yin Min Goh[1], Noah Schnitzer[3], Ismail El Baggari[1], Kai Sun[2], Lena Kourkoutis[3], John T. Heron[2] and Robert Hovden[2]; [1]Harvard University, United States; [2]University of Michigan, United States; [3]Cornell University, United States

Charge density waves (CDWs) are an emergent periodic modulation of the electron density that spans a crystal with strong electron-lattice coupling. CDW phases spontaneously break crystal symmetry, facilitate metal–insulator transitions, and compete with superconductivity [1–4]. At elevated temperatures, many materials exhibit a CDW incommensurate (IC-) with the high symmetry parent phase [5–8]. Unfortunately, the IC-CDWs are inherently weak and disordered. In TaS_2, a popular layered CDW material, long-range order has not been demonstrated for the IC-CDW [9–11]. Using new methods of endotaxial polytype engineering [12] we show it is possible to restore long-range order of the IC-CDW phase. Through this process, 2D CDW layers are encapsulated within metallic polytypes to enhance charge order. Furthermore, with restored IC-CDWs we can better understand the nature of disorder in these systems. We show that the IC-CDWs in 1T-TaS_2 are hexatically disordered and undergo a continuous melting as temperature is increased. The hexatic CDW phase retains six-fold orientational order while translation order quickly decays from proliferation of defects with temperature.

Here we use endotaxial engineering to enhance CDWs—even at elevated temperatures. The polytype heterostructures consist of monolayers of octahedrally coordinated charge ordered TaS_2 embedded within matrices of metallic prismatic TaS_2. These endotaxial heterostructures have been shown to raise the critical temperature of the long-range ordered commensurate (C-) CDW phase by 150 K [12].

Surprisingly, long-range order of the IC-CDW phase is significantly enhanced in the polytype heterostructures [13]; in-situ selected area electron diffraction (SAED) of the heterostructures shows sharper and brighter superlattice peaks than the IC-CDW phase in pristine 1T-TaS_2. This enhancement of long-range CDW order is accompanied by a marked increase in the in-plane resistivity of the IC phase. The increased intensity is surprising given the number of charge ordered TaS_2 layers is decreasing.

The signature of IC-CDWs in TaS_2 is the presence of azimuthally diffused superlattice peaks decorating bright Bragg peaks in SAEDs. These azimuthally blurred superlattice peaks strongly resemble the structure factor of hexatic phases found in two-dimensional (2D) systems. 2D crystals can melt continuously through intermediate orientationally ordered hexatic phase [14–17]. Similarly, in pristine 1T-TaS_2, the IC-CDW phase is in a hexatic glassy state due to intrinsic disorder. By restoring crystallinity of the IC-CDW, we observe the full hexatic melting process: heating further melts the ordered IC-CDW phase with continuous azimuthal broadening and weakening of superlattice peaks as expected for hexatic phases.

In summary, we demonstrate that polytype engineering can stabilize fragile long-range order in IC-CDW even at high temperatures. The ordered IC-CDW phase melts continuously with hexatic characteristics.

***In-Situ* TEM Full Temperature Range Cooling, Heating and Electrical Biasing Sample Holder** Calvin A. Parkin, Norman Salmon and Daan Hein Alsem; Hummingbird Scientific, United States

Cryogenic cooling of specimens during scanning/transmission electron microscopy (S/TEM) has enabled the characterization of various quantum interfaces and phase interactions in strongly correlated systems. Investigation of such quantum properties at the fundamental level has historically been challenging due to inadequate spatial and temporal resolution of characterization techniques as well as inadequate sample stability. Quantum materials must be studied at cryogenic temperatures because many of the relevant properties in these quantum materials only manifest at such low temperatures.

Cryogenic S/TEM sample holders have not only enabled the study of quantum topological insulators in two-dimensional (2D) materials but also atomic resolution observation of battery interfaces, which is traditionally difficult to achieve because they are sensitive to air and prone to electron beam damage at room temperature. However, lack of biasing capability has limited the study of electrical responses in these materials systems. With increasing demand for batteries that function at high temperatures and material phase information across a wide range of temperatures from cryogenic to high temperature, expanded versatility will be required of temperature-controlled in-situ electrical biasing systems.

Here, we present a novel in-situ electrical biasing S/TEM holder that simultaneously allows electrical stimulus and high-resolution imaging of a sample in-situ across the full temperature range, from cryogenic up to high temperatures. The holder is exceptionally stable, with drift speeds across the entire temperature range comparable to standard holders at room temperature. Battery processes were demonstrated in a single nanowire system using this holder at near-liquid nitrogen temperature (<-170°C) up to room temperature. Electrical biasing was performed on a nanowire sample bridging the electrodes on the biasing chip. A constant current experiment at cold temperatures on the nanowire showed a voltage drop as the reaction proceeds with the growth of a dendrite layer plated on the nanowire's surface. With the new heating capability, such experiments are extended to >1000°C using heating on the same chip that electrically biases the sample to achieve these higher temperatures. This enables studying the temperature dependence of chemical and microstructural evolution under electrical bias. Far below room temperature where on-chip temperature measurements become increasingly inaccurate, precise temperature control is maintained using a conventional resistance heater and miniature thermocouple at the sample in the TEM holder tip. At intermediately cold temperatures, the on-chip heating/temperature sensing can be combined with tip heating and temperature measurement for precisely controlled rapid heating experiments. For quantum nanomaterials, this enables their synthesis and processing to be studied across a range of different temperatures in the

low temperature regime, and their quantum response to electrical biasing to be measured at cryogenic temperatures. Batteries may now be electrochemically cycled at elevated temperature and then returned to cryogenic temperature for imaging, without the need to change holders. The cryo-biasing TEM holder with heating will empower scientists to nimbly investigate structure-property relationships in materials, specifically electronic properties, across the full temperature range. This versatile tool will accelerate the development of the next generation of electronic, quantum, and energy storage materials devices.

5:00 PM CH02.05.02
A Surface Science Investigation of Hydrocarbons Adsorption to a Ru/Al2O3 Catalyst Erin E. Dunphy; University of Colorado Boulder, United States

Hydrogenolysis is an extremely effective method for plastic upcycling. Specifically, Ru-based catalysts supported on metal oxides have shown high reactivity for polyethylene upcycling. Polyethylene hydrogenolysis is an extremely structure-sensitive reaction, where product distribution depends on the size of the adsorbing alkyl chain and the hydrogen availability at the metal oxide support interface. However, surface science studies are required to characterize the structural impact of these dependencies directly.
To study the arrangement of hydrocarbons to the catalyst support, we utilize X-Ray Reflectivity (XRR) and Molecular Dynamics (MD) simulations, and to study the local chemical environment changes of the Ru active site, we utilize Extended X-Ray Adsorption Fine Edge Structure (EXAFS). By utilizing hydrocarbons of various lengths (methane, hexane, dodecane, triacontane, and low-density polyethylene), we will understand preferential adsorption arrangements for undesirable and desirable product species.
We theorize that as hydrocarbon chain length increases, the polymer will adsorb to the support with increased structural order, resulting in increased adsorption potential to the Ru active site. MD simulations of n-dodecane at various temperatures indicate that the preferential adsorption of species parallel to an alumina interface changes, and the application of the distorted crystal model confirms the viability of XRR as an experimental technique, as seen in the attached image. EXAFS and XRD data are currently being processed and will yield information about the local relaxation of Ru nanoparticles and the alumina support during species adsorption.
This work aims to understand the structure and arrangement of hydrocarbons to the active metal site and the support, thus allowing for fundamental concepts to be unified and expanded upon. We anticipate our results to inspire future surface science studies to explore how different polymers adsorb to the catalyst surface—ultimately allowing for the creation of catalysts capable of mixed-polymer hydrogenolysis and reduction of energy requirements for polymer upcycling.

Luminescence Polarization of Rare Earth Microcrystals under High Pressure Haoran Zhao; Peking University, China

In recent years, the polarization properties of rare earth luminescent materials have attracted extensive attention. The fine spectral splittings generated by the crystal field effect has fingerprint-like polarization characteristics[1], but its influence factors needs to be studied. High pressure is an important protocol to adjust the structure and properties of materials, which can change the unit cell parameters and local symmetry of rare earth luminescent materials, and further affect the crystal field parameters, emission wavelength and intensity[2]. However, the effect of high pressure on the polarization of rare earth emissions has not been studied. Hexagonal phased $NaREF_4$, which has an anisotropic crystallographic structure, is a decent host material for emission polarization. We studied the emission polarization of $NaREF_4$ microcrystals under high pressure. Through adjusting the symmetry of crystal structure by high pressure, the influence of crystal structure symmetry on rare earth emission polarization was investigated, meanwhile, the correlation between the direction of emission polarization and the axis of crystal symmetry was analyzed[3]. Taking the 700.4 nm emission as an example, its polarization degree decreased with the increased pressure, while the polarization direction rotated by 90°. These findings benefit to the in-depth understanding of the mechanism of rare earth emission polarization and are informative for the design of new rare earth polarized luminescent materials.

Electrochemical Lithium Intercalation & Exfoliation in 2D TMDs and its *In-Situ* Studies Zhiyuan Zeng; City University of Hong Kong, Hong Kong

We developed a lithium ion battery intercalation & exfoliation method with detailed experimental procedures for the mass production of 11 two dimensional TMDs and inorganic nanosheets, such as MoS_2, WS_2, TiS_2, TaS_2, ZrS_2, graphene, h-BN, $NbSe_2$, WSe_2, Sb_2Se_3 and Bi_2Te_3, among them 3 TMDs achieved mono- or double layer yield > 90%. This method involves the electrochemical intercalation of lithium ions into layered inorganic materials and a mild sonication process. The Li insertion can be monitored and finely controlled in the battery testing system, so that the galvanostatic discharge process is stopped at a proper Li content to avoid decomposition of the intercalated compounds. The intercalation strategy can also be used to tune 2D TMDs' physical and chemical properties for various applications. For example, we developed a one-step covalent functionalization method on MoS_2 nanosheets for membrane fabrication, which exhibited excellent water desalination performance. For lithium intercalation mechanism, the state-of-the-art In-Situ Liquid Phase TEM is an ideal technique for identifying the phase changes during intercalation process. With self-designed electrochemical liquid cell utilized, we can directly vapture the dynamic electrochemical lithiation and delithiation of electrode in a commercial $LiPF_6$/EC/DEC electrolyte, such as LiF nanocrystal formation, lithium metal dendritic growth, electrolyte decomposition, and solid-electrolyte interface (SEI) formation. Combining with other in-situ techniques, such as in-situ XAS, XRD and Raman, etc, the underlying lithium intercalation mechanism in TMDs were further investigated, which render us a comprehensive understanding of the intrinsic correlation between the intercalation process and TMDs.

Seeing the Invisible: Ultrathin (UT) Membrane Chip for Fluidic-Cell Electron Microscopy Vinayak P. Dravid; Northwestern University, United States

In the recent decade, *in-situ* or operando S/TEM utilizing SiNx membrane encapsulated chips to confine fluids for electron microscopy examination has become popular, A great number of prior innovators have shown this to be an effective approach for probing fluid-surface/nanostructure interactions and related phenomena or reactions. Such a “closed cell” chip based on silicon nitride (SiN_x) membranes as electron transparent encapsulation material, has many practical and technological advantages over the differential pumping environmental TEM (ETEM). Unfortunately, however, conventional fluid-cells suffer from additional and significant electron scattering from the top and the bottom membranes, which are typically 30-50nm thick to maintain integrity/stability during the operation. Thus, the total thickness of >70-80 nm of the encapsulating membranes imposes many adverse effects on the post electron optics, such as increased chromatic aberrations. This naturally results in significant degeneration of signal quality and loss of spatiotemporal resolution, diffused interference in the electron diffraction, and plasmon-dominated electron energy loss spectra (EELS).
Further, to implement advanced STEM techniques such as quantitative EELS analysis to resolve electronic structure and 4D-STEM for pixel-specific acquisition, one needs to significantly reduce electron scattering, which primarily stem from the thick SiN_x windows in gas-cells. For example, the log-ratio of scattered electron over zero-loss electron () already exceeds ~1 for two-50 nm SiN_x encapsulation (without any specimen). Howwever, low scattering “thin” membrane is risky since the mechanical robustness is compromised, resulting in potentially catastrophic failure. Thus, novel design strategies for fabrication of stable ultrathin SiN_x membrane are needed.
We have recently developed a robust, functional and scalable backing support strategy to enable the thinnest possible (<10 nm) SiN_x gas encapsulation material [2]. Inspired by the natural honeycomb geometry, our novel design provides for honeycomb backbone that can neatly anchor ultrathin (~<10 nm) SiNx membrane with excellent stability and consistent performance. It can still withstand up to *6 Atm* pressure with ~50 % less bulging. Unlike graphene-based encapsulations [3], stability under the electron beam is comparable to a 50 nm SiN_x membrane, which is sufficient for most high-resolution S/TEM applications on non-electron sensitive materials.
We show that our UT chip increases contrast of typical nanoparticles at *1 atm* Ar gas by ~70 % and the accessible information limit is enhanced by >130 % compared to the conventional encapsulation. More importantly, the is reduced from nominally ~1.0 to 0.3 using a *1 Atm* gas cell. This greatly enhances spectral visibility and significantly improved S/N for EELS excitations. Thus, spatiotemporal detection of gas species, down to ~nanometer scale, which otherwise is unachievable with integrated residual gas analyser (RGA), is being achieved.
The presentation will cover the design and implementation of UT membrane fluid-cell for in-situ gas-solid interactions. [4]

***In Situ* Study of Electrified Solid-Liquid Interfaces using Liquid Cell TEM combining with other Advanced EM Techniques** Haimei Zheng; Lawrence Berkeley National Laboratory, United States

Electrified solid-liquid interfaces play a key role in various electrochemical processes relevant to electrocatalysis, batteries, and supercapacitors. The electron and mass transport at the electrified interfaces may result in structural modifications that remarkably influence the reaction pathways.
Extensive studies of the electrified solid-liquid interfaces have been on the physisorption and chemisorption of species at the interfaces. However, the microscopic details of electrified solid-liquid interfaces, especially their atomic-scale structural evolution during electrochemical reactions, remain unclear. In situ transmission electron microscopy (TEM) allows tracking of the evolution of individual nanocatalysts during reactions. With our development of advanced high resolution electrochemical liquid cells for TEM, we monitor the atomic dynamics of electrified solid-liquid interfaces during Cu-catalyzed CO_2 electroreduction reactions. Other techniques, such as, Cryo-EM of certain reaction states by fast freezing of the same liquid cell, chemical analysis with energy dispersive x-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS)
Our systematic study unveils fascinating atomic dynamics as well as structural and chemical evolution of the electrified solid-liquid interfaces. The combination of experimental observation and theoretical calculations reveals an amorphization-mediated restructuring mechanism resulting from charge-activated surface reactions with the electrolyte. Our results hold significant implications for utilizing interphases to control catalyst surface restructuring, thus tuning the catalytic reactions.

Operating a Solid Oxide Fuel Cell in The Environmental Transmission Electron Microscope Matthieu Bugnet[1], Thierry Epicier[1,2], Cedric Frantz[3], Stefan Diethelm[3], Dario Montinaro[4], Elizaveta Tyukalova[5], Yevheniy Pivak[6], Jan Van Herle[3], Aicha Hessler-Wyser[7], Martial Duchamp[5,8] and Quentin Jeangros[7,9]; [1]University Lyon, CNRS, INSA Lyon, UCBL, MATEIS, France; [2]University Lyon, UCBL, IRCELYON, France; [3]Group of Energy Materials (GEM), École Polytechnique Fédérale de Lausanne (EPFL), Switzerland; [4]SolydEra S.P.A., Italy; [5]Nanyang Technological University (NTU), Singapore; [6]DENS solutions, Netherlands; [7]Photovoltaics and Thin-Film Electronics Laboratory (PV-Lab), École Polytechnique Fédérale de Lausanne (EPFL), Switzerland; [8]MajuLab, International Joint Research Unit, CNRS, Université Côte d’Azur, Sorbonne Université, National University of Singapore, Nanyang Technological University, Singapore; [9]Centre Suisse d’Electronique et de Microtechnique (CSEM), Saint Barthélemy

Solid oxide fuel cells (SOFC) are a class of solid-state electrochemical conversion devices that produce electricity directly by oxidizing a fuel gas. They consist in an anode-cathode duet separated by a solid electrolyte, i.e., a material conducting oxygen ions. The anode is fed with hydrogen or other fuels whereas the cathode is in contact with air, meaning oxygen. Overall, a SOFC operates thanks to the combined action of two external stimuli: a gaseous environment and temperature. Owing to the recent advances in *in situ* and *operando* transmission electron microscopy (TEM), we have set up an experiment to operate a SOFC inside an environmental TEM to identify how the device microstructure determines its electrical properties. To do so, an elementary anode-electrolyte-cathode sandwich was prepared by focused ion beam (FIB) and mounted on a heating and biasing microelectromechanical

(MEMS)-based specimen holder (DENSsolutions) and inserted in an Environmental TEM (FEI Titan ETEM), as shown in Fig. 1.
Standard SOFC materials were investigated: the cathode was strontium-doped lanthanum manganite (LSM) co-sintered with yttria-stabilized zirconia (YSZ), the electrolyte was YSZ, and the anode a cermet of NiO co-sintered with YSZ. NiO was first reduced to Ni, leaving pores in the structure due to the volume loss and hence enabling the penetration of the fuel to the triple phase boundaries Ni/YSZ/porosity at the anode side. For practical reasons, we used a single chamber configuration to trigger the operation the cell: the anode and cathode were exposed simultaneously to the oxidant and reducing gases. Due to a difference in the catalytic activity between the electrodes, O_2 should reduce at the cathode, while H_2 should oxidize at the anode, thus leading to a voltage difference between the two terminals.
The reduction of NiO was first performed under a forming gas N_2:H_2 in the ratio 20:1 under 15 mbar up to 750°C (N_2 was constantly used as a mixing gas for safety reasons due to the need of mixing O_2 and H_2 in the single-chamber configuration). The O_2 to H_2 ratio was then increased to trigger the operation of the cell. A small quantity of O_2 was introduced into the microscope, leading to a total pressure of about 16 mbar at 600°C. At this point, the variation of voltage between the anode and cathode was correlated to the gas composition and the anode microstructure (see Fig. 2). The latter was analyzed by means of conventional and high-resolution imaging, diffraction, and EELS (electron energy-loss spectroscopy). The system was cycled several times by decreasing and re-increasing the O_2 concentration in the gas flow, and correlations between microstructure, gas composition, and cell voltage were established, as it will be discussed at the conference. Results were further confirmed by macroscopic *ex situ* tests in an oven using the same materials [1]. The operation of a SOFC in a single chamber configuration was demonstrated using *operando* ETEM. Such *operando* experiments open numerous perspectives to investigate the root cause of failure pathways affecting SOFCs, like poisoning of active sites or coarsening of the Ni catalyst [2].

9:45 AM CH02.06.05
Electric-Field-Assisted Phase Switching in GaAs Nanowires Qiang Yu[1], Khalil Hassebi[1], Khakimjon Saidov[2], Ivan Erofeev[2], Charles Renard[1], Laetitia Vincent[1], Frank Glas[1], Utkur Mirsaidov[2] and Federico Panciera[1]; [1]Université Paris-Saclay, CNRS, Centre de Nanosciences et de Nanotechnologies, France; [2]Centre for BioImaging Sciences, Department of Biological Sciences and Physics, National University of Singapore, Singapore

The vapor-liquid-solid (VLS) method for nanowires growth was introduced by Wagner and Ellis in the 1960s[1]. Since then, intensive researches focus on engineering the morphology, composition and crystal phase of nanowires due to their promising applications in nanotechnology[2]. While III-V bulk semiconductors generally exist in only one crystal phase, in nanowires, multiple crystal phases can coexist (polytypism). On the one hand, this phenomenon can be considered as a crystal defect; on the other hand, it enables the formation of crystal phase quantum dots (CPQDs), i.e. insertion of segments of one phase within a nanowire of a different phase. Due to the band alignment of two crystal phases and confinement of nanowire size, CPQDs feature sharp and intense spectral lines, single-photon emission and sub-nanosecond exciton lifetime[3]. Moreover, in contrast to compositional heterojunctions, CPQDs have intrinsically abrupt interfaces and do not suffer from alloy intermixing, which hampers precise control of the electronic properties in compositional heterostructures. However, despite over 15-year of research, technological applications of CPQDs remain severely limited by the poor understanding of the phase switching mechanisms and the difficulty of controlling their formation. In this study, beyond commonly used methods of flux and temperature modulation, we solve this issue by introducing an external electric field (E-field)[4] to instantaneously switch the crystal phase and create GaAs CPQDs with monolayer precision. This process is monitored in real-time using in-situ transmission electron microscopy (TEM). Thanks to custom-made substrates, GaAs nanowires are grown epitaxially on Si (111) by chemical vapor deposition inside TEM. The substrate is shaped as a micro capacitor which allows us to apply an E-filed up to several V/nm in the direction parallel to the nanowire growth, and this strong E-field allows to achieve phase switching faster than monolayer formation. We will present high-resolution videos showing the controlled phase switching induced by the E-field in GaAs nanowires, and the formation of single and multiple CPQDs. Finally, we will discuss the E-field-induced phase switching mechanisms and propose a model to explain the experimental results based on theoretical calculations and finite element simulations.

Insight into Energy Storage Materials Science from a Reductionist Perspective Lin Gu; Tsinghua University, China

Establishing a correlation between the structure and functionality of materials has been a long-standing challenge. Materials science based on reductionism greatly depends on one's knowledge of the elements. This understanding ranges from entirely solvable atomic energy levels to fundamentally solvable energy bands of phases under specific boundary conditions, and finally, to macroscopic material properties that may have only statistical solutions. Along this clue, here the macroscopic material is split into phase, until cell, atom, and electron step by step, exploring the material properties starting from the elementary particles. We mainly focus on band structure and dispersion relation in reciprocal space, and the distribution of four fundamental degrees of freedom (lattice, charge, orbital, spin) in real space. As a powerful characterization method, spherical aberration corrected electron microscopy could acquire information about atomic-scale structure and electronic structure, which could get rid of the constraint condition of periodic potential field, single electron approximation, and adiabatic approximation theories to obtain the structure-activity relationship in solid materials. We focused on the atomic and electronic structure of energy storage materials from lattice and charge degrees of freedom. On this basis, the direct observation of electron occupied states is realized at orbital scale, which has a substantial impact on materials' performance. This report will focus on physical mechanism of functional materials to discuss the correlation between microstructure and electronic structure based on reductionism.

11:00 AM *CH02.06.07
Cryo-EM Imaging of Li Metal Polyhedra formed by Ultrafast Electrodeposition Yuzhang Li; University of California, Los Angeles, United States

Electrodeposition of lithium (Li) metal is critical for high-energy batteries[1]. However, the simultaneous formation of a surface corrosion film termed the solid electrolyte interphase (SEI)[2] complicates the deposition process, which underpins our poor understanding of Li metal electrodeposition. Here we decouple these two intertwined processes by outpacing SEI formation at ultrafast deposition current densities[3] while also avoiding mass transport limitations. By using cryogenic electron microscopy[4,5,6,7], we discover the intrinsic deposition morphology of metallic Li to be that of a rhombic dodecahedron, which is surprisingly independent of electrolyte chemistry or current collector substrate. In a coin cell architecture, these rhombic dodecahedra exhibit near point-contact connectivity with the current collector, which can accelerate inactive Li formation[8]. We propose a pulse-current protocol that overcomes this failure mode by leveraging Li rhombic dodecahedra as nucleation seeds, enabling the subsequent growth of dense Li that improves battery performance compared with a baseline. While Li deposition and SEI formation have always been tightly linked in past studies, our experimental approach enables new opportunities to fundamentally understand these processes decoupled from each other and bring about new insights to engineer better batteries.

Combining *Operando* LCTEM and Cryogenic APT to Directly Visualise and Characterise Nanoscale Liquid-Solid Interfaces Neil Mulcahy, Mary Ryan and Shelly Michele Conroy; Imperial College, United Kingdom

Materials which are critical for the creation of new technologies to tackle global problems such as climate change are often highly complex, multifarious, and difficult to characterise using standardised techniques. This is particularly the case for electrochemical systems which often contain liquid-solid or liquid-liquid interfaces involving low atomic weight, and mobile elements such as hydrogen, carbon, or lithium. These elements are notoriously challenging to quantitatively characterise in their state of interest. It is essential to gain understandings of the phase, chemistry, and morphology of these systems at multiple length scales to better understand what controls their behaviour and limits their performance. This understanding at fundamental length scales is currently limited due to a lack of high-resolution characterisation techniques which are compatible with both the liquid and solid components of the interface and those which are capable of capturing a dynamic system in its exact state of interest. This lack of understanding has ultimately limited the performance and future development of many liquid-based systems using fundamental atomic-level insights. This has crucially led to understandings of various phenomena within battery research such as dendrite growth and solid-electrolyte (SEI) interface formation remaining elusive from a fundamental perspective.

Liquid microscopy techniques have shown the greatest promise in capturing dynamic nanoscale liquid-based systems in their exact state of interest through techniques such as liquid cell transmission electron microscopy (LCTEM). LCTEM is capable of capturing solution phase static and dynamic processes at high temporal and spatial resolutions, allowing for dynamic nanoscale imaging of various processes in real-time. LCTEM has been used to probe electrochemical processes using unique cell setups allowing for electrical biasing of electrodes within the cell as an electrolytic solution is flowing. While this setup does give unique nanoscale insights into these processes, key problems with respect to spatial resolution and beam-induced effects hinder the necessary sub-nanometre spatial resolution needed to resolve these complex dynamic liquid-based electrochemical systems, particularly those containing light elements. While various strategies have been employed to overcome these problems through state-of-the-art dose limitation techniques and alternative liquid cell setups involving 2D materials, the necessary resolutions have not been achieved under in operando conditions.

The work presented here provides an alternative approach that seeks to combine dynamic liquid microscopy techniques with high-resolution cryogenic microscopy techniques. The emerging field of cryogenic microscopy for material science has been proven capable of capturing a solid-liquid interface in its state of interest through techniques such as cryogenic STEM and cryogenic atom probe tomography (APT). Cryo APT can provide 3D compositional reconstructions of frozen nanoscale volumes with sub-nanometre spatial resolutions and has a chemical sensitivity of ppm for all elements including hydrogen, lithium, and carbon. Cryogenic microscopy techniques are however only capable of offering a snapshot of a particular system when a full dynamic understanding is required. This makes dynamic liquid microscopy techniques and high-resolution cryogenic microscopy techniques extremely complimentary.

This work has successfully combined operando LCTEM with cryogenic APT through the use of a cryogenic FIB/SEM, vacuum cryo transfer module technology (VCTM), and an inert glovebox. The combination of these distinct microscopy techniques has allowed for dynamic sub-nanometre understandings of various phenomena within nanoscale electrochemical systems such as dendrite growth as well as SEI growth and formation. This presentation will discuss the workflow needed to realise this combination and the results produced thus far.

11:45 AM CH02.06.09

Infrared Nanospectroscopy Characterization of Initial Stages of the SEI Layer Formation at The Amorphous Si/Electrolyte Interface Andrew Dopilka[1], Jonathan M. Larson[2,1] and Robert Kostecki[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Baylor University, United States

The solid electrolyte interphase (SEI) layer is a crucial component in the function and lifetime of Li-ion batteries; however, the nanoscale mechanism of its growth and evolution are often elusive due to the difficultly in characterizing its structure under in situ conditions. Recently, our group has been utilizing nano-FTIR spectroscopy to investigate the structure and composition of battery interfaces with nanometer scale chemical resolution in a nondestructive manner. For instance, this technique was used to probe the graphene/polymer electrolyte interface *in situ*[1] as well as the liquid/graphene interface thus allowing opportunities to characterize the electrical double layer.[2]

The nano-FTIR technique is implemented within an atomic force microscope using a metallically coated tip. By illuminating the tip/sample interface with a broadband infrared laser, plasmonic enhancement occurs at the apex of metallic tip inducing a nanoscopic near-field interaction with the sample. This near-field interaction couples with the infrared active vibrational modes of the sample and causes a change in the amplitude and phase of the backscattered infrared light which can be detected and then separated from the far-field signal with lock-in amplification at the tapping amplitude of the probe. The result is nanoscale, broadband infrared reflection and absorption of the sample with a probing area on the order of the tip radius (~20 nm), far beyond the diffraction limit of conventional infrared microscopy.

In this presentation, we will discuss how nano-FTIR spectroscopy is used to characterize and observe the initial formation of the SEI layer at the interface between an amorphous Si surface and a carbonate electrolyte. By fabricating a 25 nm thin, free-standing amorphous Si film and encapsulating electrolyte with this thin layer, the Si can act as a window for the infrared light as well as an electrode to apply potential to the surface and induce electrolyte decomposition. Because of the nanometer scale spatial resolution and sensitivity to the electrolyte components, we observe subtle nanoscale heterogeneities in the electrolyte composition at the interface prior to the polarization of the Si electrode. After polarization of the cell to 0.5 V vs Li/Li^+, we observe that $LiPF_6$ reacts to form LiF at the surface of the Si and find further inhomogeneity in the formed layer with spatial dependent measurements. Based on the technique's high chemical sensitivity, spatial resolution, and nondestructive nature, *in situ* nano-FTIR spectroscopy is anticipated to be an important tool to unravel the elusive nanoscale formation and growth mechanisms of the SEI layer.

This research was supported by the US Department of Energy (DOE)'s Vehicle Technologies Office under the Silicon Consortium Project directed by Brian Cunningham and managed by Anthony Burrell. The work at the Molecular Foundry was supported by the Office of Science, Office of Basic Energy Sciences, of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231. This research used resources of the Advanced Light Source from

beamline 2.4, which is a DOE Office of Science User Facility under contract no. DE-AC02-05CH11231

Microscopic View of Carbon Dioxide Adsorption in Amine-Decorated Porous Silicates for Direct Air Capture Wei-Chang David Yang, Marcus J. Carter, John R. Hoffman, Avery E. Baumann, Christopher M. Stafford and Renu Sharma; National Institute of Standards and Technology, United States

Organic-inorganic hybrid sorbents, based on mesoporous silicates and polymers, are a leading candidate for CO_2 capture under ambient pressure, which takes advantage of the high surface area of the silicates. [1]. An impregnation process allows active functional groups, such as polymer-based alkyl amines, to decorate the internal surface of mesoporous silicates and improve the adsorption-desorption kinetics at a reduced energy expense [2]. The mesopore surface was shown to interact with aqueous polyethyleneimine (PEI) to create the amine-modified sites for CO_2 adsorption [3]. However, the beam-sensitive specimen has limited electron microscopy in measuring these adsorption sites' structure and chemistry within the nanometer-sized mesopores [4]. In this work, we adopted a new approach that combines *in situ* cryogenic scanning transmission electron microscopy (STEM) and electron energy-loss spectroscopy (EELS) in an environmental transmission electron microscope (ETEM) to probe the interactions among CO_2, PEI, and mesoporous silicates.

The ETEM is equipped with a monochromated electron source to achieve an EELS energy resolution of up to 80 meV at 80 kV and a custom-built optical spectroscopy system to measure Raman shifts from a ten-micrometer-in-diameter area centered around the electron-beam location [5]. The amine-modified silicates were prepared by impregnating about 60 wt.% of PEI with a molecular weight of 800 g/mol into pristine silicates (e.g., MCM-41). A liquid-nitrogen-cooled holder was used to freeze the amine-modified sample in the ETEM and, therefore, mitigated electron beam damages as monitored with the spatially correlated Raman spectra. We used *in situ* EELS hyperspectral imaging to benchmark the mesopore surface's interaction with CO_2, either with or without PEI impregnation. For the pristine MCM-41 mesopores, we obtained carbon K-edge maps based on the distinct π^* peak at $\approx$ 290 eV to show physisorption in a CO_2 environment and subsequent desorption in the ETEM baseline vacuum [6]. On the other hand, the amine-modified MCM-41 was activated at 60 °C in the ETEM baseline pressure and then exposed to CO_2. After evacuating CO_2, we froze the sample *in situ* by adding liquid nitrogen to the cooling holder. The approach allowed us to analyze EELS data obtained from specimens in the frozen state, whether they had been exposed to CO_2 or not. We identified the energy loss near edge structure (ELNES) associated with the carbonyl core to $\pi^*_{C=O}$ transition ($\approx$ 289 eV) in ammonium carbamate [7], which indicates the formation of chemisorbed species when exposed to CO_2 under a water-free condition. Another ELNES of the amide core to π^* transition ($\approx$ 401 eV) was also detected to support the above observation. Compared to the ETEM result, the same type of PEI film on a metal substrate was examined using polarization modulation-infrared reflection adsorption spectroscopy (PM-IRRAS). The carbamate peak intensity changes in response to the adsorption and desorption processes confirmed carbamate formation in a dry CO_2 environment.

We show here that *in situ* cryogenic STEM-EELS enables the direct observation of CO_2 chemisorption and the ability to benchmark the properties and performance of PEI-decorated MCM-41 at the nanoscale. We continue pushing the frontier of understanding the dynamic structure and chemistry in a broad range of beam-sensitive materials with our new approach to elucidate the fundamental principle that leverages adsorption sites for new direct air capture technologies.

Autonomous Characterization for Investigating Cathode Active Materials and Solid-Solid/Solid-Liquid Interphaces in Energy Storage Devices Huolin Xin, Chunyang Wang, Peichao Zou and Yubin He; University of California, Irvine, United States

The characterization of complex energy materials often requires detailed structural and functional analysis across multiple length and time scales. While in-situ and operando transmission electron microscopy (TEM) provide dynamic information [1], they can be lacking in resolution and sensitivity to some degree, particularly when studying cathode active materials and solid-solid or solid-liquid interfaces/interphases [2-4]. Cryogenic electron microscopy (cryoEM) has successfully filled this gap as a 'freeze-the-moment' technique, allowing for the imaging of dose-sensitive interphases in a protected environment. CryoEM is particularly well-suited for investigating solid-solid and solid-liquid interfaces in energy materials, where these interfaces play critical roles in determining material properties and performance [4]. By combining cryoEM with an autonomous characterization system, we can overcome the limitations of human operators and improve sensitivity and resolution for these interfaces. This approach has the potential to revolutionize basic energy research, enabling comprehensive investigations of complex materials at multiple length and time scales. [5]

Real-Space Visualization of Frequency-Dependent Anisotropy of Atomic Vibrations Xingxu Yan[1], Paul Zeiger[2], Jan Rusz[2] and Xiaoqing Pan[1,3]; [1]University of California, Irvine, United States; [2]Uppsala University, Sweden; [3]University of California, United States

Advancements in transmission electron microscopy (TEM) have revolutionized the study of interfaces and nanostructured materials. Innovations like aberration correctors, pixelated direct electron detectors, and monochromators have enabled atomic-resolution scanning transmission electron microscopy (STEM) and electron energy-loss spectroscopy (EELS), facilitating investigations into local structure, properties, and dynamic behaviors. Using a space- and angle-resolved vibrational EELS technique, we have recently observed red shifts and intensity changes in acoustic vibration modes near a single stacking fault in cubic silicon carbide, and nanoscale composition-induced red shifts in Si optical modes in SiGe quantum dots. We also developed a method for differentially mapping phonon momenta revealing the interplay between diffuse and specular reflection. In this talk, I present a novel approach, employing dark-field monochromated electron energy-loss spectroscopy for momentum-selective vibrational spectroscopy. This technique allows us to map phonon polarization vectors. When applied to centrosymmetric cubic-phase strontium titanate, we discover two types of oxygen atoms with contrasting vibrational anisotropies below and above 60 meV, based on mean-squared displacements. These transformations are supported by theoretical models, revealing the transition from oblate ellipsoids at low energies to prolate ellipsoids at high energies. These frequency-dependent thermal ellipsoids provide insights into the thermal and optical behaviors associated with acoustic and optical phonons. Our method enables the visualization of phonon eigenvectors at specific crystalline sites, opening new avenues for exploring dielectric, optical, and thermal properties with exceptional spatial resolutions.

***In Situ* Analytical Electron Microscopy and Cryogenic Electron Microscopy for Characterizing Nanoscale Materials in Electrochemical Process** Minghao Zhang[1] and Y. Shirley Meng[2]; [1]University of California, San Diego, United States; [2]The University of Chicago, United States

Lithium-ion batteries (LIBs) commercially dominate portable energy storage and have been extended to hybrid/electric vehicles by utilizing electrode materials with enhanced energy density. However, the energy density and cycling life of LIBs must extend beyond the current reach of commercial electrodes to meet the performance requirements for transportation applications. Carbon-based anodes, serving as the main negative electrodes in LIBs, have an intrinsic capacity limitation due to the intercalation mechanism. Alternative anodes are being explored, including nanosized metal sulfides and oxides which were found to possess better cycling stability and larger reversible capacities. Recently, researchers proposed to use Li metal as the anode to achieve even higher energy density. However, the dendritic growth of Li metal during cycling will result in low coulombic efficiency as well as safety issues which is detrimental for practical applications.
Further improvements and developments of electrode materials rely on a fundamental understanding of their electrochemical cycling mechanisms. On the one hand, real-time (in situ) studies with high spatial resolution are required for characterizing microstructural evolution and specific electrochemical reactions upon cycling. In situ TEM coupled with electron energy loss spectroscopy (EELS) has thus been considered as one of the most powerful techniques for monitoring electrochemical processes in electrode materials. EELS spectra interpretation is critical for chemical information analysis including oxidation state, charge transfer, bonding environment, etc. On the other hand, metal anode and solid electrolyte interphase (SEI) are chemically reactive and sensitive to electron-beam irradiation. TEM studies of batteries in their native environment can be problematic. Cryogenic electron microscopy (cryo-EM) can potentially be a powerful technique to image beam sensitive battery electrode materials.
In this work, the lithiation mechanism of nanosized metal sulfides and oxides is explored using in situ TEM. Multi-steps lithiation mechanism was revealed with discovery of a fascinating, spontaneously formed, self-assembling nanocomposite framework. This framework provides adequate room to accommodate the volume expansion during lithiation while ensuring enhanced contact among the active materials. Probing these dynamic evolution processes is not only necessary for fundamental understanding of electrochemical mechanisms, but also beneficial for designing novel materials in batteries with improved performance. This work will also cover recent advances on cryo-EM development for metal dendritic growth and SEI. The detailed structure of electrochemically deposited Li and the SEI composition at the nanoscale were revealed with minimized beam damage during imaging. Our findings not only illustrate the capabilities of cryogenic microscopy for beam (thermal)-sensitive materials but also yield crucial structural information on the Li metal deposition.

3:45 PM CH02.07.06
Probing Volumetric Effects in Suspended Binary Superlattices of Infrared Colloidal Nanocrystals using Transmission Electron Microscopy and Optical Characterization Todd H. Brintlinger, Patrick Y. Yee, Veronica R. Policht, Paul D. Cunningham, Janice E. Boercker and Sarah Brittman; U.S. Naval Research Lab, United States

By combining two types of infrared colloidal nanocrystals (NCs) into binary superlattices, a type of ‘artificial solid’ can be created where the NCs would be ‘atoms’ and NC-to-NC interactions are ‘bonds.’ These binary superlattices then allow for control of desired optoelectronic properties and offer the technological advantage of scalable solution-based synthesis for low-cost infrared optoelectronics. One roadblock in these engineered systems is the small size of individual ordered domains (analogous to grain size in polycrystalline materials), which prohibits detailed understanding of structure-property relationships. Expanding on our previous work [1, 2], we manipulate the surface chemistry in these artificial solids to create enlarged (>1 μm) domains of binary components comprised of infrared plasmonic $Cu_{2-x}S$/PbS core/shell and excitonic PbS nanocrystals. These superlattices are suspended across holes, proving both their ability to be self-supporting as well as allowing for transmission electron microscopy and optical characterization without need to account for substrate effects. However, as structured solids with a three-dimensional extent, we then face a challenge in determining volumes of superlattice domains when suspended in this fashion. Here, we determine both thickness and spatial extent of the superlattice to define the local volume in individual superlattice domains, and then compare these to correlated photoluminescence from the same domains. Combined with time-resolved photoluminescence spectroscopy, these results suggest that energy transfer occurs between the excitonic emitters and plasmonic nanocrystals.

Reversible Oxidation of Copper via Chemical Interaction with Carbon Dioxide Investigated by Ambient Pressure X-Ray Photoelectron Spectroscopy Haoyi Li[1], Asmita Jana[1], Angel T. Garcia-Esparza[1], Dimosthenis Sokaras[2], Junko Yano[1] and Ethan Crumlin[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]SLAC National Accelerator Laboratory, United States

A fundamental understanding of the chemical interactions between copper (Cu) and carbon dioxide molecules is pivotal to gain detailed insights on the initial steps of carbon dioxide conversion on Cu surfaces. Herein, ambient pressure X-ray photoelectron spectroscopy using synchrotron radiation-based tender X-rays (4 keV) was employed to study the chemical dynamics of Cu surfaces with increasing the pressure of carbon dioxide. The surface Cu of polycrystalline metal foil was oxidized to Cu(II) upon exposure to carbon dioxide, particularly beyond 10 Torr, and then reduced back when removing the carbon dioxide gas to restore high vacuum condition. A linear correlation was built up between carbon dioxide pressure and surface Cu(II) proportion. The growth and recession of the Cu(II) overlayer is attributed to the interaction of adsorbed oxygen species from the direct dissociation of adsorbed carbon dioxide with the surface metallic Cu sites and their fast transport through the Cu(II) overlayer. The observed reversible phenomenon of the Cu(II) layer evolution induced by dissociative carbon dioxide adsorption on Cu surface has been verified on other two reported carbon dioxide-reduction systems: p-GaN/Au/Cu and p-Si/TaOx/Cu. We unveil a universal and reversible oxidation of Cu towards Cu(II) at the initial step of carbon dioxide conversion, providing atomistic insights for the design and construction of highly efficient and selective Cu-based catalysts.

4:15 PM CH02.07.08

Positron Annihilation Method of Identifying Bismuth Centers in Silicon for Quantum Computing and Communications: Effects of 15 MeV Proton Irradiation Nikolay Arutyunov[1], Vadim Emtsev[2], Reinhard Krause-Rehberg[3], Mohamed Elsayed[3], Nikolay Abrosimov[4], Gagik Oganesyan[2] and Vitali Kozlovski[5]; [1]MLU (Halle, Germany), IKZ (Berlin), IPLT (former Institute of Electronics), Uzbekistan; [2]Ioffe Physico-Technical Institute, Russian Federation; [3]Department of Physics, Martin Luther University (MLU) Halle, Germany; [4]Leibniz-Institut für Kristallzüchtung (IKZ) Berlin, Germany; [5]St. Petersburg State Polytechnical University, Russian Federation

In search of a high-performance interface between telecom photons and matter qubits, bismuth (Bi) centers are being scrutinized in floating zone (FZ) silicon of n–type, mostly, by the resonance and optical methods. Meanwhile, data on electron and micro-structural properties of Bi centers in silicon beyond narrow zones of the resonance and optical transitions is scarce. To gain deeper insight into properties of both the spin system and open volume related to the Bi donor center, we have probed the microstructure of the Bi center by positrons registering their two-quantum annihilation with electrons. Data about microstructure of the radiation defects formed in silicon is of paramount importance for the material which must function on the low Earth orbit satellite where the most damaging factor is the irradiation by protons of MeV energies. The challenging points in identification of the radiation defects concern practically all devices on silicon platform (e. g., of such as single-photon detectors and the devices for quantum communications).

We will discuss the data obtained, mostly, for the samples irradiated with 15 MeV protons at room temperature. For characterization of the material, low-temperature Hall's measurements were carried out on the samples-satellites.

For the first time, an inhibition and a delay of emission of two annihilation quanta has been revealed at the declining temperature, when the electron density contacting positron at the Bi center increases. This paradoxical observation performed by high-resolution positron annihilation lifetime spectroscopy is suggested to be due to non-local interaction between the nuclear (J) and electron spins of atoms of the magnetic isotope ^{29}Si(J = 1/2) and of the centers of Bi(J = 9/2) [1]. Interestingly, this interaction does not manifest itself in the enriched ^{28}Si(Bi) material (i.e., in so-called ^{28}Si "semiconductor vacuum" where the residual concentration of atoms of ^{29}Si (J=1/2) isotope ambient Bi impurity center is as low as 50 ppm). We believe that the data obtained demonstrate for the first time the influence of a non-local interaction of the spin systems of Bi(J = 9/2) and ^{29}Si (J=1/2) centers in silicon on the essentially local phenomenon of emission of the two-quantum electron-positron annihilation radiation.

The Bi center acquires an open volume V_{op} as a result of interaction with the point defects created by the proton irradiation. It is argued that the thermally stable complex [V_{op} – Bi] possesses D_{3d} symmetry [1]; this comes into line with the data on the electrical properties of the electron-irradiated n–FZ–Si(Bi) material [2]. The complex manifests itself as deep donor center.

The [V_{op} – Bi] center is decomposing during a fast stage of isochronal annealing over the temperature range $\Delta T_{ann.}$= 320 to 470 °C [1]; the estimated activation energy is equal to E_a = 0.89 ± 0.08 eV and is surprisingly close to the energy ~0.92 eV characterizing structural stability of the center where Bi donor impurity atom is coupled with the modeled vacancy (see [1] and references therein). It is worth mentioning that the thermally stable radiation complexes related to the phosphorus (P) impurity centers in the proton-irradiated material are annealed during a somewhat broader stage, $\Delta T_{ann.}$= ~ 430 to ~ 650 °C (E_a = 1.05 ± 0.21 eV [3,4]).

The results available for the Bi and P centers of radiation origin in FZ silicon are compared and the conclusion is made about necessity of reconsideration of a whole conception of formation of point radiation defects in moderately doped n–type silicon subjected to irradiation with protons and electrons [5].

Towards Artificially Intelligent Microscopy of Functional Materials Steven R. Spurgeon; Pacific Northwest National Laboratory, United States

Artificial intelligence (AI) promises to reshape scientific inquiry and enable breakthrough discoveries in areas such as quantum computing, energy storage, and advanced manufacturing. While it is now possible to produce materials in almost limitless configurations, engineering of desirable functionality depends on precise control of structure and defects across scales. Complex synthesis pathways can lead to significant deviations from idealized structures,

which occur at length and time scales that are challenging to probe experimentally and theoretically. Mastery of materials is therefore predicated on the ability to acquire and act on complex, heterogeneous, and fast-evolving microscopy data streams, a task uniquely suited to emerging AI and machine learning methods. Here I will discuss my research efforts to develop a new framework for materials discovery, leveraging embedded automation, domain-grounded analytics, and predictive control for human-like reasoning. I will show how AI is transforming the present and future of materials discovery and design, allowing us to richly manipulate matter for emerging technologies.

9:00 AM *CH02.08.02
Elucidating Metal and Oxide Nanoparticle Surface Dynamics through *In Situ* TEM and Artificial Intelligence Piyush Haluai[1], Mai Tan[1], Adrià Marcos Morales[2], Matan Leibovich[2], Sreyas Mohan[2], Yifan Wang[1], Carlos Fernandez-Granda[2] and Peter A. Crozier[1]; [1]Arizona State University, United States; [2]New York University, United States

Nanoparticle systems often show high degrees of instability which are strongly influenced by size and ambient environment. These dynamic structural changes modify material properties such as reactivity, phase changes and catalysis. Atomic-level surface dynamics may play a significant role in defining particle structures and functionalities but characterizing nanoparticle surface structures with high spatial and temporal resolution simultaneously has proven challenging. Transmission electron microscopy (TEM) is a key tool to visualize local atomic structure of nanoparticles. Ultrafast TEM can now achieve picosecond temporal resolution but is limited to a spatial resolution of about 2 nm. Fortunately, modern detectors now provide readout rates in excess of 1000 frames per second, offering the potential to investigate atomic-level structural evolutions with time resolutions down to a millisecond. However, in most situations, the need to limit electron dose rates results in high temporal resolution movies that are dominated by shot noise, which often obscures surface structural dynamics. In order to address this challenge, we propose a fully-unsupervised AI denoising framework, which enables recovery of atomic-resolution information from such data. The unsupervised deep video denoising framework [1] improves the signal-to-noise ratio (SNR) by a factor of 30 at a spatial resolution of 1 Å and time resolution of 10 ms. For this investigation, we explore structural dynamics of metal and oxide nanoparticle particles under combinations of CO and O_2 at temperatures up to 300ºC. The enhanced time resolution reveals that supposedly stable, low-energy surfaces can display highly active dynamics, triggering nanoparticle instabilities resulting in rapid structural fluctuations. The new spatiotemporal capability enabled by the proposed framework dramatically enhances our ability to explore surface dynamics and the evolution of metastable states in nanoparticles at the atomic level, offering new insights into their functionality.

***In-Situ* Observations of Non-Classical Crystal Growth of Au Nanoparticles on Hematite** Xiang Wang[1], Sichuang Xue[1], Xin Qi[2], Duo Song[1], Maria Sushko[1], Xin Zhang[1] and Kevin Rosso[1]; [1]Pacific Northwest National Laboratory, United States; [2]Dartmouth College, United States

A significant research gap exists regarding the comprehensive investigation of crystallization mechanisms and facet-dependent stability of atomically precise metal clusters on metal oxide nanoparticles. To address this gap, our study focuses on a detailed examination of the sintering process of gold (Au) on facet-controlled hematite (α-Fe_2O_3) {104} and {001} nanoparticles through in-situ TEM observation. Our findings reveal the existence of three distinct crystal growth pathways of Au on hematite nanoparticles: Ostwald ripening, particle coalescence, and disordered intermediate-phase-mediated growth, where particle coalescence plays a dominant role in the sintering process. Furthermore, analysis of Au crystal growth kinetics on different hematite facets highlights the important influence of interfacial structure on the process, where hematite {001} stabilizes Au nanoparticles and suppresses their sintering more effectively than {104} facets. First-principles density functional theory calculations and atomistic molecular dynamics simulations with enhanced sampling provide valuable support for the crystal growth pathway selection of Au nanoparticles on hematite. Our research significantly contributes to the understanding of metal crystallization on hematite surfaces and offers essential guidelines for selecting hematite supports for heterogeneous catalysts.

9:45 AM CH02.08.04
Interface Strains in 1D and 2D Si/Ge Structures for Quantum Computing Alicia Ruiz-Caridad[1], Arianna Nigro[1], Nicolas Forrer[1] and Ilaria Zardo[1,2]; [1]Universität Basel, Switzerland; [2]SNI, Switzerland

During the last decade great efforts were put in the development of materials for quantum computing for its outstanding properties such as high speed, large store capacity and low power consumption [1]. Silicon is the preferred platform for microelectronics infrastructures due to its scalability, low economic costs, harmless for the environment, established fabrication processes and easy implementation of advanced engineering techniques [2,3]. Moreover, silicon is a good quantum material due to its long coherence time of spins of localized electrons and efficient controllability [4]. Germanium is a semiconductor material compatible with silicon. Material engineering of Si-Ge in form of epitaxial planar heterostructures or nanowires lead to enhanced mobility properties for quantum purposes. Despite, strains arising from the 4% mismatch between Ge and Si lattice parameter create defects, these defects hinder mobility. With the purpose to achieve higher mobility, scattering must be minimized by diminishing strains and interface roughness. In this regard, an effective tool to evaluate strains and interface roughness is electron microscopy combined with Raman spectroscopy which allows structural and chemical characterization of samples at the nanoscale.
In this work, we growth by chemical vapor deposition (CVD) 2D and 1D structures: (i) planar heterostructure's composed with variable percentage of Si/Ge barrier's and a Ge QW; and (ii) Ge-Si core-shell nanowires for quantum computing purposes. In a first step we chemically and structurally localized the Ge and Si by energy-dispersive X-ray (EDX) spectroscopy and scanning transmission electron microscopy (STEM) techniques. Finally, we aim to study strain of the Ge QW and core-shell interfaces by means of geometric phase analysis (GPA) and µ-Raman spectroscopy. High-resolution transmission electron microscope (HR-TEM) images of the samples were performed in a Jeol JEM F200 cFEG TEM/STEM to evaluate roughness of interfaces and defects. GPA is a microscopic technique by TEM based on the signal processing of HR-TEM images and its Fourier transform. For the µ-Raman measurements were performed at 633 nm wavelength in back scattering geometry with the help of a Horiba T64000 triple spectrometer and a liquid nitrogen-cooled CCD detector. The combination of both methods permits the control, calculation and mapping of strains in different directions (rotation xy, ε_{xx}, ε_{xy} and ε_{yy}) at high precision. By engineering the core-shell diameter ratio in 1D structures and Si_xGe_{1-x} composition of the barriers and Ge QW thicknesses in 2D structures, we proved and measured tensile/compressive strains in the interfaces between Ge QW and SiGe barriers and between core and shell NWs making our material suitable for integration in Si platforms for.quantum computing applications.

Advanced *In-Situ* Electron Microscopy for Energy and Quantum Materials Yimei Zhu; Brookhaven National Laboratory, United States

In this presentation, I will give an overview of our recent work on advanced in-situ microscopy characterization of energy and quantum materials. I will focus on the correlation of electrons, spin and lattice and their degrees of freedom as well as the critical roles of heterogeneity, interfaces, and disorder under external electric, magnetic and photonic excitations to reveal materials' response. For instance, I will show our cryogenic microscopy study of atomically resolved imaging and electron energy-loss spectroscopy to understand the interface-enhanced superconductivity and of Lorentz phase microscopy to explore the intriguing transformations among various topological chiral spin states including skyrmions under applied electromagnetic fields. Studying spin wave dynamics in nanoscale magnetic architecture under microwave excitation and Li-ion transport mechanisms of battery materials with ionic liquid in operando will also be presented.
The author would like to acknowledge the electron microscopy group at CMPMS, BNL for assistance. The work was supported by the US DOE/BES-MSED under Contract DE-SC0012704.

Investigation of Dislocation-Controlled Domain Nucleation and Domain-Wall Pinning in Single-Crystal $BaTiO_3$ by Multi-Stimuli MEMS-Based *In Situ* TEM Tianshu Jiang[1], Fangping Zhuo[1], Oscar Recalde[1], Yevheniy Pivak[2] and Leopoldo Molina-Luna[1]; [1]TU Darmstadt, Germany; [2]DENSsolutions, Netherlands

Engineering domain walls at the nanoscale to influence macroscopic functional properties presents significant potential in electromechanics and electronics. This potential is particularly apparent in introducing topological defects into functional materials, highlighting the broad possibilities in this area. However, our comprehensive understanding of defect-mediated domain nucleation and domain wall mobility remains limited.

In this work, we achieved well-aligned dislocations with {100}<100> slip systems oriented in the [001] out-of-plane direction in single-crystal $BaTiO_3$. This was accomplished through high-temperature uniaxial compression on a notched sample. Utilizing MEMS-based *in situ* heating and cryo scanning/transmission electron microscopy (S/TEM), we were able to observe the dislocation-mediated domain nucleation and dynamic interactions between domain walls and these topological defects. These observations spanned a wide temperature range, from -175 °C to 200 °C, covering all phases of $BaTiO_3$ from rhombohedral to cubic, offering high-resolution insights into the electro-mechanical interactions within this ferroelectric material. Furthermore, we explore the direct manipulation of the domain wall motion using *in situ* biasing TEM. Under various stimuli, we observed the pinning of ferroelastic domain walls by these imprinted dislocations, attributed to the stress fields from the dislocations.

Our findings not only deepen the understanding of domain wall engineering in ferroelectric materials but also introduce a novel approach suitable for both advanced nanoelectronics and bulk applications across various temperatures.

Facilitating *In Situ* 4D STEM with Advances in Software for Ultrafast Direct Detectors Barnaby D. Levin, Aziz Aitouchen and Benjamin Bammes; Direct Electron LP, United States

Four-dimensional scanning transmission electron microscopy (4D STEM) involves imaging a diffracted electron beam with a pixelated detector at each probe position of a STEM scan. The resulting information-rich datasets allow multiple types of analyses of a specimen, including high-resolution structural visualization, and mapping of crystal grain structure, molecular orientation, strain, electric and magnetic fields, and more [1]. Typically, 4D STEM involves recording large (several Gigabyte to several Terabyte) 4D datasets to disk to be analyzed with post-acquisition software such as LiberTEM [2], py4DSTEM [3], or custom written code. Post-acquisition analysis enables a range of complex data analysis techniques to be applied to the data, but the efficiency of 4D STEM experiments can be severely impacted by the substantial time needed to go from data acquisition to data visualization.

Lack of real-time visualization poses challenges for both manual data acquisition, and for the development of automated 4D STEM workflows. However, with ultrafast direct detectors, such as the Celeritas XS camera, able to acquire data at rates approaching 5 Gigabytes per second, developing real-time 4D STEM analysis software involves its own significant challenges. These challenges are compounded when considering *in situ* 4D STEM, (sometimes referred to as 5D STEM), where the goal is not only to record one large 4D dataset, but multiple large 4D datasets over a period of time so that dynamic processes such as changes in strain, crystal structure, or electric fields in a specimen can be observed [4].

Here, we present a new 4D STEM software platform that aims to address these challenges by leveraging GPU processing for real-time virtual STEM image generation during repeated 4D STEM acquisition. The software is compatible with Direct Electron's Celeritas XS, Celeritas, DE-16, DirectView2 and DE-64 cameras, as well as the DE-FreeScan scan generator, and allows the user to stream a series of full 4D STEM datasets to disk, even whilst simultaneously generating a live-view of up to four different types of virtual STEM image. In addition to viewing virtual images and camera frames in the software's native interface, the system can be controlled via an API, allowing for integration into 3rd-party software, as well as custom software for microscope automation.

Further developments are ongoing to augment this software platform with additional features with the goal of making 4D STEM and *in situ* 4D STEM more accessible techniques for electron microscopists to perform.

Recent Developments of High Energy Resolution X-Ray Spectroscopic Methods for Energy Materials at NSLS-II Denis Leshchev and Eli Stavitski; Brookhaven National Laboratory, United States

X-ray absorption spectroscopy (XAS), first used to be applied in the field of energy materials, such as catalysts, over 50 years ago, has evolved into an indispensable tool in the arsenal of characterization techniques. XAS is element-specific method which compatible with a variety of sample environments, enabling in situ and operando experiments. An extension of XAS spectroscopy, high energy resolution (HR) X-ray spectroscopy, a collection of techniques which resolves the energy of the fluorescence photons with high accuracy, opened new opportunities in the field [1]. Among these methods is a high-energy resolution fluorescence detection (HERFD) XAS allows to overcome the limitations of traditional XAS by selectively detecting fluorescence photon within narrow energy band. Another is Valence-to-Core X-ray Emission Spectroscopy (VtC XES) which probes electronic states in the valence band, making is a far more sensitive to subtle electronic changes than the traditional Extended X-ray Absorption Fine Structure (EXAFS). In this contribution we review recent innovations at the National Synchrotron Light Source II (NSLS-II) which enable applications of HR XAS to energy-relevant systems as well as several examples to demonstrate the advantages of these techniques.

SESSION CH02.09: New Applications in *In-Situ* Microscopy and Spectroscopy
Session Chairs: Qianqian Li, Qianqian Li, Leopoldo Molina-Luna, Yaobin Xu and Di Zhang
Friday Afternoon, April 26, 2024
Room 440, Level 4, Summit

2:00 PM CH02.09.01
Novel Environmental TEM Holder for *In Situ* Research of Nano-Electronic Devices and Energy Materials Yevheniy Pivak[1], Oscar Recalde[2], Hector H. Perez-Garza[1] and Leopoldo Molina-Luna[2]; [1]Denssolutions, Netherlands; [2]TU Darmstadt, Germany

The rapid development of in situ transmission electron microscopy (TEM) has become possible due to advancements of the functionalized microelectromechanical systems (MEMS)-based sample carriers. Nowadays, there exists a great variety of MEMS chips that enable the application of an individual stimulus like thermal, electric, gas, liquid, force, etc. or, usually, a combination of two stimuli. Specifically, multi thermal and electric stimuli have been extensively used to study electronic and energy materials and devices like ferroelectrics, magnetic materials, solid state batteries, thermoelectric, memristors, solar cells and many more.
The study of structure and electrical properties of nano-electronic materials and devices is mainly performed in vacuum. This, however, doesn't represent real-life working conditions as the presence of oxygen might lead to different behaviour and properties of materials. An environmental TEM can be used to perform an in situ heating and biasing experiments in an atmosphere, but the gas pressure is limited to roughtly 20 mbar which still possess a challenge. In this work we present the development of a new multi-stimuli environmental TEM sample holder. The holder allows the application of thermal and electrical stimuli in ambient environmental conditions. This is achieved through a newly designed dual chip environmental cell with an increased number of contacts. Additional electrodes on the chip are used to prepare a FIB lamella and to characterize the electrical performance of the sample either in 2- or 4-contact mode. Using a newly developed FIB sample preparation procedure, it is possible to prepare contamination-free samples on gas, heating and biasing chips with no electrical short circuits and minimized leakage currents. This development represents a significant step forward towards the realization of real operational conditions inside the TEM offering the potential to further explore and deeper understand of the real properties of nano-electronic devices and energy related materials.

2:15 PM CH02.09.02
Investigation of Amorphous Silicon Nanoparticles dispersed in Silicon Nitride Passivation Layer for Semiconductor Industry Filippo Sabatini[1,2]; [1]Politecnico di Milano, Italy; [2]ST Microelectronics, Italy

During the formation process of a typical integrated circuit (IC), a passivation layer is deposited to protect the internal semiconductor device after the metallization steps. These passivation layers are typically formed by oxide or nitride layers, most of the time deposited by plasma enhanced chemical vapor deposition (PECVD). As part of my PhD research, in collaboration between Politecnico di Milano and ST Microelectronics, I had to perform extensive characterization of different types of silicon nitride (SiN) in order to optimize its adhesion with an epoxy resin deposited on top of it. During these analysis, I detected the presence of amorphous silicon clusters dispersed within the nitride matrix through the presence of strong photoluminescence (PL) effects observed by Raman spectroscopy characterizations. Photoluminescence effects generally originate from the presence of defects or inhomogeneities of such size as to generate energy quantization. In both cases, electrons in the material, excited by the Raman laser beam, occupy energy levels intermediate to the energy gap and subsequently decay emitting photons that result in the formation of very intense bands in the Raman spectrum, called photoluminescence bands. This phenomenon was most pronounced in SiN samples with higher silicon overstoichiometry, which was intentional by company recipe and confirmed by XRD analysis. The silicon overstoichiometry thus led to spontaneous segregation of amorphous silicon into nanoparticles dispersed in the silicon nitride matrix and this phenomenon is almost nonexistent in samples with stoichiometries closer to equilibrium (%At Si/N equal to 0.75). To corroborate the assumptions made from the photoluminescence phenomenon, it was possible to directly observe the nanoparticles by TEM microscopy in some of the characterized samples.

The presence of these nanoparticles is not only interesting from an academic point of view, but could also have an interesting application aspect: one of the major criticalities of passivation layers is their high fragility, and the presence of inhomogeneous agglomerates could lead to an increase in the toughness of the material due to *crack deflection* phenomena, which have been studied for years in the field of composite materials. This effect occurs when the crack sliding is delayed by the presence of areas with a different thermal expansion index from that of the matrix: at the interface between these areas occurs the formation of compressive or tensile stress fields which attract or repel the crack tip, forcing it to deflect its path and thus increasing the energy required to slide (hence the toughness of the material). The phenomenon of *crack deflection* is generally observed in composite materials in which the inhomogeneity has a significant size, comparable to or larger than that of the crack tip. In the case of "Silicon Rich" silicon nitride (the sample with high silicon overstechiometry), the nanoparticles observed are too small in size to make an effective contribution to the toughness of the material, and for this reason my project has now focused on finding deposition methods that can lead to the formation of larger amorphous silicon agglomerates.

Obtaining a material suitable for the role of a passivation layer that at the same time exhibits high toughness would be a great step forward in the semiconductor manufacturing industry and could solve several crack failure issues that usually form large blocking point in the development of new devices.

2:30 PM CH02.09.03
Bypassing The Energy Gap Law in Organic Semiconductors Pratyush Ghosh, Richard Friend and Akshay Rao; University of Cambridge, United Kingdom

Strong nonradiative recombination mediated through exciton-phonon coupling has been a major limitation for efficient emission in organic semiconductors. This effect is far more pronounced for low energy-gap materials as predicted by the energy-gap law. High-frequency quantum modes (skeletal C-C, C=C stretching vibrations) are the major channels of non-radiative recombination.
In recent years, spin-radical doublet emitters have emerged as the highest efficiency deep red/nir OLEDs. We are exploring the vibrational coupling of the photoexcited states of these materials by tracking vibrational coherences generated by impulsive photo-excitation with an ultrashort laser pulse. This experiment is known to be impulsive vibrational spectroscopy (IVS) and our method shows the application of this technique to probe exciton-phonon coupling in semiconductors. For the CT-type doublet emitters and certain TADFs, we find the absence of any coupling to high-frequency vibrational modes, which is conventionally considered unavoidable in organics. This is potential to provide a real clue behind the high photoluminescence yield of these materials. We also revealed that the extent of the high-frequency vibrational coupling is related to the nature of the delocalization of the electronic state.
With a joint contribution of IVS supported with first-principle calculations, our work suggests a molecular-level design principle of next-generation organic semiconductors with limited non-radiative loss.

2:45 PM CH02.09.04
AFM-SEM Correlative Microscopy Imaging for TEM Grid Mounted Samples Stefano Spagna[1], Kerim Arat[1], Will Neils[1], Christian H. Schwalb[2], Hajo Frerichs[2], Sebastian Seibert[2], Lukas Stuhn[2] and Marion Wolff[2]; [1]Quantum Design Inc., United States; [2]Quantum Design Microscopy GmbH, Germany

Microscopists utilizing Transmission Electron Microscopy (TEM) and TEM based Energy Electron Loss Spectroscopy (EELS) in their studies, frequently require the characterization of physical parameters such as heights and cross-sectional shapes of the examined sample[1]. Because of the typical sub-five nanometer thickness of membranes in TEM grids, Atomic Force Microscopy (AFM) measurements of grid mounted samples are presently challenging and time consuming. In this paper, we present the first truly integrated AFM and Scanning Electron Microscope (SEM) correlative workstation[2], which allows imaging of samples directly on a TEM grid, utilizing these two techniques. The highly integrated and easy-to-use AFM-SEM microscopy workstation opens unprecedented measurement capabilities at the nanoscale in challenging geometries. AFM-SEM imaging of TEM grid mounted samples simplifies measurement workflows to yield a higher rate of data output. In addition to topography measurement, the platform allows easy expansion of capabilities, such as elemental analysis via Energy Dispersive X-ray Spectroscopy (EDS). The rich set of AFM modes (Contact, Tapping, Off-resonance, Conductive, Magnetic, and Electrostatic) allows the extraction of various physical properties from the sample.

***In Situ* Characterization Possibilities at The Mosaic Platform - JANNuS-Orsay Present and Future** Stephanie Jublot-Leclerc, Frederico Garrido and Aurelie Gentils; Universite Paris-Saclay, CNRS/IN2P3, IJCLab, France

Mosaic is the new name of the platform involving the ion accelerators and the tools of chemical and structural characterization of materials located at IJCLab [1]. This includes the JANNuS-Orsay experimental hall, which is in particular known from the community of nuclear materials for the diversity of ion beams that can be produced, as well as the possibilities of *in situ* characterization of the microstructural evolution of ion implanted or irradiated materials. *In situ* Transmission Electron Microscopy (TEM) with one or two ion beams can be performed in a large range of temperatures for studies at the nanometric scale. The damage induced in a single crystal can also be studied through *in situ* Rutherford Backscattered Spectrometry in Channelling

geometry (RBS-C) experiments thanks to the coupling of two ion accelerators. The possibilities, and some limitations, of these two *in situ* characterization methods currently available at Mosaic will be developed through a few examples of experiments performed on materials of interest for nuclear applications. The Mosaic platform is also in the process of completing its range of *in situ* tools for the characterization of irradiated materials with the acquisition of an X-ray diffractometer that will be modified for *in situ* measurements, and that will be available at the beginning of 2026. Examples of future possible experiments will be given along with the characteristics of this X-ray diffractometer.

The MOSAIC technical staff, in particular C. Bachelet, C. Baumier, P. Benoit-Lamaitrie, J. Bourçois, L. Delbecq, S. Hervé, C. Oriol, F. Pallier, and S. Picard, are gratefully acknowledged for their unfailing assistance during *in situ* experiments.

11:00 AM *CH03.01.02
Developing a Comprehensive *In-Situ* Irradiation Testing Facility at Tennessee Ion Beam Materials Laboratory Khalid Hattar and Miguel Crespillo; University of Tennessee, United States

Validating and refining simulation of reactor materials evolution for either next generation fission or fusion energy systems, as well as models to extend the lifetime of current reactor fleet would benefit from controlled experiments in coupled extreme environments. This presentation will highlight the expansion of Tennessee Ion Beam Materials Laboratory (TIBML) from a world-class Ion Beam Analysis (IBA) facility based on a 3 MV Tandem Accelerator to a diverse facility designed to understand materials and device evolution in coupled extreme environments. To expand the irradiation environment, the facility will be adding a 300 keV NEC implanter, 20 kV and 5 kV Nonsequitur ion sources, a 30 kV Kimball Physics electron gun, and a Nd:YAG laser from Quantum-Ray with output energies up to 1 J at 1064 nm. The facility is already capable of performing ion irradiation and implantation experiments at temperatures ranging from 30 to 1473 K. In addition, the TIBML facility is developing capabilities to perform in-situ irradiation during photoluminescence, cathodoluminescence, ion beam induced luminescence, Raman, acoustic emission, IBA, nanomechanical testing, and Scanning Transmission Electron Microscopy (STEM). The latter will be done utilizing a higlhy modified JEOL 2100+ that was installed in October of 2023. The high tilt polepiece, additional electron beam condenser lens, and LaB_6 filament were selected to optimize the characterization of radiation damage. In addition, the STEM was coupled with Nanomegas Automated Crystallographic Orientation Mapping (ACOM) and Theia scientific edge computing systems for machine learning to characterize the impact of radiation damage on phase, orientation, and grain boundary evolution, as well as the size distribution of internal matrix radiation damage, respectively. This presentation will highlight the current status of the TIBML facility development and the initial results of the coupled environment. Finally, this presentation will discuss the potential future opportunities to explore increasingly complex coupled environments in a controlled manner.

11:30 AM CH03.01.03
Deployment and In-Reactor Testing of an Instrument for Real-Tme Monitoring Thermal Conductivity Evolution of Nuclear Fuels Zilong Hua[1], Caleb Picklesimer[1], Austin Fleming[1], David Hurley[1], Weiyue Zhou[2], Michael P. Short[2] and David Carpenter[2]; [1]Idaho National Laboratory, United States; [2]Massachusetts Institute of Technology, United States

Thermal conductivity of nuclear fuels directly ties to the reactor safety and efficiency. Because of the microstructure defects generated and evolved in the extreme reactor environment, thermal conductivity of nuclear fuels reduces significantly during the reactor operation. Currently the experimental efforts on understanding such effects are primarily from the post-irradiation-examination (PIE) testing. However, an important type of phonon scatters, point defects, anneal at high temperature after the reactor shutdown and before PIE can be performed. In order to fill this technical gap, we developed an instrument that can perform real-time thermal conductivity measurements in reactor. Here we presented the latest testing results of this instrument in Massachusetts Institute of Technology Research Reactor (MITR). The final objective is to provide the routine measurement capability of thermal conductivity of nuclear fuels and materials in reactor. It will make better understandings of the scattering mechanisms between defects and thermal carriers possible, and help predict the fuel performances in reactor.

SESSION CH03.02: Equipment and *In Situ* Platforms for Characterization of Nuclear Materials II
Session Chairs: Aurelie Gentils, Mercedes Hernandez Mayoral and Djamel Kaoumi
Tuesday Afternoon, April 23, 2024
Room 441, Level 4, Summit

1:30 PM *CH03.02.01
An *In-Situ* Platform for Studying Metal Films under Simultaneous Extreme Conditions in The SEM Benjamin K. Derby[1], Eric Lang[2], Trevor Clark[2], Ryan Schoell[2], Jon Baldwin[1], Darrick Williams[1], Michael McBride[1], Khalid Hattar[2] and Nan Li[1]; [1]Los Alamos National Laboratory, United States; [2]Sandia National Laboratories, United States

We report on a novel technique for the in-situ characterization of a sample exposed to ion irradiation in a corrosive medium. A sample chamber has been built that can expose a metal film to a corrosive liquid environment and placed into the environmental scanning electron microscope (SEM) in line with the ion beam accelerator located at the Center for Integrated Nanotechnologies' (CINT) Ion Beam Laboratory (IBL) at Sandia National Laboratory. In this work, we expose an epitaxial Fe thin film grown on MgO to 6 MeV Fe ions while the sample surface is exposed to pure H20, 0.1M NaCl, and 0.1M B4Na2O7 solutions. SEM imaging and post-mortem XEDS captured the complex oxide development on the surface over time. This experiment elucidates how the ion beam affected the complex oxide growth in the corrosive media, and how the surface oxide impacts further corrosion processes. This understanding will directly inform the development of new materials required for future nuclear energy sources.

2:00 PM CH03.02.02
Towards Measuring Hydrogen Dynamics in Yttrium Hydride Moderators James Torres[1,2], Alexander Long[2], Dale T. Carver[2], Sven C. Vogel[2], Aditya Shivprasad[2], Tyler Smith[2], Caitlin Kohnert[2], Erik Luther[2] and Holly Trellue[2]; [1]Oak Ridge National Laboratory, United States; [2]Los Alamos National Laboratory, United States

A compact, nuclear microreactor that utilizes low-enriched uranium fuel is a promising solution to meet US demands in remote and decentralized energy grids. Yttrium hydride (YH) is the candidate moderator material for the microreactor design, chosen based on its superior retention of hydrogen at high temperatures. Hydrogen diffusion properties in YH are highly sought after for computer model validation and reactor prototyping. To meet design

objectives, the so-called compact dual-zone furnace was developed at the Los Alamos Neutron Science Center (LANSCE) with the goal of characterizing hydrogen diffusion in YH samples as a function of applied temperature gradients. Herein, we share our recent progress in technique and hardware developments and include initial results from recent concentration- and temperature-gradient measurements at LANSCE.[i]

2:15 PM *CH03.02.03
Characterization of The Solid Electrolyte Interphase with Cryogenic Ion and Electron Microscopy Hyeongjun Koh, Eric Detsi and Eric A. Stach; University of Pennsylvania, United States

Characterizing the nanoscale structure and chemistry of energy storage materials is critical due to their significant impact on battery performance. However, conventional sample preparation methods required for high-resolution imaging often fundamentally alter reactive battery components. In this work, the authors employ cryogenic focused ion beam milling (FIB) in a plasma-focused ion beam/scanning electron microscope system to prepare sensitive lithium metal specimens, allowing them to assess potential ion beam damage. Cryogenic transmission electron microscopy reveals that while the lithium itself is not damaged during cryo-FIB milling, lithium oxide shells form around the sample in the instrument chamber, evidenced by diffraction data from thin lamellae prepared at two different thicknesses. Cryogenic electron energy loss spectroscopy further confirms the oxidation of lithium during sample preparation. Consulting the Ellingham diagram indicates that lithium can react with trace oxygen gas in the FIB/SEM chamber at cryogenic temperatures; notably, liquid oxygen exposure does not contribute to lithium oxidation here. This approach allowed the examination of Li metal batteries with vitrified liquid electrolytes and facilitated the discovery of an elusive solid-electrolyte interphase (SEI) component, lithium fluoride. This has not been observed when using conventional sample preparation techniques involving rinsing. Furthermore, diffraction data reveals the presence of short-range order at different regions in the SEI structures, presumably influencing and controlling lithium metal growth. Overall, these results highlight the valuable role cryogenic lift-out and cryogenic scanning transmission electron microscopy can play in enabling nano- to atomic-scale characterization of energy storage devices containing reactive materials or solid-liquid interfaces.

3:15 PM *CH03.03.01
Contribution of Raman Spectroscopy to The Understanding of Defect Formation Mechanisms Gaelle Gutierrez, Arthur Georgesco, Claire Onofri-Marroncle and Dominique Gosset; CEA, France

Ion accelerators have been used for decades to study radiation damage in nuclear materials, simulating their behavior in reactors. The diversity of irradiation conditions (ions, energy, fluence, temperature, etc.) is a major advantage of ion beams. This allows for systematic studies aimed at better understanding defect formation mechanisms and the resulting microstructural evolution. Additionally, the very short irradiation times and the handling of non-radioactive samples significantly reduce the cost and duration of experiments compared to reactor irradiations. The coupling of multiple ion beams, the use of heated/cooled sample holders, and the implementation of in situ characterization open the way for real-time observation of microstructure evolution under various extreme radiation conditions. Among these techniques, Raman spectroscopy provides a quick and non-destructive means to monitor vibrational mode evolution. Under irradiation, structural bands evolve, indicating the level of stress and the local structural disorder. Some bands may also appear, providing information about the level of damage and the type of defects formed.
The JANNuS Saclay platform is equipped with a Raman spectrometer installed in the triple-beam irradiation chamber [1]. This allows for in situ monitoring of vibrational modes when atomic displacements and/or ionizations and electronic excitations are generated within the structure. Studies have thus highlighted the use of Raman spectroscopy in characterizing amorphization mechanisms or phase changes occurring under irradiation [2-4]. In non-amorphizable systems, in situ measurements provide insights into damage kinetics related to the formation of point defects [5].
This paper will focus on several examples illustrating the use of ion beams coupled with Raman analyses to investigate the radiation resistance of current and future nuclear ceramic materials.

Uncovering Grain Boundary Metastability as a Response to Radiation in FCC and BCC Single Phase Compositionally Complex Alloys Anne Barnett, Emily Hopkins, Mitra L. Taheri and Michael Falk; Johns Hopkins University, United States

Compositionally complex alloys (CCAs) are promising for the future materials of extreme radiation environments, but nuances in unique defect formation and evolution properties have yet to be thoroughly understood. In comparison to their dilute and pure counterparts, both fcc and bcc complex alloys retain local chemical order which increases the radiation tolerance due to a convoluted matrix defect bias. This bias profoundly influences grain boundary (GB) metastability under irradiation conditions, resulting in an increase in radiation tolerance with alloy complexity. A combined molecular dynamics and experimental in-situ study is preformed to demonstrate GB metastability during point defect bombardment, highlighting the fundamental differences between fcc and bcc alloys, in addition to environments with and without local chemical order.

4:00 PM CH03.03.03
Clarifying Phase Instabilities Induced by Irradiation in a FCC-Based FeNiCrMn HEA through *In-Situ* Irradiation Antoine Dartois[1], Maylise Nastar[1], Brigitte Décamps[2], Anna Fraczkiewicz[3] and Estelle Meslin[1]; [1]Université Paris-Saclay, CEA, France; [2]Université Paris-Saclay, France; [3]MINES St-Etienne, France

Recent studies have highlighted the promising behavior of High Entropy Alloys (HEAs) under irradiation, exhibiting improved swelling resistance [1] and

reduced radiation-induced segregation (RIS) [2]. For evident safety concern, they need to maintain high single-phase stability to ensure stable mechanical properties under operating conditions.

In this context, our study focuses on the quaternary $Fe_{37}Ni_{34}Cr_{16}Mn_{13}$. Before irradiation, this high-purity alloy, annealed at 1473 K for 4 hours, is a single FCC phase. However, after heavy-ion irradiation within the JANNuS Saclay facility at 823 K up to 2 dpa, phase instability was detected by means of CTEM (Conventional transmission electron microscopy) and STEM/EDX (Scanning TEM/Energy dispersive X-rays) within a double-corrected Jeol Neo-ARM TEM.

It is well known that irradiation generates point defects – vacancies and self-interstitials – that subsequently agglomerate into dislocation loops, voids or precipitates [3]. Besides, net fluxes of point defects toward sinks lead to RIS potentially leading to radiation-induced precipitation (RIP) [4].

In the current study, phase instability is characterized by the precipitation of nanometer-sized Cr-Mn enriched precipitates. These intragranular precipitates have a spherical shape with an approximate diameter of 10 nm. Their crystallographic structure needs to be examined thoroughly. Considering previous analyses on similar alloys [5], a BCC phase could be expected. The matter balance between self-interstitial atoms (SIAs) and vacancies respectively stored into dislocation loops and precipitates tends to confirm the less dense BCC structure of the precipitates. We hence may expect these precipitates to result from a RIP mechanism explained by the elimination of irradiation-generated vacancies accommodating the volume mismatch between less dense precipitates and the matrix [3].

This phase instability is also correlated with a microstructural evolution. Indeed, both faulted and perfect dislocation loops are formed. According to atom probe tomography (APT) and STEM/EDX analysis, RIS occurs at these radiation-induced defects. Indeed, a strong Ni enrichment and Fe, Mn and Cr depletions, have been detected. An inverse Kirkendall model of atomic fluxes, mediated by vacancies and fitted on tracer diffusion coefficients of the well-known FeCoCrMnNi Cantor alloy, corroborates the identified RIS trend. We highlight a reduced Cr depletion, compared to conventional austenitic steels [6], potentially reducing the irradiation-assisted stress corrosion cracking (IASCC) phenomena.

In order to elucidate the precipitation mechanisms, microstructures exposed to several radiation doses have been compared. First, samples have been irradiated from 0.2 dpa to 2 dpa. Secondly, an analysis of the microstructure at increasing thicknesses has enabled us to compare various stages of irradiation progress. Indeed, point defects elimination on surfaces is stronger in thinner areas, where effective damage is therefore reduced, whereas this phenomenon is negligible in thicker areas, experiencing a stronger effective damage. On-zone axis STEM imaging shows the formation of a dislocation network, resulting from the interaction of perfect loops as well as a decrease of the density of both Frank loops and precipitates with increasing depth.

To further investigate the precipitation mechanisms, in-situ irradiations are essential. These will be conducted inside a TEM in November 2023 within the JANNuS-Orsay facilities, to track both the microstructural evolution as well as the precipitation using electron diffraction spots signal produced by the formation of Cr-Mn precipitates.

Effect of Al Addition to The Multi-Principal Elemental CrFeMnNi Alloy System in Terms of The Resulting Microstructure and Radiation Resistance Saikumaran Ayyappan[1,1], Kara Krogh[1,1], Geoffrey Beausoleil[2] and Djamel Kaoumi[1,1]; [1]North Carolina State University, United States; [2]Idaho National Laboratory, United States

In recent times, High-Entropy Alloys (HEAs) or Multi Principal Elemental Alloys (MPEAs) have been attracting much attention as new structural materials for nuclear reactor in-core applications due to their structural stability and excellent mechanical properties. However, their microstructural behaviour under irradiation still requires special attention. Particularly, the impact of specific chemical elements on the irradiation response of the alloys still needs to be evidenced and is at the core of this NSF funded project. The current work compares the radiation behaviour of CrFeMnNi, $Al_{0.3}$CrFeMnNi and $Al_{0.8}$CrFeMnNi alloys. The alloys, which were prepared through Plasma Spark Sintering (SPS), were irradiated in-situ in a Transmission Electron Microscope (TEM) using 1 MeV Kr^{+} ions up to 10 dpa at room temperature (RT) and at 300 °C. Since the starting microstructure depends not only on the composition but also on the way of processing, thorough pre-irradiation characterization of all the three alloys was carried out using X-Ray Diffraction (XRD) and TEM which showed the formation of (BCC+FCC) phases in major proportion. Addition of Al resulted in an increase in the proportion of BCC phase along with the formation of NiAl based ordered phase. At RT, with increased irradiation dose, the phases with more uniformly distributed elemental composition showed the dynamic formation and annihilation of irradiation induced defects. However, the Cr-segregated phase in the ($Al_{0.3}$CrFeMnNi) alloy showed amorphization behaviour with increasing irradiation dose. At RT, the alloys did not show the formation of voids or Radiation induced Segregation (RIS). However, at 300 °C, the alloys showed the formation of voids at doses around ~5 dpa. Also, Ni segregation at the void/matrix interfaces has been observed in the $Al_{0.3}$CrFeMnNi alloy at 300 °C. Overall, the void formation was observed to depend on the local chemistry and temperature of irradiation. Additionally, irradiation at 300 °C also resulted in Radiation Induced Precipitation (RIP) in these alloys, the existence of which were confirmed through extensive post-irradiation TEM diffraction analysis, which showed low intensity crystalline spots and streaks around the major diffraction spots. The Cr-rich phase in $Al_{0.3}$CrFeMnNi alloy showed the formation of nano-crystalline features. The Ni-rich phase showed the formation and Nano-structuring of irradiation-induced defects. The in-situ TEM experiments allowed to clearly evidence how variations in local chemistry and microstructural features in these MPEAs affect the local response to irradiation (at the nm/micron level).

Dislocation Loop Evolution in Ni-Based fcc Model Alloys by *In-Situ* Self-Ion Irradiation at High Temperatures Marie Loyer-Prost[1], Kan Ma[1,2], Brigitte Décamps[3], Liangzahao Huang[1], Maylise Nastar[1], M.A. Belghoul[1], Anna Fraczkiewicz[4], Robin Schaüblin[5], Philippe Vermaut[6,7] and Frédéric Prima[7]; [1]Université Paris-Saclay, CEA, France; [2]University of Birmingham, United Kingdom; [3]CNRS, Université Paris-Saclay, France; [4]Ecole Nationale Supérieure des Mines de Saint Etienne, France; [5]ETH Zürich, Switzerland; [6]Sorbonne Université, France; [7]ChimieParisTech, PSL Research University, CNRS, France

Austenitic Stainless Steels (ASSs) are foreseen as cladding material for next generation reactors even though their swelling under irradiation will limit the fuel burnup. Solute elements, such as titanium and carbon, efficiently reduce this swelling but the mechanism is still ambiguous.
Here we focus on the effect of a progressive addition of titanium on the microstructure evolution of nickel at small irradiation dose and on the loop interaction during irradiation. Nickel is considered as a model alloy for ASSs (same crystallographic structure). Pure Ni and nickel alloyed with various percentages of titanium (x ranging from 0.4% to 1.2% by mass), are *in-situ* irradiated at 450°C and 510°C within a Transmission Electron Microscope using the JANNuS-Orsay facility.
The in-situ microstructural evolution and dislocation loop characteristics are finely analyzed in function of specimen composition and doses. We reveal a strong impact of micro-alloying on microstructure: loop nature, growth rate, formation thickness, density, Burgers vector and mobility. A direct correlation of Frank loop morphology and nature is observed. Finally, a temperature-dependent critical Ti content for Frank loop nature is highlighted and discussed.

Investigaion of Grain Growth in Nanocrystalline Oxide Thin Films during Iradiation and Heating using *In-Situ* Tem Dmitrii Kretov[1], Tiffany Kaspar[2], Benjamin K. Derby[3] and Djamel Kaoumi[1]; [1]North Carolina State University, United States; [2]Pacific Northwest National Laboratory, United States; [3]Los Alamos National Laboratory, United States

Grain growth, which occurs at elevated temperatures and under irradiation is manifests by an increase in the average grain size, a decrease in the number of grains, and a decrease in grain boundary total area. Nanocrystalline metals having very small sizes and high GB densities are of interest to the nuclear materials community not only for their improved mechanical properties but also for their radiation resistance, since grain boundaries are effective sinks for radiation-induced defects, ultimately impacting the radiation tolerance of nanocrystalline materials against net defect accumulation. However, even if nanocrystalline metals present increased radiation tolerance at the nanoscale, irradiation-induced grain growth is responsible for grain enlargement and annihilation of these benefits. While the literature shows several studies on this particular topic of grain growth in nanocrystalline metals, very little focus was put on grain growth in nanocrystalline oxides, especially under irradiation. The scarce available literature focuses on fuel oxides. In this work, grain growth kinetics was studied in Fe_2O_3, Fe_3O_4, Cr_2O_3 which are oxides commonly forming on components in nuclear reactor such as the ones made of steel. Thin films with nanocrystalline grain size were grown by Pulse Laser Deposition or Sputtering Deposition and subject to thermal annealing *in situ* in a Transmission Electron Microscope to follow the grain-growth. Samples were also irradiated *in situ* in the TEM at temperatures from 50 K to 773 K using 1 MeV Kr^{2+} ions to 10 dpa to study grain-growth under irradiation. Grain size was measured as a function of time for the thermal grain growth and in terms of irradiation dose (i.e. dpa) for the irradiated samples. The kinetics of grain growth was then discussed in the light of the literature and how it compares to the thermal spike model developed for metals.

Unveiling The Microstructural Evolution in Irradiated Zirconium Alloys Through *In-Situ* Transmission Electron Microscopy Zhongwen Yao; Queen's University, Canada

Understanding the impact of irradiation on the microstructure of zirconium alloys is critical for ensuring the safety and reliability of nuclear reactors. In this presentation, we applied in-situ transmission electron microscopy (TEM) as a powerful tool to unravel the dynamic evolution of zirconium alloy microstructures during irradiation or after irradiation.
Through real-time TEM/STEM imaging, we explore the intricate processes taking place within zirconium alloys, such as Excel alloy, Zr-2.5Nb and Zircaloy as they are subjected to ion irradiation. We observe and analyze the complicated changes in microstructure, including a-type and c-type dislocation formation, defect accumulation, and phase transformations. These microstructural changes have a direct bearing on the material's mechanical properties and dimensional stability, making this research crucial for the nuclear industry.
This presentation highlights the invaluable contribution of in-situ TEM techniques in providing real-time, atomic-scale observations of zirconium alloy behavior during irradiation, paving the way for enhanced material design and reactor safety.

Real Time Monitoring of Defect Evolution and Relaxation by *In-Situ* Positron Annihilation Spectroscopy Farida Selim[1], Adric Jones[2], Thaighang Chung[2], Matthew Chancey[3], Riley Ferguson[3], Peter Hosemann[4], Yongqiang Wang[3] and Blas P. Uberuaga[3]; [1]Arizona State University, United States; [2]Bowling Green State University, United States; [3]Los Alamos National Laboratory, United States; [4]UC Berkeley, United States

In-situ measurements during irradiation are critical to monitor material response to irradiation in real time; several in-situ techniques with remarkable capabilities have been developed to address that and examine material structure, properties, and performance under extreme radiation environments. In-situ TEM has been particularly powerful in monitoring the microstructural changes and growth of cavities in real time during irradiation. However, revealing the mechanisms governing early formation of defects and their evolution in extreme environments require measuring defects on all length scale from atomic- to meso-scale. Positron annihilation spectroscopy (PAS) is uniquely sensitive to atomic scale defects revealing their density and structure even in the very early stages of damage and has been shown to be an effective tool to probe vacancies and stresses in nuclear and structural materials [1,2].
Here we report the first in-situ PAS (iPAS) measurements during high energy ion irradiation. The measurements reveal that vacancies are formed and their number increases during collision cascades without change in structure or clustering. However, vacancies are shown to coarsen, and their structure substantially change during relaxation after ceasing irradiation. The trend is shown to dominate in the low irradiation regime and the defect density

increases linearly with irradiation time up to 0.1 dpa. In higher regime above 1 dpa, vacancies are formed and coarsen during collision cascades. Further, iPAS during annealing reveals the various recovery stages of induced radiation and the defect type involved in each stage. Lastly, I will discuss how iPAS may shed the light on the mechanism behind some interesting phenomena such as radiation induced vacancy injection in muti-phase materials that we recently observed in Fe / Fe_2O_3 bilayers.

This work was funded as part of FUTURE (Fundamental Understanding of Transport Under Reactor Extremes), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences.

***In situ* Performance of Non-Volatile Memory under Mixed Radiation Environment** Chaitanya Sharma and Juan Nino; University of Florida, United States

Nonvolatile memory technologies have paved the way for in-memory computing, eliminating the constant need to move data between storage and processing units. This reduces the von Neumann bottleneck and can significantly boost a system's effective floating operations per second (FLOPs). However, their performance evolution under irradiation from cosmic rays, solar storms, neutrons, and other secondary sources has not been extensively studied. To explore device degradation, we developed a testing apparatus at the University of Florida training reactor (UFTR) to perform in situ electronic measurements under varying gamma and neutron radiation profiles. The 6" diameter cylindrical setup fits inside one of the reactor beam ports and includes a Peltier thermal controller coupled to a 4-terminal electrical microprobe with variable radiation shielding. To delineate different radiation beam environments, specifically gamma rays, thermal, epithermal, and fast neutrons, shielding materials such as borated polyethylene, standard polyethylene, and lead are used. Here, we demonstrate the platform's effectiveness by examining self-directed channel (SDC) memristors, ferroelectric capacitors (FeCAPs), and resistive random-access memory (ReRAM) devices both in volatile and non-volatile configurations (i.e., 1T-1R and 1R). The experiments were conducted within the temperature range of -30° C to 120° C across a range of reactor power levels from 1W to 10kW with a total flux of 2.035 x 10^8 particles/cm^2 at 100kW. We will further discuss radiation effects pertinent to various memory architectures, elaborating on device failure induced under radiation and total ionizing dose.

Beam-On Effects during Irradiation of Nuclear Materials Michael P. Short; Massachusetts Institute of Technology, United States

In situ characterization methods for nuclear materials performance hold enormous promise for faster discovery of nuclear materials science, radiation effects, and down-selection of optimal alloys for nuclear power applications. Advancements in combining traditional irradiations and post-irradiation examination with new, rapid analysis tools promises, and will be shown in this talk, to hasten data throughput by up to 1000x compared to purely traditional methods. Particular emphasis on building robust inference models, whereby properties of ultimate interest are tightly correlated to those which are more readily measured by *in situ* techniques, will be made via illustrative examples of nuclear materials discovery, down-selection, and optimization. We specifically focus on utilizing *in situ* ion irradiation transient grating spectroscopy (I3TGS) for prediction of high-temperature superconductor performance during irradiation, rapidly exploring new ternary alloy compositions for fusion structural and functional materials, and sorting materials by their resistance to major degradation modes such as void swelling. Finally, we will present a call to collaboration and requests for input from the community, on how to best build robust and easy-to-use TGS systems to help others establish similar *in situ* capabilities of their own.

SESSION CH03.06: *In Situ* Electrochemical Methods
Session Chairs: Aurelie Gentils, Mercedes Hernandez Mayoral and Djamel Kaoumi

8:30 AM *CH03.06.01
Understanding Oxidation Mechanism using *In Situ* Analytical Transmission Electron Microscopy Eric Prestat[1], Giacomo Bertali[2], Duc Nguyen-Manh[1], Joven Lim[1], Anicha Reuban[3], Andrey Litnovsky[3] and Grace Burke[4]; [1]UK Atomic Energy Authority, United Kingdom; [2]University of Manchester, United Kingdom; [3]Forschungszentrum Juelich, Germany; [4]Idaho National Laboratory, United States

Environment-sensitive behaviour of materials encompasses a broad range of degradation phenomena in metals and alloys. The interaction of metallic materials with the environment is of fundamental importance in understanding a material's performance in "real world" applications. Of particular significance is the effect of liquid and/or gaseous environments on the material of interest. The ability to visualize the localised changes associated with oxidation in gaseous environments and dissolution reactions in liquids coupled with qualitative STEM-XED spectrum imaging and analysis is now providing unprecedented opportunities for real-time observations that can lead to improved mechanistic understanding of nanoscale oxidation, and localised dissolution/corrosion.
In this presentation, we will discuss the application of in situ gas microscopy to understand the oxidation behaviour of metallic materials using open cell and closed cell system. For the closed system, two 30 nm thick SiN electron transparent membranes are used to contain up to 1 bar atmospheric pressure from the vacuum of the TEM columns. We have applied the Protochips in situ platforms to examine gaseous environmental interactions in structural alloys such as Ni-base alloys (Alloy 600) and tungsten. The Protochips Atmosphere system interfaced with an FEI Titan G2 200 kV S/TEM equipped with X-FEG and Super X (4 SDDs) or a JEOL NeoARM 200kV wide gap pole piece cold FEG and Dual-EDS system has been successfully used in a variety of gaseous environments. Open cell experiments were performed on a Hitachi H-9500 TEM operating at 300 kV and fitted with an add-on gas injection system for windowless environmental conditions up to ~0.1 Pa at the sample.
Critical to any in situ experiment is the preparation of representative electron-transparent samples, so as to provide a valid link with bulk behaviour. Electron-transparent specimens were prepared using the hybrid method [1]. These specimens can then be attached to an Atmosphere heating chip with Pt. A series of examples will be discussed that are related to the detailed study of bulk material behaviour including localised oxidation reactions pertinent to stress corrosion cracking in Ni-base alloys as well as the study of oxidation of tungsten alloys. The successful experiments using the gas reaction cell

system in a variety of H2-containing environments at elevated temperatures can be further refined to assess variables such as H2 and O2 partial pressures, and can also be used to assess localised reactions in 1 bar gas over a range of temperatures of interest and thus provide insight at the nanoscale about diffusion-induced grain boundary migration, internal oxidation, and the role of carbides in preferential oxidation. Similarly, S/TEM imaging and Electron energy loss spectroscopy (EELS) was used for ex situ and in situ study of the oxidation of self-passivating tungsten alloys using. Mapping the elemental distribution of W, Cr, Y at the nanoscale shows that Cr-rich grains undergoes Cr/W phase separation exhibiting characteristics of spinodal decomposition, which is in good agreement with first-principles modelling predictions. Similar Cr/W phase separation was observed at grain boundaries. The in situ (S/TEM) oxidation shows that the Cr-rich grain exhibiting Cr/W phase separation are oxidized first and formed a dense Cr oxide, providing a stable oxide layer. Additionally, in the vicinity of the yttria precipitates present at grain boundaries or grain triple junctions the oxide growth is reduced in the initial stage of oxidation. Inhomogeneity in the layer oxidation could lead to localised failure of the oxide layer, such as delamination of the protective oxide layer.

9:00 AM *CH03.06.02
***In Situ* Sample Thickness Monitoring in Simultaneous Irradiation-Corrosion Experiments** Franziska Schmidt[1,2], Matthew Chancey[1], Hyosim Kim[1] and Yongqiang Wang[1]; [1]Los Alamos National Laboratory, United States; [2]University of California, Berkeley, United States

Irradiation-corrosion experiments have recently become a popular approach to studying the simultaneous effects of both extremes on materials. Each individual experiment requires extensive preparation and yields one sample exposed to one set of conditions (temperature, damage rate, etc.) that can then be analyzed ex situ. In this talk, we will discuss the potential for the in situ monitoring of long-term (hours to tens of hours) irradiation-corrosion experiments with ion beam analysis techniques, such as particle-induced x-ray emission spectroscopy (PIXE) and Rutherford backscatter spectroscopy (RBS). Both can be used to provide information about changes in the average sample thickness while under irradiation, which is tied to corrosion kinetics. We will lay out different options for the interpretation of PIXE data based on signal from the sample alone or a mixture of sample and corrosive medium signals. The different approaches allow the use of these techniques for different combinations of samples and corrosive media, such as water, heavy liquid metals, or molten salts. As an example, we will show recent experimental data for pure Fe under proton-irradiation simultaneously corroded by lead-bismuth eutectic (LBE), a Gen-IV nuclear reactor coolant. The Fe-LBE system provides the unique opportunity to compare the accuracy of the two data interpretation options for PIXE with each other as well as with RBS, all of which provide in situ insight into Fe corrosion under irradiation not attainable from ex situ observations.

9:30 AM *CH03.06.03
Electrochemical Impedance Spectroscopic Study of Oxide Scales on 316L Stainless Steel in Molten FLiNaK Salt Jie Qiu; Xi'an Jiaotong University, China

Molten fluoride salts have been proposed to be excellent candidates as primary reactor coolant and liquid fuel in a Molten Salt Reactor (MSR) due to their advantages of high thermal conductivities, low viscosities, high boiling points and high specific heats, etc. However, the corrosion of structural materials in molten fluoride salts at high temperature is a great challenge that prevents the successful fruition of MSR. In most corrosive environments, materials derive their corrosion resistance by the formation of a protective oxide scales and/or passive films. However, these oxide films are chemically unstable in high temperature molten fluoride salts and cannot provide protection of materials from corrosion. An understanding of in-situ dissolution rate and corrosion mechanism of oxide film in fluoride salt is significantly important for the development of MSR.
In this work, coupons of 316L stainless steel (SS) were pre-oxidized in hot air and then immersed in molten FLiNaK salt at 700 ºC for electrochemical experiments. The impedance of oxide films on 316L SS as a function of exposure time were investigated using in-situ electrochemical impedance spectroscopy (EIS). The oxide resistance and capacitance under different exposure time were compared. The results show that the resistance of the oxide film decreases with increasing the exposure time, due to the dissolution of the Fe and Cr elements into the molten FLiNaK salt. After experiments, the structures of the oxide film were characterized and compared.

10:30 AM CH03.06.04
Understanding Transient Kinetics under Irradiation with *In Situ* EIS Franziska Schmidt, Cortney Kreller, Yongqiang Wang, James Valdez and Blas P. Uberuaga; Los Alamos National Laboratory, United States

Particle irradiation introduces a large amount of energy into a material, creating a multitude of metastable defect structures. These defects are then responsible for the microstructural evolution of the material, which often comes down to a balance of kinetic processes that determine whether the material will recover or whether larger-scale defect aggregates such as voids and loops will form. Critically, the defects most responsible for this evolution – the fastest moving defects – disappear quickly once the radiation source is removed. Thus, post-mortem examination can only provide indirect evidence of their presence and is unable to characterize neither the nature nor properties of these defects.

To better understand the transient behavior associated with fast moving radiation-induced defects, we have developed an in situ electrochemical impedance spectroscopy system that allows us to measure the conductivity of the material as it is being irradiated. This provides unprecedented insight into the kinetic nature of defects, both as the material approaches a steady-state defect concentration under irradiation and as it recovers once the irradiation source is removed.

We demonstrate this new capability on complex oxides. For example, in yttrium-stabilized zirconia, we find that there is an enhancement of the conductivity of the material during irradiation, leading to an effectively lower activation energy for conduction as the material is being irradiated. However, once the radiation source is turned off, the conductivity quickly recovers to the pre-irradiated value, emphasizing the critical need for in situ diagnostics to probe the properties of these transient defects.

10:45 AM CH03.06.05
Highlighting the Influence of Radiolysis at The Interface between 316L Stainless Steel using *In Situ* Electrochemical Techniques Nicolas Bererd[1,2,3], Nathalie Moncoffre[1,3], Sabrina Marcelin[4,3,2], Alexis Eynard[1,3], Thierry Dupasquier[1,3], Dominique Baux[5,3] and Bernard Normand[4,3,2]; [1]Institute of Physics of The Two Infinites of Lyon, France; [2]Université Claude Bernard Lyon 1, France; [3]CNRS, France; [4]INSA Lyon/MATEIS, France; [5]CEMHTI, France

The study of water radiolysis at the solid/solution interface is an experimental challenge. Here, we present two original and complementary setups: the PATRICIA cell (Passivation - Tribology - Irradiation) and the RADEAU cell.
The PATRICIA configuration allows to study the tribocorrosion of a stainless steel under extreme conditions (proton irradiation, submission to radiolysis product). For instance, a proton beam can irradiate the interface formed by the contact between a liquid and a passivable material (such as 316L stainless steel). An alumina pin can induce friction on the sample's surface. Electrochemical techniques enable the *in situ* characterization of the evolution of the

RedOx potentials of the solution, as well as the evolution of the passive film present on the steel surface. Through the PATRICIA cell, we demonstrated that, regardless of the beam's energy, the corrosion potential remains unchanged. This indicates that it is the highly reactive, short-lived radiolysis products that determine the corrosion potential, rather than just long-lived radiolysis products like H_2O_2. During irradiation, the evolution of resistivity profiles within the thickness of the passive film, obtained from electrochemical impedance spectroscopy measurements, shows that the inner Cr_2O_3 layer of the passive film becomes thinner, leading to a reduction in the corrosion resistance of 316L stainless steel. This evolution could be attributed to the radiolysis of water molecules bound within the passive film.
In the RADEAU configuration, a thin layer of water is irradiated in front of a passivable material. The system's evolution is also monitored through *in situ* electrochemical techniques. In this geometry, only the water or the system {water + interface} can be irradiated, which allows for the discrimination of the passive layer's role in the corrosion process of 316L stainless steel.
These two complementary setups enable the *in situ* study of the interface's role in the mechanisms of steel corrosion.

11:00 AM CH03.06.06
Microstructure and Phase Characterization of Carbonation Accelerated Concretes Proposed for Deep Geologic Repositories using Simultaneous Synchrotron X-Ray Computed Microtomography (XCT) and Spatially Resolved Energy Dispersive X-Ray Diffraction (EDX-XRD) Yeu Chen, Anthony J. Gironda, Jared Abramson and Gerald Seidler; University of Washington, United States

Long-term storage and eventual disposal of spent nuclear fuel (SNF) is a challenging materials problem, with deep geologic repositories (DGR) widely considered the best solution. The general design of DGRs is widely agreed upon, requiring an engineered barrier system (EBS) and disposal site-specific local geology to contain SNF on geologic timescales of 100,000 – 1M years, but specific details are less certain. An understanding of the stability of the materials used in the EBS in geologic conditions is crucial in a once-through nuclear cycle, such as in the United States, where SNF disposal needs are greatest. Cement and cementitious barriers are a key component in EBS systems and serve as a barrier between steel casques that contain the SNF and the local geologic environment its embedded in, creating separation of the waste from the biosphere by trapping radionucleotides that escape the primary containment particularly in the first 10,000 years of storage. There are two key issues in this field of study. First, projecting the stability of cementitious materials over geologic timescales by developing an accelerated aging model that is reliable. Second, characterization techniques of corrosion mechanism in concrete, particularly specific to DGR conditions such as high pressure, high temperature, temperature cycling, radiolysis, chloride ion attack, entrapped gasses (methane, carbon dioxide), and interfacial corrosion between the steel casque and cementitious barrier. This work details a preliminary approach addressing both concerns, an accelerated aging protocol of cements in carbonating conditions and simultaneous synchrotron methods to nondestructively characterize carbonation effects on cement phase and microstructure.

To develop aging techniques, representative cement cylinders were aged in 100% CO_2 atmosphere at room and elevated temperatures for varying durations of time. The pore structure and carbonation front progression were studied using x-ray computed microtomography (XCT) finding a clear delineation between the carbonated and uncarbonated regions. Additionally, spatially resolved energy dispersive x-ray diffraction (EDX-XRD) was used to identify phase changes to the cement's alkaline portlandite buffer, a key component of the cement's barrier capabilities to radionucleotides, as it was depleted with the dissolution of CO_2 into the cement's pore solution during the carbonation process. These phase changes showed clear signatures in the EDX-XRD and corroborated the carbonation depth found from the XCT. Both XCT and EDX-XRD were measured at Sector 7-BM at the Advanced Photon Source. The kinetics and near-field chemistry of concrete and cementitious materials has many unanswered questions as it's difficult to model and quantitatively measure, especially under conditions expected in DGRs. This work has shown the ability to study concrete subjected to DGR conditions and measure one of the key aspects in its usefulness as a ESB material.

SESSION CH03.07: *In Situ* Annealing Related Techniques

Thursday Afternoon, April 25, 2024
Room 441, Level 4, Summit

1:30 PM *CH03.07.01
Recrystallization Behavior of Laser Powder Bed Fused 316L Stainless Steel by *In-Situ* Annealing Yanling Ge[1], Zaiqing Que[1], Witold Chrominski[2], Maciej Zielinski[2], Kimmo Kaunisto[1] and Iwona Jozwik[2]; [1]VTT Technical Research Centre of Finland, Finland; [2]National Center for Nuclear Research, Poland

Laser powder bed fusion (LPBF) addition manufactured (AM) 316L stainless steel (SS) shows superior mechanical and corrosion properties duo to its heterogeneous microstructure. The recrystallization behavior of LPBF stainless steel is a key knowledge for application of AM material in nuclear sector. The two unique microstructure features of AM 316L, dislocation cellular structure and nanoscale oxide inclusions, are important controlling factors on recrystallization behavior and annealing structure. The recovery and recrystallization of LPBF 316L SS are analyzed with differential scanning calorimetry (DSC). The evolution of microstructure is studied with in-situ x-ray diffraction (XRD) and in-situ electron backscattered diffraction (EBSD) in scanning electron microscopy (SEM). The detailed dislocation network evolution and nanosized oxides interaction with grain boundaries during annealing are studied with in-situ transmission electron microscopy (TEM).

2:00 PM CH03.07.02
Heterogeneous Grain Boundary Corrosion in Ni-Cr Alloy Exposed to Molten Fluorinated Eutectic Salts under Applied Potential Sean Mills[1,2], Ho L. Chan[3], Nathan Bieberdorf[1], Minsung Hong[1], Elena Romanovskaia[3], Chaitanya Peddeti[1], Laurent Capolungo[4], Mark Asta[1], John Scully[3], Peter Hosemann[1] and Andrew M. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of Virginia, United States; [4]Los Alamos National Laboratory, United States

Structural materials used in nuclear reactor environments are exposed to coupled extremes such as irradiation, high temperature, and corrosion which act synergistically to degrade their performance. Integral features of these processes are that defects produced under irradiation directly limit or accelerate the corrosion rates. Moreover, in molten-salt reactor environments, previous experimental work has shown that Cr dealloying is strongly coupled to the microstructure evolution of these alloys. Connecting corrosion attack with alloy microstructure such as grain boundaries and accumulating point defects is imperative to understanding underlying mechanisms. However, it is challenging to predict how varied alloying elements, salt species, and nanoscale point defects interact with one another to lead to the failure of materials, as the multiscale nature of these reactions is hidden. Until recently, the capabilities to directly measure vacancies, interstitials and black spot damage have been limited to bulk techniques such as positron annihilation spectroscopy or x-ray diffraction measurement of lattice parameters. The recent developments in 4D-STEM with high-speed direct electron detectors and atomic resolution

STEM provide an opportunity for potentially mapping point defect distributions at the nanoscale and their associated strains, both of which have far-reaching implications for detailed analysis of complex irradiation / corrosion damage.

Active corrosion mechanisms are investigated in a model $Ni_{80}Cr_{20}$ metal alloy exposed to molten LiF-NaF-KF eutectic (FLiNaK) at 600C. When a critical applied potential of 2.1V is reached, this enables both Cr and Ni dissolution and the formation of salt-filled corrosion channels at grain boundaries. For post-corrosion characterization, we implement microscale techniques such as energy dispersive spectroscopy (EDS) and electron backscatter diffraction (EBSD) to uncover variations in morphology and composition that are tied to non-uniform corrosion damage. This grain boundary corrosion mechanism is connected to a pure Ni de-alloyed region that forms within the salt-filled cavity. These findings are supported by phase-field modeling that describes an infiltrating salt-filled corrosion channel between two grains where Ni dissolves preferentially and re-forms on the opposing grain. This is attributed to the redox potential that is modified by the interfacial energies between grains. Building off the conditions that promote grain boundary corrosion and de-alloying, we conduct an in-situ experiment to track local changes in structure, morphology, and transport of species within a pre-fabricated salt-filled corrosion channel. The sample is annealed in the TEM at elevated temperatures (350–900C via MEMS heating + biasing holder) to simulate typical molten salt reactor operating conditions. Further, we perform simultaneous EDX-STEM and 4D-STEM to correlate changes in structure and composition that result from surface diffusion or by bulk lattice diffusion in response to non-uniform corrosion.

This extensive study aims to fundamentally improve the understanding of complex corrosion processes and provide a new pathway for engineering materials designed in future nuclear energy systems. The project is part of FUTURE Energy Frontiers Research Center (EFRC), which aims to study how the coupled extremes of irradiation and corrosion work in concert to modify the evolution of materials by coupling experiments and modeling that target fundamental mechanisms.

Complementing *In Situ* Microscopy with Multimodal Synchrotron Experiments in the Characterization of Radiation Damage Jason R. Trelewicz, Cormac Killeen, Yang Zhang, Spencer Thomas and David J. Sprouster; Stony Brook University, United States

The formation of gaseous defects during irradiation due to, e.g., transmutation or ion implantation, involves a transition from defect clustering to the nucleation of bubbles and its biasing to various microstructural sinks such as grain boundaries. In situ microscopy techniques are limited in their ability to resolve the behavior of sub-nanometer helium clusters during the incubation stages of bubble formation while common X-ray techniques such as X-ray diffraction (XRD) provide information specifically pertaining to changes in the lattice parameter in the presence of such defect clusters. In this study, a region of reciprocal space accessible via wide angle X-ray scattering (WAXS) is identified that allows for the direct probing of sub-nanometer helium clusters irresolvable through transmission electron microscopy (TEM) and small angle X-ray scattering (SAXS) and only indirectly quantified by an XRD lattice parameter analysis. Using WAXS in a multimodal characterization campaign with TEM informed SAXS analysis and XRD of irradiated tungsten, our experiments build a more complete picture of the transition from helium defect clustering to the nucleation of bubbles and their subsequent biasing to grain boundaries. Specifically, nanoscale cavity formation is shown to accompany clustering with increasing fluence but with cavities homogeneously distributed between the grain matrix and boundary regions of the microstructure. An increase in temperature shifted the cavity population to a bimodal distribution containing small nanometer intragranular cavities and larger cavities biased to the grain boundaries, which was accompanied by a decrease in the sub-nanometer helium cluster population. Leveraging the defect distributions as a function of fluence and temperature, the mechanisms underpinning these transitions are discussed using insights from molecular dynamics simulations. Results demonstrate the utility of our multimodal approach in probing the incubation stages of cavity formation and its subsequent transition to biased cavity populations, thereby helping to close the analysis gap between nanoscale in situ TEM imaging and atomic-scale XRD measurements.

Bi-Directionally Tuning the Thermal Resistance of Materials and Interfaces with Irradiation-Induced Defects Patrick E. Hopkins; University of Virginia, United States

Materials in radiative environments (e.g., nuclear reactors, spacecraft, research instruments, among others) are subject to unique forms of damage. The microstructural damage results in a change in electron and phonon scattering rates in materials, which typically leads to a reduction in thermal conductivity. For example, in a study focused on silicon wafers irradiated with an array of ions (C2+, N2+, Al2+, Si2+, P2+, or Ge2+), we demonstrate that an increase in ion dose results in a significant reduction in thermal conductivity (up to an order of magnitude reduction) of the silicon within damaged region [1]. These reductions in thermal properties are general predicted based on the displacements-per-atom (dpa). While dpa and resulting defects lead to reductions in thermal conductivity in crystalline materials, we observe the opposite trend in thermal conductivity of amorphous materials and thermal boundary conductance across interfaces. For example, we demonstrate the ability to increase the thermal conductivity of amorphous solids through ion irradiation, in turn, altering the bonding network configuration. We report on the thermal conductivity of hydrogenated amorphous carbon implanted with C+ ions, in which the films' thermal conductivities reveal significant enhancement after ion irradiation, up to a factor of 3, depending upon the preirradiation composition [2]. Films with higher initial hydrogen content provide the greatest increase, which is complemented by an increased stiffening and densification from the irradiation process. This enhancement in vibrational transport is unique when contrasted to crystalline materials, for which ion implantation is known to produce structural degradation and significantly reduced thermal conductivities. At solid/solid interfaces, we also observe this ion irradiation-induced increase in thermal conductance. We experimentally demonstrate this increase in thermal boundary conductance (TBC) by ion irradiating Gallium Nitride to produce near interface point defects. GaN is bombarded with varying doses of C+, N+, and Ga3+ ions, with a maximum target near-interface defect density of 2%. We show an increase in the measured Al/GaN TBC. Our results show an increased level of scattering within the defected material, which assists in the thermalization between interfacial and bulk vibrational modes and decreases TBR. This is in contrast to conventional formalisms, where scattering across the interface is said to dominate thermal transport.

3:30 PM *CH03.08.01
Investigating Dislocation Loop Nucleation and Growth under Stress by *In-Situ* TEM in Al Daphné Da Fonseca[1], Thomas Jourdan[1], Fabien Onimus[1] and Frederic Mompiou[2]; [1]CEA, France; [2]CEMES-CNRS, France

Irradiation creep that occurs both under stress and irradiation flux, even at moderate temperature, has a profound impact on mechanical properties in structural materials. For instance, it leads to deleterious permanent deformation in austenitic steel vessel internals in pressurized water nuclear reactors. Although this phenomena has been documented in the 70's and 80's, experimental and theoretical investigations proposed have never found consensus so far. It was proposed that irradiation would contribute to dislocation climb but the role of anisotropic growth of irradiation loops was the subject of debates and contradictory results. From early microstructural observations, showing a bias in the development of Frank loops in austenitic steels, two models have emerged. They postulate that the applied stress biases either loop nucleation or their growth which lead to different loop populations density and size. Experimental results, provided by post-mortem TEM observations at high doses, were not able to discriminate clearly between the two models, while in-situ observations carried out in high voltage microscopes reported opposite trends.

To gain knowledge in these phenomena, we studied loop nucleation and growth during in-situ TEM experiments under stress and irradiation at low doses. To that purpose, we take advantage of the low energy displacement threshold of aluminum, to both irradiate and observe samples at the same time, in-situ in a conventional transmission electron microscope.
We show that close to the elastic limit, almost only interstitial Frank loops are formed in the {111} planes normal to the tensile direction. Deep learning and tracking approaches were used to follow the kinetics and distribution of loops during these experiments. They reveal that loop growth is in average linear with time, i.e. with electron fluence, but with numerous cases of stagnation or accelerated growth. More importantly, we demonstrate that the anisotropy of loop population is determined at early stage, probably at the nucleation, and that the growth kinetic only plays a minor role in the development of the observed loop population. These findings echo simulations performed both at atomic scale for the nucleation processes (molecular dynamics Frenkel-pair accumulation), and at mesoscale (Object Kinetic Monte-Carlo) for elastic-diffusion mechanisms of loop growth.

4:00 PM CH03.08.02
Investigating Localized Deformation in Irradiated Stainless Steels through TEM *In Situ* Straining Experiments Silvia Guerra[1], Marta Navas[1], Jia-Chao Chen[2], Shavkat Akhmadaliev[3] and Mercedes Hernandez Mayoral[1]; [1]Centre for Energy, Environmental and Technological Research, Spain; [2]Paul Scherrer Institute, Switzerland; [3]Helmholtz-Zentrum Dresden-Rossendorf, Germany

This research focuses on comprehending the processes occurring in austenitic stainless steels during the initial stages of deformation that can lead to localized deformation, and the impact of irradiation in the deformation modes of the material.
To achieve these goals, the methodology employed in this study deals with performing in-situ straining experiments at the interior of a Transmission Electron Microscope (TEM). These experiments offer direct insights into the microstructural processes that occur in real time during sample deformation. This includes the observation of phenomena like nucleation and movement of dislocations, the interaction between dislocations and defects as well as early stages of defect-free channel formation.
These in situ straining experiments were conducted as interrupted tests, and the resulting microstructure was characterized by means of SEM/EBSD and TEM before and after each in-situ experiment in order to observe the evolution of the deformation in each sample and compare them.
The material under study is the AISI-316L, because due to its high corrosion resistance and good mechanical properties, it is a recurrent material in the construction of internal components of nuclear power plants. Two irradiation conditions have been studied, (1) with helium ions and (2) with iron ions, and each of them along with the non-implanted material, have been characterized.
A systematic study of the irradiated and deformed microstructures has been carried out with the aim to identify, describe, and classify features generated after interrupted testing and assess the influence of the irradiation conditions studied. Results will be presented and discussed.

4:15 PM CH03.08.03
Recent Innovation in Scanning Electron Microscope (SEM) *In-Situ* Extreme Micromechanical Tests in Nuclear Environments Nicholas Randall; Alemnis AG, Switzerland

Nanomechanical tests are already being used to investigate material properties at very small scales. Such testing of nuclear materials may be used to evaluate samples so small that radiation levels fall below critical thresholds, or may be used to simulate failure in the microstructure.
Such measurements have moved beyond the basic measurement of hardness and elastic modulus to encompass a host of different mechanical properties such as strain rate sensitivity, stress relaxation, creep, and fracture toughness by taking advantage of focused ion beam milled geometries. New developments, such as high cycle fatigue, are extending the range of properties which can be studied at the micro and nanoscale. However, such techniques are challenging due to low oscillation frequencies, long duration of tests and large thermal drift when attempted with standard indentation instruments. Novel piezo-based nanoindentation methods are now allowing access to extremely high strain rates ($>10^4$ s^{-1}) and high oscillation frequencies (up to 10 kHz).
Until only recently, high strain rate testing of materials at strain rates from ~100/s – 10000/s has only been possible using macroscale techniques, such as split Hopkinson bar, Kolsky bars and plate impact testers. At the microscale, strain rates have typically been limited to ~0.1/s or less, owing to limitations in instrumentation, insufficient data acquisition rates and elastic wave propagation conflicts during testing.
This talk will focus on the most recent developments in instrumentation for in-situ extreme mechanics testing at the micro and nanoscales, with specific focus on a testing platform capable of strain rate testing over the range 0.0001/s up to 10'000/s (8 orders of magnitude) with simultaneous high speed actuation and sensing capabilities, with nanometer and micronewton resolution respectively.
The additional challenge of performing extreme mechanics in nuclear environments and over the temperature range -150 to 1000 °C will be discussed together with the associated technological and protocol advances required. The inherent advantages of using small volumes of sample material, e.g., small ion beam milled pillars, will be discussed together with the associated instrumentation, technique development, data analysis methodology and experimental protocols. Some examples of test data will be presented where a wide range of strain rate has been combined with variable temperature in order to investigate rate effects as a function of temperature.
Specific focus will be given to test setup modifications required for testing of radioactive materials. Long term exposure trial data will be presented which confirms the applicability of the nanoindentation apparatus for quantitative measurements. Data will also be presented on a new stress-strain nanoindentation measurement technique which allows the localized mapping of yield point across a surface, in addition to hardness, elastic modulus and other mechanical properties (Ref. 1)
Finally, future research directions in this sub-field of micromechanics will be discussed.

SESSION CH03.09: Computational and Simulation Tools Helping in the Interpretation and Management of *In Situ* Characterization Data
Session Chairs: Aurelie Gentils, Mercedes Hernandez Mayoral and Djamel Kaoumi
Friday Morning, April 26, 2024
Room 441, Level 4, Summit

8:30 AM *CH03.09.01
Advancements in Real-Time Quantification for *In-Situ* Materials in Extreme Environments Kevin G. Field[1,2], Hangyu Li[1], Kai Sun[1], Robert Renfrow[1], Matthew Lynch[1], Ryan Jacobs[3], Aidan Pilny[2], Benjamin Eftink[4], Dane Morgan[3] and Chris Field[2]; [1]University of Michigan, United States; [2]Theia Scientific, LLC, United States; [3]University of Wisconsin–Madison, United States; [4]Los Alamos National Laboratory, United States

In this talk, we discuss our recent developments on integrating automated detection of defects[1–5], stereomicroscopy[6,7], edge-computing[8], and *in situ* ion irradiations to form a high-throughput, limited-bias workflow for studies on materials in extreme environments. Materials in extreme environments has been identified as a key research challenge for the materials community[9], where radiation at elevated temperature, as well as stress, is one facet of the materials in extreme environments paradigm. Experiments on radiation-temperature effects is highly complex and dynamical, where defects are nucleated and can move in 1D and 3D with changes in their size, morphology, character, and can be annihilated. We discuss the application of machine learning to form a backbone for a high-fidelity, rapid quantification architecture that can perform 2D-projection and 3D visualization of defects and analysis of these complex dynamical events per frame and in near real-time fashion. We show that performance of deep learning methods, such as Mask R-CNN and You Only Look Once (YOLO), demonstrate performance levels that are at or exceed human performance with inference times below 100 ms. We see that such high-level model performance persists even when trained using physics-based synthetic datasets. We explore the application of deep learning coupled to tracking algorithms, such as DeepSORT, ByteTrack and BoT-SORT, to track hundreds of defects during extreme exposures, including during in-situ transmission electron microscopy (TEM) ion irradiations of several FeCrAl alloy variants on edge and near-edge computing devices. Then, we will show how object detection and tracking can be coupled with 2-tilt stereomicroscopy via the Obtain3D code package[7] to form 3D reconstructions allowing for detailed 3D analysis such as pair distribution evolution of defects and 1D/3D diffusion of slow-moving defects under irradiation. The capabilities of this algorithm ensemble for high fidelity quantification are realized through a platform that couples a modern web application (webapp) hosted on edge or near-edge computing devices that is seamlessly coupled with a state-of-the-art *in situ* TEM ion irradiation facility. This platform enables real-time application of the algorithm ensemble and corresponding graphical displays and overlays from the *in situ* video feed during irradiation providing for *in operando* microscopy. The edge-device with a hosted webapp platform, termed Theiascope™, has been demonstrated for *in situ* TEM ion irradiations. It will be shown the platform is system agnostic (both in hardware and experiment) allowing for immediate feedback of materials evolution when exposed to extreme environments in other imaging systems such as scanning electron microscopy. We will conclude the discussion with recent innovations and thinking on extending the overall presented framework and advances to automated microscopy experimentation through integration with microscopy vendor software APIs.

Bubble Stability and Mobility in Nickel under *In Situ* Ion Irradiation Wei-Ying Chen, Logan Ward and Zhi-Gang Mei; Argonne National Laboratory, United States

Materials within nuclear reactors undergo irradiation that results in adverse microstructural changes, including the formation of point defects, defect clusters, voids, dislocation loops, segregation, and precipitation. The Intermediate voltage electron microscope (IVEM)-Tandem Facility at Argonne National Laboratory is a user facility for *in situ* TEM study of the radiation effects on material microstructures. It interfaces a 500 kV ion accelerator and a 20 kV helium ion source to a 300 kV Hitachi H-9000NAR TEM, allowing real-time microscopy under dual-beam ion irradiation damage/implantation with well-controlled conditions including specimen orientation, temperature, ion type, ion energy, dose, dose rate, applied strain. *In situ* TEM has unique capability to capture videos, offering quantitative insights into the dynamic process that cannot be obtained with *ex situ* experiments.
Our previous study in IVEM observed voids growing or shrinking in nickel at various temperatures from 525°C to 650°C under 1 MeV krypton ion irradiation with a flux of 6.3x1011 ions-cm^{-2}-s^{-1}. Initially, 6 samples underwent irradiation at 600°C to achieve a damage level of 0.5 dpa, which resulted in the formation of voids with an average size of about 15 nm within the TEM foil. Subsequently, the temperature was individually adjusted to 525°C, 550°C, 575°C, 600°C, 625°C, and 650°C. Following this temperature adjustment, irradiation continued for an additional 1 dpa. The stability of the voids at these new temperatures was monitored through *in situ* videos in regions where the foil thickness was approximately 100 nm. A total of about 5000 frames of videos were recorded. We applied deep learning-based semantic segmentation model (IoU score = 0.8135) to automatically analyze the videos and showed that voids shrank at low temperatures and grew at high temperatures under irradiation, where the transition occurred at 575°C (~0.5 TM).
This presentation will focus on the behavior of small Kr-containing bubbles, which had a size smaller than 10 nm. Unlike larger, immobile voids, these small bubbles are mobile under irradiation. Notably, the bubbles were often found tagging along with the irradiation-induced dislocations loops. The movement of those bubbles was confined to the path where dislocation loops expanded or shrank. For bubbles not associated with dislocations, on the other hand, their movements appeared to be random. Besides, while large voids tended to grow steadily at temperatures above 575°C, the bubbles were unstable, switching between growth and shrinkage. The behavior of individual bubbles may be affected by its own unique surroundings such as nearby voids, bubbles, dislocations, and concentration of point defects. Understanding how these individual bubbles exhibited heterogeneous behavior and added up contributing to the resultant macroscopic property requires tracking capability.

We developed a tracking algorithm using Trackpy, and showed that, in average, void stability increases with void size, while void mobility decreases with void size. Nonetheless, there is significant variability in growth or mobility across voids of the same size and for the same void at different times. Besides, the analysis allows us to identify the threshold size at which bubbles transition from instability to steady growth. The temperature dependence on the bubble stability and mobility will also be discussed.

9:30 AM CH03.09.03
Kinetics Governed by Elastic Bias in *In-Situ* Electron Irradiated Aluminium: A Coupled Experimental and Modeling Study Camille Jacquelin, Thomas Jourdan, Maylise Nastar, Chu Chun Fu and Estelle Meslin; CEA Saclay, France

In this study, we investigate the direct in-situ formation of nanometer-scale radiation damage, including voids and loops, using a High-Resolution Transmission Electron Microscope (HRTEM). We observe a size-dependent effect on the shape of cavities induced by electron irradiation, with non-truncated and cross shapes appearing at sizes below 2 nm, while larger sizes exhibit truncated shapes, consistent with DFT based-equilibrium shapes. This effect is explained by our multi-scale modelling, considering the effects of finite size and network discretization on void shapes. The observed dispersion in cavity shape during their growth and shrinkage is primarily influenced by magic numbers, determined by geometry and network frustration. Additionally, not only the voids but also loops were followed in-situ. Loops grow until they eliminate at the surface, while voids go through periodic growth and shrinkage. We demonstrate that the evolution of both objects is linked and governed by elastic bias. The unexpected void shrinkage is attributed to the change of the main sink for the elimination of interstitials. Void growth occurs when the main sinks for interstitials are the strongly biased dislocation loops, generating a stronger vacancy flux towards voids. Conversely, cavity shrinkage occurs when the loops are absent, and the main sinks for interstitials are the foil surface, generating a stronger interstitials flux towards voids.
We reproduce accurately this phenomenon through Object-Kinetic Monte Carlo (OKMC) modelling.

9:45 AM CH03.09.04
Automated Defect Detection in Electron Microscopy of Radiation Damage in Metals Dane Morgan[1], Ryan Jacobs[1], Ajay Annamareddy[1], Matthew Lynch[2] and Kevin G. Field[2]; [1]University of Wisconsin--Madison, United States; [2]University of Michigan–Ann Arbor, United States

In this talk, we discuss our recent work on automating detection of defects in electron microscopy images of irradiated metals relevant for advancing the capabilities of in situ defect characterization of nuclear materials [1–5]. Radiation response of materials is a critical design constraint for future nuclear fission and fusion materials. Electron microscopy is widely used to explore defects in crystal structures, but human tracking of defects can be time-consuming, error prone, unreliable, and is not scalable to large numbers of images or real-time analysis. In this work, we discuss application of machine learning approaches to find the location and geometry of different defects in irradiated alloys, such as dislocation loops, black dot interstitial clusters, and cavities. We explore multiple deep learning methods and generally find performance approaching or equivalent that of human accuracy. We explore multiple avenues of assessment, including canonical classification metrics like precision and recall of specific defect identification (F1≈0.8), accuracy of microstructurally-relevant defect properties (e.g., average defect areal density and size distribution (≈10% fractional errors), and accuracy of macroscopic engineering properties such as hardening (10-20 MPa errors, or about 10% of total hardening) and swelling (≈0.3% swelling errors). These results suggest that specific images can have significant errors, but averaging over many images yields quite good results. We explore convergence of the results with number of training samples, finding that certain defect types are significantly less well detected, likely due both to their having reduced sampling and greater variability, as well as labeling and model limitations for small size features. Finally, we discuss recent efforts using synthetic data to improve object detection model training and reduce the need for a large corpus of labeled experimental data. We explore both deep learning approaches of image generation (namely variational autoencoders) to create synthetic dislocation loop images and physics-based electron dynamics simulations to create synthetic cavities. We generally find that the use of synthetic data is a practical path toward generating new training data essentially instantaneously, leading to improvements in objection detection model performance.

10:00 AM BREAK

10:30 AM *CH03.09.05
A Comprehensive Study on The Kinetics of Defect Formation and Interaction Coupling *In-Situ* TEM with Deep Neural Networks Kory D. Burns[1], Caitlin Kohnert[2] and Khalid Hattar[3]; [1]University of Virginia, United States; [2]Los Alamos National Laboratory, United States; [3]The University of Tennessee, Knoxville, United States

Simulating reactor conditions inside a transmission electron microscope (TEM) gives insight into the rate of defect formation and survivability of materials in the environments in which they were designed to perform. Efforts to fully encapsulate dynamic processes occurring in a material have been challenging, owing to the large volume of information collected from an individual experiment and multiple interactions occurring simultaneously. Hereby, deep neural networks emerge as a suitable method to extract complicated information from input images and output useful analytics that help understand the physics of a reaction. This talk discusses strategies for handling a range of datasets from *in situ* TEM experiments that span different material systems, imaging conditions, and irradiation conditions to predict the stability of materials. Emphasis will be placed on developing end-to-end process flows equipped with generating synthetic data to learn feature representations of images, pattern recognition to highlight hidden trends in the data, and overall implications for the advancement of nuclear materials characterization.

11:00 AM CH03.09.06
Investigation of Extended Defect Evolution in UO_2 and ThO_2 during Ion Irradiation and Post-Irradiation Annealing Marat Khafizov[1], Joshua Ferrigno[1], Mutaz Alshannaq[1], Md Minaruzzaman[1], Kaustubh Bawane[2], Miaomiao Jin[3], Yongfeng Zhang[4], Boopathy Kombaiah[2], Lingfeng He[5] and David Hurley[2]; [1]The Ohio State University, United States; [2]Idaho National Laboratory, United States; [3]The Pennsylvania State University, United States;

[4]University of Wisconsin–Madison, United States; [5]North Carolina State University, United States

A rate theory model is applied to analyze the kinetics of extended defect evolution revealed by in-situ transmission electron microscopy characterization during ion irradiation and post-irradiation annealing of uranium dioxide (UO_2) and thorium dioxide (ThO_2). The objective is to investigate mechanisms governing dislocation loop growth, unfaulting of Frank loops, and extended defect coarsening. In-situ characterization of krypton ion irradiated ThO_2 reveals that loop growth is limited by the mobility of cation interstitial and loop nucleation is influenced by the mobility of both cation and anion interstitials. Similar conclusion has been obtained from ex-situ characterization of proton irradiated ThO_2. Additionally, we determined that during in-situ experiments utilizing TEM lamellae it is important to include surface as a sink for both extended and point defects. Observed extended defect coarsening under in-situ annealing is best described by coalescence mechanism resulting from migration of extended defects. This detailed understanding of extended defect evolution allows to improve assessment of physical properties important for nuclear fuel performance analysis. The established procedure also allows to infer point defect concentration, which are more impactful in determining several physical properties, such as thermal conductivity and atomic diffusion.

Tuesday Morning, April 23, 2024
Room 443, Level 4, Summit

10:30 AM *CH04.01.01
***Operando*, Multimodal Characterization of Bimetallic Catalysts with Electrons and X-Rays** Alexandre Foucher[1,2], Nicholas Marcella[2,3], Jennifer Lee[4,5], Daniel Rosen[4], Ryan Tappero[3], Christopher B. Murray[4], Anatoly Frenkel[2,3] and Eric A. Stach[4]; [1]Massachusetts Institute of Technology, United States; [2]Stony Brook University, The State University of New York, United States; [3]Brookhaven National Laboratory, United States; [4]University of Pennsylvania, United States; [5]University of California, Merced, United States

Alloyed nanoparticles are of increasing interest in many applications, most notably as heterogeneous catalysts. Alloying allows the tuning of composition and structure to increase functionality, most specifically reactivity and selectivity. However, harsh, reactive environments can induce changes in the structure and composition of these materials in unexpected ways, which can inhibit their performance. These materials also present a significant characterization challenge: they are tiny (from single atoms to particles of 10 nm) and can also be heterogeneous in size, composition, and structure.

I will describe how we have developed a new approach to characterize catalysts using so-called 'operando' methods to take measurements. At the same time, the materials are 'in a working condition': i.e., in a reactive environment performing their function. We use a microreactor system compatible with imaging, diffraction, and spectroscopy, using electron, photon, and x-ray probes. The presentation will describe how this multimodal approach can provide unique insights into the dynamic changes in these complex systems as they function.

There will be two specific applications. In the first portion, I will show how we can exploit an innovative colloidal synthesis method to produce highly monodisperse Cu-Pt alloy nanoparticles with a Pt-rich shell and Cu-rich core; the intermetallic CuPt phase formed after annealing shows enhanced and stable catalytic activity for CO oxidation compared to pure Pt nanoparticles or the fresh Cu-Pt particles with a Pt-shell. This synthesis route allows control over Cu-Pt nanostructures, demonstrating Cu-Pt alloys' promising catalytic properties. In the second portion, I will show how Ni-Cu alloy nanoparticles undergo compositional and morphological changes during redox cycles that simulate catalytic reactions; specifically, while Cu segregates in the fresh catalyst, oxidation at 400°C leads to restructuring into hollow particles with heterogenous Ni-Cu composition, explaining the deactivation observed for conversion of biomass-derived 5-hydroxymethylfurfural over $NiCu_3$/C.

11:00 AM CH04.01.02
Advancing Multimodal Characterization at The Nanoscale with The Tescan Tensor Analytical 4D-Stem Robert Stroud; Tescan USA, United States

Nanoscale imaging is important, but in materials characterization information about crystalline structure, as revealed by the diffraction pattern, and the

ability to relate that information to a particular location in the image, is equally valuable. The power of 4D analytical STEM lies in its ability to acquire complete image, crystallographic and compositional information across the field of view with nanometer-scale spatial resolution.
Scientists and engineers who need this kind of information work in a variety of disciplines, including materials science, semiconductor manufacturing, pharmaceutical research, product development, and many more. Across these disciplines, practitioners were aware of the potential benefits of S/TEM but have historically been turned off by the perceived operational difficulty of the instrumentation. They want practical results, and the less time, effort, and money required to get the result, the better.
TESCAN TENSOR addresses these needs by automating almost every microscope function. This unprecedented automation is only possible because it has been integrated into the microscope design at every level from the ground up. The designers' singular focus on completely automated 4D-STEM operation has delivered a microscope without peer in that application.
The methodology behind TESCAN's Analytical 4D-STEM microscope will be explained as the solution of choice for a range of nanoscale applications. Examples including results from nickel-based superalloy indentation studies, complex semiconductors, and battery anodes will be presented.
Nickel superalloys. An investigation into the crystallographic grain reorientation caused by Vickers indentation induced plastic deformation, studied by precession-assisted 4D-STEM with automated crystal orientation analysis will be presented, including high resolution mapping of the resulting indentation induced crystallographic orientation gradient.
4D-STEM phase and orientation analysis of lithium-ion battery anode materials. Precession-assisted 4D-STEM was used to produce maps of $LiTi2(PO_4)_3$, TiO_2 and $LiTiOPO_4$ phases present in spindle-like battery anode particles. 4D-STEM phase analysis will be presented showing that TiO_2 nanoparticles form a network at the $LiTi_2(PO_4)_3$ sub-particle boundaries, which may provide a more effective diffusion pathway for lithium ions at higher cycling rates.
Multimodal phase and orientation analysis of complex semiconductor devices. For semiconductor manufacturers, it is desired to have comprehensive analytical capabilities, with the ability to measure chemical and structural properties, complementary to specimen morphology, down to the sub-nanometer scale. This is generally addressed using Energy Dispersive X-Ray (EDX) mapping, defect analysis through diffraction measurements, crystal orientation and phase mapping, and critical dimension imaging. These capabilities are important as the electrical performance of devices depends strongly on the type and distribution of crystalline phases in individual layers.
The TESCAN TENSOR analytical 4D-STEM provides a unique workflow interface to facilitate efficient chemical and structural analysis using EDX mapping, and precession-assisted phase and orientation mapping. The alignment and workflow automation enables effortless, automated switching between measurements optimized for STEM imaging, EDX analysis, or analytical 4D-STEM.
With a result-centric design, TESCAN TENSOR's quality, throughput, and robustness of 4D-STEM acquisition, analysis, and processing has been optimized with state-of-the-art technologies, such as Precession Electron Diffraction (PED), 4D-STEM computing and visualization, electrostatic beam blanking, and ultra-high vacuum at the specimen area. Additionally, TESCAN TENSOR features real-time, automated data analysis and processing, which empowers an unprecedented level of system accessibility, utilization, and productivity.

Understanding Particle-Mediated Growth Pathways by using Advanced Transmission Electron Microscopy and X-Ray Scattering Techniques Xin Zhang[1], Xiaoxu Li[1], Yining Wang[1], Jianbin Zhou[1], Sebastian T. Mergelsberg[1], Tuan Ho[2], Lili Liu[1], Honghu Zhang[3], Ruipeng Li[3], Mark Bowden[1], Ping P. Chen[1], Maria Sushko[1], Carolyn Pearce[1], James J. De Yoreo[1] and Kevin Rosso[1]; [1]Pacific Northwest National Laboratory, United States; [2]Sandia National Laboratories, United States; [3]Brookhaven National Laboratory, United States

Particle aggregation involves the phenomenon of oriented attachment (OA), where crystalline particles join together by attaching to specific crystal faces with lattice matching, is a prevalent mechanism in crystal growth and has been extensively utilized in the development of hierarchically structured crystalline materials, which has been applied to catalysis, energy storage, environmental conservation, biological medicine, etc. Using a combination of advanced transmission electron microscopy (TEM) and small-angle X-ray scattering/wide-angle X-ray scattering (WAXS) techniques and computational methods, we are investigating these phenomena for several metal oxide systems and their relationship to interfacial structure in vacuum and water vapor. Here we discuss three cases. In the first, we use high-resolution TEM and scanning TEM (STEM) to explore the aggregation behaviors of hematite nanocrystals with different exposed facets including {001}, {012}, {104} and {116}. The experimental data indicates that hematite nanoparticles aggregation-based crystallization is orientation dependent (along the [001] direction), not relies on exposed facet. We then compare the results to the predictions of density functional theory (DFT) to relate the behavior to surface interactions. In the second case, we report the formation of gibbsite mesocrystals in pure water. By evaporating the suspension of monodisperse gibbsite nanoplates with a diameter of around 100 nm, plate-like mesocrystals with a diameter of up to a hundred micrometers were formed. The single crystal XRD pattern and SAXS/WAXS of the mesocrystals matched that of bulk gibbsite crystal along the specific zone axis, indicating well-aligned particles in the monocrystals. Further analysis through scanning electron microscopy (SEM) and TEM revealed a hexagonal columnar superstructure. Moreover, the *in situ* liquid phase TEM was conducted and observed the OA of a few gibbsite nanoplates in pure water, and the result matched well with ex *situ* characterizations. The MD simulation was used to investigate the energy-structure relationship for the sliding motion of two co-planar gibbsite nanoplatelets along the (010) direction. The results indicated that to obtain the first perfectly aligned configuration, sliding in the (010) direction exhibits a smaller energy barrier than sliding in the (100) direction (0.89 vs. 2.49 kcal/mol). In the third case, the measurement of anisotropic forces between rutile TiO_2 (001) nanocrystals as a function of their azimuthal orientation and surface hydration extent using a combined environmental TEM-atomic force microscopy (AFM) technique. At tens of nanometers of separation, the attractive forces are weak and show no dependence on azimuthal alignment nor surface hydration. At separations of approximately one hydration layer, attractive forces are strongly dependent on azimuthal alignment and systematically decrease as intervening water density increases. Measured forces closely agree with predictions from Lifshitz theory and show that dispersion forces are capable of generating a torque between particles to align them.

SESSION CH04.02: Advanced Characterization of Energy Materials

Origin of Structural Degradation in Lithium Layered Oxide Cathode Luxi Li[1], Tongchao Liu[1], Ian Robinson[2,3], Ross Harder[1] and Wonsuk Cha[1]; [1]Argonne National Laboratory, United States; [2]Brookhaven National Laboratory, United States; [3]University College London, United Kingdom

Li and Mn-rich (LMR) layered oxide cathode materials can substantially increase battery energy density by facilitating both cation and anion redox energy. However, the cathode material suffers from continuous voltage decay over the charge/discharge cycles and results in capacity loss. Coherent X-ray Diffraction (CXD) techniques are invaluable for investigating the morphology, structural and strain information in crystalline specimens under in-situ and operando conditions [1-2]. In this presentation, $Li_{1.2}Ni_{0.13}Mn_{0.54}Co_{0.13}O_2$ is used as a benchmark to explore the origin of structural degradation in LMR

cathode materials [3]. In-situ CXD techniques are used to visualize the strain accumulation in the charging process that leads to an abrupt oxygen loss to release the lattice strain. In the meanwhile, a new phase with a trace quantity is observed from the microbeam diffraction that supports the hypothesis of oxygen loss. These results highlight the significance of lattice strain in the voltage decay mechanism and will inspire a wave of efforts that seek novel solutions for eliminating this issue.

X-Ray Nano-Scale Spectroscopic Imaging on Battery Research – A Case Study Xianghui Xiao[1], Dong Hou[2], Feng Lin[3] and Zhengrui Xu[3]; [1]Brookhaven National Laboratory, United States; [2]University of Louisiana at Lafayette, United States; [3]Virginia Tech, United States

Chemical reaction heterogeneity is ubiquitous at both interparticle and intraparticle scales during battery cycling. Spectroscopic imaging provides position-dependent chemical state information that is directly related to the chemical reaction heterogeneity in the samples. Transmission X-ray Microscope has been widely used in battery research as a spectroscopic imaging modality. Simultaneously, it also provides morphological structure information. In this paper, we will present a case study of the characterizations of two types of high-Ni NMC cathode materials that have different primary particle arrangement patterns. They show distinct performances at room temperature. Nonetheless, the thermal stabilities of these two types of materials are inverse compared to their electrochemical performances. The chemical state distributions and morphological structures at the single particle level show consistent evolution behaviors as the observations with neutron diffraction. The results help to reveal the fundamental mechanisms that cause the differences. The case demonstrates the capability of TXM as a spectroscopic imaging tool and its applications in battery research.

Boosting the CO_2 Uptake of MgO-Based Sorbents using Na_2CO_3 as Nucleation Seeds: Mechanistic Insights via *In Situ* Synchrotron XRD Annelies Landuyt[1], Ilia Kochetygov[2], Maximilian Krödel[1], Wendy L. Queen[2], Paula Abdala[1] and Christoph R. Müller[1]; [1]ETH Zürich, Switzerland; [2]EPFL, Switzerland

CO_2 capture, utilization and storage (CCUS) is a key technology to reach net zero CO_2 emissions and mitigate global warming. Therefore, there is an urgent need to develop functional materials that can capture and release CO_2 under industrially relevant conditions. Solid oxide materials such as MgO are earth-abundant and constitute a promising family of materials for CO_2 capture.[1] MgO-based CO_2 sorbents are characterized by favorable carbonation thermodynamics and high gravimetric CO_2 uptake capacities but display limited CO_2 uptake due to slow carbonation kinetics. The first step that partially resolves the slow kinetics involves the addition of alkali metal nitrates, which are molten under operation conditions.[2] Here, we show a second sorbent engineering step that effectively resolves the limited CO_2 uptake kinetics of MgO-sorbents, by co-promoting MgO with $NaNO_3$ and Na_2CO_3, resulting in fast CO_2 uptake rates. We demonstrate the mechanism behind this promotion via in-situ synchrotron XRD measurements (1 s resolution), revealing that Na_2CO_3 rapidly (within seconds) transforms into $Na_2Mg(CO_3)_2$, which acts as a nucleation seed for $MgCO_3$ growth. $Na_2Mg(CO_3)_2$ seeds facilitate $MgCO_3$ nucleation, which has been identified as the rate-determining step, resulting in increased CO_2 uptake kinetics (from minutes to seconds). Lastly, using electron-microscopy techniques, we visualize the nucleation of $MgCO_3$ directly onto the $Na_2Mg(CO_3)_2$ seeds. Taken together, we show that the co-promotion of MgO with Na_2CO_3 and $NaNO_3$ is a facile, inexpensive and highly promising strategy for improving MgO–based CO_2 capture sorbents.

Depth-Profiling Spectroscopic Investigation of The Activation Mechanism of $LiMn_2O_4$: Micro-SORS Method Wang-Hyo Kim[1], So Yeon Yoon[1], Myeong-Hee Lee[1], Byung-Man Kim[2] and Tae-Hyuk Kwon[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]University of Cambridge, United Kingdom

Lithium manganese oxide (LiMn2O4, LMO) stands out as a promising material for lithium-ion batteries due to its high thermal stability, low cost, abundance, and environmental compatibility. However, the dynamics of LMO's behavior in electrode is still unknown. In this study, we explore LMO as a storage electrode in photo-rechargeable batteries (PRB) using non-invasive depth profiling techniques, specifically micro-spatially offset Raman spectroscopy (micro-SORS). We delve into the Raman profiles of LMO layers, examining their variations based on depth after galvanostatic charging and discharging cycles of PRB. During these cycles, the oxidation state of manganese species shifts from Mn^{3+} to $Mn^{3.5+}$, accompanied by a phase transition from cubic to tetragonal. This transition results in increased capacity. To unravel this mechanism, we analyze depth-dependent Raman profiles corresponding to the phase transition throughout charging and discharging cycles. To validate our micro-SORS findings, we employ X-ray absorption fine structure (XAFS) and X-ray absorption near edge structure (XANES) techniques, confirming both oxidation states and phases. The XAFS and XANES data reveal the accumulation of an irreversible charged state (Li2Mn2O4, L2MO) over repeated charging-discharging cycles. By integrating micro-SORS analysis with this information, we pinpoint the specific site of accumulation in the electrode, elucidating the capacity increment mechanism through tracking this accumulation. While Raman analysis is common in battery research, this study marks the pioneering use of non-destructive, depth-dependent analysis using micro-SORS. This innovative approach not only provides valuable insights into battery degradation but also offers a revolutionary perspective, capturing macroscopic changes with microscopic precision.

3:00 PM BREAK

3:30 PM *CH04.02.05
Developing Automation and *In-Situ* Capabilities for X-Ray Scattering towards Autonomous Lab-At-Beamline Ruipeng Li; Brookhaven National Laboratory, United States

X-ray scattering is a unique tool for revealing material structures, spanning from the atomic level to hundreds of nanometers. Its broad probe range and flexibility make it invaluable for in-situ and operando studies across various materials research fields. The development of the in-situ capabilities, coupled with technological advances in light sources and detectors, have increased our ability to explore complex material processing, resulting in vast amounts of data in more intricate parameter spaces.
In this presentation, I will discuss recent developments in in-situ capabilities at the Complex Materials Scattering (CMS) beamline of NSLS II, as well as our journey toward automation and autonomous exploration of materials. I will also outline our strategy to integrate automation, advanced data analysis, in-situ capabilities, and other characterizations to develop the beamline into an autonomous lab-at-beamline.

4:00 PM *CH04.02.06
Advancing Research with Combined Synchrotron Techniques at 7-BM NSLS II Lu Ma; Brookhaven National Laboratory, United States

At the 7-BM, NSLS II, we've developed combined synchrotron techniques for materials characterization, particularly X-ray absorption spectroscopy (XAS)/X-ray diffraction (XRD) and XAS/ Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS). These combined approaches yield numerous advantages including comprehensive analysis, real-time monitoring, and the maximization of data yield during valuable beamtime. Notably, their integration often reveals unexpected material properties and bridges gaps across varied research areas.
The combination of XRD and XAS offers an all-encompassing perspective on material structure/properties. XRD examines phase identification, crystal structure, and other microstructural properties, while XAS studies the electronic configurations, oxidation states, and the intricacies of local coordination. With XAS elucidating details of the catalyst structure and DRIFTS offering a snapshot of surface interactions and molecular dynamics, this combination proves to be a powerful tool for gaining a comprehensive view of catalytic reactions.
Leveraging these integrated techniques at the 7-BM NSLS II, we not only enhance our understanding of material properties but also set the stage for future innovations in diverse research fields.

4:30 PM CH04.02.07
Designing The Next Generation Silicon/Graphite Anodes for Lithium-Ion Batteries: From The Nanoscale to The Macroscale Benjamen Reed, Sofia Marchesini, Carmen Lopez, Andrew Wain, Rudra Samajdar, Ken Mingard, Vivian Tong, Helen Jones, Daniel O'Connor, Giannis Chatzopoulos and Andrew Pollard; National Physical Laboratory, United Kingdom

Reaching net-zero emissions and transitioning to widespread electrification of vehicles have emerged as key challenges for ensuring a sustainable future. Central to these goals is the critical role played by energy storage systems, which are pivotal in enabling the efficient utilisation and distribution of renewable energy. The advancement of energy storage technologies, particularly in the realm of lithium-ion batteries, holds the key to mitigating the challenges posed by intermittent renewable energy sources. Moreover, electrification of the transportation sector, primarily through electric vehicles, is fundamental to reducing greenhouse gas emissions.
The operating range for electric vehicles is determined by the energy density of the battery, which in the case of anode materials is directly correlated to their lithium storage capacity. While traditional graphite anodes have a theoretical capacity of 360 mAh/g, silicon has a much larger theoretical capacity (3600 mAh/g) and silicon-based lithium-ion batteries have therefore emerged as a promising technology.
However, silicon anodes suffer from large volume expansion (up to 300 %) during cycling, which cause a drop in capacity. Recent industrial advances allowed to engineer silicon/graphite composite materials with limited volume expansion and increased capacity. However, while these materials showed improved electrochemical performance, little is understood on the physicochemical mechanisms underpinning these improvements. The successful advancement of this technology necessitates a thorough understanding of intricate phenomena such as particle cracking, volume changes on various length scales (from pouch cell level down to individual particles), and the formation of solid electrolyte interphase (SEI) layers.
Herein, we employed a suite of complementary physical and chemical characterisation techniques using both post-mortem and operando methods, across a range of length scales, from pouch cells down to individual particles observed at the nanoscale. Collaboration with an industrial supplier of these anodes and cells allowed the elucidation of the material degradation phenomena and the correlation to their electrochemical cycling performance.
This work highlights the significance of integrating multiple characterisation methods to unravel the underlying degradation mechanisms in silicon-based anodes, paving the way for the design and engineering of efficient silicon and graphite anodes, thus propelling the evolution of lithium-ion battery technology.

4:45 PM CH04.02.08
Evaluations of Reaction Heterogeneities in Battery Electrodes upon Fast Charging using *Operando* Focused Beam X-Ray Diffraction Tianyi Li[1], Donal Finegan[2] and Kamila Wiaderek[1]; [1]Argonne National Laboratory, United States; [2]National Renewable Energy Laboratory, United States

Recently, the use of thick electrodes in lithium-ion batteries has drawn extensive attention as it effectively promotes cell-level energy density by reducing the fraction of inactive components such as separators and current collectors. However, the spatially non-uniform reaction can easily arise within a thick electrode design due to the sluggish electrolyte transport. Understanding the heterogeneous reaction and preventing it is happening are therefore critical as it may result in inferior rate performance, fast capacity degradation, and even safety hazards. This study aims to experimentally evaluate the reaction heterogeneities in thick electrodes by employing operando focused beam X-ray diffraction (XRD). We will compare the traditional graphite anode with laser ablated sample in full cells upon 6C fast charging, therefore, quantitatively assessing the degree of reaction along the depth direction in electrodes under operational conditions. A detailed comparison between the experiments and simulations will help us better understand the origin of reaction heterogeneities in electrodes and guide the design of battery materials and structures in the future.

SESSION CH04.03: Poster Session I

5:00 PM CH04.03.01
Grand Canonical Monte Carlo Simulation with MOF-303 and Metal-Coated MOF-303 Jeognho An and Kunok Chang; Kyung Hee University, Korea (the Republic of)

Managing Xe/Kr radioactive novel gas generated from spent nuclear fuel is critical for both environmental and human radiation protection. While numerous experimental methods applied to find effective adsorbent, the computational simulation can help minimize experimental costs and help pre-screening effective materials. The Grand Canonical Monte Carlo(GCMC) Simulations are used to explore selective adsorptions at Metal-Organic Frameworks(MOFs). This study aims to use GCMC to select MOFs that have a large capture capacity and selective adsorption of gaseous radionuclides emitted from spent nuclear fuel such as Xe/Kr. Among the MOFs, MOF-303 shows improvement it’s total uptakes and selectivity when it doped with metal such as Cu. Through GCMC calculations, the effect of Cu doping on the gas adsorption of MOF-303 was evaluated, and the effects on the capture capacity and selectivity changes were quantitatively analysed.

5:00 PM CH04.03.02

Excited-State Dynamic in Thiophene/Phenylene Co-Oligomer Nanocrystals Andi M. Panre, Hitoshi Mizuno, Tomomi Jinjyo and Hiroyuki Katsuki; Nara Institute of Science and Technology, Japan

Thiophene/phenylene co-oligomer (TPCO) nanocrystals (NCs) hold strong promise for nano-environment photoluminescence probes, qubits, and quantum light source. Their optical properties show considerable versatility and flexibility depending on the size of the nanocrystals. This adaptability enhances light emission efficiency, making them a promising choice for improving organic light-emitting diodes (OLED) technology, especially as active layers. To extend the potential applications of these nanocrystals, it is essential to investigate how the size of nanocrystals is related with the excited state relaxation and photoluminescence (PL) dynamics. For example, we expect the excited state lifetime for smaller NCs should be affected by the enhanced spatial overlap of electron and hole states. In the present study, we observe the transient absorption spectrum in NCs of 5,5'-bis(4'-cyanobiphenyl-4-yl)-2,2'-bithiophene (BP2T-CN). BP2T-CN NCs with an average size of 75 nm were prepared by the reprecipitation method, which show strong yellow emission centered around 555 nm. The size-dependent steady-state optical properties were elucidated through the measurement of absorption and PL spectra. In comparison to vapor-deposited films, the BP2T-CN NCs water dispersion displayed shifts in the 0-1 and 0-2 absorption bands, attributed to lattice softening (surface effect) and quantum effects. Additionally, PL lifetime measurements yielded a decay time of 1.33 ns at an excitation wavelength of 400 nm. The transient absorption signal in the yellow-emitting BP2T-CN NCs is characterized by three exponential decays with 0.65 ps, 2.3 ps, and 75 ps components. These time constants shed light on relaxation processes, including electron trapping, intra-band relaxation, and non-radiative decay. Photoinduced absorption bands (PA, $\Delta T/T < 0$) appeared at 670-700 nm from the lowest excited state. Our findings will give a clue on the photophysical processes within these co-oligomer NCs, providing valuable insights for potential applications in optoelectronic devices and photonics, especially in OLED development.

5:00 PM CH04.03.03
Role of Aluminium in STE Engineering in $Cs_2AgInCl_6$:Al^{3+} Double Perovskite Nanocrystals Rachna . and Sameer Sapra; Indian Institute of Technology, India

Significant research efforts have been directed towards modification of STEs in lead-free halide double perovskite $Cs_2AgInCl_6$ to improve its suitability for white light applications. However, limited attention has been given to exploring the fundamental photophysical phenomenon of this material. Herein, we have demonstrated that the precise introduction of Al^{3+} can effectively adjust the material's bandgap, leading to red shifted excitation energy and enhanced STE emission. Additionally, cryogenic PL measurements discovered an inhomogeneous nature of STE emission due to the presence of defect states and is subject to thermal quenching. The increased Hyang Rhys factor show better electron phonon coupling and high density of STE states post Al^{3+} doping. Ultrafast transient absorption spectroscopy elucidated the trapping of charge carriers and provided insights into the effects of Al^{3+} doping on the formation self-trapped states. Overall, this study offers a comprehensive understanding of the origins of self-trapping in $Cs_2AgInCl_6$ and emphasizes the potential of compositional engineering to mitigate self-trapping in this material.

5:00 PM CH04.03.04
Microscopic Behaviour of Hydrogen and hHydrides in Atom Probe Tomography of Zirconium Aïssatou Diagne and Lorenzo Rigutti; University of Rouen Normandie, France

The understanding of Zirconium (Zr) and Hydrogen (H) interactions is a topic of interest in the field of materials science. Zr is known to have a strong affinity with hydrogen, which can lead to the formation of hydrides that can affect the mechanical properties (embrittlement, cracking, etc) of the material [1]. Our studies are carried out on pure Zr analysed by laser-assisted atom probe tomography. This is complex, because the hydrogen detected during the analysis could come from the analysis chamber (parasitic hydrogen) or from the material (hydrogen contained in the material). Our results show the formation of hydrogen species H^+, H_2^+, H_3^+ and hydrides ZrH_x^{2+}. The evolution of the relative abundances of H^+, H_2^+, H_3^+ depends on the surface field estimated from the Zr^{3+}/Zr^{2+} ratios, as seen in previous studies on other materials[2]. This is not the case for the hydrides which overlap with the Zr isotopic species. In this contribution we will discuss the quantification of hydrogen and zirconium hydrides and their dependence on the field.

[1] J. Bair, M. Asle Zaeem, et M. Tonks, « A review on hydride precipitation in zirconium alloys », *J. Nucl. Mater.*, vol. 466, p. 12, nov. 2015, doi: 10.1016/j.jnucmat.2015.07.014.
[2] L. Rigutti *et al.*, « Surface Microscopy of Atomic and Molecular Hydrogen from Field-Evaporating Semiconductors », *J. Phys. Chem. C*, vol. 125, nº 31, p. 17078, août 2021, doi: 10.1021/acs.jpcc.1c04778.

5:00 PM CH04.03.05
Atomic Spatiotemporal Characterization of Light-Emitting 2D Materials by Cathodoluminescence and Femtosecond Photoluminescence Spectroscopies Ruofei Zheng[1], Ariel Petruk[1], Kostyantyn Pichugin[1], Mike Fleischauer[2], Darren Homeniuk[2], Tyler Lott[1], Mark Salomons[2] and Germán Sciaini[1]; [1]University of Waterloo, Canada; [2]National Research Council of Canada, Canada

The emerging realm of two-dimensional (2D) materials has introduced remarkable advancements in the fields of optoelectronics and photonics. To harness the full potential of these materials, a comprehensive understanding of their light-emitting characteristics at atomic spatiotemporal scales is indispensable. Cathodoluminescence (CL) integrated within a scanning electron microscope (CL-SEM) or scanning transmission electron microscope (CL-STEM) is capable of conferring material properties with sub-nanometer spatial and spectral resolutions, surpassing the limitations of traditional photoluminescence (PL) techniques imposed by the Abbe diffraction limit. Furthermore, time-resolved photoluminescence (TrPL) spectroscopy enables the characterization of ultrafast electron-hole recombination dynamics through the up-conversion technique, employing ultrashort excitation and gating laser pulses. In this context, our specifically designed sample holder and spectrometer, integrated with the high-resolution Hitachi S5500 SEM and equipped with sample loading chips featuring ultrathin windows, are aimed to develop an atomic-resolution hyperspectral CL-SEM/STEM imaging system. Additionally, in conjunction with our homemade ultrafast TrPL setup, the ultimate goal is to investigate the electronic and optical characteristics of 2D materials at the atomic scale, encompassing both spatial and temporal dimensions.

5:00 PM CH04.03.06
Photoluminescence of Up-Conversion Nanoparticles with High Spatial Resolution Eugeny Ermilov, Christian Oelsner, Volker Buschmann, Matthias Patting and Rainer Erdmann; PicoQuant GmbH, Germany

Up-conversion nanoparticles (UCNPs) are highly attractive for avoiding autofluorescence in application cases in biosensing and imaging. Characterizing the photophysical properties of such nanoparticles is essential to enhance the efficiency of preparation methods as well as their electronic and optical properties. Up-conversion is a strongly power dependent energy-transfer process which is based on excitation in the NIR and photon emission in visible range. The commonly used steady-state methods (i.e. excitation and emission spectroscopy) provide valuable insights into the photophysics of samples. However, such results give only a partial view of a sample's behavior after photoexcitation. A further piece of the puzzle is often revealed by performing

time-resolved luminescence spectroscopy. Combination of spectral and lifetime information of a sample's luminescence allows for a deeper insight into photophysical processes occurring after light absorption. This can be further enhanced by including spatial information. Time-resolved photoluminescence (TRPL) imaging is a powerful technique for characterizing and inferring structural-to-photophysical relationships in up-conversion materials. Additionally, the kind of imaging method and the power applied to the sample are further parameters which are important for understanding TRPL imaging results. Gathering such information and knowing the chosen parameters are important steps toward the optimization of structure as well as preparation process of UCNPs, resulting in increased performance of such materials.
We will demonstrate here the performance of a spectrometer-microscope assembly for characterization and analysis of UCNPs in terms of lifetime, spectral, and spatial resolution, which provides more information in combination than can be obtained using only lifetime or only steady-state experiments.

5:00 PM CH04.03.07
Multi-Modal Synchrotron X-Ray Techniques for Visualizing 3D Brittle Fracture Sara F. Gorske[1], Mythreyi Ramesh[2], Jun-Sang Park[3], Peter Kenesei[3], Hemant Sharma[3], Jonathan Almer[3], Peter Voorhees[2] and Katherine Faber[1]; [1]California Institute of Technology, United States; [2]Northwestern University, United States; [3]Argonne National Laboratory, United States

Fracture is difficult to assess in real time. Even when crack propagation can be measured as it is occurring, usually only a 2-dimensional state can be quantified. Assessing 3-dimensional (3D) fracture has traditionally relied on post mortem analysis, but this does not capture the full intricacies of a growing crack front, such as a nonconstant velocity and shape. For brittle fracture, where very little plastic deformation occurs between the accumulation of stress concentration at a crack tip and its extension, these difficulties are compounded. Furthermore, a material's microstructure has a major effect on crack propagation, including its direction, speed, tortuosity, and even whether it arrests at points as a result of unequal stress distribution. Because of these complications, predicting crack paths, speeds, and shapes is a thorny problem which needs more in-situ data from 3D cracks occurring in real materials. Utilizing multi-modal x-ray characterization techniques available at a synchrotron source is a promising method for visualizing a crack's growth and directly relating it to the microstructure and micromechanical state of the studied material.

Our suite of multi-modal characterization techniques include far-field high-energy diffraction microscopy (FF-HEDM), near-field high-energy diffraction microscopy (NF-HEDM), and micro-computed tomography (u-CT). FF-HEDM provides per-grain elastic strain tensors, while NF-HEDM provides a high-quality shape and location for each grain. u-CT identifies the location of a crack in a material. Combining this information allows us to relate the grain structure and mechanical state found by the HEDM techniques with the crack location.

In this work, the material studied was aluminum oxynitride (AlON), a cubic ceramic with randomly oriented anisotropic grains on the order of 100 um. The Rotational and Axial Motion System (RAMS) [1] at the 1-ID beamline of the Advanced Photon Source at Argonne National Laboratory was used to carefully grow the crack and conduct these experiments. The sample being investigated was machined into the double-cleavage drilled compression (DCDC) geometry with parallelipiped dimensions of 18 mm x 1.4 mm x 1.4 mm and a hole diameter of 0.42 mm. The application of a uniaxial compressive load caused a crack to pop in to a length on the order of 100 um, and the crack was grown to over 1 mm by the application of further compressive load.

Every grain in the material had unique stress and strain tensors at each load that were not identical to the applied stress. Crack propagation characteristics such as its speed and path (intragranular or intergranular) were influenced as the crack interacted with these grains and complex micromechanical stress states. Because of the DCDC geometry, the crack could be grown a short distance, and then the loading could be paused along with the crack extension, creating a near in-situ state for analysis. By taking u-CT and HEDM scans in this load-controlled state, the relative extension of the crack with the increase in loading could be monitored, while also providing information on what features and grains in the microstructure caused the crack to slow down, arrest its propagation, or divert its direction of extension. We have found that certain grain orientations and accompanying stress tensors acted as barriers to crack extension and forced the crack either to change directions or to pause and accumulate enough stress concentration energy to advance. These findings can be used to inform computational methods and predictive models for future studies of brittle fracture.

Thermal Stability of Calcium Carbonate and its Relationship with The Crystalline Growth of The Mineralized Phases Present in Chicken Eggshells Nerith R. Elejalde-Cadena and Lauro Bucio-Galindo; National Autonomous University of Mexico, Mexico

Biomineralization processes in nature are associated with a structural control carried out by biomolecules (DNAs, proteins, and polysaccharides). There are two biomineralization processes, which are usually used by living organisms in terms of producing biominerals: (1) organic matrix-mediated biomineralization, known to be a highly regulated and homogeneous process; (2) biologically induced biomineralization, where mineralization deposits occur indefinitely and heterogeneously. However, little structural information is known about the macromolecules that constitute and act in the living organisms in these processes, since the level of structural organization of biominerals is often hierarchical in different structural orders to produce a final structure with a unique morphology with properties that until now have not been reproduced by man. Among the processes mediated by a membrane, like in diatoms, of which the importance of biological entities is appreciated, there is a rigid and porous cell wall called a frustule composed of amorphous silica. It also appears in bones comprised mainly of calcium phosphate, and in eggshells whose percentage of calcium carbonate can vary depending on the species.
However, there is a lack of a universal model that will allow us to obtain information about these two biomineralization processes. Therefore, this poster presentation will be focused on using the mineral phase and the membranes of the eggshells from chickens that are with a controlled diet (industrial sale) and those that are free (organic) as a model to differentiate the calcification, ensuring its permeability to stabilize the amorphous mineral part. By the thermal stability analysis, we will be able to obtain information on the process of formation of the eggshells as well as on the change that occurs in the membrane during the formation of crystals. The topographical analysis was performed via X-ray diffraction (XRD) and scanning electronic microscopy (SEM). The investigation has an important impact in the fields of biological and materials sciences, which would provide an effective understanding of the biomineralization processes. Additionally, this research will also allow us to know how to mimic them since most of the studies carried out are focused on immunohistochemical studies on the formation of the chicken eggshell.

Monitoring Ultrafast Structural Phenomena in 2D Materials by Femtosecond Electron Diffraction Christian Viernes, Sam Netzke, Kostyantyn Pichugin and Germán Sciaini; University of Waterloo, Canada

The structure of a material is a large factor determining its properties. An emerging field of research and development is in 2D materials which can exhibit

very different physical properties compared to their bulk counterparts. Transition metal dichalcogenides are of particular interest owing to their band structure tunability, such as a transformation from an indirect to direct band gap when thinned down to a monolayer and band gap shifts by vertically stacking TMDCs into a heterostructure, giving these crystals a wide range of potential applications in electronics. Additionally, TMDCs are able to crystallize into several different structures. Combined with the use of ultrafast lasers, it is possible to drive structural phase transitions allowing control and switching between desirable properties. However, in order to take advantage of these characteristics, a better understanding of the photoinduced structural dynamics is required.

In our presentation, we introduce an ultracompact 100-kV femtosecond electron diffraction (FED) setup. This instrument has been designed to produce ultrashort electron bursts, approximately 200-fs in duration, containing 10000 electrons. Ultrafast structural dynamics in solids often unfold within hundreds of femtoseconds to tens of picoseconds, necessitating cutting-edge techniques like femtosecond electron diffraction. This pump-probe method is sensitive to structural alterations. Here, an ultrafast laser splits into two beams: the pump and probe. The laser pump pulse initiates the changes whereas a time-delayed electron probe bunch monitors, stroboscopically, the sample's structure. We will show some recent FED results obtained in a model TMDC system.

5:00 PM CH04.03.10
Structural Evolution and Phase Transition of Geopolymers in Extreme Environmental Conditions: *In-Situ* SAXS/WAXS Study at High Temperatures under Uniaxial Tension S A K V Miyurudarshi Piyathilake[1], Ivan Kuzmenko[2], Luckshitha Suriyasena Liyanage[3,4] and Christopher Bareither[1]; [1]Colorado State University, United States; [2]Argonne National Laboratory, United States; [3]National Institute of Standards and Technology, United States; [4]University of Colorado Boulder, United States

Polyethylene based geomembrane (PE GMB) waste containment infrastructures are used as barrier systems to mitigate contaminant release to protect the environment. In the field, PE GMBs are exposed to extreme environmental conditions such as harsh mining solutions, high stress and elevated temperatures that could compromise durability and performance due to geochemical reactions, microstructural phase transitions and crystallinity changes. Therefore, it is essential to investigate real-time, high temperature structural evolution of PE GMBs in the field.

In this study we performed in-situ SAXS/WAXS experiments to evaluate the impact of temperature and stress on chemically and mechanically treated PE GMBs using synchrotron radiation at Argonne National Laboratory. Initially, they were exposed to bauxite mining process solution (pH=12.3) for 10 months and 2 GPa normal stress to simulate real-world environmental conditions. Subsequently, in-situ SAXS/WAXS data was collected every 10 seconds while applying tensile stress (strain rate of 83 um/sec) at 25°C and 65°C. Tensile stress-strain traces were obtained simultaneously.

SAXS/WAXS data provide valuable insights into micro and atomic level changes as well as the microscopic phase transitions of PE GMBs. As we stretch samples at 25°C, initial isotropic 2D SAXS pattern (that corresponds to spherulitic structure of lamellae with initial long period of 20.9 nm) gradually becomes anisotropic and decreases in q-peak intensity indicating extension of the long period due to orientation of crystals along stretch direction. The intensity of the q-peak shows a significant drop at 23% of tensile strain for the untreated reference sample. However, this structural transformation occurs at 46% of strain for the treated specimens, indicating a delay compared to the untreated ones. This suggests increased material rigidity/stiffness after treatments. The formation of cross-linking due to polymer oxidation in harsh chemical environments and strain crystallization under 2 GPa stress contribute to the higher stiffness of the treated specimens. XPS and FTIR analysis confirm the formation of free radicals and oxidative byproducts (alcohols, ketones, carbonyl compounds) in the treated specimens. The tensile strength data further support these conclusions by demonstrating increased stiffness in the treated specimens. In addition, as the stress is applied, WAXS crystalline peaks from (110) and (200) planes show a reduction in crystallinity for treated and untreated specimens at 99% and 30% tensile strains respectively. These results again indicate chemically treated specimens have become stiffer and lost their original elasticity post exposure.

At 65C, a new crystalline peak emerges with a long period of 15.7 nm representing the formation of shish-kebab superstructure consisting of long central fiber core (shish) and lamellae crystals (kebab) periodically growing along the shish under hot-stretching. This recrystallization transition occurs sooner in treated specimens which once again confirms mechanical property alteration of treated specimen under extreme environmental conditions.

Yield strength values obtained from stress-strain traces are also consistent with the increase of material rigidity after treatments. The initial yield strength of treated samples at both 25°C (11.5 MPa) and 65°C (6.4 MPa) are higher than those of untreated samples at 25°C (10.6 MPa) and 65°C (5.6 MPa). We propose in-situ SAXS/WAXS technique to study the dynamic structural evolution and phase transition phenomena in polymer based geomaterials under high temperatures, stresses, and harsh chemical environments to build robust waste containment systems to protect the environment.

5:00 PM CH04.03.11
Effect of Phase Transition caused by Different Treatment Process on Mechanical Properties of Powder Metallurgy Titanium Alloys Jie Wu; Institute of Metal Research, Chinese Academy of Sciences, China

The microstructural evolution and mechanical properties of powder metallurgy Ti-22Al-24Nb-0.5Mo prepared by combination of hot isostatic pressing, ring rolling, and heat treatment were investigated. Ring rolled and solution treatment in the (α_2 + B2 + O) region led to the refinement of grain size and long lath O phase and α_2 phase mostly located at the grain boundaries. Aging treatment in the (B2 + O) region caused the occurrence of peritectoid reaction B2 + α_2 → O owing to the segregation of the Nb element and refined the acicular O phase. The mechanical properties of PM alloys varied with the size and volume fraction of O phase and α_2 phase. The long lath O phases improve the elongation and acicular O precipitates are benefit to the elevation of alloy strength.

5:00 PM CH04.03.12
Microstructural Investigation of Work Hardening Behavior of Lightweight Steel using *In-Situ* Straining TEM Sung-Dae Kim; Pukyong National University, Korea (the Republic of)

We conducted microstructural investigations on the effect of κ-carbide precipitates on the strain hardening behavior of aged Fe-Mn-Al-C alloys. The precipitate-strengthened Fe-Mn-Al-C alloys exhibited a superior strength-ductility properties which are enabled by the strain hardening rate recovery. To understand the relation between the precipitates and strain hardening recovery, dislocation gliding alloys during plastic deformation was analyzed through in situ tensile transmission electron microscopy (TEM). The in situ TEM results confirmed the particle shearing mechanism leads to planar dislocation glide. During deformation of the overaged alloy, some gliding dislocations were strongly blocked by the large κ-carbide precipitates and were prone to cross-slip, leading to the activation of multiple slip systems. The abrupt decline in the dislocation mean free path by the activation of multiple slip leads the rapid saturation of the strain hardening recovery. It is concluded that the planar dislocation glide and sequential activation of slip systems are key to induce strain hardening recovery in polycrystalline metals. . In the present study, we conducted the in-situ straining TEM experiments with a precipitation hardened (PH) Fe-Mn-Al-C alloy. By observing the dislocations/precipitates interaction in real-time, clear understandings of the hardening mechanism

could be extracted.

5:00 PM CH04.03.13
A Micro Mechanical and Chemical Analysis of a New Vitrified Rock Material for use in Environmental Sustainability Eve Meltzer and Herbert Einstein; Massachusetts Institute of Technology, United States

Extraction of the energy available via geothermal heat in the Earth could provide substantial contributions to U.S. energy needs long-term. However, there are major technical and economic limitations with the current technology available for Enhanced Geothermal Systems (EGS). I work on a new technology in the field of EGS that uses a millimeter (MM) wave gyrotron, which allows for more efficient ultra-deep drilling. The gyrotron heats rock to temperatures ranging from 1500 to 3000°C, transforming the rock into its liquid state. Upon cooling, the new material solidifies around the circumference of a well bore hole, creating a vitrified lining.

I have conducted an in-depth micro-mechanical and chemical analysis of the vitrified material from the melting and re-solidifying of basalt. Basalt is an igneous rock that forms from the solidification of molten lava and primarily consists of minerals such as plagioclase, feldspar, pyroxenes, and olivine. And thus, when heated, the elements within these minerals go through transformation processes; this includes the formation of iron oxides as well as the possible reduction of iron. To do my study I used a combination of experimental methods including Scanning Electron Microscopy (SEM), Energy Dispersive X-ray Spectroscopy (EDS), optical imagery, micro-and nano-indentation, and Raman spectrometry. These experiments allow me to quantify the micro- and nano-scale properties. The presence of mineral phase changes and elemental differences in the basalt pre- and post-melting are evident and thus understanding these differences can give insight into the future use of this material in the field of EGS, sustainable mineral extraction, and beyond.

Quenching Effects on Topological Defects in Magnetoelectric CuO Nanoparticles Nimish P. Nazirkar, Xiaowen Shi and Edwin Fohtung; Rensselaer Polytechnic Institute, India

CuO stands out among the few identified binary multiferroic materials, boasting a transition temperature of about 230 K — a value notably higher than other materials. In CuO, electric polarization emerges due to spontaneous magnetic order. Even a minimal application of magnetic fields can induce a transition from the paraelectric to a ferroelectric phase, observed at 213 K [1]. Interestingly, topological defects in such materials exhibit remarkably different properties at the nanoscale compared to their bulk counterparts [2]. Bragg coherent diffractive imaging has proven to be a reliable method for the three-dimensional characterization of nanoscale ferroelectrics [3,4]. By integrating magnetic quenching with Bragg Coherent Diffractive Imaging on CuO nanoparticles, we successfully investigated the nanocrystal's structural alterations and how they relate to the material's ferroelectric landscape.

8:00 AM CH04.04.01
Modulation Excitation Coupled with X-Ray Absorption Spectroscopy for Probing The Restructuring Dynamics of Surface Species in Bimetallic Nanocatalysts Prahlad Kumar Routh and Anatoly Frenkel; Stony Brook University, United States

Rational catalyst design guided by a combined theoretical-computational-experimental approach has recently allowed the development of a “dynamic catalyst” using dilute alloy components. These bimetallic nanocatalysts possess dual functionality with a minority metal as the active element and a majority element as a less reactive environment to impart selectivity. Furthermore, the composition and pretreatment of these nanocatalysts can be used to selectively tune the active species on surface. Such dynamic restructuring of surfaces creates a complex behavior of these dynamic catalysts, under operando conditions in response to the changes in reactive environment. A notable challenge is the detailed understanding of the structure and evolving composition of catalytic species on nanoparticle surfaces during reactions. In-situ X-ray absorption spectroscopy (XAS) is a potential tool to elucidate this, but its efficacy is hampered by the dilute and varied nature of active sites. However, the dilute nature of the active sites, heterogeneity associated with nanoparticles as well as active sites, and the ensemble nature of XAS itself, presents significant challenges in sensitivity to active species.

In this work, we addressed these challenges by enhancing XAS sensitivity with a modulation excitation approach, focusing on 30% Pd-Au supported bimetallic nanocatalysts. We applied a modulation excitation approach to the X-ray absorption spectroscopy (ME-XAS) by inducing structural changes in the 30% Pd-Au supported bimetallic nanocatalysts (ca. 6 nm in diameter) via the gas (H_2 and O_2) concentration modulation and resolved the structure and kinetics of different surface species with 1s time resolution. We demonstrated that ME-XAS dramatically improves the sensitivity towards surface species in bimetallic alloys – the active species in dynamic catalysts. We isolated the minor contributions (3-7 at. %) of different surface species, such as Pd-Au ensembles and Pd oxides, from the total XAS data and discovered that they respond dynamically to the periodic modulation conditions. During the oxygen pulse, the formation of surface PdO_x species dominates over the bulk-to-surface segregation of Pd. During the hydrogen pulse, Pd dissolution within the Au

host drives the oxide decomposition. Such direct experimental measurement of the active species in various catalytic systems has been a challenge, given the heterogeneity associated with these active sites and the absence of a technique which can selectively measure the active species and its dynamic evolution as the reaction conditions progress. This work provides an experimental pathway to not only study the dynamic nature of active species but also enables designing non-equilibrium states of dynamic catalysts. The methodology and findings presented herein can be applied to a broad class of multicomponent nanoalloys and processes involving the active minority species, for which the ensemble-average spectroscopy data are dominated by spectators.

***In-Situ*/*Operando* Bragg Coherent X-Ray Diffraction Imaging for Visualization of Nanoscale Structural Evolution** Wonsuk Cha; Argonne National Laboratory, United States

In the last two decades, Bragg Coherent X-ray Diffraction Imaging (BCDI) has become a powerful non-destructive 3D characterization tool for features in nanoscale [1]. Because of unique sensitivity to lattice, BCDI has been employed on various nano-scaled materials such as metal, metal oxide, and mineral, to reveal 3D map of lattice distortion and strain distribution. Adding in-situ and operando approaches to BCDI enables to address scientific questions on physics, chemistry, and materials science in recent years.
In this talk, I will introduce current state-of-art of BCDI and recent experimental results on in-situ and operando BCDI. Annealing effect on gold grains on thin films [2], relaxation of strain inside quantum materials such as nanodiamond and silicon carbide [3, 4]. Strain and defect in battery materials [5] and in catalysts [6] will be discussed. In addition, some estimates of BCDI in the near future will be discussed.

8:30 AM *CH04.04.03
Nanoscale Imaging of Structure and Dynamics through Time-Resolved Hard X-Ray Diffraction Microscopy Martin V. Holt and Tao Zhou; Argonne National Laboratory, United States

The unique imaging power of nano-focused synchrotron hard x-rays can be harnessed to provide non-destructive methods for 3D visualization of crystallographic phase and strain in solid-state materials. This gives access to understanding extremely subtle lattice perturbations (<10^-4 dc/c) near optically active defects or interfaces within fabricated heterostructures that can be located potentially microns away from surfaces without sectioning the sample. The use of time-resolved coherent synchrotron illumination synchronized to external stimuli can further augment this approach to understand excitation-driven energy flow and dynamic structure-function relationships across broad classes of classical and quantum materials for energy. Current work and future directions enabled by the near-term completion of diffraction limited storage rings such as the Advanced Photon Source Upgrade (APSU) and correlative data synthesis with quantitative electron microscopy methods will be explored in the context of recent results

9:00 AM *CH04.04.04
Coherent Acoustic Wave Propagation in Two-Dimensional Metal Halide Perovskites Peijun Guo; Yale University, United States

I will discuss our recent efforts on the development of spatiotemporal optical imaging techniques to examine coherent strain waves in quasi-two-dimensional (2D) metal halide perovskites (MHPs). Specifically, I will describe our experiments performed on a variety of 2D MHPs with different number of octahedral layers, where the experiments employ hyperspectrally-resolved pump and probe pulses and cover a unique nanosecond-to-microsecond time range. The effects of the choices on the halides and the organic cations will be discussed as well. If time permits, I will also discuss our results on the self-trapped excitons in double perovskites examined by optical-pump x-ray diffraction experiments.

9:30 AM CH04.04.05
Full-Field Strain Measurements in Homogeneous Solids: High-Resolution Speckle-Free Flux Enhanced Tomography Zifan Wang; University of Cambridge, United Kingdom

X-ray computed tomography (XCT) is a reliable tool for measuring internal flaws and microstructural features in engineering materials. As an extension to XCT, Digital Volume Correlation (DVC) methodology enables tracking 3D deformations based on local grayscale contrast. Nevertheless, its applicability and spatial resolution have been limited by the need for tracer particles or inherent microstructural features that are properly distributed in the material. To address these limitations, we developed a Flux Enhanced Tomography for Correlation (FETC) technique that leverages inherent inhomogeneities in engineering materials (polymers to metals) to track 3D material point displacements without relying on artificial speckles or inclusions. Combined with a Eulerian/Lagrangian transformation in a DVC methodology, FETC allows us to measure all nine components of the deformation gradient within specimens undergoing extreme deformations at microscale resolution. FETC expands the capabilities of laboratory-based XCT and provides large datasets for data-driven constitutive modelling approaches.

10:15 AM *CH04.04.06
Keyhole Dynamics in Laser Powder Bed Fusion Additive Manufacturing Tao Sun; Northwestern University, United States

Laser powder bed fusion (LPBF) is the most extensively used metal additive manufacturing technology due to its unique capabilities in building parts with high geometric complexity and fine features. During the LPBF process, sparks (i.e., spattered particles) can be observed following the laser scanning path, indicating the presence of high-velocity vapor arising from the melt pool. Indeed, strong metal vaporization occurs in LPBF, resulting in recoil pressure that creates a depression in the melt pool, often referred to as a keyhole. The keyhole is an important dynamic structural feature in LPBF as it influences energy coupling, metal melting mode, and defect generation. Without a keyhole, the laser is absorbed by the metal surface only once, with significant amount of energy being reflected away. In contrast, with the presence of a deep keyhole, multiple laser absorption events occur, significantly increasing laser absorption efficiency. The laser melting mode can shift from conduction to transition, stable keyhole, and then unstable keyhole as the energy input increases. When the conduction mode is applied, lack-of-fusion voids may be generated during the build. An unstable keyhole condition also leads to porosity.

Keyhole porosity is a major defect that hinders the widespread adoption of laser-based metal additive manufacturing technologies. With simultaneous high-speed synchrotron X-ray imaging and thermal imaging, coupled with multi-physics simulations, we discovered two types of keyhole oscillation in laser powder bed fusion of Ti-6Al-4V. Amplifying this understanding with machine learning, we developed an approach for detecting the stochastic keyhole porosity generation events with sub-millisecond temporal resolution and near-perfect prediction rate. The highly accurate data labeling enabled by operando X-ray imaging allowed us to demonstrate a facile and practical way to adopt our approach in commercial systems.

10:45 AM CH04.04.07
Gas Pore Formation in Powder Bed Fusion Kaitlin Lyszak, Erin B. Curry, Lauren A. Gorman, Donal Sheets, Lukas Lasig and Jason Hancock; University of Connecticut, United States

Additive manufacturing (AM) of metal materials based on powder bed fusion technology is widely used now in many industries. A known limitation of this type of manufacturing is the formation of gas pores in bulk material arising from stochastic events related to molten metal fluid instabilities of a vapor depression. Here we present a combined X-ray imaging and infrared pyrometry study of pore formation in repeated adjacent tracks, and quantify the correlations of pore positions and sizes for a common material (Aluminum 6061) of interest in AM as a function of its laser processing conditions. We find in both cases that an existing pore in one track often catalyzes the formation of another pore in a consecutive track at the distance of closest approach. In a raster scan strategy commonly used to construct bulk material, this phenomenon has the result of forming perforations, or lines of pores transverse to the scanning direction in a rastered patch. If controlled, this effect can be eliminated to improve the yield strength of the build, or exploited to create programmable failures for specific purposes.

11:00 AM CH04.04.08
Thermal Dynamics of $Na_{0.67}Ni_{0.33}Mn_{0.67}O_2$ Cathode Materials for Sodium Ion Batteries studied by *In Situ* Analysis Dewen Hou[1], Eric Gabriel[1], Tianyi Li[2], Yuzi Liu[2] and Claire Xiong[1]; [1]Boise State University, United States; [2]Argonne National Laboratory, United States

Layered $Na_{0.67}Ni_{0.33}Mn_{0.67}O_2$ is an attractive cathode material for sodium ion batteries. The thermal stability of cathode materials is crucial to their practical applications. In this work, we investigate structural and morphological evolution in layered P2-type $Na_{0.67}Ni_{0.33}Mn_{0.67}O_2$ cathode materials during annealing via in situ synchrotron X-ray diffraction and transmission electron microscopy. Insights are obtained from two complementary in situ characterizations at different length scales in terms of the thermal stability of P2-$Na_{0.67}Ni_{0.33}Mn_{0.67}O_2$ cathode materials. The results indicate that the hexagonal P2 phase remains unchanged during the heat-treatment process, and thermally driven expansion/contraction of the lattice parameters exhibits an anisotropic change in the *a* and *c* directions. In addition, interfaces/grain boundaries play an important role in the structural stability, which leads to the distinct morphological evolution between the polycrystalline and single-crystal particles.

11:15 AM CH04.04.09
***Operando* XAS-XRD Reveals Structural Dynamics in CoPt Nanoparticles under Dry Reforming of Methane Conditions** David Niedbalka, Marcel Janak, Diana Piankova, Paula Abdala and Christoph R. Müller; ETH Zurich, Switzerland

Gaining insight into how the geometric and electronic structure of (mono)metallic nanoparticles is modified through the addition of a second metal (bimetallic nanoparticles) and how such structural changes affect in turn their catalytic properties[1] is crucial for the rational advancement of catalysts. Further, as the structure of a catalyst is often dynamic[2] *ex-situ* characterization methods may be insufficient to describe the active phases of a catalyst. Therefore, *operando* studies are key to correlate a catalyst's structure to its performance while relying at the same time on well-defined model systems.

The dry reforming of methane (DRM) is a reaction that converts CH_4 and CO_2 into a synthesis gas at 600-1000 °C and is typically catalyzed by transition metals such as Ni, Co, or Pt. However, such monometallic catalysts often suffer from deactivation due to particle growth, carbon deposition, and/or oxidation.

In this study, we investigate SiO_2-supported, bimetallic CoPt nanoparticles and their monometallic counterparts (CoPt/SiO_2, Co/SiO_2, and Pt/SiO_2) for the DRM. Prior to the catalytic DRM tests, all catalysts were activated *in-situ* in a H_2/N_2 mixture (1-2 h). The bimetallic CoPt/SiO_2 catalyst shows superior activity and stability under DRM conditions (800 °C and 1 bar, CH_4:CO_2 ratio = 1, space velocity = 30.000 ml g^{-1} h^{-1}) in comparison to its monometallic counterparts. Specifically, while Pt/SiO_2 showed the lowest CH_4 conversion (10%), Co/SiO_2 underwent deactivation, resulting in a decrease in CH_4 conversion from 30% to 15% within 120 min. Conversely, CoPt/SiO_2 showed a stable performance of 35% CH_4 conversion over 6 h.

To elucidate the structure of the active phase in CoPt/SiO_2 under DRM conditions, and to probe structural dynamics, we conducted *operando* experiments using combined synchrotron X-ray absorption spectroscopy (XAS) and X-ray diffraction (XRD). Co K-edge and Pt L_3-edge XAS analysis shows that in CoPt/SiO_2 during *in-situ* H_2 activation Co and Pt become both fully reduced to their metallic states. We further observe differences in the Co K-edge and Pt L_3-edge XAS features of CoPt/SiO_2 when compared to Co/SiO_2 or Pt/SiO_2, possibly due to a charge transfer between the metals, orbital hybridization in the CoPt alloy and/or a change in the local structure of Pt and Co.[3] Rietveld analysis of the acquired XRD data after *in-situ* activation at 800 °C indicates the formation of two types of CoPt alloys: an ordered (intermetallic) CoPt (52%) and a random CoPt alloy (48%). Interestingly, upon switching to DRM conditions (800 °C, CH_4:CO_2 ratio = 1) XRD analysis revealed an instantaneous transformation of the intermetallic phase into a random alloy. This phase transition was also evidenced in the Pt L_3-edge XAS data but did not change the electronic structure/oxidation state of Co (i.e., Co K-edge remained invariant prior to and during DRM). In contrast, under DRM conditions, Co/SiO_2 underwent a partial oxidation showcasing the stabilization of the metallic state of Co through its alloying with Pt. This stabilization, combined with changes in the electronic/local structure and site isolation that very likely suppresses coking on Pt, contribute to the superior activity of CoPt/SiO_2 compared to Co/SiO_2 and Pt/SiO_2.

We also observe a phase transition from a random to intermetallic alloy during the cooling down to room temperature of the reacted catalyst, underscoring the significance of *operando* characterization in capturing dynamic changes and identifying the catalytically active phase.

11:30 AM CH04.04.10
Revealing The Mechanisms of Ultrafast Transient Liquid Assisted Growth of REBCO-Type Superconducting Thin Films by Synchrotron Radiation *In-Situ* X-Ray Diffraction Elzbieta Pach[1,2], Lavinia Saltarelli[1], Diana G. Franco[1], Carla Torres[1], Daniel Sánchez[3], Jordi Farjas[3], Eduardo Solano[4], Cristian Mocuta[2], Xavier Obradors Berenguer[1] and Teresa Puig[1]; [1]ICMAB-CSIC, Spain; [2]Soleil Synchrotron, France; [3]GRMT, University of

Girona, Spain; [4]ALBA Synchrotron, Spain

The novel ultrafast Transient Liquid Assisted Growth (TLAG) method [1-3] is an outstanding opportunity to fabricate low-cost, high throughput epitaxial superconducting $YBa_2Cu_3O_7$ (YBCO) films using scalable methods. However, the fast kinetics of this non-equilibrium process require in-situ techniques to understand its growth mechanism and determine key process parameters. A specialized instrumentation was developed to allow investigating the dynamics of TLAG process based on in-situ monitoring of the precursors reaction, intermediate phases evolution and final products of the YBCO growth by in-situ XRD at synchrotron radiation sources at acquisition times from 2 - 100 ms/frame. This set-up allows to control the key parameters of growth of the YBCO by TLAG, this includes the temperature, partial oxygen pressure, total pressure and the heating rate, as well as to perform very fast changes in total and partial oxygen pressures. Additionally, Mass Spectrometry measures the gaseous products of the reaction. Furthermore, the resistance is measured in-situ throughout all the growth process providing valuable information on the growth rate of the superconducting phase. The installation is placed in a movable rack that allows its use in different synchrotron facilities and all the equipment is time synchronized. All of the acquired data during the combined experiments is advancing our understanding of the non-equilibrium growth mechanism and pinpoints the direction to the optimal conditions for ultrafast epitaxial growth of YBCO reaching up to 1000 nm/s.

Peering into the Self- and Directed-Assembly of Nanoparticles Hongyou Fan; Sandia National Laboratories, United States

Self-assembly of synthetic nanoparticles enables the positioning of nanoparticles into one to three dimensional ordered arrays, facilitating integration of nanoparticle lattices into nanophotonic and nanoelectronic architectures. The functional properties of these particle materials are expected to be highly sensitive to structural factors such as coordination number, degree of long-range order, or interparticle separation distance, requiring the development of robust self- and directed-assembly pathways for precise control of structural parameters to improve optical and electronic properties of functional nanoparticles. In this presentation, I will review our past efforts in development of self-assembled nanoparticles thin film arrays and in-situ structural evolution at ambient condition. I will then extend my presentation to our recent progress in development of a new Stress-Induced Fabrication method in which we applied high pressure or stress to nanoparticle arrays to induce structural phase transition and to consolidate new nanomaterials with precisely controlled structures and tunable properties. By manipulating nanoparticle coupling through external pressure, a reversible change in their assemblies and properties can be achieved and demonstrated. In addition, over a certain threshold, the external pressure will force these nanoparticles into contact, thereby allowing the formation and consolidation of one- to three-dimensional nanostructures. Through stress induced nanoparticle assembly, materials engineering and synthesis become remarkably flexible without relying on traditional crystallization process where atoms/ions are locked in a specific crystal structure. Therefore, morphology or architecture can be readily tuned to produce desirable properties for practical applications.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

Design of Open Systems using Aqueous Polymer Solutions causing Meniscus Splitting Phenomena Reina Hagiwara and Kosuke Okeyoshi; Japan Advanced Institute of Science and Technology, Japan

Self-organization is a process commonly observed in soft matter and in spontaneous phenomena of life. Extracting and reproducing in vitro the physicochemical conditions is an important step beyond designing "life-like" materials having smart responses to environmental change. The behavior of polymeric solutions is known as viscous fingering. We have reported "meniscus splitting"[1], in which the pattern formed on a substrate is developed into a millimeter-scale spatiotemporal structure. This is a non-equilibrium phenomenon in the controlled evaporation of polymer solution that splits the air-water interface into multiple regions. Drying an aqueous polymer dispersion from one interface in a limited space causes the polymer to precipitate at a specific position, driven by capillary forces. Also, the deposited polymer membrane has an oriented structure and becomes a functional material such as a humidity actuator [2]. However, the specific spatiotemporal changes at the interface observed in the meniscus-splitting phenomenon have been only shown using some biopolymers, and the regulatory factors toward the universalization are unclear.
In this study, we demonstrate that meniscus splitting can happen with chemical species independence, and it is a universal phenomenon, through the experiment. Polyacrylic acid (PAAc), polyacrylamide (PAAm), and polyvinyl alcohol (PVA) were used as synthetic vinyl polymers for the demonstration. The effect of different molecular weights on the interfacial behavior was pronounced, indicating that molecular weights with appropriate viscosity are necessary for membrane formation. PAAc and PAAm exhibited a splitting pattern like that of the polysaccharides reported previously. On the other hand, PVA did not form vertical membranes, but rather horizontal ones. This difference is thought to be due to the retentivity of water, and PVA's propensity to form intra- and intermolecular hydrogen bonds. When the relative humidity was adjusted, vertical membrane was also formed for PVA as well as for the other chemical species. Furthermore, we attempted a mathematical analysis of the spatiotemporal changes in the specific interfacial shape observed during the drying process. To understand the transformation of the interface the characteristic interface curves were fitted by a hyperbolic curve or an elliptic curve. Through the fitting evaluation, it was suggested that the interface curves transformed from a hyperbolic curve to an elliptic curve during the

splitting.

SESSION CH04.06: Surface and Chemistry
Session Chairs: Luxi Li and Yang Yang
Wednesday Afternoon, April 24, 2024
Room 443, Level 4, Summit

3:30 PM CH04.06.01
Electronic Characterization of 9A-GNR on H:Si(100) using a Scanning Tunneling Microscope Abigail Berg[1], Mamun Sarker[2], Anshual Saxena[3], Narayana R. Aluru[3], Alexander Sinitskii[2] and Joseph Lyding[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Nebraska–Lincoln, United States; [3]The University of Texas at Austin, United States

We present the electronic characterization of a new solution-synthesized type graphene nanoribbon (GNR). The GNR was synthesized with two different precursors to form coves along the length of an N=9 armchair GNR. The GNR also contains two different functional end groups, -NO2 and -NH2, with each synthesized to attach to the two different precursors. Atomically precise graphene nanoribbons with functional end groups have the potential for further modification and integration into complex electronic structures. We use the dry-contact transfer (DCT) method to exfoliate the GNRs onto hydrogen passivated Si(100) in a room temperature ultra-high vacuum (UHV) scanning tunneling microscope (STM). The bandgap and density of states are probed using scanning tunneling spectroscopy (STS) and current imaging tunneling spectroscopy (CITS). We find that GNRs tend to cluster in groups and form weak bonds at the functionalized ends. We also find evidence of missing phenyl groups during synthesis which form extra-large coves in the final structure of the GNR. Simulation data indicates that the DFT bandgap is 1.4 eV and an increased density of states over the NO2 end group. Experimentally we see that one end of the GNR appears to be metallic using STS, which we attribute to the NO2 end group. The bandgap appears to have a lateral dependence from 1.7 eV to 2.3 eV along the GNR which will be explored in more detail. Finally, we present the effects of using nanolithography to depassivate the H:Si(100) below the GNR.

3:45 PM CH04.06.03
Effects of Anions on Phase Transformation and Crystallization of Aluminum Hydroxide Ping P. Chen, Suyun Wang, Trent R. Graham, Duo Song, Xiaodong Zhao, Zheming Wang, Carolyn Pearce, Kevin Rosso and Xin Zhang; Pacific Northwest National Laboratory, United States

Gibbsite (α-$Al(OH)_3$) is naturally abundant and plays a vital role as a raw material in various industrial applications. Furthermore, it constitutes a significant portion of the solid components in caustic nuclear waste at the Hanford Site (WA, USA). While extensive research has been conducted to understand gibbsite's behavior in processes such as crystallization, dissolution, phase transformation, solution chemistry, and irradiation-induced changes, the effects of co-existing high concentrations of salts on gibbsite's nucleation and growth remain a less-explored area. In this study, we investigated gibbsite crystallization from the solutions containing six sodium-based salts, specifically sodium salts of fluoride, chlorine, bromide, nitrate, phosphate, and sulfate. Our findings illuminate the diverse ways in which different anions can influence the crystal phase, structure, morphology, and growth rate of gibbsite as determined with various advanced techniques, including X-ray diffraction (XRD), Fourier-transform infrared spectroscopy (FTIR), Raman, nuclear magnetic resonance (NMR), scanning electron microscopy (SEM), and scanning/transmission electron microscopy (S/TEM). These results were further substantiated through the calculation of molecular cluster energies using density functional theory. In summary, our exploration of gibbsite crystallization in complex, multicomponent electrolytes simulates the compositional complexity encountered in nuclear waste, shedding light on the intricate interplay between gibbsite and co-existing salts.

4:00 PM CH04.06.04
Temperature-Dependent Structural and Elastic Properties of Cubic and Hexagonal $Sc_xAl_{1-x}N$ Saskia Mihalic[1], Lucia Ciprian[1], Christopher Lüttich[2], Elisa Wade[1], Armin Dadgar[2], Björn Christian[1], André Strittmatter[2] and Oliver Ambacher[1]; [1]University of Freiburg, Germany; [2]Otto von Guericke Universität Magdeburg, Germany

The novel wide-bandgap semiconductor, Scandium Aluminum Nitride ($Sc_xAl_{1-x}N$) significantly enhances its piezoelectric properties compared to Aluminum Nitride (AlN). This unique increase in piezoelectric coefficient $d_{33}(x)$ makes $Sc_xAl_{1-x}N$ a highly favorable material for numerous applications, including improved piezo-acoustic devices, which can be utilized as high-frequency filters [1]. The optimization of the devices is impeded by the trade-off between piezoelectric response and the stiffness of the crystal. To address this, a detailed investigation of the anisotropic elastic, piezoelectric, and thermodynamic properties is necessary. However, the ternary alloy $Sc_xAl_{1-x}N$ undergoes a solid-solid phase transition from hexagonal wurtzite (wz) to cubic rock salt (rs) structure as the Sc content x increases, which differs from other ternary nitrides [2]. The coefficient $d_{33}(x)$ of wz-$Sc_xAl_{1-x}N$ exhibits the highest values and the elastic properties undergo significant changes when the Sc content is proximate to this transition. The specific Sc:Al ratio, pressure and temperature conditions and seed layer selection (either AlN(0001) or ScN(111)) that induce this B4-B1 transition have yet been explored und will be discussed in this work. Accordingly, this study will discuss these conditions as they provide valuable insights to improve the efficiency of devices that rely on maximum piezoelectric responses. The physical properties of resonators are dependent on the operating temperature (T). The structural changes can be described utilizing lattice parameters $c(x, T)$ and $a(x, T)$, internal parameter $u(x, T)$, and elastic tensor $C_{ij}(x, T)$. In order to determine temperature-dependent structural properties of pulsed magnetron co-sputtered thin films, in-situ X-ray diffractometry measurements ranging from 300 K to 1000 K were conducted to determine the lattice parameters $c(x, T)$ and $a(x, T)$ for hexagonal and cubic $Sc_xAl_{1-x}N$(0001)/Si(111) thin films, respectively. The Debye model was utilized to determine the coefficients of linear thermal expansion α_a and α_c for wz-$Sc_xAl_{1-x}N$ along the 〈1000〉 and [0001] directions and $\alpha_{a'}$ for rs-$Sc_xAl_{1-x}N$ along the 100 directions. For the first time, the linear thermal expansion coefficient was experimentally determined for wz-$Sc_xAl_{1-x}N$ ($0.0<x<0.5$) and rs-$Sc_xAl_{1-x}N$ ($0.5<x<1.0$). This temperature-dependent structural information was used to compute additional structural specifications such as bond lengths and bond angles for random alloys of wz-$Sc_xAl_{1-x}N$ and rs-$Sc_xAl_{1-x}N$. Scanning electron microscopy (SEM) was utilized to observe the effects of heating on surface morphology. To understand the elastic properties of wz- and rs-$Sc_xAl_{1-x}N$ fully, various anisotropic elastic properties including shear modulus G and Young's modulus E were calculated for multiple crystallographic planes, by employing simulated tensor quantities at ambient conditions. For the first time, the in-plane epitaxial relation between rs-$Sc_xAl_{1-x}N$(111) and Si(111) was determined, which is rs-$Sc_xAl_{1-x}N$[110] ‖ Si[100]. Further thermodynamic properties such as specific heat, heat conductivity and Debye temperature were calculated. This newfound knowledge of temperature- and direction-dependent structural and elastic properties offers the potential for improved efficiency of piezo-acoustic devices.

Tailored Aluminum Surfaces for Adhesive Bonding – Joint Properties and Moisture induced Damage Mechanisms Jonathan Freund[1], Miriam Löbbecke[1], Frank Förste[2], Michael Wiedenbeck[3], Ioanna Mantouvalou[4] and Jan Haubrich[1]; [1]German Aerospace Center (DLR), Germany; [2]TU Berlin, Germany; [3]Helmholtz-Zentrum Potsdam, Germany; [4]Helmholtz-Zentrum Berlin, Germany

For the energy efficiency of future vehicles and aircraft, weight reductions through the use of alternative materials and joining techniques will be essential. Structural adhesive bonding is one technique to join dissimilar materials, eliminating the need for additional fasteners like bolts or rivets while enabling a uniform stress distribution across the bonded materials.
However, the fundamental understanding of the relationships between the physical and chemical surface properties of the interfaces and the resulting joint properties is needed. One major concern is joint weakening due to exposure to moisture, which has blocked the widespread uptake of adhesive bonding technologies in safety relevant applications [1]. Despite such aging process being difficult to detect non-destructively, further research into the mechanisms that cause such weakening is necessary if long-term durable adhesive joints are to be achieved.
Pulsed laser surface pretreatment of metal surfaces prior to adhesive bonding can significantly increases the mechanical strength and the long-term durability of metal-polymer joints. This benefit is often attributed to cleaning effects while also generating structures with suitable roughness on the metal surface that allow a better mechanical interlocking with the polymer matrix [2]. However, an enlarged, roughened metal oxide surface will also offer more surface area for chemical bonding with the polymer adhesive. The reasons for the improved aging properties provided by such laser surface pretreatment remains a matter of investigation, and here atomic-scale diffusion can play a role. Since the joint interface is buried and since the hydrogen and the oxygen atoms from water molecules cannot be distinguished easily from those native to the surface oxide film and polymer, it is difficult to study the diffusion in the joints.
Our study uses on a new approach for investigating the role of diffusion in modifying laser-pretreated adhesive joints. Scanning electron microscopy (SEM) can characterize the laser-modification of such surfaces down to the nanometer scale. We combined this information with observed diffusion rates determined by micro-x-ray fluorescence spectroscopy (μ-XRF) and secondary ion mass spectrometry (SIMS), which used elemental and ^{18}O tracers, respectively. The preliminary results from our tracer studies indicate that significant diffusion in the polymer-metal interface and within the bulk polymer occurs. We also used single-lap shear tests of both unaged and hydrothermally aged specimens both with and without laser-pretreatment to link surface features and diffusion lengths with the mechanical strength of the specimens. This brought new insights concerning the mechanisms responsible for the loss of mechanical joint performance due to moisture and the role of interface features in suppressing this problem.

Atom Probe Tomography for Dynamic Characterization of Materials Surface Phenomena Lorenzo Rigutti[1], Aïssatou Diagne[1], Samba Ndiaye[1], Christian Bacchi[1], Benjamin Klaes[1], Noelle Gogneau[2], Mariaconcetta Canino[3] and François Vurpillot[1]; [1]University of Rouen Normandie, France; [2]C2N, France; [3]IMM CNR, Italy

Atom Probe Tomography (APT) is a microscopy and micro-analysis technique based on field ion evaporation. Its standard application to materials science yields a *static picture* of a system, providing a set of 3D reconstructed positions of ions chemically identified through their mass/charge ratio. However, field ion evaporation is a complex *dynamic process*, driven by the system chemistry and by environmental parameters such as temperature, electric field, intensity and wavelength of laser pulses [1]. The correlated evaporation of spatially neighboring atoms, the formation and evaporation of molecular ions either through surface dynamics or through the interaction of residual gas molecules and the surface, the dissociation of molecular ions are examples of processes that occur and carry specific traces in APT datasets. This information is typically neglected in APT analysis, but may give important insight about surface chemistry under high field (with or without laser illumination), which makes of APT a technique for *dynamic studies* of material surfaces.
In this contribution several examples of a dynamic use of APT will be reported: (i) the formation of molecular ions in silicon carbide, with its consequences on spatial and compositional accuracy of APT reconstructions[2], (ii) the microscopic assessment of single reactions involving molecular hydrogen adsorbed at the surface of III-N materials [3] and (iii) the field-dependent formation of hydride molecules in III-N materials.
The perspective extension of these dynamic APT approaches to other materials and surface chemical reactions will finally be discussed.

Room 443, Level 4, Summit

8:00 AM *CH04.07.01
4D-STEM Imaging of The Evolution and Performance Relevance of Microstructures in Cathode Nanoparticles Qian Chen; University of Illinois at Urbana-Champaign, United States

In this talk, I will discuss our recent efforts on utilizing four-dimensional scanning transmission electron microscopy (4D-STEM) to image the microstructures in cathode nanoparticles in rechargeable multivalent-ion batteries. We use metal oxide nanoparticles, either single-crystalline or defect-laden ones, as the cathodes, which undergo electrochemically driven phase transformation during charge and discharge cycles. The phase transformation

induces the emergence of complex microstructures in the nanoparticles, such as phase orientation domains, domain boundaries, and defects such as stacking faults and dislocations. These microstructures ultimately change the energy barriers associated with ion diffusivity, the capacity, and cyclability of the battery systems. Our work demonstrates the prospect of "microstructure" engineering in energy storage materials, where spatiotemporal heterogeneity from the atomic to the nanoscale can impact macroscopic performances.

8:30 AM *CH04.07.02
Probing Grain Boundary Dynamics in Polycrystalline Materials by *In-Situ*TEM Yuan Tian, Yutong Bi and Xiaoqing Pan; University of California, Irvine, United States

Understanding grain boundary (GB) dynamics in polycrystalline materials is crucial for predicting their macroscopic properties, such as mechanical strength, ductility, and conductivity. The migration and interaction of GBs are key factors affecting the thermal and mechanical stability of these materials. In situ transmission electron microscopy (TEM) plays an important role in investigating GB dynamics at the atomic scale. However, the lack of statistics for atomic scale study presents challenges in uncovering the predominance of multiple mechanisms in certain dynamic processes. This study employs cutting-edge four-dimensional transmission electron microscopy (4D-STEM) techniques for *in situ* experiments to shed light on the mechanisms of grain boundary migration at the microstructural and statistical level.
In the first part of the study, an *in situ* 4D-STEM experiment was conducted on a Pt polycrystal thin film sample at an elevated temperature. The datasets were cyclically collected in the same region of the sample after predetermined annealing times. Crystallographic orientation information was derived from the 4D-STEM datasets through cross-correlation between the experimental and simulated diffraction patterns of the Pt sample. By utilizing grain segmentation and inter-frame association, the evolution of grain orientation and GB dynamics was traced. The observations revealed ubiquitous grain rotation and GB migration during the annealing process, as well as a strong correlation between GB migration and grain rotation. Subsequently, atomic-resolution high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) observations of grain boundary migration were conducted on the Pt sample. These observations at the atomic scale demonstrated that GB migration occurs through disconnection propagation, leading to the induction of local shear strain. This shear strain accumulates near the GB and needs to be released before further migration can occur. The findings from this observation indicate that grain rotation and annealing twin formation serve as effective pathways for releasing the strain generated by shear-coupled GB migration. This comprehensive study provides valuable insights into the complex mechanisms governing grain boundary migration in polycrystalline materials, contributing to our understanding of their macroscopic properties and potential applications in material science and engineering.

9:00 AM CH04.07.03
Imaging Mobility of Charge Order Topology via Charge Density Wave Interferometery Suk Hyun Sung[1,2], Noah Schnitzer[3], Ismail El Baggari[1], Lena Kourkoutis[3] and Robert Hovden[2]; [1]Harvard University, United States; [2]University of Michigan, United States; [3]Cornell University, United States

Charge density waves (CDWs) are emergent correlated electron behavior that span crystals with strong electron-lattice coupling and are associated with exciting phenomena such as metal–insulator transitions and superconductivity. Often described as a superlattice crystal of electrons, CDWs can also accommodate defects such as dislocations and elastic deformations. CDW defects are of a particular interest as they are believed to dominate conductance [1] and mediate phase transitions of the charge lattice itself [2–4]. Topological defects in a CDW are even expected to locally host superconductivity [5]. Therefore, understanding the formation, destruction, and mechanics of CDW defects is paramount to harnessing the full potential of charge ordered materials.

TaS_2 is prototypical layered CDW system that hosts multiple CDW phases tuned by temperature, thickness and polytype [6–8]. Octahedrally coordinated 1T-TaS_2 at room temperature hosts a nearly-commensurate (NC-) CDW lacking long-range order, and a long-range ordered commensurate (C-) CDW below 200 K. While the nature of order in NC-CDW phase remains unclear, it is generally accepted that NC-CDW incorporates discommensurations (i.e., slips in the CDW phase) [3, 4]. Real space measurement of the nanoscale structure of the NC-CDW is complicated by out-of-plane incoherence of the CDW; features are washed out in atomic resolution measurements. Here we use CDW moiré engineering to magnify and image the structure of CDW dislocations in the NC-CDW phase of TaS_2.

We generate a CDW moiré by synthesizing an endotaxial polytype heterostructure [9] that stabilizes both NC- and C-CDW phase layers embedded in a metallic prismatic matrix. Here the long-range ordered C-CDW serves as a grating with which the NC-CDW interferes. The resulting moiré interference pattern resolves a topological defect present in the NC-CDW. This pattern effectively encodes and magnifies the phase information in the NC- and C-CDW phases, taking advantage of the fact that NC- and C-CDWs diffract electrons with only slightly different momentum. By collecting scanned nanobeam diffraction patterns (i.e., 4D scanning transmission electron microscopy (STEM)) with the convergence angle and camera length tuned such that both C and NC reflections are incident on a single pixel of an electron microscope pixel array detector (EMPAD), moiré interference patterns are speedily acquired in parallel at every point in reciprocal space that the superlattice peaks nearly coincide.

In summary, we image CDW defects by employing 4D-STEM on polytype heterostructures of TaS_2. The interference from C and NC-CDW forms a moiré pattern that encodes the phase disorder of the NC phase, allowing defects to be imaged despite the out of plane incoherence inherent to the system. This work suggests a new experimental framework that can shed light on difficult-to-study CDW mechanics.

Nanoscale Evaluation of SiO_2 Density by Stretching Vibrations Measurement using STEM–EELS Takanori Asano, Manabu Tezura, Masumi Saitoh and Hiroki Tanaka; Kioxia Corporation, Japan

SiO_2 is one of the most important dielectric materials used as gate insulators and interlayer films in nanoelectronic devices. Although the density of SiO_2 has been evaluated by the Si-O-Si stretching vibration peak using IR (infrared spectroscopy) [1] so far, there is no established technique to evaluate the density distribution in the nanoscale area. In this work, we develop a technique for nanoscale evaluation of SiO_2 using STEM (scanning transmission electron microscopy) – EELS (electron energy loss spectroscopy). While there are a number of reports on vibrational spectra measured by STEM-EELS

[2,3], a method for density evaluation using EELS has not been established yet. We found differences in the stretching vibration peaks reflecting the density between SiO_2 with different atomic structures: α-quartz (2.648 g/cm^3) and silica glass (2.2 g/cm^3). The dependence of the stretching peak on the thickness of the STEM specimen was investigated in detail by experiment and spectral calculation using a dielectric model.

IR spectra showed that the FWHM (full width at half maximum) of the stretching peak was larger for silica glass than for α-quartz. This corresponds to lower density in the silica glass as a result of greater variation in the Si-O-Si bond angle [3]. We also measured vibrational EELS spectra using STEM with a nanometer resolution and a high energy resolution of 16 meV (FWHM of the zero-loss peak). The FWHM of the stretching peak for silica glass was observed to be 5 meV larger than that for α-quartz, which is consistent with the IR results. On the other hand, simulations based on the Kröger formula [4] showed the experimental stretching peaks reflect both surface scattering and bulk scattering. This simulation suggests the specimen thickness is a key factor when comparing the different samples, because the contribution of surface scattering strongly depends on the specimen thickness. Thus, to establish our evaluation method by STEM–EELS, we investigated in detail the dependence of the stretching peaks on specimen thickness in the range of 30 nm to 100 nm. By comparing the FWHM of the samples with the same specimen thickness, we confirmed that there is a significant difference of more than 4 meV in the stretching peaks between silica glass and α-quartz for all the thicknesses.

We prepared α-quartz locally amorphized by electron irradiation for a longer duration (~50,000 times longer) than the vibrational EELS measurements, and investigated its density using the established evaluation method. As a result, the amorphized α-quartz was found to be denser than silica glass and to have the same density as α-quartz. This suggests that the atomic number of α-quartz is maintained during the amorphization under the low electron current (~10 pA) irradiation, which does not cause significant atomic desorption. These results indicate that vibrational EELS using STEM is a promising technique for local density analysis of SiO_2.

Surface oxidation is an important process for corrosion, which costs a few percent of the U.S. Gross Domestic Product (GDP) each year. Much is known about oxygen interaction with metal surfaces and the macroscopic growth of thermodynamically stable oxides. At present, however, the transient stages of oxidation - from nucleation of the metal oxide to formation of the thermodynamically stable oxide - represent a scientifically challenging and technologically important terra incognito. These issues can only be understood through a detailed study of the relevant microscopic processes at the nanoscale in situ. We have previously demonstrated via in situ transmission electron microscopy (TEM) that the formation of epitaxial Cu2O islands during the transient oxidation of Cu(100), (110), and (111) films bear a striking resemblance to heteroepitaxy, where the initial stages of growth are dominated by oxygen surface diffusion and strain impacts the evolution of the oxide morphologies. To deepen our understanding of the atomic-scale dynamic processes of Cu2O island formation on Cu during oxidation in situ, we are presently using correlated in situ high-resolution environmental TEM (ETEM) and atomistic theoretical simulations. As an example of this approach, preferential monolayer-by-monolayer growth along Cu2O(110) planes was noted instead of along Cu2O(100) planes. Correlated Density Functional Theory (DFT) simulations on the surface and diffusion energies during Cu2O growth on various Cu2O surface orientations and terminations were carried out. Our DFT results show that monolayer formation of Cu2O along Cu2O(110) was both thermodynamically and kinetically preferred over that of Cu2O(100) during Cu2O growth, which explains the observed phenomenon. These results shed new light on the epitaxial oxide growth mechanism and provide a deeper understanding of the dynamic processes involved in initial oxidation, which will ultimately help to precisely predict, design, and control nanostructured oxide growth for either corrosion-protection or creating nano-oxides for their functional properties. Furthermore, advancing hardware and software for enhancing in situ experiments will be discussed. We gratefully acknowledge support from the National Science Foundation (NSF), including NSF-CMMI 1905647, NSF-DMR 1410055, 1508417, 1410335. This research used the electron microscopy resources of the Center for Functional Nanomaterials (CFN), which is a U.S. Department of Energy Office of Science User Facility, at Brookhaven National Laboratory under Contract No. DE-SC0012704.

Enabling sustainable chemical manufacturing with atomically-optimized photocatalysts Jennifer A. Dionne; Stanford University, United States

Chemical manufacturing is critical for industries spanning construction, plastics, pharmaceuticals, food, and fertilizers, yet remains among the most energy-demanding practices. Optical excitation of plasmons offers a route to more sustainable chemical synthesis. Plasmons create nanoscopic regions of high electromagnetic field intensity that can modify electronic and molecular energy levels, enable access to excited-state dynamics, and open new reaction pathways that are impossible to achieve under typical conditions. Further, plasmons can be efficiently excited with sunlight or solar-driven LEDs, for sustainable chemical transformations.

Here, we present our research advancing plasmon photocatalysis from the atomic to the reactor scale (see Figure 1). First, we describe advances in in-situ atomic-scale catalyst characterization, using environmental optically-coupled transmission electron microscopy. With both light and reactive gases introduced into the column of an electron microscope, we can monitor chemical transformations under various illumination conditions, gaseous environments, and at controlled temperatures, correlating three-dimensional atomic-scale catalyst structure with photo-chemical reactivity. Then, we describe how these atomic-scale insights enable optimized reactor-scale performance. As model systems, we consider three reactions: 1) acetylene hydrogenation with Ag-Pd catalysts; 2) CO2 reduction with Au-Pd catalysts; and 3) nitrogen fixation with AuRu catalysts. Here, Au/Ag acts as a strong plasmonic light absorber while Pd/Ru serves as the catalyst. We find that plasmons modify the rate of distinct reaction steps differently and that reaction nucleation occurs at electromagnetic hot-spots – even when those hot-spots do not occur in the preferred nucleation site. Plasmons also open new reaction pathways that are not observed without illumination, enabling both high-efficiency and selective catalysis with tuned bimetallic catalyst composition. Our results provide a roadmap for how atomically-architected photocatalysts can precisely control molecular interactions for high-efficiency and product-selective chemistry.

Structural Studies of 2D Perovskites for Catalyst Support Applications by Environmental Transmission Electron Microscopy Dmitri N. Zakharov;

Brookhaven National Laboratory, United States

Two-dimensional perovskites materials gained traction for applications in various optoelectronic and sensor devices. Another potential application for this class of the material is a catalyst support, as epitaxial relationships between catalyst and support can be utilized to gain control over catalyst active sites in catalyst activity studies. Nanosheets of $Sr_2Nb_3O_{10}$(SNO) with thicknesses down to 1.8 nm were synthesized by liquid exfoliation technique. Palladium film of a nominal thickness of 1.0 nm was deposited by electron beam evaporation to form Pd particles supported on SNO, which was picked up as a model system. Structural characterization was done in the column of C_s-corrected environmental FEI Titan scanning transmission electron microscope (ETEM). Bright field (BF) and dark field (DF) imaging revealed nanosheets of sizes of few squared micrometers. SNO flakes show contrast revealing strain and deviation from the exact [001] zone axis across the nanosheet. A perfect orientation down to the [001] zone axis was limited to a few hundred square nanometers. DF images of the SNO flakes acquired in several two-beam conditions show contrast from grain boundaries of misoriented grains. Planar defects (PD) running at an angle to the imaging plane reveal alternating contrast. Some areas show defected structure on HREM images, which also reveals itself by additional diffraction spots on the FFT in comparison with the perfect perovskites structure. In addition to vacuum environment, deposited films were also studied in the presence of Hydrogen in environmental regime of the same Titan (S)TEM. The sample was heated to 900C in the presence of 80mTorr Hydrogen. Nanoparticles supported on SNO exhibit faceted nature compared to those supported on amorphous SiN support, which potentially opens a way to controllable studies of catalyst's active sites. This research used the Electron Microscopy facility of the Center for Functional Nanomaterials (CFN), which is a U.S. Department of Energy Office of Science User Facility, at Brookhaven National Laboratory under Contract No. DESC0012704.

11:15 AM CH04.07.08
Real-Time Observation of GaN Nanowire Growth by *In-Situ* TEM Nessrine Benaziz[1,2], Chen Wei[1,2], Frank Glas[1,2], Noelle Gogneau[1,2], Charles Renard[1,2], Laetitia Vincent[1,2], Laurent Travers[1,2], Pavel Bulkin[3] and Federico Panciera[1,2]; [1]CNRS, France; [2]Université Paris-Saclay, France; [3]École Polytechnique, France

Gallium nitride (GaN) is widely used in photonic devices such as blue and white light emitting diodes and lasers. However, its large lattice mismatch with commonly used substrates such as Si (111) imposes the growth of thick and complex buffer layers to reduce the defect density. GaN nanowires (NWs) however, having a small footprint on the substrate, can easily accommodate the lattice mismatch and allow monolithic integration of high quality GaN on Si (111). Thus, GaN NWs on Si structures have been a source of great attention due to its fundamental properties and technological uses. GaN NWs can be grown with and without catalyst, but the uncatalyzed growth is preferred since it eliminates any risk of contamination. This growth mode often results in NWs having different polarities and in some cases in the simultaneous presence of both polarities on a single NW. The growth mechanism of uncatalyzed GaN NWs, in particular in the presence of multiple polarities, is not fully understood.
To shed some light on the growth of these nanostructures, we carried out in-situ transmission electron microscopy (in-situ TEM) experiments. A special TEM-compatible Si substrate with heating capability was fabricated using MEMS technology. This substrate presents a vertical (111) surface on which nanowires can be grown epitaxially and oriented perpendicular to the electron beam. The growth of GaN NWs was carried out inside the TEM by plasma-assisted MOCVD using TMGa and N_2 as precursor gasses at a temperature around 850 °C. Pure wurtzite phase GaN NWs were grown epitaxially on the Si (111) substrate. The majority of NWs showed a central Ga-polar domain completely surrounded by an N-polar domain. We will present atomic resolution videos displaying the monolayer-by-monolayer growth of these NWs using both a cross-sectional and an inclined view. This second configuration reveals the nucleation site of each monolayer on the top facets (Ga-polar and N-polar) and the propagation mechanism of the monolayer. Finally, we will discuss the impact of grow conditions on the top surface morphology and the overall NW aspect ratio and present a model to rationalize our observations.

SESSION CH04.08: Ultrafast Dynamics
Session Chairs: Yuzi Liu and Michelle Mejía
Thursday Afternoon, April 25, 2024
Room 443, Level 4, Summit

1:30 PM *CH04.08.01
Ultrafast Dynamics in Materials Haihua Liu, Thomas Gage and Ilke Arslan; Argonne National Laboratory, United States

Ultrafast transmission electron microscopy (UEM) methods have become a new frontier in materials science due to the ability to follow dynamics on time scales down to hundreds of femtoseconds with nanometer spatial resolution. Imaging on ultrafast time scales reveals nonequilibrium metastable states of matter, phonon transport pathways in materials, and plasmon dynamics. This presentation will overview some of these ultrafast methods, and provide examples of how they have been used to enable new understanding of materials.

Work performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, was supported by the U.S. DOE, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

2:00 PM *CH04.08.02
MeV Electron Time-Resolved Total Scattering for Material Dynamics Xijie Wang; SLAC National Accelerator Laboratory, United States

The MeV electrons produced by the photocathode RF gun made it feasible for MeV ultrafast electron scattering [1-2]. MeV ultrafast electron scattering became a new frontier in ultrafast science due to its capability of following dynamics on femtoseconds scale with the high spatial resolution and sensitivity [3-4]. Furthermore, MeV electrons experience less multiple-scattering, and possess "real" flat Ewald-sphere; MeV ultrafast electron diffraction (MeV-UED) is an ideal tool to explore both structure and dynamics using total scattering technique. Total scattering has been explored by X-ray and Neutron scattering communities to study energy materials, the time-resolved total scattering enabled by MeV-UED make it feasible to image strcture dynamics and energy transfer in 2-D heterostructure [3] and revealing the intricate relation between dynamics and function of 2-D perovskite [4].

I will discuss many advantages of MeV electron for total scattering. MeV electron total scattering not only produces stronger diffraction signal and sensitive to the structure change, but also has less background and no geometric correction. Furthermore, we have experimentally demonstrated that MeV electron total scattering is capable of probing both electronic and nuclear structure dynamic [5]. MeV-UED enabled the first ultrafast operando [6] and in-situ [7] experiments.

Capturing Laser Induced Dynamics of Materials via Ultrafast Transmission Electron Microscopy Volkan Ortalan; University of Connecticut, United States

Recent developments in instrumentation have made it a very exciting time to perform both fundamental and applied research in the electron microscope. In-situ microscopy is moving forward at a rapid pace with the development of gas/liquid stages that permit reaction processes to be imaged and analyzed at atomic resolution. Moreover, the development of nanosecond and faster photoemission electron sources offers the chance to move the high spatial resolution world of electron microscopy into the ultrafast world of materials dynamics. Conventional in-situ TEM coupled with ultrafast TEM can be utilized to gain a fundamental understanding of dynamic processes occurring in materials. The combination of these capabilities allow for vast improvements of in-situ TEM studies limited by video rate in that many processes span multiple time and length scales. Ultrafast in-situ electron microscopy promises to answer challenging questions in the fields ranging from materials science and chemistry to nanoscience and biology. In this presentation, examples of ultrafast electron microscopy studies will be presented for selected systems. Short lived transient processes involved in dynamic processes in materials will be discussed to obtain new insights. Additionally, the potential of novel in-situ stages for various data acquisition schemes to push the envelope of ultrafast electron microscopy for the investigation of materials will be discussed.

2:45 PM CH04.08.04
High-Speed Imaging Techniques for Imaging High-Jitter Dielectric Breakdown Noah Hoppis[1], Kathryn Sturge[1], Jonathan E. Barney[2], Brian L. Beaudoin[1], Ariana Bussio[1], Ashley E. Hammell[1], Samuel Henderson[2], James Krutzler[1], Joseph P. Lichthardt[1], Alexander H. Mueller[2], Karl Smith[2], Bryce Tappan[2] and Timothy W. Koeth[1,2]; [1]University of Maryland, United States; [2]Los Alamos National Laboratory, United States

Imaging mechanically induced dielectric breakdown, which unfolds on ultra-short timescales, poses a formidable challenge. A significant hurdle in this endeavor is breakdown initiation jitter, where even a tenth of a microsecond of timing deviation can frustrate imaging efforts. Our initial attempt to use a gigahertz frame rate camera to record dielectric breakdown initiated by an exploding bridge wire detonator was hindered by pronounced initiation jitter.

To surmount this obstacle, we developed an innovative optical image delay line apparatus to mitigate the effects of breakdown jitter on imaging timing. In this presentation, we delve into the design and performance of this optical delay line apparatus, showcasing its transformative impact. The integration of the optical delay line increased image capture success rate from 25% to 94%. Moreover, it facilitated superior temporal resolution. Beyond its applicability in the realm of dielectric breakdown, this technique holds promise for imaging other high-jitter, ultra-fast phenomena

3:30 PM *CH04.08.05
Imaging Quantum Coherence using Electron Wavepackets Ido Kaminer[1] and Giovanni Maria Vanacore[2]; [1]Technion, Israel; [2]The University of Milano-Bicocca, Italy

Until recently, work in quantum optics focused on light interacting with *bound-electron* systems such as atoms, quantum dots, and nonlinear optical crystals. In contrast, *free-electron* systems enable fundamentally different physical phenomena, as their energy distribution is continuous and not discrete, allowing for tunable transitions and selection rules. Free electrons also enable unique capabilities in microscopy and spectroscopy that are otherwise inaccessible.

Recent theoretical and experimental breakthroughs involving quantum interactions of free electrons spawned an exciting new field: *free-electron quantum optics*. We developed a platform for exploring coherent free-electron interactions at the nanoscale, and used it to demonstrate the first coherent interaction of a free electron with quantum statistics of photons.

These capabilities open new paths toward using free electrons as carriers of quantum information. Concepts of quantum optics with free electrons also promote new modalities in electron microscopy. We recently demonstrated the first instance of coherent amplification in electron microscopy. Specifically, we present an algorithm-based microscopy approach that uses light-induced electron modulation to demonstrate the coherent amplification effect in electron imaging of optical near-fields. We provide a simultaneous time-, space-, and phase-resolved measurement in a microdrum made from a hexagonal boron nitride membrane, visualizing the sub-cycle dynamics of 2D polariton wavepackets therein. Our experiments show a 20-fold coherent amplification of the near-field signal compared to conventional electron near-field imaging, resolving peak field amplitudes of few kV/m.

Our vision is to develop a microscope that can image coherence, going beyond conventional imaging of matter to also *image the quantum state of matter* and probe quantum correlations between individual quantum systems.

New Approaches of Ultrafast Electron Microscopy for Quantum Materials Yimei Zhu; Brookhaven National Laboratory, United States

In this presentation, several of our research examples are selected to highlight the characterization of materials dynamics in strongly correlated systems. I will focus on ultrafast phenomena and charge-lattice and spin-lattice correlations. For instance, I will show: 1) a new two-color scheme based on near-field electron microscopy (PINEM), one for temporal gating, the other for pumping to achieve nm-fs spatiotemporal resolution to visualize ultrafast dielectric response and insulator-to-metal transition in nanowires [1]; 2) quantitative diffraction and diffuse scattering analysis to capture the photoinduced ultrafast atom dimerization and rotation dynamic pathways [2] and the evolution of optical and acoustic phonon population in charge-density-wave materials [3] using MeV-UED; and 3) study electromagnetic wave propagation in interdigitated comb device that is widely used as an antenna or sensor in mobile platforms [4] and observe spin wave dynamics under microwave excitation using the GHz electron pulser we developed at BNL. The ability to probe materials dynamic responses under RF excitations has promising applications for qubit devices and quantum information science.

Work at BNL was supported by the DOE-BES-MSED under the grant DE-SC0012704.

Interfacial Charge Dynamics in Si-Ge Heterojunctions imaged by Scanning Ultrafast Electron Microscopy Basamat Shaheen; University of California, Santa Barbara, United States

With the growing demand for efficient energy systems and electric devices, semiconductor heterostructures have garnered increasing attention due to their distinctive interfaces and synergistic effects. Understanding their fundamental nature is crucial for further developments. Surface and interfacial properties play the key role in heterostructures where the chemical composition and charge distribution change due to different sets of bonds, band structures, majority carrier concentrations, and Fermi levels. Combining the time resolution of femtosecond lasers and the spatial resolution of electron microscopes, scanning ultrafast electron microscopy (SUEM) has a unique capability to visualize charge dynamics at surfaces and interfaces. In this study, we utilize SUEM to image photocarrier dynamics in Si-Ge heterojunctions fabricated through direct wafer bonding. The charge dynamics are selectively examined across the interface and compared to the individual materials. The photo-induced SUEM contrast, corresponding to the local change in secondary electron emission, shifts from bright to dark on the Si side as it approaches the interface. On the Ge side, the contrast remains dark at the interface and beyond. Additionally, it is observed that the dispersion of the dark contrast on the Si side is wider than that on the Ge side at the interface. These findings are elucidated with insights from other surface techniques such as X-ray photoelectron spectroscopy and Kelvin probe microscopy, as well as Finite-Difference Time-Domain (FDTD) simulations of the built-in electric field across the interface.

4:45 PM CH04.08.08
Uncovering Microscopic Interactions in Skyrmion Hosts via Lattice Dynamics Andi M. Barbour[1], Myung-Geun Han[1], Fernando Camino[1], Chuhang Liu[1], Mario Cuoco[2], Yimei Zhu[1] and Claudio Mazzoli[1]; [1]Brookhaven National Laboratory, United States; [2]Consiglio Nazionale delle Ricerche, Italy

NSLS-II's Coherent Soft X-ray (CSX) beamline has world leading coherent soft x-ray flux and, as such, can provide insight to materials traditionally studied with either neutrons or electron microscopy (EM). In other words, bulk versus neara-surface, respectively. The highly tunable CSX beamline can close this gap since "bulk-like" and EM specific free-standing films are readily investigated using soft x-ray resonant elastic scattering (REXS). Capitalizing on this capability, we turn to study interacting skyrmions. Most skyrmion hosting materials are conducting metal alloys (the B20 metals), and these materials do exhibit interesting skyrmion lattice dynamics. However, Cu_2OSeO_3 (CSO) offers an interesting comparison since it is a vastly different material, being an insulator and exhibiting magnetoelectric coupling – which are attractive properties for devices. We will present new findings associated with skyrmion lattice (SkL) dynamics in CSO. Recently reported rotational dynamics of the SkL are currently thought to be induced by either thermal gradients [1] or magnetic field gradients [2]. By combining coherent X-rays and REXS, we can interrogate the structure and dynamics of rotating and non-rotating SkL points in a highly controlled manner. In collaboration with LTEM researachers, we are able to expand our findings with complementary LTEM experiments.

Preliminary Study on The Microstructure Evolution and Deformation Behavior of Ti6Al4V-5Cu Alloy at Low Forming Temperatures Solomon K. Yeshanew; Dire Dawa University, Institute of Technology, School of Mechanical and Industrial Engineering, Ethiopia

The cold workability behavior of the Ti6Al4V-5Cu alloy was investigated using a hot compression experiment in the temperature range of 450 − 650 °C and strain rates interval of $10^{-4} - 10^{-1}$ s^{-1} with strains of 0.4 and 0.6. Deformation mechanisms and microstructural evolution of the alloy are characterized by means of the Gleeble 3800 compression test, establishing constitutive relationship that relates the microstructure of the deformed specimen with process variables (Temperature, strain rate, and strain). Unpleasant product features identified using a scanning electron microscope and an electron backscattered diffraction study, such as edge cracking defects caused by high strain conditions at low deformation temperatures (< 450 °C) and faster strain rates. Grain

boundary splitting occurs at the α/α phase interface. The splitting occurred because of the formation of weak structures due to the presence of aluminum as a major phase constituent element, indicating that pseudo-super plasticity behavior existed via the sliding of α/α phase grains. The β-phase was found in relatively dense concentrations at the grain boundary teared region of the α/α phase interface, which helped to prevent the cracked edges along the grain boundaries from widening and propagating further. On the single α-phase region, the alloy activation energy (Q) monitored to be 29.58 kJ/mol. The alloy strain rate sensitivity (m) and power dissipation efficiency (η) were also calculated as 0.45 and 22.22%, respectively. Together with the microstructure evolution, true strain-stress curve, and generated processing map, Ti6Al4V- 5Cu alloy were found with low metallurgical transformation ability during forming below 650 °C (< 2.58T m).

5:00 PM CH04.09.02
Identifying Degradation Mechanism in Cathode Materials for Lithium Ion Batteries with Precession Electron Diffraction Hyungcheoul Shim[1], Young-Woon Byeon[2], Seungmin Hyun[1] and Jae-Pyoung Ahn[2]; [1]Korea Institute of Machinery and Materials, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Due to the explosive growth of the electric vehicle market, recently, attention to lithium ion batteries (LiBs) is increased. The specialty of automotive applications is promoting the development of long-life batteries based on material reliability. Developing a reliable LiB begins with understanding the mechanism of degradation of the material. In other words, based on the degradation mechanism of the material analyzed from accurate and various angles, we can propose a design method of robust material that is one step further.
In this study, we tried to analyze the cause of the deterioration of cycling characteristics for $Li(Ni_{1/3}Co_{1/3}Mn_{1/3})O_2$, which is mainly used as a cathode material for LiBs, by precession electron diffraction (PED). In other words, we wanted to know the causes of degradation in the whole system by analyzing the material properties at a single crystal in nanoscale. For the analysis of extremely small ranges of materials, we analyzed the degradation mechanism of the material in the sub-10nm range using Precession Electron Diffraction (PED) techniques.
The PED method can reduce the dynamic diffraction phenomenon according to the thickness of the TEM sample, so that the diffraction intensity can be quantified within a very small range. By using the PED technique based on nano-sized electron beams, we were able to map the structural change of $Li(Ni_{1/3}Co_{1/3}Mn_{1/3})O_2$ material in a single crystalline unit over a long period of electrochemical cycles.
It is known that the main cause of the decrease in LiB's capacity over the electrochemical cycles is the formation of an electrochemically irreversible rock salt phase inside the cathode material. However, the PED analysis showed that we could identify the existence of new metastable phase that had not discovered before. In other words, accelerated testing results revealed new unstable phases due to cation migration and found that the presence and distribution of these phases had a decisive effect on LiB's electrochemical degradation. In addition, the quantitative relationship between the strain and phase transition also could be derived. Therefore, based on these results, we expect that PED based on nano-sized electron beams can add new perspectives to the analysis of the degradation mechanism of materials for LiBs.

5:00 PM CH04.09.03
Unveiling The Distribution and Dynamic Behavior of Multi-Valent Chromium Ions in $Li(Sc_{1-x}In_x)O_2$:Cr Phosphors via In-Depth X-Ray Characterization Yi-Ting Tsai and Mu Huai Fang; Research Center for Applied Sciences, Academia Sinica (RCAS), Taiwan

Cr^{3+}-doped inorganic compounds have played an important role in the development of near-infrared optical materials. However, the presence and distribution of multi-valent Cr ions remains unclear. In this study, we examined a series of $Li(Sc_{1-x}In_x)O_2$ phosphors doped with Cr^{3+} using X-ray techniques from National Synchrotron Radiation Research Center. Through high-resolution synchrotron X-ray diffraction, we identified two closely related phases within $Li(Sc_{1-x}In_x)O_2$. Raman spectra also confirmed distinctive scattering patterns for the two end-members of the compositional range, consistent with our XRD results. Further investigation using Cr K-edge X-ray absorption near edge structure and extended X-ray absorption fine structure techniques revealed the prevalence of Cr^{6+} ions in the initial samples. However, a significant shift occurred towards Cr^{3+} dominance upon water washing. We also used X-ray fluorescence and X-ray excited optical luminescence methods to analyze the source and spatial distribution of Cr^{3+} and Cr^{6+} ions in both as-prepared and washed samples. Our analysis indicated that Cr^{6+} ions aggregate within the material, while Cr^{3+} ions exhibit a more uniform dispersion. By utilizing photoluminescence, decay curve, and lineshape analyses, we were able to understand the electron-lattice interactions responsible for the optical properties. Our study explains the multi-valent, low-concentration ion distribution in solid-state materials and provides valuable insights into precise methodologies for discerning subtle alterations in crystal structures, contributing to the development of tailored optical materials.

5:00 PM CH04.09.05
Unraveling The Interfacial Behavior of Double Functionalized Silica Nanoparticles at Oil-Water Interfaces: Insights from Atomic Force Microscopy, In *Operando* Ultrasmall and Small-Angle and X-Ray and Interfacial Rheology Measurements Ahmed W. Alsmaeil[1], Sohaib Mohammed[1], Bashayer Aldakkan[1], Nikolaos Chalmpes[1], Antonios Kouloumpis[1], Georgia Potsi[1], Greeshma Gadikota[1], Mazen Kanj[2] and Emmanuel P. Giannelis[1]; [1]Cornell University, United States; [2]King Fahd University of Petroleum and Minerals, Saudi Arabia

Tuning interfacial interactions of emulsions is of utmost importance in addressing hydrocarbon contamination of water resources and facilitating sustainable synthesis and processing of organics across different industries, such as energy recovery, pharmaceuticals, and the food industry. In this comprehensive study, we investigated the assembly of colloidally stable silica nanoparticles (NPs) at the oil-water interface, employing a novel double functionalization strategy. The NPs were functionalized with a blend of two silanes, one based on a quaternary ammonium group and the other combining primary and secondary amine groups, thereby endowing them with a positive charge. By modulating the charges on both the NP's surface groups and the oil phase, either by pH adjustments or the addition of electrolytes, we controlled the assembly and behavior of the emulsion. The careful combination of tunable charge and specifically chosen silane coupling agents provided the NPs with outstanding colloidal stability, which is significant for practical applications.
To evaluate the colloidal stability of the NPs, we conducted accelerated Space-Time Extinction Profiles (STEP®) measurements in brine solutions up to 60,000 ppm containing monovalent and divalent electrolytes and temperatures up to 60 °C. Remarkably, even under these harsh conditions, the NPs displayed exceptional stability. Assembly of the NPs at the oil-water interface can be controlled by controlling the pH or in the presence of electrolytes. Specifically, at pH 9 or in high salt concentrations, the interfacial tension (IFT) was substantially reduced from 35 mN/m to 5 mN/m and 2 mN/m, respectively.
To gain further insights into the interfacial properties of the emulsion, we used Ultrasmall/Small-angle X-ray scattering measurements, which unequivocally confirmed the presence of nanoparticles at the interface. Moreover, we found a correlation between the time-dependent scattering profiles and the dynamics of the growth of the interfacial film. To explore the nanomechanical characteristics of the interface, Atomic Force Microscopy (AFM) was employed. Notably, in the presence of the NPs at pH 9, the stiffness of the interface was substantially lower compared to acidic and neutral conditions, in brine or at pH 9 the assembly leads to jamming, reminiscent of an elastic membrane characterized by high dilatational and storage moduli. Leveraging the jamming phenomenon, we demonstrated the efficacy of our approach in herding oil droplets, thereby showcasing its potential for oil spill remediation. Additionally, our method facilitated the production of highly moldable and printable oil-in-water emulsions, presenting novel opportunities for various applications in the fields of environmental remediation, catalysis, drug delivery, food technology, and oil recovery.

Investigating The Effect of Blend Composition on The Burning Rate of PTT-PP and PTT- LLDPE Blends and Mechanism Thereof Shrikant Deo[1], Kavita Pande[2], Swamini Chopra[3] and Dilip Peshwe[1]; [1]Visvesvaraya National Institute of Technology, Nagpur, India; [2]GHR Labs and Research Centre, India; [3]MIT, Aurangabad, India

The present manuscript focuses on assessing the fire retardant performance of PTT polymer blended with varying proportions of PP and LLDPE, separately. This work explores the impact of varying the blend composition on the burning rate as per ASTM standard D635 for two series of blends; PTT-PP and PTT-LLDPE. The thermal degradation behavior is studied using Fourier transform infrared spectroscopy (FTIR) and the structure of the blends observed by Scanning electron microscope (SEM). The blend composition plays a vital role on the burning rate, and therefore the fire retardancy, of PPT polymer after blending. For PTT-LLDPE blends, the increase in the addition of LLDPE lowers the burning rate till 20 wt.% LLDPE. A further addition increases the burning rate of the blends due to the fact that pure LLDPE burns faster
than pure PTT. In case of PTT-PP blends, the burning rate of pure PP is lower than that of pure PTT by ~22%, while the PTT-PP blends exhibit a burning rate closer to that of pure PTT. Though the PTT-PP blends may not exhibit excellent fire retardancy behavior like PTT-LLDPE blends, the addition of 15 wt.% PP can be cost effective than pure PTT, all the while exhibiting similar burning rate characteristics. Thus, this study infers that blending of PTT-LLDPE not only enhances the fire retardancy behavior of PTT by ~46%, but is also a cost effective alternative to using pure PTT. The FTIR analysis provides insight into the chemical changes occurring during the thermal degradation of the blends, thereby supporting to understand the fire-resistant mechanism of the blends.

Effects of Topological Parameters on Thermal Properties of Single-Walled Carbon Nanotubes by Molecular Dynamics Simulation Lida Najmi and Zhong Hu; South Dakota State University, United States

Due to their enhanced properties, carbon nanotubes (CNTs) are increasingly used in various industrial sectors. Specifically, the thermal conductivity of these materials is affected by heat transfer mechanisms across multiple scales, leading to a complex relationship between the effective response and the microscopic characteristics of the material. Due to their high thermal conductivity, CNTs have applications in various fields including electronics, materials science, and thermal management. They are incorporated into composites, films, and other materials to enhance their thermal performance. In this topic, the thermal properties of single-walled carbon nanotubes (SWNTs) are investigated using molecular dynamics (MD) simulation. The effects of the chirality, diameter, and length of SWNTs on the thermal properties were studied using the reverse non-equilibrium molecular dynamics (RNEMD) method and the carbon-carbon based Tersoff interatomic potential based on the Large-scaled Atomic/Molecular Massively Parallel Simulator (LAMMPS). The SWNTs studied have tube lengths of 5, 10, 15 and 20 nm, respectively. The thermal conductivity follows $a\ L^B$ law. The exponent B is insensitive to the chiral angle of the CNT; B at room temperature is about 0.89 and 0.69 for zigzag and armchair CNTs, respectively. Although thermal conductivity increases with increasing the chiral angle, and armchair SWNTs have higher thermal conductivity than zigzag CNTs, the effect of chirality on the thermal conductivity for longer CNTs decreases. Therefore, for longer length SWNTs, the thermal conductivity of the zigzag is greater than that of the armchair ones. Through research on SWNTs of different diameters, it was found that at the same chiral angle, the thermal conductivity of SWNTs decreases with the increase in diameter, while SWNTs with greater chiral angles exhibit higher thermal conductivity than those of the same diameter. The thermal conductivity follows $a\ D^{-B}$ trend, and the *exponent B* is insensitive to the chiral angle of the CNTs; the B of zigzag and armchair CNTs at room temperature are about 0.43 and 0.26, respectively. In addition, the thermal resistance at the CNT's interfaces was studied as a function of the nanotube spacing, overlap, and length. The simulation results were compared with the experiments and simulation results from the literature which are in agreement. The presented approach can be applied to study the properties of other advanced materials.

5:00 PM CH04.09.08
***In-Situ* Electron Channeling Contrast Imaging of Local Deformation Behavior of Lath Martensite in Low-Carbon-Steel** Shuang Gong and Junya Inoue; University of Tokyo, Japan

This study reveals the dislocation dynamics that control the local deformation behavior of lath martensite in low-carbon steel using a combination of in-situ tensile Electron Channeling Contrast Imaging (ECCI) and X-ray based Convolutional Multiple Whole Profile (CMWP) fitting methods.

Lath martensite, characterized by distinct anisotropy in its local deformation behavior, poses challenges for its ductility in engineering applications. Unveiling the local dislocation dynamics driving this behavior is crucial for material optimization. Recent studies using X-ray and neutron diffraction line profiles have successfully employed the CMWP fitting method to probe the macroscopic evolution of dislocations in this material. Building on the foundation of this innovative approach, this study presents an integrative use of advanced X-ray analysis and in-situ tensile ECCI, which allows for microscopic direct observation of dislocation motion dynamics, directly linking them with the macroscopic evolutions.

By capturing X-ray diffraction patterns before and after a specific elongation threshold, and applying CMWP fitting, the study accurately determines the dislocation density, character, and arrangement within the lath. The analysis meticulously tracks the behavior of dislocations, identifying intra-lath crystallographic slip and boundary sliding as the two primary deformation processes. The onset of dislocation movement signifies the commencement of microscopic yielding. As the stress applied to the material increases, a transition to macroscopic yielding is observed, characterized by the ability of dislocations to navigate through and overcome densely packed dislocation walls within the laths. Near the lath boundaries, the pile-up of dislocations from out-of-lath-plane slip systems contrasts with the ongoing movement of those in-lath-plane, which are mainly responsible for plastic deformation. Further, this study successfully captures the boundary sliding phenomenon and clarifies the critical resolved shear stress (CRSS) required for this process to become the dominant form of plastic deformation following work hardening. The swift movement of the dislocation network close to the boundaries is particularly emphasized, as it plays an important role in mediating boundary sliding.

In summary, the correlation between the dislocation structure evolution observed through in-situ tensile ECCI and the evaluation made by CMWP fitting elucidate the intricate mechanism of plastic deformation in low-carbon steel lath martensite, with profound implications for enhancing the ductility of the material for industrial applications.

5:00 PM CH04.09.09
Disentangling Thermal from Electronic Contributions in The Spectral Response of Photo-Excited Perovskite Materials Lijie Wang[1,2], Razan O. Nughays[1], Omar F Mohammed[1] and Majed Chergui[2]; [1]KAUST, Saudi Arabia; [2]EPFL, Switzerland

Disentangling electronic and thermal effects in photo-excited perovskite materials is crucial for photovoltaic and optoelectronic applications, but remains a challenge due to their intertwined nature in both the time and energy domains. In this study, we employed temperature-dependent variable-angle spectroscopic ellipsometry, density functional theory calculations, and broadband transient absorption spectroscopy spanning from the visible to mid-to-deep-Ultraviolet (UV) ranges on $MAPbBr_3$ thin films. The use of deep-UV detection opens a new spectral window that enables the exploration of high-

energy excitations at various symmetry points within the Brillouin zone, facilitating the understanding of the ultrafast responses of the UV bands and the underlying mechanisms governing them. Our investigation reveals that the photo-induced spectral features remarkably resemble those generated by pure lattice heating, and we disentangle the relative thermal and electronic contributions and their evolutions at different delay times using combinations of decay-associated spectra and temperature-induced differential absorption. The results demonstrate that the photo-induced transients possess a significant thermal origin and cannot be attributed solely to electronic effects. Following photo-excitation, as carriers (electrons and holes) transfer their energy to lattice, the thermal contribution increases from ~15% at 1 ps to ~55% at 500 ps, and subsequently decreases to ~35-50% at 1 ns. These findings elucidate the intricate energy exchange between charge carriers and lattice in photo-excited perovskite materials, and provide insights into the limited utilization efficiency of photo-generated charge carriers.

5:00 PM CH04.09.10
Highly Porous Structure Improves Molecular Dynamics of Cobalt-Based Composite Nanomaterials for Hybrid Supercapacitors Ziwei Gan, Xiaohe Ren, Yongxiu Sun, Mengxuan Sun and Zhijie Li; University of Electronic Science and Technology of China, United States

Cobalt-based nanomaterials are a highly promising class of energy storage materials with high theoretical capacity and excellent long-term service life, such as metal doping and structural porousness of these cobalt-based nanocomposites, have been regarded as effective methods to further increase their active sites and improve their conductivity and performance. However, synthesizing cathode materials with high specific capacity and energy density through simplistic methods remains an immense obstacle. In this study, Mn doped cobalt-based hydroxide/sulfide nanocomposites with large pore volume as well as specific surface area were successfully synthesized. The $Co(OH)_2$/CoS electrode doped with Mn has better charge storage capacity (capacity increase from 586.5C g^{-1} to 1030.8C g^{-1} at 0.5 A g^{-1}), excellent rate performance (with a capacity retention of 75.8 % at 10 A g^{-1}). Additionally, a hybrid supercapacitor (HSC) was constructed utilizing Mn-$Co(OH)_2$/CoS and activated carbon (AC). HSC exhibited excellent charge storage capacity (166.3 F g^{-1} at 0.5 A g^{-1}) and remained at 164.1 % of its original value after 30,000 cycles of testing with high current density. In addition, at a power density of 410.0 W kg^{-1}, the assembled HSC device demonstrates a significant energy density of 62.1 Wh kg^{-1}, revealing that porous Mn-$Co(OH)_2$/CoS electrode materials showed excellent energy storage properties.

5:00 PM CH04.09.11
Non-Newtonian Dynamics in Water-In-Salt Electrolytes Marie-Louise Saboungi[1], David Price[2], Andrei Dukhin[3], Tsuyoshi Yamaguchi[4] and Dongzhou Zhang[5]; [1]IMPMC -Sorbonne Université, France; [2]CEMHTI, France; [3]Dispersion Technology Inc, United States; [4]Nagoya University, Japan; [5]University of Chicago, United States

Water-in-salt electrolytes have attracted considerable interest in the past decade for advanced lithium-ion batteries, possessing important advantages over the non-aqueous electrolytes currently in use. A battery with a LiTFSI−water electrolyte was demonstrated in which an operating window of 3 V is made possible by a solid−electrolyte interface. Viscosity is an important property for such electrolytes, because high viscosity is normally associated with low ionic conductivity. Here, we investigate shear and longitudinal viscosities using shear stress and compressional longitudinal stress measurements as functions of frequency and concentration. We find that both viscosities are frequency-dependent and exhibit almost identical frequency and concentration dependences in the high-concentration region. A comparison to quasielastic neutron scattering experiments suggests that both are governed by structural relaxation of the TFSI− network. Thus, LiFTSI−water electrolytes appear to be an unusual case of a non-Newtonian fluid, where shear and longitudinal viscosities are determined by the same relaxation mechanism.

Evaluation of Anti-Icing/De-Icing Performance of PU Topcoat with CNT Addition in Aircraft Applications Lee Donghyeon, Yang Seong Baek and Kwon Dong-Jun; Gyeongsang National University, Korea (the Republic of)

Icing on aircraft can lead to increased weight, reduced lift, and pose a risk of accidents. Methods for removing aircraft icing include the use of deicing solutions like glycol or employing techniques such as heating and vibration. However, these methods have limitations in terms of applicable areas, energy consumption, duration constraints, and low efficiency. To prevent ice formation on the aircraft itself, anti-icing methods are employed.
Anti-icing methods involve surface etching on metal surfaces or the application of hydrophobic polymer coatings. Commonly used polymers for this purpose are polytetrafluoroethylene (PTFE) and polyurethane due to their ability to cure at room temperature and compatibility with base materials like epoxy. To enhance hydrophobic effects, research is exploring the addition of hydrophobic nanoparticles to create nanostructured surfaces. Nanoparticles, acting as binders, form the topcoat in the coating layer. However, nano surfaces face challenges related to durability and sustainability.
In this study, a nanostructured surface was achieved by incorporating hydrophobic nanoparticles, specifically carbon nanotubes (CNT), into the polymeric topcoat. Polyurethane was utilized as the topcoat, and CNT dispersed in a solvent such as xylene was sprayed after coating. To address durability issues associated with previously researched nano surfaces, CNT was dispersed in the binder to enhance the strength of the topcoat and increase the adhesion between the binder and the exposed CNT on the surface. Additionally, the conductivity of CNT dispersed in the topcoat contributed to higher thermal conductivity compared to coating CNT only on the surface.
To expose hydrophobic CNT on the surface, some hardening of the topcoat surface was induced before coating with xylene. This allowed for the manifestation of the hydrophobic effect from the carbon surface of CNT and also contributed to surface morphology effects induced by CNT. The addition of CNT increased the contact angle with water from 74.3 degrees to 121.2 degrees, resulting in a significant delay in icing effects, approximately a 260% increase. Moreover, a decrease in adhesion time and strength of ice on the surface was observed. When a current of 3V was applied, a temperature increase of about 54 degrees was noted, effectively causing the ice to melt and slide off.
Ongoing research involves investigating the impact of surface roughness changes on aircraft wings or similar structures when applied as an actual model. The study aims to understand the influence of surface variations on aircraft wings and related components.

This research was supported by the National Research Foundation of Korea(NRF) funded by the Ministry of Science and ICT (RS-2023-00211944). This work was supported by Policy R&D program funded by Korea Ceramic Engineering & Technology, Republic of Korea(No. KPP23006-0-01).

5:00 PM CH04.09.13
Advanced Characterization Approaches for Anisotropic Metal Patchy Particles Julia S. Seifert[1], Andreas Voelkl[1], Dominik Drobek[2], Nabi E. Traoré[1], Paola Cardenas Lopez[1], Mingjian Wu[2], Benjamin Apeleo-Zubiri[2], Johannes Walter[1] and Robin N. Klupp Taylor[1]; [1]Institute of Particle Technology, Germany; [2]Institute of Micro- and Nanostructure Research & Center for Nanoanalysis and Electron Microscopy, Germany

Plasmon resonant nanoparticles have garnered significant interest in recent decades due to their potential as sensing or marker particles in various applications. Particularly, anisotropic plasmonic particles offer the advantage of highly tunable optical properties within a particle system. However, the increased number of shape parameters compared to isotropic particles, challenges for thorough particle characterization. Precise descriptions of particle shape and product yield are, nevertheless, indispensable for product optimization, which requires, for example, particle growth models. Therefore, in this contribution we present a variety of characterization methods used to extract information from our anisotropic particle system, obtaining the desired parameters on different levels.
We have developed several continuous flow processes for synthesizing gold and silver patchy particles whereby dielectric core particles are coated with thin islands of metal. The size, shape and morphology of the patches determine the optical resonance position which can be tuned over the visible and near-infrared spectral range. The synthesis is performed in a seed-mediated two-step process. Understanding the influence of seed particles on the growth of patches with different dimensions and morphologies is crucial. To this end, we will show how newly developed 4D-STEM analysis can resolve individual crystal grains' orientations and probe the influence of seed particles on the crystal growth directions in the patch.
On the whole patch scale, coating dimensions and morphology must be thoroughly characterized to obtain quantitative size parameters. These are essential for optical simulations and the development of patch growth models. STEM analysis and electron tomography are indispensable for revealing the patch structures where SEM imaging fails due to resolution limitations. Here we will show how these techniques can be applied to quenched samples, in which the growth has been "frozen" during patch formation, thus providing insight into the growth process. Additionally, patch shape degradation after synthesis, observed as changes in the optical spectra, can only be resolved through TEM imaging. Here, 3D data obtained from electron tomography can further be used as direct input for optical simulations to compare the obtained results with experimental spectra.
At the overall particle level, it is important to note that not every particle is coated with a patch. Determining the so-called patch yield is crucial for optimizing process efficiency. In this regard, we demonstrate the use of different methods to identify the patch yield of the product. Firstly, single particle scattering and extinction, a novel technique derived from flow cytometry, can distinguish between bare and gold-coated polystyrene particles due to their different optical responses. Secondly, analytical ultracentrifugation, as an ensemble measurement, is used to determine product yield based on differences in particle density and sedimentation velocity.
The diverse characterization methods we demonstrate for patchy particles enhance our understanding of their complex properties and synthesis. These methodologies, adaptable to other anisotropic systems, are expected to be pivotal for future advancements in plasmonic nanoparticle applications.

5:00 PM CH04.09.14
Self-Healing Polymer Composites with Enhanced Strength for Use in Protective Textiles Evan A. Griffiths, Blaine M. Barrington, Jessica M. Andriolo, Scott Coguill, Brahmananda Pramanik, Richard LaDouceur and Jack L. Skinner; Montana Technological University, United States

Self-healing materials have the potential to increase the lifetime of products exponentially through both non-reversible healing and reversible healing processes. For instance, non-reversible healing has been demonstrated with the use of micro-spheres filled with healing-compounds used to mitigate micro-crack propagation in materials like concrete or asphalt. Upon use, however, micro-sphere rupture is irreversible. Reversible self-healing traditionally takes the form of polymeric or rubber materials designed to exhibit both covalent and ionic bonds within the same material. Reversible self-healing materials not only repair other products but can have extended lifetimes themselves. However, reversible self-healing materials are often mechanically weak when compared to non-reversible self-healing materials, thereby, limiting applications. In this work we report mechanical results of aramid nanofiber (ANF) reinforcement of polycaprolactone (PCL). These results and future testing will then be applied to self-healing polymer materials to observe the mechanical reinforcement factors.

To fabricate the aramid nanofibers, macroscale fibers were broken down through hydrolysis in a dimethyl sulfoxide and potassium hydroxide solution. Fibers were then reformed through the addition of water and filtered to remove larger fibers. Following filtration, the remaining fibers were suspended in PCL that had been pre-dissolved in trifluoroethanol. The ANF/PCL suspension was sonicated for dispersion of the nanofibers within the polymer matrix. For this study, the samples examined were: 1) PCL melted and impregnated with ANFs before solidifying, 2) PCL that was solvent-dissolved before ANFs were blended into the liquid polymer and then let dry to evaporate solvent, 3) and solvent-dissolved PCL/ANF composites (1 and 2 wt%) that were embedded with ANFs before solvent was evaporated from the samples. Mechanical testing for this study included compressive, tensile and split-Hopkinson pressure bar (SHPB). Results of this testing demonstrated an increase of compressive yield strength by 22 %, an increase in tensile Young's modulus by 28 %, and a decrease in ultimate strength by 32 %. SHPB testing also revealed an increase in dynamic resistance when absorbing impacts at speeds ranging from 10 to 22 m/s where impact duration lasted as much as 23 % longer. Further testing will be performed to characterize shear performance of the samples as well as the Charpy impact energy absorption. Transmission electron microscopy and energy dispersive spectroscopy will be used to correlate embedded fiber morphologies and distributions with mechanical properties.

The primary objective of this work is to provide self-healing textiles with enhanced strength for soldiers in the field to maintain protection following damage of protective gear or uniforms. Following determination of a preferable aramid concentration in a reinforced polymer matrix, the polymer will be electrospun into fibrous textiles for further mechanical testing, to monitor properties following impact and self-repair, and determine sustainability.

SESSION CH04.10: Emerging Characterization and Modeling
Session Chairs: Tianyi Li, Michelle Mejía and Yang Yang
Friday Morning, April 26, 2024
Room 443, Level 4, Summit

8:00 AM CH04.10.01
Hydrogen Exchange and Diffusion Kinetics at Elevated Temperatures in Proton-Conducting Solid Oxide Materials Mudasir A. Yatoo[1], Sakuda Yuichi[2], Kataro Fujii[2], Masatomo Yashima[2] and Stephen Skinner[1]; [1]Imperial College London, United Kingdom; [2]Tokyo Institute of Technology, Japan

Storage of purified hydrogen is one of the central challenges in addressing climate change and reducing our reliance on fossil fuels for energy conversion and storage, and therefore there is a global surge in research and development concerning hydrogen purification and storage. In this regard, we are studying proton conduction in solid oxide materials at elevated temperatures for applications in hydrogen separation and compression membranes. Hydrogen compression is the most recommended method to store hydrogen for automotive applications as it allows an increase in the hydrogen volumetric energy density.

Traditionally the protonic conductivity in these materials is measured by indirect methods. For example, conductivity measurements in mixed gas

atmospheres, comparing for example dry N_2 with humidified N_2, thereby allowing the contribution of protons to be evaluated. In this study, we for the first time report the evaluation of protonic conductivity in $BaZr_{1-x}Ce_xY_{0.2}O_{3-\delta}$, $BaZr_{0.1}Ce_{0.7}Y_{0.2-x}Yb_xO_{3-\delta}$, $Ba_7Nb_4MoO_{20}$ and $Ba_7Nb_4MoO_{20.1}$ by direct measurements afforded by the Isotope Exchange Depth Profiling technique with deuterium labelling. We also report the kinetics of H/D transport through the bulk materials and across metal-ceramic interfaces with a particular interest in the behaviour of the interface between the key Pd/Pd alloy catalyst component and the hydrogen-transporting oxide ceramic material. The transport and interface behaviour information will be of significance in designing hydrogen separation and compression membranes.

8:15 AM CH04.10.02
Novel Electrical Tree Type Observed using Gigahertz Frame Rate Camera to Image Dielectric Breakdown in Space-Charged Polymer Kathryn Sturge[1], Noah Hoppis[1], Ariana Bussio[1], Jonathan E. Barney[2], Brian L. Beaudoin[1], Cameron Brown[2], Bruce Carlsten[2], Carolyn Chun[1], Nicholas Dallmann[2], Jack Fitzgibbon[1], Ashley E. Hammell[1], Samuel Henderson[2], Miriam Hiebert[1], James Krutzler[1], Joseph P. Lichthardt[2], Mark Marr-Lyon[2], Nathan Moody[2], Alexander H. Mueller[2], Patrick O'Shea[1], Ryan Schneider[1], Karl Smith[2], Bryce Tappan[2], Clayton Tiemann[2], David Walter[2] and Timothy W. Koeth[1]; [1]University of Maryland, College Park, United States; [2]Los Alamos National Laboratory, United States

We have successfully imaged dielectric breakdown occurring in electron irradiated space-charged polymethyl methacrylate (PMMA) blocks at a nanosecond time resolution. These images, which are the first of their kind, reveal two distinct dielectric breakdown treeing effects, one of which is absent from the present literature on dielectric breakdown. This new mode of electrical tree formed during dielectric breakdown of a space-charged polymer demonstrates unique behavior from its better-documented and widely known “branch-type” channels, including structural and formation dynamics differences. Due to its threadlike, smooth appearance, this new type of electrical tree has been coined “vine-type,” in contrast to its “branch-type” counterpart. Both vine-type and branch-type electrical trees were imaged as they formed in the electron irradiated samples, allowing for close study of the channel formation dynamics. The speeds at which the channels form for both types were directly measured from these images and found to exceed 10^7 m/s and 10^6 m/s for vine-type and branch-type, respectively—speeds approaching 4% the speed of light in the material. These speeds are faster than previously predicted by models and imply the channel growth is the fastest physical phenomenon in a solid material. Further, the propagation of the electrical tree formation was imaged and three regimes of breakdown channel formation were identified and characterized for the two modes of electrical trees, solving a decades-long mystery on the plasma channel formation process in space-charge dielectric breakdown.

8:30 AM CH04.10.03
Hygromechanical Behavior of Cellulose-Based Materials Caterina Czibula[1], Ulrich Hirn[1] and Kristie J. Koski[2]; [1]Graz University of Technology, Austria; [2]University of California, Davis, United States

Cellulose is the most abundant biopolymer on Earth and, as most biological materials, has a hierarchical, anisotropic structure. Its mechanical properties are strongly influenced by environmental conditions such as temperature and moisture content. Especially the influence of humidity is very difficult to investigate. In most cases, water behaves like a plasticizer and leads to lower mechanical properties, swelling of the material and shows an apparent effect on the viscoelastic behavior of the material. This has strong implications for the technical use of cellulose-based materials. The production of paper is a classic example with the material going through different process steps, which have an influence on the chemical and physical properties, and at the same time also cause different hydration states in the material. When the product is finished and put into use, the effects of moisture changes trigger undesirable effects and have an impact on service life.
Here, Brillouin Light Scattering Spectroscopy (BLS) is applied as a non-contact, optical method based on inelastic scattering of laser light by acoustic phonons in the sample material to study the mechanical properties. By using BLS, the mechanical behavior in the GHz frequency regime is investigated with a high time resolution during wetting and drying of cellulose-based materials. In this talk, first results of such experiments will be presented.

8:45 AM CH04.10.04
Interpreting Spectroscopic Data in Halide Perovskites using Bayesian Inference Tobias Rudolph[1], Chris Dreessen[1,2] and Thomas Kirchartz[1,3]; [1]IEK5-Photovoltaik, Germany; [2]Instituto de Ciencia Molecular, ICMol, Spain; [3]Faculty of Engineering and CENIDE, Germany

The characterization of recombination processes is a crucial step in the development of solar cells. TRPL is a traditional characterization method for observing recombination mechanisms, frequently used for instance in the field of lead-halide perovskites for photovoltaic and optoelectronic applications. However, especially in the fairly intrinsic lead-halide perovskites, the interpretation of data is complicated because many processes, such as different recombination mechanisms and charge transport, occur at similar time scales. While it is reasonably straightforward to solve the forward problem of simulating TRPL transients for a given set of material parameters, the inverse problem of inferring the material parameters from measured transients is difficult. Fitting analytical models typically leads to an oversimplified model while fitting numerical simulations is very time consuming.
In this study, we propose a novel approach that combines Bayesian inference with surrogate models to increase computational speed. Using our approach, we obtained results from a typical TRPL dataset in less than an hour on an ordinary desktop PC. Instead of using the drift-diffusion simulations during fitting, we used ~10^6 simulations to train a convolutional neural network which works as a surrogate model. Reading out the surrogate model for a certain material parameter combination is approximately as fast as the evaluation of an analytical equation but allows the inclusion of significantly more complexity in the choice of model. Given the speed of comparing the output of the surrogate model with the experimental data, it becomes feasible to evaluate the physically plausible parameter space by slow methods such as grid search. This approach allows us to obtain a profound understanding of parameter correlations and can estimate fitting errors.
Conventional methods used to experimentally determine TRPL transients such as TCSPC suffer from a limited dynamic range. However, the recombination parameters only become visible in data that covers several orders (>4) of magnitude in PL intensity and time. Thus, we used a gated CCD setup to measure TRPL over a wide dynamic range of up to eight orders of magnitude. This provides insights into the recombination processes that would be difficult to obtain otherwise. A noteworthy result in the context of lead-halide perovskite thin films is the predominance of recombination via shallow defects and the apparent complete absence of deep defect recombination in the data that we observe over a wide range of compositions. We can infer important parameters, such as trap depths, trap density, and capture cross-sections from the TRPL data. Our method offers rapid and comprehensive insights into the parameters governing the recombination process in solar cells.

9:00 AM CH04.10.05
High Operation Stability of Solution-Processed Ultrathin (John Jinwook Kim[1], Haibin Su[2] and Wallace C. Choy[1]; [1]The University of Hong Kong, Hong Kong; [2]The Hong Kong University of Science and Technology, Hong Kong

Ultrathin flexible transparent electrodes (*u*FTEs) are an indispensable component in emerging flexible electronics due to a high level of compatibility and comfortability while there is an ever-increasing demand for low-cost solution-process-based high-throughput production for *u*FTEs. Owing to the successful advances of solution-processed nanomaterials [1], *u*FTE composites from transparent metal-oxide-semiconductors (TMOS) and silver nanowires (^{Ag}NWs) have been extensively reported. However, there is still a big gap in achieving simultaneous multi-loading operations (i.e., folding cycles with <1.5 mm radius of curvature, current bias with >300 mA cm^{-2}, and humid environments at 85 % of relative humidity (RH)), which is highly required as one of

the practically rigorous environments.
The fundamental bottleneck is to achieve high-quality interfaces simultaneously by performing tri-system integration in ^{Ag}NW-^{TMOS}NP hybrid *u*FTEs. The tri-system includes three different interfaces ^{Ag}NW-^{Ag}NW, ^{TMOS}NP-^{TMOS}NP, and ^{Ag}NW-^{TMOS}NP. All interfaces play key roles in the long operational stability against the simultaneous multi-loading operations. Although excellent works have been reported in the individual systems of ^{Ag}NW-^{Ag}NW networks [2] and TMOS-TMOS nanocrystal films [3], importantly, the quality of ^{Ag}NW-^{TMOS}NP heterogeneous interfaces needs substantially improving due to the mismatched interaction between ^{Ag}NW and ^{TMOS}NP. As a consequence, there are primary need to realize the tri-system integration for achieving the mechanical, electrical, and chemical stability in the solution-processed ^{Ag}NW-^{TMOS}NP composites for better *u*FTEs.
In this study, we develop a simple one-step *in situ* solution processed method (*i*SPM) to fabricate the solution-processed tri-system-integrated *u*FTEs (greatly thin less than 1μm) composed of ^{Ag}NWs and ^{ZnO}NPs at room temperature. The *i*SPM is developed for both (i) removing the capping agents from ^{Ag}NWs and (ii) facilitating ^{ZnO}NPs with flexible geometric shapes through the course of the coalescence process. The provided condition from both (i) and (ii) enables the ^{ZnO}NPs to be capable of in situ nano-adhesion into the cleaned surface of ^{Ag}NWs via flexible geometric shapes. Fundamentally, we show the in-situ atomic passivating mechanism of ^{Ag}NW by the liquid-like spreading dynamics of solid-state ^{ZnO}NP being wetted on the ^{Ag}NW surface. The nanonet *u*FTEs with *tri-system integration* via *i*SPM show very good mechanical-electrical-thermal-moisture stability of the current density fluctuations less than 5 % against simultaneous multi-loading fatigue tests (10,000 cyclic mechanical folding with approximately 0.5 mm of FR, continuous electrical bias of 8.4 MA cm^{-2}, and 85 % RH condition). The superior electrical/optical properties (<10 Ω sq.$^{-1}$ of sheet resistance and >88 % of diffused transmittance in the region of wavelengths 400-1000 nm) and smooth surface topography (within ~1 nm of RMS and ~5 nm of PtV roughness) have been achieved within all the *i*SPM-treated ^{Ag}NW-^{ZnO}NP nanonet *u*FTEs. Consequently, our finding unveils the complex interfacial dynamics associated with the heterogeneous interface system between ^{Ag}NWs and ^{ZnO}NPs and holds great promise in understanding the in-situ nano-adhesion process and increasing the design flexibility of promising solution-processed *u*FTEs.

Structure and Dynamics of Water Ice Ih Tianran Chen and David A. Tennant; The University of Tennessee, Knoxville, United States

Water ice Ih is a non-periodic system with proton disorder due to the large number of possible configurations of hydrogen atoms that follow the ice rule. Understanding the structure and dynamics of water ice Ih is important for various scientific and technological applications. In this work, we measured the static and dynamic structure factors of a single crystal ice Ih at different temperatures using elastic and inelastic neutron scattering techniques. We showed that our static structure factors could be well explained by the Fourier transform of the simulated spatial configurations of water ice.

We derived the formula to calculate the dynamic structure factor of non-periodic systems. We showed the limitations of classical first-principle phonon calculations when dealing with non-periodic systems. We presented a novel method to calculate the dynamics of water ice Ih. We constructed the force constant matrices using a mathematical model based on the local symmetry guaranteed by the ice rule. The model parameters were first fitted to first-principle phonon results and then fine-tuned to fit the neutron scattering data. Our results showed the detailed short-range interactions of water ice Ih with high accuracy and corrected the underestimated hydrogen interactions using classical first-principle phonon calculations. Our results provided new insights into the lattice dynamics and thermal properties of water ice Ih and offered potential applications for understanding other non-periodic systems with local symmetry.

Energy Storage using Order-Disorder Phase Transitions in Plastic Crystals Ares Sanuy, Gustavo Madrigal, Carlos Escorihuela, Claudio Cazorla and Luis Carlos Pardo Soto; Universitat Politècnica de Catalunya, Spain

Energy storage materials based on order-disorder phase transitions are a promising strategy for harnessing solar energy in a simple and efficient manner. Thermal energy is stored by inducing a phase transition between an ordered solid phase, where molecules are ordered both translationally and orientationally, and a plastic phase where molecules are allowed to rotate in a more or less free way. Two materials that can be used for this purpose are Neopentyl Glycol (NPG) and methylammonium-lead-iodide (MAPI), the latter having an organic molecule inserted into an inorganic framework, in contrast to the former. From a theoretical perspective, the strategy of harnessing energy through order-disorder transitions requires a deep understanding of the nature of disorder in the plastic phases. This understanding is crucial for analyzing existing materials and developing new ones based on the same principle. In this work, we present Molecular Dynamics simulations aimed at establishing a unified microscopic description that rationalizes the experiments conducted so far. Additionally, the study proposes a standardized protocol for investigating order-disorder phase transitions.

10:15 AM CH04.10.08
Unraveling The Catalytic Effect of Hydrogen Adsorption on Pt Nanoparticle Shape-Change Cameron J. Owen[1], Nicholas Marcella[2], Yu Xie[1], Jonathan Vandermause[1], Anatoly Frenkel[3,4], Ralph Nuzzo[2] and Boris Kozinsky[1,5]; [1]Harvard University, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Stony Brook University, The State University of New York, United States; [4]Brookhaven National Laboratory, United States; [5]Robert Bosch LLC, United States

The activity of metal catalysts depends sensitively on dynamic structural changes that occur during operating conditions. The mechanistic understanding underlying such transformations in small Pt nanoparticles (NPs) of ~1-5 nm in diameter, commonly used in hydrogenation reactions, is currently far from complete. In this study, we investigate the structural evolution of Pt NPs in the presence of hydrogen using long time-scale reactive molecular dynamics (MD) simulations paired with experimental X-ray absorption spectroscopy. From these comparisons, we obtain atomic-level mechanistic insights into `order-disorder' structural transformations exhibited by highly dispersed Pt NP catalysts upon exposure to hydrogen. We report the emergence of previously unknown candidate structures in the 1 nm Pt NP size range, where exposure to hydrogen leads to the appearance of a `quasi-icosahedral' intermediate symmetry, followed by the formation of `rosettes' on the NP surface. Hydrogen adsorption is found to catalyze these shape transitions by lowering their temperatures and increasing the apparent rates at which these candidate structures appear, revealing the mutually catalytic and dynamic nature of interaction between nanoparticle and adsorbate. This study offers a new pathway for deciphering the reversible evolution of catalyst structure resulting from the chemisorption of reactive species, enabling the determination of active sites and improved interpretation of experimental results with atomic resolution.

Temperature-Dependent Mechanical Properties of Organic Semiconductors Kehinde Fagbohungbe, Connor Callaway and Chad Risko; University of Kentucky, United States

Rationalizing the deformation of molecular and polymer-based organic semiconductors (OSC) under mechanical stress across a range of operating temperatures is critical both to the development of OSC for flexible devices and to a more general understanding of the degradation of OSC performance. Here, we develop and deploy atomistic molecular dynamics simulations to determine stress-strain relationships of molecular (i.e., non-fullerene and fullerene acceptors) and polymer (i.e., P3HT)-based OSC of interest for organic solar cells. A key goal of this work is to clarify how changes in chemical structure of the OSC building blocks, packing configurations, polymer chain entanglement, and both local and long-range material order (e.g., torsional disorder, crystallinity, etc.) influence properties such as the elastic modulus. By making connections with other (thermo)mechanical and optoelectronic works in the literature, the results discussed here seek to provide insights into upper and lower temperature limits for OSC during device operation and overall material stability.

10:45 AM CH04.10.10
Real Time Sensing of One Dimensional Nanostring Vibrations Michael C. Skripalsh, Arnab Manna, Laurel E. Anderson and Arthur Barnard; University of Washington, Seattle, United States

Micromechanical resonators host localized vibrations which make them useful tools for sensing and exploring the physics of small-scale systems. Devices such as silicon nitride cantilevers or suspended carbon nanotubes can be used as sensing devices through measurements of how their resonant frequencies change due to local perturbations. The small size of these resonators enables extremely precise resolution of masses and forces. While reducing the size of mechanical resonators conceptually improves sensitivity, when a resonator is shrunk down to the molecular scale, a much more complex regime emerges. Polymers, for instance, are known to be highly entropic: coupling to their environment causes large thermal fluctuations among their many flexural modes. The dynamics of such systems are well understood in highly damped environments such as biopolymers inside a living cell. However, in underdamped environments the dynamics are largely unexplored.
In this study, single molecules of DNA are suspended between SU-8 nanopillars with superhydrophobic surfaces that clamp the DNA nanostrings to both ends. The vibrations are measured by using a scannable photonic crystal cavity coupled to a tapered optical fiber. When the cavity is positioned close to the DNA, the near field coupling between the cavity and resonator allows for real-time measurement of the flexural dynamics of the nanostring via optical readout. These measurements are conducted at room temperature and can be used to further study the complex behavior of the nanostring's flexural modes such as thermalization, nonlinear coupling, and chaotic behavior. Looking forward, resonators made from DNA can be programmed to have arbitrary structures to tune their phononic character for added functionality and to probe the physics of nanostrings.

Morphology-Driven Magnetic Property Manipulation in Binary Particle Mixtures for Microscale Magnetic Control. Khalil ur Rehman[1,2], Mario Hofmann[1] and Ya-Ping Hsieh[2,2]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

Magnetic microactuators and microrobots have the potential to revolutionize remote manipulation and swarm-based collaboration. Unfortunately, conventional approaches to controlling individual magnetic systems cannot be shrunk to the microscale due to fundamental challenges in the generation and modification of magnetic fields. We here demonstrate the manipulation of magnetic properties in binary particle mixtures through morphology control. A combination of ferromagnetic and non-magnetic particles demonstrates the emergence of ordering and magnetic anisotropy under conditions that induce mechanical jamming in the assembly. A combined theoretical and experimental investigation confirms the importance of arresting forces from neighboring particles as the origin of this behavior. Utilizing this insight, a novel actuator, termed “Magnet with Mechanical Tunability (MagMeT)” was developed that transduces mechanical deformation in magneto/elastomer particle mixtures into magnetic torque. Our results open up a route toward actively controlling magnetic microrobots for future remote operating applications.

Controlling Interfaces toward Area Selective Atomic Layer Deposition Stacey F. Bent; Stanford University, United States

With the growing demands on nanostructure fabrication for advanced electronics, atomic layer deposition (ALD) continues to gain attention as an important method to achieve pattern features at the sub-10 nm length scale. Based on sequential, self-limiting vapor-surface reactions, ALD offers exceptional conformality, thickness control at the Angstrom level, and tunable film composition. Due to the chemical specificity of ALD reactions, several molecular-level system parameters can strongly impact the ALD nucleation and growth rate, including the specific substrate interface as well as the type of ALD precursor. As a result, the substrate interface and precursor selection can be tuned to intentionally control nucleation rates in ALD, which in turn provides a means to achieve selectivity on spatially patterned substrates. The resulting process of area selective atomic layer deposition (AS-ALD) has attracted significant attention in recent years. In this talk, we will provide examples of tuning surface chemistry to achieve AS-ALD. The development of inhibitory layers such as self-assembled monolayers (SAMs) and small molecule inhibitors (SMIs) to alter the native surface reactivity will be described. Some new SMIs include aryl or alkyl thiol, amine, nitro, and sulfonic acid compounds. The inhibition strategies demonstrate good selectivity in the deposition of thin films on a variety of substrate materials, and selectivity in AS-ALD can be further enhanced by choice of ALD precursor. Finally, we will describe the development of carbon-free inhibitor layers for AS-ALD.

11:00 AM EL01.01.02
Investigation of The Optical Constants of Absorbing Atomic Layer Deposition (ALD)-Grown TiO_2 Thin Films Nimarta Chowdhary and Theodosia Gougousi; UMBC, United States

Titanium dioxide, TiO_2, has been investigated extensively due to its unique and tailorable optical properties, including high refractive index, high dielectric constant, and high photocatalytic activity. The optical properties of thin films can be affected by the deposition process, composition, thickness, conductivity, and density. While TiO_2 is typically regarded as a wide band-gap semiconductor, with applications limited to the UV light range, TiO_2-based modified materials show promising results for applications with harvesting renewable solar energy. Applications of these sorts, however, require TiO_2-based materials to exhibit absorption in the visible light range. This can be achieved with band gap and optical property engineering.

For Atomic layer deposition (ALD), the process temperature is known to affect the film composition and, consequently, optical properties. We have used ALD to deposit 20-130 nm TiO_2 thin films from tetrakis(dimethyl amino) titanium (TDMAT, $Ti[N(CH_3)_2]_4$) and deionized (DI) H_2O at process temperatures ranging from 200 to 350°C. For films of the same thickness, the actual coloration is dependent on the deposition conditions. Control TiO_2 samples have been produced by a physical vapor deposition method (PVD) at room temperature from a TiO_2 target. X-ray photoelectron spectroscopy (XPS) analysis shows that ALD-grown TiO_2 films incorporate Ti-N/Ti-O-N metallic bonds while the PVD-produced films are purer, as expected. As the ALD process temperature increases, so is the measured at. % of Ti-O-N/Ti-N metallic bonding ranging from ~1 at. % at 250°C to ~4.5 at. % at 350°C.

Ultraviolet-visible spectroscopy (UV-VIS) confirms that the ALD-grown thin films are partially absorbing in the visible range with their absorbance dependent on the process temperature. Similar measurements have shown that PVD-grown films are transparent, as expected. The optical properties of the films have been investigated using spectroscopic ellipsometry (SE) at 380-900 nm. For these partially absorbing ALD films, conventional single-angle SE approaches fail to provide the requisite number of linearly independent equations to allow for the determination of the optical constants, n and k, and film thickness d. We have developed a modified ALD approach that produces samples on quartz substrates that are suitable to be used with a combination of single-angle ellipsometry (SE) data and intensity-based transmission (T) measurements to determine these parameters (n, k d) and their spectral dependence simultaneously.

When compared to pure PVD TiO_2 films, the partially absorbing ALD TiO_2 films exhibit a reduced n (ε_1) and increased k (ε_2), [TG5] which is consistent with the presence of TiO_xN_y bonding in the film. At 633 nm, n and k for PVD TiO_2 films are ~2.4 and 0, respectively, which is consistent with the literature. For the ALD films, the optical constants are found to depend on the ALD process temperature; values for n range from ~1.7 - 2.3, and k ranges from ~ 0.2 - 1.2 at 633 nm.

When the as-deposited ALD-grown TiO_2 thin films are annealed at 900°C in an argon environment, the thin film coloration changes, indicating a structural and compositional change. XPS analysis shows that the metallic bonding detectable in the as-deposited films has been removed and the films are fully oxidized TiO_2. We demonstrate that the ALD process temperature, as well as post-deposition thermal treatment for the films, are both avenues for controlling the band gap and tailoring the optical constants of TiO_2 films for a wide variety of applications.

11:15 AM *EL01.01.03
A Public-Private-Academic Partnership: The Microelectronics Commons Alison Smith; NSWC Crane, United States

Public-private-academic partnerships have the potential to drive innovation by leveraging the collective expertise and resources of government agencies, industry, and academic institutions to solve complex challenges. The Microelectronics Commons (Commons) is a key national initiative that is executed with oversight from the Office of the Under Secretary of Defense for Research and Engineering's (OUSD(R&E)'s) Principal Director for Microelectronics. This effort benefits both the Department of Defense (DoD) and the United States in spurring development of a domestic microelectronics manufacturing industry by forging critical partnerships with commercial industry, academic, and government partners. The Commons supports laboratory to fabrication (lab-to-fab) testing and prototyping hubs to create a network focused on maturing emerging microelectronics technologies, strengthening microelectronics education and training, and developing a pipeline of talent to bolster local semiconductor economies and contribute to the growth of a domestic semiconductor workforce. In particular, the Commons will address the need for processes, materials, devices, and architectures to be developed and transitioned from research labs to small-volume prototyping in a fab or foundry.

11:45 AM EL01.01.04
CHIPS and Science Act: Opportunities for Materials Science Community Santanu Bag; Huntington Ingalls Industries, United States

With the passage of the CHIPS and Science Act of 2022, a flurry of activity is expected to kick-off in the semiconducting research, development, and manufacturing field. Numerous programs and funding opportunities have been announced to tackle different challenges in the semiconducting value chain. The CHIPS funding will benefit not only U.S. chip manufacturers, but also tool vendors, U.S. universities, defense contractors, community colleges, K-12 STEM educational programs, and regional hubs. Materials science community plays an important part in the semiconducting industry and could be benefited from this opportunity as well. In this talk, an overview of all these opportunities will be discussed.

SESSION EL01.02: Surfaces and Interfaces I

1:30 PM *EL01.02.05
Scaling and Scale Up Effects during Area Selective Deposition using Self-Assembled Monolayers and Small Molecule Inhibitors Angel Yanguas-Gil; Argonne National Laboratory, United States

Area selective deposition (ASD) is a promising bottom-up patterning approach that has attracted significant interest in microelectronics. Area selective deposition methods can be roughly divided into two classes: intrinsically selective processes, which take advantage of preferential reactivity of precursors, and processes based on surface passivation. While growth selectivity is often used as a benchmark to quantify the performance of an ASD process, the scalability of ASD both in terms of pattern size (scaling) and substrate size (in terms of area and aspect ratio) is comparatively less understood.

In this presentation, I will focus on two case studies that explore the scalability of different area selective deposition approaches: the first example explores the impact of pattern size on the stability and density of defects of self-assembled monolayers (SAMs). SAMs exhibit a range of dynamic behaviors that can greatly affect their effectivity blocking precursors: these include order/disorder transitions, non-negligible surface mobility, or the presence of so-called gauche defects. Using simple dynamic models, we have explored how pattern size affect the stability of SAMs, and how, depending on chain-chain and surface interactions, size effects can lead to substantial changes on the areal density and distributions of defects in SAMs.

In the second example, I focus on how heterogeneous processes during small molecule area selective deposition can affect the scale up of area selective deposition to large scale (i.e. wafer size) and high surface area (i.e. high aspect ratio) substrates. A key aspect of area selective deposition processes using small molecule inhibitors is the need of effectively remove them from the substrate after each ALD cycle. Through a combination of in-situ characterization techniques, kinetic models, and transport models both within features and at the reactor scale, we have explored the impact that surface kinetics has on the elimination of inhibitor molecules. Our results show that reversibility in the inhibition process can greatly increase the purge times required to effectively remove inhibitors from large area substrates, creating inhomogeneities in film thickness even when processes are fully self-limited.

These two examples exemplify the tight coupling between the fundamental aspects of area selective deposition processes and their behavior under conditions relevant for semiconductor manufacturing.

2:00 PM EL01.02.02
Synthesis and Guided Self-Assembly of Mixed-Metal Oxide Arrays from Undercooled Liquid Metal Julia J. Chang, Andrew Martin, Alana Pauls, Dhanush Jamadgni and Martin M. Thuo; North Carolina State University, United States

In the Information Age, inexorable progression of big data demands rapid upgradation of modern electronics. Internet of Things (IoT), for example, requires numerous “communicable” electronics and powerful central processing units to build a “smart” world, where every physical object is digitally connected. With vast amount of high-performance electronics in-need, advancement of nanofabrication technologies become pivotal. Contradiction between better performance and lower cost, however, has long been unreconciled for electronic fabrication, and Moore’s law is an exemplary case of facing such challenge. While Moore’s law has inspired disparate advances in Complementary Metal Oxide Semiconductor (CMOS) devices (>20 doubling in transistors per chip every year), the scaling approach that drives these advances is predicted to stall after ~27 doubling events. This scaling approach faces a triple challenge in: i) continued miniaturization with concomitant need for more tools, characterization, metrology, among others, transitioning Moore’s law into ‘more’ law. ii) a looming fabrication challenge as we approach the sub nanometer-length (atomic) scale per component, and iii) global demand for more computation presents an energy and supply challenge unless new, rapid, energy efficient fabrication methods are realized. New paradigm(s) in multiscale manufacturing of microelectronics is therefore needed, among which interface-based (43 more doublings) and/or self-assembled organic (>100 doublings) post-CMOS devices pertains great potential. This calls for a significant shift in microelectronic fabrication with an emphasis to the introduction of new chemistries, composition and functionality while maintaining energy efficiency and low-cost through a device lifecycle.
Liquid metal particles bear great potential to reduce energy and capital cost in functional array fabrication since they can act as a controlled reservoir for metal ions. Exploiting partial miscibility of organometallic adducts in aqueous media, steady-state kinetics *ad-infinitum* living polymerization was demonstrated using liquid metal particles as an infinitely large metal ion reservoir – the so-called HetMet reaction. This reaction led to synthesis of high aspect ratio self-assembled beams that were then translated to graphitic-carbon coated metal oxides with tunable band gaps. Herein, we extend this work by coupling the HetMet reaction with confinement from nanograting templates to separate the metal particles from the self-assembling adducts. Using molds bearing channels with desired dimensions and periodicity enables deposition of desired arrays, and exploiting fluidic dynamics of this process allows us to control both the nucleation point and the rate of ion transport to the growing seed. Driven by capillary action and solution evaporation, large-area, high-quality organometallic nanowire arrays were fabricated by D-Met, of which an in-air heat-treatment conveniently transformed the organic wires into mixed-metal oxide without compromising wire continuity or array periodicity. Besides planar patterns, fabrication of multi-layer nanostructures such as 2-layer arrays were also achieved, which is promising for design and fabrication of 3D electronics. With the high structural precision of D-Met fabricated wire arrays, we demonstrate unique electrical and optical properties including diode behavior and guided wave resonance.

2:15 PM EL01.02.03
Delafossite-Coated Cotton Fabrics and Their Potential Applications in The Textile Industry for Photocatalytic Self-Cleaning, UV-Blocking and Antimicrobial Activity Shahria Ahmed, Sachin Chopra, Swati Mohan and Jasim Uddin; The University of Texas Rio Grande Valley, United States

Delafossite materials demonstrate multifunctional applications due to their excellent catalytic properties, which vary depending on their morphology, particle size, and synthetic method. Herein, a few novel applications of the delafossites are reported, which can be implemented in commercial, medical, and domestic settings. In present work we are presenting two different delafossite $CuGaO_2$ and $CuFeO_2$ nanoparticles and its composite with cotton fiber. Multifunctional cotton fabric is prepared by depositing a uniform coating layer of $CuGaO_2$ and $CuFeO_2$, exhibits excellent photocatalytic self-cleaning, UV blocking, and antimicrobial activity. $CuGaO_2$ and $CuFeO_2$ nanoparticles concentration of 1mM and 2mM were deposited over cotton fabric using citric acid as a binder by a simple sonication method.Surface analysis, bindings, stability, stain resistance, and UV blocking characteristics of the functionalized cotton fabric are performed by SEM, EDX, XRD, FTIR, and UV-vis spectroscopy. Both $CuGaO_2$-cotton and $CuFeO_2$-cotton exhibit excellent photocatalytic activity, which is evident from the UV-Vis spectroscopic analysis after mixing with methylene blue dye and subsequent exposure to simulated solar light. 2 mM $CuGaO_2$-cotton fabric has the highest rate of stain extinction compared to others. In addition, $CuGaO_2$-cotton and $CuFeO_2$-cotton block most of the harmful UV radiation, 95–97.5% (approx.) in the case of $CuGaO_2$ and 90% (approx.) in the case of $CuFeO_2$. The modified cotton fabrics present good antimicrobial activity against gram-positive and gram-negative bacteria, which is confirmed by antimicrobial tests with Staphylococcus aureus and E. coli bacteria. The newly fabricated cotton-delafossite composite, with all its promising applications, can be viewed as a valuable, sustainable contribution of materials science to humanity.

Impact of The Wafer-Scale Fabrication on The Performance of Graphene-Based Flexible Microelectronics and New Strategies for Improvement
Elena del Corro[1], Marta Delga-Fernandez[1], Aina Galceran[1], Anton Guimera[2], Xavi Illa[2] and Jose A. Garrido[1,3]; [1]ICN2, Spain; [2]IMB-CNM, Spain; [3]ICREA, Spain

Graphene possesses unique mechanical and electronic properties that make it a crucial material in the biomedical field. Specifically, graphene-based electronic devices have been developed and are in continuous improvement for biomedical recording, stimulating and sensing purposes[1,2]. Despite the demonstrated capabilities of graphene-based solution-gated field-effect transistors (SGFETs) in this field, their wafer-scale fabrication process introduces uncontrolled residual charges on the graphene surface, which has an impact on the final functionality of the devices in the form of undesired doping and thus a deterioration of the general electrical performance.

In this work, we present a detailed study of the effect of residues presence at each step of photolithography in the wafer-scale fabrication process of graphene microtechnology. By means of Raman spectroscopy and spectro-electrochemistry we monitor the doping state of graphene during fabrication processes. As function of pH and the ionic strength of the electrolyte in contact with graphene, we register the frequency of the graphene's G phonon that can be directly related with the Fermi energy and doping state of graphene[3].

Our study reveals that certain steps in the fabrication process leave a major amount of residues on the graphene surface that leads to inhomogeneities at cm scale in terms of device performance. With this information in hand, we propose a new fabrication strategy including the deposition of a sacrificial copper layer on graphene to protect it against induced contamination during the whole photolithography process. We analyze the impact of this additional layer on the quality of graphene material, after deposition and final etching procedures. Finalized graphene devices and electrically characterized and compared with standard technology.

Reinforced Interfaces to Realize Multifunctional Supercapacitors Tse Nga Ng; University of California, San Diego, United States

Today’s electrochemical storage devices are restricted in capacity, a key challenge that limits the operational time of wireless devices. To increase the energy storage capacity, multifunctional structures such as structural supercapacitors combine load-bearing and energy-storage functions into the same device, resulting in weight savings and safety improvements. To achieve an efficient structural supercapacitor, we developed strategies based on interfacial engineering to improve both the electrodes and electrolytes.

The structural electrodes were reinforced by coating carbon-fiber weaves with a uniquely stable conjugated redox polymer and reduced graphene oxide that raised pseudocapacitive capacitance and tensile strength. The solid polymer electrolyte was tuned to a gradient configuration, where it facilitated high ionic conductivity at the electrode-electrolyte interfaces and transitioned to a composition with high mechanical strength in the bulk for load support. The gradient design enabled the multilayer structural supercapacitors to reach state-of-the-art performance matching the level of monofunctional supercapacitors (Science Advances 2023, 9, eadh0069)

Lastly, as a feasibility study, we fabricated a structural supercapacitor to serve as the weight-bearing hull of a model boat. The boat was integrated with a solar panel for charging up the supercapacitor hull, which in turn powered up the boat motor to cruise across a pool. This demonstration showed the potential of structural supercapacitors to facilitate mass savings and increase the capacity for energy harvesting and storage in future electric systems.

3:45 PM EL01.02.06
Enhancing The Hole Conductivity of an Undoped Silicon Channel by Defect Engineering of Surrounding SiO_2 Dielectric Soundarya Nagarajan[1], Daniel Hiller[2], Ingmar Ratschinski[2], Dirk König[3], Thomas Mikolajick[1,4] and Jens Trommer[1]; [1]NaMLab gGmbH, Germany; [2]TU Bergakademie Freiberg, Germany; [3]Australian National University, Australia; [4]TU Dresden, Germany

The road to miniaturization in semiconductor microelectronic technology has led to an ongoing demand for identification of suitable approaches for device performance enhancements and raised requirements of new materials and device structures [1].

Here, we report the electronic device performance improvement opportunity of silicon nanostructures without direct channel doping by adding Al acceptor states into a thin SiO_2 layer surrounding the silicon [2]. This novel concept is analogous to modulation doping in III-V semiconductors. The manifestation of the dielectric by incorporation of trivalent Al impurities gives the possibility for electrons from silicon to tunnel to the acceptor states in SiO_2 yielding

silicon with holes as majority carriers. Our method removes the disadvantages of impurity doping, namely a required thermal ionization, inelastic impurity scattering, problematic dopant activation vs. out-diffusion and statistical fluctuations of dopant density [3-4]. The SiO_2 doping also facilitates interface passivation by discharging the dangling bond defects at Si/SiO_2 interface [5]. To this end, the doping approach is demonstrated on silicon channels fabricated on a silicon-on-insulator (SOI) substrate with nickel silicide contacts. The same layers sequence is extended to a transfer length measurement (TLM) structure.

It was experimentally observed that the energetic state of Al-acceptors in SiO_2 formed by atomic layer deposition of Al_2O_3 on thin thermally grown SiO_2 induces a corresponding shift in the Fermi level of silicon towards the valence band. A variation in the density of hole carriers in the silicon channel is regulated by the variation of number of ALD Al_2O_3 cycles [6] which governs both the silicon resistivity and the specific contact resistivity. The effect of addition of a monolayer of ALD Al_2O_3 is reflected in the reduction of silicon resistivity to a value as low as 0.04-0.06 Ω●cm and a contact resistivity as low as 3.5E-7 $\Omega\bullet cm^2$ [7].

A single segment of the fabricated TLM structure can also perform equivalently as a transistor with the body contact operated as a back gate. The performance of the transistor is improved by an enhanced hole carrier transport with an I_{ON}/I_{OFF} ratio of up to 10^6 at a drain voltage of -1V. The NiSi source/drain contacts placed directly within the SOI region also undergoes a transition from Schottky to low-resistance contact as an effect of the barrier height reduction [8]. The drawbacks of conventional impurity doped devices such as dopant scattering, fluctuating device performance due to dopant diffusion, and even requirements of lightly or heavily doped source/drain regions can be circumvented by the new method. The aforesaid impurity free doping of the channel would be ideal for a high performance, high mobility device and enables new advancements encompassing areas of low-temperature physics and quantum technology.

Multiplexing Reactor for the High-Throughput Screening of Molecular Layer Deposition Processes David S. Bergsman, Yuri Choe and Duncan Reece; University of Washington, United States

Continued progress in information and communication technologies requires sustained innovations in memory and storage devices' architecture and production processes. For example, scaling technology to sub-5nm using extreme ultraviolet (EUV) sources necessitates new processes for making hybrid organic-inorganic thin film photoresist materials that are highly adsorbing of EUV. One potential approach for making these films is through molecular layer deposition (MLD), the organic analog of atomic layer deposition. However, the discovery of desirable MLD materials is slowed by the large number of combinations of inorganic and organic reactants available.

Here, we present an approach for rapidly screening new materials deposited by MLD using a custom-built, high-throughput, multiplexing MLD-style reactor. In such a system, multiple reaction chambers are connected to shared reactants and pumping lines, allowing for the elimination of redundant reactor components and reducing capital costs compared to an equivalent number of independent systems. By carefully controlling pressure gradients in the system and valve operation, different MLD processes can be performed simultaneously in separate reaction chambers, allowing for many materials to be produced at the same time. These materials can then be screened for their properties of interest. To demonstrate this approach, a multiplexing reactor of this design was constructed with six independent reactor systems, two shared reactant manifold lines, and one shared pumping line. Using the well-studied trimethylaluminum (TMA) and water reaction into alumina, depositions in this system are shown to be reproducible, comparable to depositions shown in the literature, and without cross-contamination between chambers. In demonstration of the capabilities of this system, a TMA/water growth curve is developed using a combination of depositions in all systems, along with a measurement of the ALD temperature window using simultaneous depositions in all six chambers at different temperatures. Finally, the ability to simultaneously deposit multiple films is demonstrated using diethylzinc and one of six different organic diols. Using such a system can enable the faster screening of processes for potential materials, like photoresists, which will be needed for many electronic and photonic materials.

SESSION EL01.03: Poster Session I: Surfaces and Interfaces I

Understanding the Degradation Mechanism of Spiro-OMeTAD during the Long-Term Operation of Perovskite Solar Cells and Mitigating it via ALD. Mayank Kedia[1,2], Chittaranjan Das[1,2] and Michael Saliba[1,2]; [1]University of Stuttgart, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Metal halide perovskites (MHPs) have emerged as promising photovoltaic (PV) materials with a power conversion efficiency (PCE) of 26% on the laboratory scale. Despite achieving high performance in less than a decade, device degradation under operating conditions is outcompeted in the PV market by silicon and CdTe technologies. To overcome this challenge, interface passivation with organic molecules and composition engineering are commonly explored to improve the device stability. While most studies have focused on the intrinsic stability of the perovskite active layer, there is a lack of understanding of the degradation of other charge-extraction layers and electrodes, and its effect on the final device performance upon aging.
In this work, triple-cation-based PSCs with a planar n-i-p architecture and a champion PCE of 20.1% were aged under maximum power point tracking (MPPT) for 1000 min under 1 sun illumination without any encapsulation in an ambient atmosphere. After aging, we performed soft Ar atom cluster sputtering XPS depth profiling to study the ionic motion/interactions between the perovskite active layer and the overlying charge extraction layer. In addition to iodine migration from the perovskite to the Spiro-OMeTAD/electrode interface, we observed a shift in the binding energies (BE) of the constituent species present in Spiro-OMeTAD with p-dopants lithium bistrifluoromethanesulfonimidate (LiTFSI) and 4-tertbutylpyridine (tBP).

When looking specifically at the core level spectra of S 2p centered at 169.3 eV are present uniformly from the Spiro/electrode interface to the Spiro/perovskite interface in the fresh PSC. Upon aging, the S 2s exhibit a lower binding energy 168.3 eV attributing to the reduction of sulfur present in the Spiro layer. Notably, the F 1s spectrum also showed an extra peak at 685.5 eV for the aged sample from 689.0 eV for the fresh sample. Additionally, the F/S ratio changed after MPPT aging, leading to a final change in the charge extraction properties of the Spiro-OMeTAD layer, leading to the final device degradation. We observed that this chemical redistribution created pinholes in the films, leading to easier penetration of H_2O and O_2, and perovskite instability. Applying near-ambient pressure XPS (NAP-XPS) on the perovskite film with and without the spiro-OMeTAD layer at 1 mbar of H_2O at 50 ˚C, 100 ˚C, and 150 ˚C showed the formation of metallic lead (Pb^0) and iodine due to the degradation of Spiro-OMeTAD, accelerating the decomposition of the perovskite. Interestingly, our XRD results confirm that the interaction between the degraded Spiro-OMeTAD and perovskite leads to the amorphization of perovskite, which is different from what is commonly observed for PbI_2. The cross-sectional SEM image of the aged PSCs highlights the spiro/perovskite interface as the breaking point under constant illumination.
Finally, to mitigate the instability caused by the degradation of Spiro-OMeTAD, robust passivation of ALD-deposited AlOx of <1 nm has proven to be an effective strategy for the long-term stability of PSCs. We examined the conformity of this sub-nanometer layer via HRTEM and observed the complete coverage of a rough perovskite layer (RMS ± 20 nm) by AlOx, which is difficult to obtain by the chemical deposition of organic passivation layers. In-situ electron diffraction also showed that the grown ALD layer was amorphous and acted not only as a surface passivation layer for perovskite but also as a barrier layer to prevent the degradation of perovskite as a result of the decomposition of Spiro-OMeTAD.
Overall, our work provides chemical and mechanical insights into the degradation of the overlying layer on perovskite by combining macroscopic, microscopic, and spectroscopic studies. We also decoupled the role of ALD as a passivation layer for perovskite intrinsic stability and as a nanoencapsulant layer for mitigating the phase transition to amorphous phases upon Spiro-OMeTAD degradation.

5:00 PM EL01.03.02
High Performance Organic and Inorganic Metal Halide Perovskite Phototransistors Jamal Aziz, Alexander Löwen, Zhuang Miao, Naveen Kolluru and Daniel Neumaier; University of Wuppertal, Germany

Perovskite has emerged as the promising material for optoelectronic applications, especially solar cells, owing to its high absorption coefficients. However, the research on perovskite based electrical devices raised serious concerns based on their operational instabilities and their ionic nature. This effect leads to perovskite-based field effect transistors (FETs) with low carrier mobility, high hysteresis, and high operating voltages due to long channel lengths. Here we have reported phototransistors based on $MAPbI_3$ and $CsPbBr_3$ perovskite with silicon back gate. Firstly, we reported bottom gate / top contact (BGTC) perovskite transistors with long channel lengths (170 µm) but however they exhibit poor electrical and light dependent response. In contrast, the bottom gate / bottom contact (BGBC) perovskite transistors with short channel lengths (6 µm) exhibit optimal performance. Ambipolar transport characteristic was observed at room temperature. The hole mobility presents light dependence whereas electron mobility is nearly the same under light for both organic and inorganic metal halide transistor. The photoresponsivity of 60 mA/W and detectivity of 10^{11} Jones was observed for $CsPbBr_3$ phototransistors under light. The hysteresis effect of both organic and inorganic metal halide transistor was studied by changing the voltage bias and the monochromatic light intensity. The hysteresis effect in both perovskite transistors is attributed to the charge trapping process. Overall, this work paves the way for perovskite based flexible, wearable and disposable electrical devices with optimal performance.

KEYWORDS: $MAPbI_3$ perovskite; $CsPbBr_3$ perovskite; Phototransistor; Hysteresis; Responsivity

Improvement in Switching Characteristics and Bias Stability of Solution-Processed Zinc–Tin Oxide Thin Film Transistors via Simple Low-Pressure Thermal Annealing Treatment Junhao Feng, Sang-Hwa Jeon and Jin-Hyuk Bae; Kyungpook National University, Korea (the Republic of)

In this study, we used a low-pressure thermal annealing (LPTA) treatment to improve the switching characteristics and bias stability of zinc–tin oxide (ZTO) thin film transistors (TFTs). For this, we first fabricated the TFT and then applied LPTA treatment at temperatures of 80°C and 140°C. The LPTA treatment reduced the number of defects in the bulk and interface of the ZTO TFTs. In addition, the changes in the water contact angle on the ZTO TFT surface indicated that the LPTA treatment reduced the surface defects. Hydrophobicity suppressed the off-current and instability under negative bias stress because of the limited absorption of moisture on the oxide surface. Moreover, the ratio of metal–oxygen bonds increased, while the ratio of oxygen–hydrogen bonds decreased. The reduced action of hydrogen as a shallow donor induced improvements in the on/off ratio (from 5.5×10^2 to 1.1×10^7) and subthreshold swing (8.63 to V dec^{-1} and 0.73 V dec^{-1}), producing ZTO TFTs with excellent switching characteristics. In addition, device-to-device uniformity was significantly improved because of the reduced defects in the LPTA-treated ZTO TFTs.

5:00 PM EL01.03.05
Tunable Dielectric Properties of CVD-Processed Polymer via Click Chemistry Seongcheol Jang[1], Gunoh Lee[2], Kyung Jin Lee[2] and Hyun-Suk Kim[1]; [1]Dongguk University, Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of)

Recently, the increasing demand for high-end displays has led to the development of flexible displays using non-traditional flexible substrates rather than traditional rigid substrate. Currently, thin-film transistors (TFTs) for flexible devices mainly use inorganic dielectrics such as SiO_2, and Al_2O_3. These inorganic gate dielectrics have critical issues to applicate in flexible devices because of their high temperature process, high-cost production, and limited flexibility. Therefore, the mass production yield inevitably decreases, leading to increase in price of devices. From this point of view, polymer dielectrics have attracted considerable attention as a gate insulator for flexible transistors because of their mechanical nature. Even if polymer gate dielectrics are suitable for future flexible electronics, properties such as dielectric constant, and leakage current, are not suitable for cutting-edge devices. Also, fabrication process for polymers is usually consist of solution process, which has poor step coverage, side effect like coffee-ring effect and pinholes.
poly(p-xylylene) (PPx, commercialized name is parylene) is well known passivation materials for various electronics, which can be fabricated by chemical vapor deposition system that can give pinhole-free conformal film. Conventional parylene family, such as parylene-C, -D, -N, and -AF4 shows low dielectric constant of ~ 3, which is does not meet requirements for future advanced electronic. However, physical, dielectric, and electrical properties of parylene family can be tuned by adjusting functional groups. We reported custom synthesized parylene-ethynyl that shows higher dielectric constant, smoother surface and similar leakage current compared to conventional parylene. This approach is quite intricate as it necessitates design from the monomer.
In this work, click chemistry was employed to further tuning the properties of custom-synthesized parylene-ethynyl for dielectric layer for TFTs. IGZO oxide semiconductors were used as the active layer to demonstrate high-performance hybrid TFTs. Unlike most polymers fabricated through solution processes, parylene's fabrication method relies on the Gorham method CVD system. This system provides a thin, conformal, and pinhole-free film, resulting in a compatible interface with oxide materials. Additionally, the deposition temperature is around room temperature, and no additional high-temperature annealing is required, making it suitable for plastic substrates with low glass transition temperatures, ideal for flexible or stretchable applications. Four types of click reactions were conducted on parylene-ethynyl, and it was confirmed that all of them exhibited click reactions. After click reaction, parylene-ethynyl demonstrated an improved dielectric constant exceeding 4 without compromising film quality. Successful fabrication of IGZO TFTs combined with parylene-ethynyl showcased reliable switching properties, indicating that the combination of parylene-ethynyl with click reaction and

IGZO posed no issues at interfaces. The click reaction is anticipated to facilitate easy adjustments to the characteristics of the polymer gate dielectric. Moreover, it opens up the possibility of manufacturing a functional device utilizing the clicked part.

5:00 PM EL01.03.06
One Pot Preparation of Spherical Magnesium Silicate by W/O/W Emulsion Precipitation Method Jung Kyeongmun[1], Youngyong Kim[2] and Kyounghoon Lee[1]; [1]Gyeongsang National University, Korea (the Republic of); [2]Denve, Korea (the Republic of)

We report on the synthetic method of spherical magnesium silicate particles with a high specific surface area via a cost-effective water-in-oil-in-water (W/O/W) emulsification process. Notably, all samples of magnesium silicates prepared by this process exhibited specific surface areas ranging from 486.41 m^2/g to 662.23 m^2/g. In particular, the EM_2.81 sample showed approximately 1.5 times higher surface area than commercially used Magnesol XL. The high surface area originated from a high fraction of micropores. SEM analysis revealed distinct sections in the samples, indicating the optimal concentration of water glass for spherical shape maintenance. Additionally, most of the emulsion-treated EM samples displayed spherical morphology around 20 microns and demonstrated characteristics of excellent dispersion without aggregation in water. These results suggest that the W/O/W single-pot emulsification process is an effective method for producing magnesium silicate particles with high specific surface area and spherical morphology.

5:00 PM EL01.03.07
Antireflective Properties of Plasma-Polymerized Biomimetic Surfaces Luigi P. Verdoni; Edmund Optics Research and Development, United States

Biomimetic surfaces inspired by Moth's eyes are characterized by the subwavelength structures that cover the eye's surface. These nanostructures, possessing tapered geometries of variable height and shape, present as a gradient refractive index and offer antireflective (AR) properties over a high angle of incidence (AOI). A facile technique utilizing inductively coupled reactive ion etching (ICP-RIE) was devised to endow the optical surface with randomly patterned subwavelength nanostructures. In this two step nanostructuring process, an etch mask and recipe were implemented to deliver AR behavior at desired wavelengths, followed by a plasma polymer deposition of a thin fluorocarbon film with a low surface energy. The resultant subwavelength antireflective surface can be tuned from the ultraviolet to infrared wavelengths and has been shown to possess utility in both antiwetting and high laser damage threshold applications.

5:00 PM EL01.03.08
Exploring Dopant Dynamics in Crystalline Germanium through Microwave Annealing (MWA) and High-Pressure Annealing (HPA): A Study on Diffusion, Activation and Recrystallization TaiChen Kuo[1] and WenHsi Lee[2]; [1]Chung Yuan Christian University, Taiwan; [2]National Cheng Kung University, Taiwan

This study delves into the nuanced activation behavior of phosphorus and boron dopants in crystalline germanium substrates through meticulous investigation of high-pressure annealing (HPA) and microwave annealing (MWA) techniques. Phosphorus implantation at 10 keV, with a dose of 5 × 10^15 atoms/cm^2, showcased intriguing profiles revealing a concentration peak exceeding the maximum equilibrium solubility in germanium. The subsequent HPA at 500 °C for 60 s resulted in a stable profile with a junction depth of 44.1 nm, contrasting the diffusion broadening observed at higher HPA temperatures. MWA at 3P to 5P demonstrated diffusion patterns akin to HPA at 500 °C. Sheet resistance comparisons between HPA and MWA unveiled the stability of sheet resistance in MWA, even at increased power levels (5P, 3000W, approximately 700°C), though not reaching the low resistance achieved with low-temperature HPA. Hall measurements after HPA at 500 °C revealed a decrease in sheet resistance to 0.63 Ω/square and an increase in N-carrier concentration to 5.76 × 10^19 P/cm^3, despite subsequent decreases in carrier concentration and mobility after 500 °C, possibly attributed to deactivation induced by high-temperature annealing. The study also explores the activation of boron, demonstrating significant enhancement through solid-phase epitaxial regrowth (SPER) with minimal diffusion, particularly notable despite the low solid solubility. The investigation involves dopant diffusion analysis using SIMS, highlighting the importance of maintaining a high dopant concentration at the surface for low contact resistivity. Sheet resistances measured by a four-point probe post-HPA and MWA underscore the effectiveness of higher temperatures in HPA for achieving high B activation through SPER. Comparative analyses and TEM images further elucidate the recovery of amorphous layers in both phosphorus and boron doping scenarios, emphasizing the advantageous SPER behavior facilitated by high-pressure annealing. In summary, this study provides comprehensive insights into the activation dynamics of phosphorus and boron in germanium substrates, emphasizing the nuanced interplay between annealing techniques and dopant behavior for advanced semiconductor device fabrication.

5:00 PM EL01.03.09
Controlled Bipolar Doping of One-Dimensional Van der Waals $Nb_2Pd_3Se_8$ Bom Lee and Jae-Young Choi; Sungkyunkwan University, Korea (the Republic of)

2D layered materials such as graphene, transition metal dichalcogenides (TMDCs), h-BN, and black phosphorous have been extensively studied in a wide range of applications due to their fascinating structural, physical, and chemical properties. However, as the width of the 2D semi-infinite plane becomes narrow to meet the stringent dimensional requirements of the transistor, the dangling bond density at the edge of 2D vdW increases, resulting in degradation of electronic performance. To solve such scale-down problems, research has been conducted in recent years on one-dimensional (1D) vdW materials with a further reduced dimension from a 2D structure. 1D vdW materials, where single molecular chains with strong covalent bonds are assembled by a weak vdW force, are free of broken or dangling bonds on the chain surface, even when separated by a diameter of less than 1 nm. On the basis of these structural features, various 1D vdW material-based applications have been demonstrated, such as molecular connectors, transistors, and sensors. In recent years, ternary 1D transition metal chalcogenides containing a noble metal such as Pd or Pt have gained attention as promising semiconducting materials for electronic and optoelectronic devices. For example, $Nb_2Pd_3Se_8$, successfully synthesized by Keszler et al. Nevertheless, research into the stable tuning of electrical properties, which is a prerequisite for basic electronic materials, is still in its infancy stage for 1D vdW materials.
In this study, we introduce a new ternary transition metal chalcogenide, $Nb_2Pd_3Se_8$, which was successfully synthesized via chemical vapor transport (CVT) method using iodine as a transport agent. Furthermore, we first demonstrated the chemical doping of $Nb_2Pd_3Se_8$, which is a representative n-type 1D vdW material, through chemically doping $AuCl_3$ and β-nicotinamide adenine dinucleotide (NADH) as p-type and n-type dopants, respectively. The concentration of holes and electrons controlled by varying the immersion time in the doping solution were effectively confirmed by spectroscopic and transport studies. In addition, we demonstrated an axial p−n junction on Nb2Pd3Se8 that exhibits near-perfect rectifying behavior using a selective doping method. We believe that this work can promote research based on 1D vdW semiconductors for future electronic applications.

5:00 PM EL01.03.10
Improving Indoor Efficiency of Inverted $Cs_{0.18}FA_{0.82}Pb(I_{0.8}Br_{0.2})_3$ Solar Cells via Surface Defect Passivation Chih-Ping Chen; Ming Chi University of Technology, Taiwan

The escalating energy consumption associated with the 'Internet of Things' (IoT)—involving the integration of sensors, telecommunications, remote

actuators, and smart devices—has created a growing need for consistent and sustainable energy sources. Self-powered integrated IoT devices, utilizing energy harvested from indoor photovoltaics (iPVs), have garnered significant attention. The crucial role of effectively suppressing trap-assisted recombination through the passivation of interfacial defects in perovskite has been demonstrated for sustaining high iPV performance under low light intensities. In this study, we introduced a p-i-n perovskite solar cell (PSC) that incorporates a hole-selective layer (2PACz) and employs a hybrid electron transport layer (ETL) composed of an A–D–A molecule (DTPTCY) and PCBM for the device. We constructed the PSC with the structure of ITO/NiO_x/2PACz/perovsktie/PCBM(with/without DTPTCY)/BCP/Ag, and used phenethylammonium iodide to further passivate interfacial defects. Various characterization techniques, including atomic-force microscopy images, X-ray diffraction patterns, X-ray photoelectron spectroscopy, photoluminescence (PL) spectra, time-resolved PL curves, and Kelvin probe force microscopy (KPFM) were performed. We controlled the blend ratio and fabrication temperature to improve miscibility, resulting in the optimized performance. GIWAXS and AFM were employed to determine the blend morphology; KPFM and UPS were used to identify the change in energy level alignment; SCLC and TPC analysis were utilized to evaluate the change in electronic transport. Within the PCBM:DTPTCY-ETL, a fibril-like structure is formed, significantly enhancing electron mobility and effectively suppressing bimolecular recombination. This leads to a reduction in defects and lower trap density within the perovskite layer. The optimized blended ETL-based $Cs_{0.18}FA_{0.82}Pb(I_{0.8}Br_{0.2})_3$ PSC demonstrated outstanding performance, achieving a power conversion efficiency of 39.9% under 3000K LED illumination (1000 lux). These experimental results suggest a promising approach utilizing A–D–A molecule-based interface modification to enhance iPV performance.

5:00 PM EL01.03.11
Direct Characterization of Single-Molecule Reaction via Tip Enhanced Raman Spectrum Ruihao Li; Arizona State University, United States

Characterizing chemical reactions at a single-molecule scale enables a deep understanding of the mechanism of complex chemical reactions and thus establishes new material science frameworks. Previous works explore the real-time current changes of reactants and its products to figure out the steps of the reaction process. However, it is hard to identify the paths of some reactions accurately because the current signal does not have fingerprint information of the reactants. Tip-enhanced Raman spectroscopy (TERS) can accurately characterize chemical reactions due to its ability to characterize chemical bond fingerprint information at single-molecule scale precision. By combining Raman spectroscopy with single-molecule Break Junction technology, we can control single-molecule reactions through electric fields and simultaneously observe the Raman shifts of its corresponding chemical bonds.

5:00 PM EL01.03.12
High-Performance and Stability of $CsPbBr_3/WSe_2$ Hybrid Photodetectors Functionalized via Quaternary Ammonium Ligand Exchange Jae-Hyeon Ahn and Jong-Soo Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The 2-Dimensional (2D) and 0-dimensional (0D) hybrid photodetector, with its high sensitivity and wavelength tunability, is reported as a promising candidate nanostructure for optoelectronic devices. The utilization of hybrid lead halide perovskite quantum dots (PQDs) in optoelectronic devices has grown due to their remarkable absorption characteristics and elevated photoluminescence quantum yield in research. Nevertheless, the stability of PQDs continues to pose a significant constraint on the overall performance of these devices. Here, it is reported that the properties and stability of the hybrid photodetectors are enhanced by surface passivation with ligand exchange using the quaternary ammonium ligand (didodecyldimethylammonium bromide, DDAB). The average lifetime of carriers in $CsPbBr_3$ PQDs is extended when treated with DDAB, showing an increase of 6.68–14.88 ns compared to untreated $CsPbBr_3$ PQDs. Furthermore, it is verified that the resistance to damage of water is only reduced by 25.8% at PL intensity, and this stability is maintained for over 16 hours. In this study, we demonstrate the hybrid WSe_2/DDAB-capped PQDs with enhanced responsivity of 1.4×10^3 A W^{-1} and detectivity of 3.1×10^{13} Jones under 40.0 μW cm^{-2} of a 405 nm laser. The hybrid WSe_2/DDAB-capped PQDs exhibited a stable time-dependent responsivity, indicating a 4.5% decrease (225.7–215.4 A W^{-1}) for the hybrid WSe_2/DDAB PQDs device, while the hybrid WSe_2/pristine PQDs device showed a 36% decrease (48.3–30.9 AW^{-1}). The results of this work highlight the importance of the surface passivation dependence of the optical properties and stability of PQDs with 2D-0D hybrid optoelectronic devices. Our work demonstrates an effective approach to improve the photodetector performance of 2D–0D hybrid photodetector based on PQDs, which can be extended to various PQDs and TMDC semiconductors.

5:00 PM EL01.03.13
Micro-Heater Integrated Nanotube Array Gas Sensor for Parts-Per-Trillion Level Gas Detection and Single Sensor-Based Gas Discrimination Wenying Tang, Zhesi CHEN and Zhiyong Fan; The Hong Kong University of Science and Technology, Hong Kong

Ensuring chemical safety and safeguarding human health require real-time monitoring and discrimination of trace gases using appropriate gas sensors. Typically, this task involves expensive, bulky, and power-intensive devices such as optical and electrochemical gas sensors. Achieving this objective with a single, miniature, low-power semiconductor gas sensor is challenging due to selectivity issues.
In this study, we demonstrated a novel gas sensor called micro-heater integrated nanotube array gas sensor (MINA sensor), which can operate in dual modes. The sensor can detect multiple gases at parts-per-trillion (ppt) level under the continuous heating (CH) mode and distinguish multiple gases under the pulse heating (PH) mode. We constructed the MINA sensor on the nano-porous anodic aluminum oxide (AAO) templates with a top-bottom electrode structure, which significantly increases the sensor's surface area for molecular access. To create the sensing material layer, we used atomic layer deposition to deposit an ultrathin and conformal SnO_2 thin film and decorated it with Pd nanoparticles. When operating under the CH mode, the MINA sensor could detect hydrogen, acetone, toluene and formaldehyde with measured LODs as low as 100 ppt, 100 ppt, 100 ppt, 4 ppb, with the corresponding theoretical LODs as 6.96 ppt, 11.88 ppt, 16.52 ppt, 70.06 ppt, respectively. Under PH mode, the MINA sensor provided varying transient responses to different gases due to the variations of gas diffusion and surface reaction activation energy of the gases. By analyzing the conductance amplitude and slope features of a single pulse, different concentrations of hydrogen, acetone, toluene, and formaldehyde can be distinguished. Furthermore, the PH mode saved 66.7% energy compared to the traditional CH mode. The remarkable capabilities of the MINA sensor make it highly appealing for various applications, including distributed low-power sensor networks and battery-powered mobile sensing systems for chemical safety, environmental monitoring, and healthcare.

5:00 PM EL01.03.14
Flexible Embedded Metal Meshes by Sputter-Free Crack Lithography for Transparent Electrodes and Electromagnetic Interference Shielding Mohammad Mehdi Zarei, Mingxuan Li and Paul Leu; University of Pittsburgh, United States

Radio frequency (RF) electromagnetic radiation has revolutionized communication networks. As we become more reliant on electronic devices and systems, there is a pressing need for the development of effective EMI shielding materials. These shielding materials protect electronic components from radiation damage and block undesirable signals. Metal networks, such as metal meshes and metal nanowires,
have been the subject of much research for transparent conducting electrodes with high transparency and low sheet resistance. In this abstract, we provide a novel approach in the field of crack lithgraphy focusing on the creation of flexible embedded metal meshes. Our novel method involves the use of a self-forming crack template as a mask.
Instead of relying on traditional lithography methods that require complex and expensive equipment to create masks for etching, this approach simplifies the mask creation step through the natural formation of cracks. Our facile fabrication method involves transferring the crack patterns to a PET substrate

using RIE. The process also eliminates the need of the sputtering process, traditionally employed in crack lithography for producing conductive meshes. After removing the crack template, we fill the embedded cracks with a highly conductive Ag ink and cure the ink. Our flexible embedded Ag meshes achieve 91.3\% visible transmission and \red{a} sheet resistance (R_s) of 0.54, which corresponds to a figure of merit of 7500. For transparent EMI shielding, the samples exhibit an SE of 42 dB with 91.3\% visible transmission

5:00 PM EL01.03.15
Superhydrophobic Surfaces and Surface Modification via Vapour Deposition Techniques Julie J. Kalmoni, Claire Carmalt and Christopher Blackman; University College London (UCL), United Kingdom

Superhydrophobicity, a common property within the field of protective coatings, was first observed in Lotus leaves where water droplets roll off the surface, taking dirt particles with them, rather than wet it.[1,2]

To replicate this process on a synthetic scale, both micro-/nano-scale roughness and a low surface energy reagent are required.[3,4] The latter employs the use of toxic fluorinated polymers (which also contributes to the robustness and high transparencies of the films) and requires high depositional temperatures.[5,6] Superhydrophobic materials have potential applications in oil-water separation and photovoltaics. However the widespread application of superhydrophobic coatings has been hindered due to their typically poor durability or robustness.[7]

A relatively unexplored technique combines the use of aerosol-assisted chemical vapour deposition (AACVD) to deposit superhydrophobic polymer films along with the resultant surface modification via AACVD of metal oxides (e.g. TiO_2 and CeO_2). AACVD is a scalable technique as it involves spraying a precursor on a heated substrate. Superhydrophobic coatings are known for their self-cleaning properties but depositing thin layers of metal oxides on top has allowed us to fabricate superhydrophobic metal oxide films, enhancing the photocatalytic properties of the superhydrophobic layer and the self-cleaning properties of the TiO_2 film.

Another surface modification technique is atomic layer deposition (ALD). ALD, a branch of chemical vapour deposition (CVD), is a technique used to deposit atomic layers of complex and layered thin films. By operating at such a scale, thickness control, conformality of the films, low temperature depositions and even the ability to scale-up are possible.[8]

This research seeks to fabricate a superhydrophobic photocatalytic self-cleaning coating, first by producing a superhydrophobic film from simple and non-toxic compounds via AACVD. This depositional technique also provides the highly textured morphology required. Thin films with a rough morphology, formed through island growth of aggregates have been produced, displaying static water contact angles > 160°, transparencies > 40% and maintained superhydrophobicity after 300 tape peel cycles.[9] Thereafter, the surfaces' properties are modified via the AACVD of TiO_2. Thus far, the deposited films are hydrophobic/superhydrophobic, exhibit photocatalytic activity and tolerate pencil hardness' of up to "6H".

This novel route could be used to produce 'easy-to-clean' coatings for slip-resistant flooring as well as coatings on solar cells.

Novel Metal/2D Insulator/Metal Junctions for Rectenna Switches Evelyn Li[1,2], Parameswari Raju[1] and Erhai Zhao[1]; [1]George Mason University, United States; [2]Thomas Jefferson High School of Science and Technology, United States

The solar cell market is dominated by Silicon-based (single- or poly-crystalline) photovoltaic cells which directly convert sunlight into electricity. For example, the most commercially available Si polycrystalline solar cells have a conversion efficiency of 14-19%. In the past decades, major research efforts have been spent on improving the conversion efficiency by using multiple-junction cells and new materials, such as organic semiconductor and perovskite materials. However, sunlight is a form of electromagnetic waves with ultra-high frequency and short wavelength, in comparison to the radio frequencies which can be collected by antenna. Although the sunlight can be collected by antenna, a fast switch to rectify the sunlight signal is needed. If successful, such a rectenna solar cell can reach very high energy conversion efficiency (85% - 90%) at very low cost. The conventional radio receivers use semiconductor PN-junction-like diodes which are not able to rectify frequencies beyond tera Hertz. Metal/insulator/metal (MIM) diodes have been proposed as the switch as the electrons are tunneling across the MIM junctions at high speed. The tunneling time is defined as : , reaching femtosecond [1], where d, m, U, e and V are barrier thickness, electron mass, barrier height, electron charge and bias across the junction. However, the conventional MIM diodes use bulk materials as the insulators which cannot be very thin and contain high-density of surface dangling bonds and defects.
In this work, we applied density function theory (DFT) method to design and study MIM junctions by using two-dimensional (2D) insulators, such as mono-, bi- and try-layer TiO_2, Ta_2O_5 and SnO_2. The 2D insulators can be obtained by oxidizing the corresponding 2D metal-sulfur materials. [2] Such 2D insulators have the smallest thickness and smoothest surface, perfect for tunneling barrier. The selection of metal electrode has a significant impact on the electrical characteristics. We found that the Au/monolayer TiO_2/Al junction exhibits the best performance in current rectifying. The tunneling time was studied by the extracted potential profile from DFT calculation, indicating the thickness and bias are the key factors. The effect of strain on the junctions was also studied. No significant effect was observed for up to ±0.6% of strain. In addition, the DFT-simulated current-voltage characteristics and tunneling time were modeled and fed into a rectenna circuit in Pspice. The circuit simulation showed excellent power output in the optical frequencies. Together, we will present a comprehensive study on MIM junctions using 2D insulators and their performance in rectenna circuits.

Wide Working Range Mechanochromic Sensor based on Multiple Photonic Crystals and Angle Compensators Hoang Minh Nguyen[1,2], Kwanoh Kim[2], Do-Hyun Kang[2], Yeong-Eun Yoo[2,1] and Jae Sung Yoon[2,1]; [1]University of Science and Technology, Korea (the Republic of); [2]Korea Institute of Machinery & Materials, Korea (the Republic of)

Flexible and wearable sensors have gained tremendous interest due to increasing demands in diverse applications such as prosthetics, personal healthcare, and e-skin. However, they are mostly based on electronic signals, restricting their potential in visualized mechanical measuring. Herein, inspired by the structural colors of natural species, we developed a novel mechanochromic sensor with a wide working range and angle compensators. Employing the colloidal lithography technique, multiple nanostructures were fabricated on a single stretchable substrate. Thus, broadening the detection range to 150% without sacrificing high sensitivity. We also introduced a novel approach using angle compensators to circumvent the issue of angle-dependent colors. By comparing the colors of rigid and stretchable photonic crystals, the users can facilely estimate the strain regardless of the incident and viewing angles. The fabrication principle in this study is based on a reusable mold, which is cost-effective for large-scale production. Thus, we believe this study will have a broad impact on the development of smart mechanochromic devices for visually measuring the deformation of materials.

Structural Assessment of (Sub-)Monolayer Coatings in Device Processing at High Spatial Resolving Power by TOF-SIMS Tandem MS Imaging Jacob Schmidt and Greg Fisher; Physical Electronics, United States

Surface characterization plays a pivotal role in the manufacturing process of next-generation electronic and heterogeneous devices. Characterizing the interfaces between different surfaces is especially challenging, primarily due to a lack of background information and the absence of reference spectra. This poses a significant challenge in supporting the analytical observations of emerging properties at these interfaces. Two case studies are presented here where there was little prior knowledge of the observed properties, but detailed answers were desired. In the first case, a carbon residue was observed by Auger electron spectroscopy (AES) imaging of etched e^- beam-patterned structures, but the source of the carbon was indeterminate. In the second case, a bi-functionalized monolayer film was ostensibly loaded with catalytically active metals to form the metal-organic ligands, but previous methods to characterize the film fell short in verifying the structure of the metal-organic ligands.

In this report, a general time-of-flight secondary ion mass spectrometry (TOF-SIMS) imaging method for unknown identification and structure elucidation is demonstrated. This method makes use of a TOF-TOF spectrometer designed for simultaneous TOF-SIMS (MS^1) imaging and tandem MS (MS^2) imaging [1-4]. Ions for TOF-SIMS tandem MS imaging were produced by a Bi_3^+ primary ion nanoprobe whereby MS^1 and MS^2 spectral data were generated from the same pixel in one duty cycle at a resolving power of 300 nm. Ion fluences were within the static limit (i.e. < 10^{13} Bi_3^+/cm^2) for nondestructive analysis, even where multiple analyses were conducted at the same position of the sample. Tandem MS peak attributions were made to a calculated mass accuracy ($\Delta_{m/z}$) of ≈ 1 ppm which provides confidence in the accuracy of the molecular identifications.

In the first example, TOF-SIMS tandem MS imaging was applied to characterize the carbon-containing residues of the lithography-patterned and etched structures. Several sets of peaks were observed at *m/z* > 150 in the MS^1 spectra. It was established and verified by tandem MS imaging that the carbon observed by AES imaging on the patterned sidewalls arose from two fatty acid (FA) contaminants; specifically, the $[M-H]^-$ ions of FA(12:0) and FA(16:0) were identified. Further, a ≈ 2:1 ratio of FA(12:0) to FA(16:0) was calculated. The high *m/z* peaks, detected only on the Cu-plated surfaces, were attributed to metal-organic complexes of Cu with the fatty acids. In the positive ion polarity, $FACu_2^+$ and $FA_2Cu_3^+$ ions were identified; in the negative ion polarity, FA^- and FA_2Cu^- ions were identified. In each case, a natural Cu isotope composition was confirmed.
In the second example, TOF-SIMS tandem MS imaging was also employed to confirm the presence and elucidate the structure of metal-organic ligands of Au, Pd or Pt atoms attached to bipyridine or triphenylphosphine within patterned monolayer films. Metal atom loading was achieved after monolayer immobilization [5]. The pattern areas were readily observed based on the atomic metal ion signatures. There were a number of MS^1 precursor ions potentially related to the metal-organic ligands based on the *m/z* values within the anticipated range for the target structures. The 2D distribution and structure of complexed bipyridine and triphenylphosphine ligands, together with observing the natural isotope distribution of the metals, was achieved by tandem MS imaging [6].

Towards a Universal Biosensing Platform based on Graphene/Pyrene Surfaces for Neurotransmitters Marta Delga-Fernandez[1], Aina Galceran[1], Jose Caicedo-Roque[1], Xavi Illa[2], Jose A. Garrido[1,3] and Elena del Corro[1]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]IMB-CNM, Spain; [3]ICREA, Spain

The development of new therapeutic treatments and diagnosis of neural-related illnesses is linked to research in the electronic devices field. Devices as neural implants allow the recording of electrical signals to better understand the central and peripheral nervous systems[1,2] and, therefore, advance in the diagnosis and treatment of these diseases. One of the main issues of current implants, mostly based on silicon technology (and thus, rigid) is that they are invasive. The use of graphene-based transistors may overcome this drawback, taking advantage of graphene's mechanical and electronic properties, and also opening the possibility to include chemical recording capabilities to the implant. Here, we develop a versatile graphene/pyrenebutyric acid (PyBA) platform for the detection of neurotransmitters, or other analytes of interest, while recording electrical neural activity.

To build this platform, we perform physical evaporation of PyBA, a molecule capable to interact with the p system of graphene thanks to its aromatic nature, and to covalently interact, due to its carboxylic group, with an aptamer of interest through the formation of a peptide bond.
We optimize the PyBA evaporation conditions, which are those leading to the formation of a PyBA monolayer on the surface of graphene. This optimization and further detailed characterization of the pyrenebutyric layer is key for ensuring an understanding of the future sensor functionality.
The viability of the system is studied with electrical characterizations of the transistors fabricated including the PyBA layer on graphene.
Then, the binding of an aptamer that recognizes a specific neurotransmitter – thrombin in our particular case- is explored and used as a prove of the utility of the platform presented. Thrombin is detected by electrical characterization of the functionalized graphene transistors, while morphological characterization of the samples is performed by Atomic force microscopy (AFM) and Raman spectroscopy.

The thrombin biosensing results reveal changes in the electrical properties of graphene corresponding to each concentration tested, and the detection range achieved is correspondent to the one achieved by reported approaches based on in-liquid functionalization[3] – more difficult to control-. This demonstrates the ability of the system to recognize the analyte of interest through binding to its specific aptamer. This graphene/PyBA universal biosensing platform is in the pipeline for the development of a new generation of multifunctional graphene-based neural implants.

Cation Bonding on Functional Groups for Greatly Enhanced Dipole Moments and Excellent SERS Sensing as a Universal Approach Ruey-Chi Wang and Hsiu-Cheng Chen; National University of Kaohsiung, Taiwan

The recently developed dipole-based surface-enhanced Raman scattering (SERS) technique has ushered in a new era of opportunities for crafting cutting-edge sensing platforms, boasting a host of advantages, including the ability to identify molecules, reduced costs, and heightened sensitivity. While significant efforts have been dedicated to augmenting the molecular dipole density on the surface to enhance sensing sensitivity, the constrained dipole moments have limited further advancement and application possibilities. In the work, we present a universal method known as cation bonding to enhance the dipole moments of oxygen-containing functional groups (OFGs) with the goal of achieving high-sensitivity trace sensing through Surface-Enhanced Raman Scattering (SERS).
Utilizing Cu^{2+} as a representative model, we have demonstrated substantial enhancements in dipole moments through density functional theory-based calculations, which have been further validated through SERS measurements. These enhancements have been compared with typical OFGs and SERS platforms based on graphene oxide (GO). The analysis results from Transmission Electron Microscopy (TEM) show no formation of copper particles, while Energy Dispersive X-ray Spectroscopy (EDS) clearly indicates the presence of copper signals, which indicates the formation of copper ions on the surface and rule out common electromagnetic mechanisms. A comprehensive analysis of the electronic structures of analytes and SERS substrates has been conducted to exclude conventional chemical mechanisms. The results obtained from Infrared Spectroscopy (IR), X-ray Photoelectron Spectroscopy (XPS), and Electrostatic Force Microscopy (EFM) confirm the formation of C-O-Cu bonds and the reversal of dipole moments through copper bonding. The Cu-OFG SERS platforms thus prepared not only exhibit remarkable sensitivity in detecting Rhodamine6G (at concentrations as low as 10^{-10} M) but also prove their utility in detecting trace amounts of nitrate (at 10^{-10} M), a harmful contaminant in drinking water, and thiabendazole (at 0.01 ppm), a parasiticide used in fruit preservation. This cation bonding strategy is highly versatile, applicable to various cations, and opens the door to creating exceptional SERS platforms for a wide array of sensing applications.

Enhanced Hole-Injective Materials Incorporating a Series of Heteroatoms for Efficient Perovskite and Organic Solar Cells Youngwan Lee and BongSoo Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Inverted structure perovskite solar cells (PSCs) are focused by many researchers in both academic and industrial photovoltaic fields. Inverted p-i-n PSCs contain multiple advantages over conventional n-i-p structure PSCs including easier fabrication processing, hysteresis-free behavior, and compatibility for tandem application. However, the maximum power conversion efficiency (PCE) of inverted PSCs still lags behind that of conventional PSCs dueto the limited number of well-matched charge-injection layers that can be energetically probable at the interfaces of inverted PSCs. In this work, we introduce excellent hole-injection materials for inverted PSCs. Newly synthesized hole-injection materials form a self-assembled monolayer (SAM) on a metal-oxide electrode, anchored by a phosphoric acid group, while a series of tricyclic aromatic rings containing O, S, or Se, respectively, as core heteroatom (denoted as Br-2EPO, Br-2EPT, and Br-2EPSe), directly contact with perovskite active layer. All of the SAMs on metal-oxide electrodes are energetically well-aligned with the perovskite photoactive layer at the interface. Notably, the Se-containing SAM exhibits the strongest interaction energy between the SAM and perovskite absorber, as investigated by density functional theory (DFT). The strong interaction energy at interfaces results in reduced interfacial defect density and an extended charge carrier lifetime. For device applications, PSCs introducing the Br-2EPSe SAM achieved a PCE of 22.73% between the series of SAM-based PSCs. Moreover, all of the SAMs were employed in organic solar cells (OSCs) and demonstrated good compatibility as a hole injection layer. The Br-2EPSe SAM-based OSCs demonstrated the highest PCE of 17.9% among the series of SAM-based OSCs, with enhanced short-circuit current density and fill factor.

Spectroscopy on The SnO2 Buffer Layer between TCO Current Collector and Fe2O3 Photoelectrode Artur Braun[1], Yelin Hu[1,2], Florent Boudoire[1], Songhak Yoon[1], Matthew T. Mayer[2] and Michael Grätzel[2]; [1]Empa, Switzerland; [2]EPFL, Switzerland

The tin oxide buffer layer between the transparent conducting oxide current collector and the hematite photoelectrode causes considerable water oxidation enhancement of that electrode. The water oxidation onset potential is lowered by 180 mV. The lifetime of photogenerated charge carriers is increased by a factor of 10. For the investigation of structure and function of the buffer layer, we designed a wedge-shaped multilayer film assembly. Oxygen 1s X-ray photoemission spectra suggest a decrease of oxygen vacancy concentration near the interface of α-Fe2O3 and FTO−SnO2, when the SnO2 buffer layer is introduced. This SnO2 buffer layer increases the crystallinity of the hematite layer. The oxygen 1s near-edge X-ray absorption fine structure shows that the buffer layer increases the Fe 3d−O 2p hybridization and affects the quasi-Fermi level of electrons in α-Fe2O3. There is some indication that the α-Fe2O3 layer contains an adverse hole state in the valence band which disappears when the α-Fe2O3 layer is grown on the SnO2 layer. This layer induces improved orbital overlap with subsequent improved charge transfer between the absorber α-Fe2O3 and the current collector FTO. Our experiments indicate that performance enhancement by this buffer layer is of electronic structure origin.

5:00 PM EL01.03.23
Electrically Tuneable Silicon-Based Photomodulator for THz Applications Xavier Romain[1], Peter R. Wilshaw[2], Rayko I. Stantchev[3,1], Tina Miao[1], Tim Niewelt[1], Shona McNab[2], Sophie L. Pain[1], Nicholas Grant[1], Ruy S. Bonilla[2], Emma Pickwell-MacPherson[1] and John D. Murphy[1]; [1]University of Warwick, United Kingdom; [2]University of Oxford, United Kingdom; [3]National Sun Yat-sen University, Taiwan

Silicon is a well-established semiconductor which is extensively used in a wide variety of applications; it is the basic component for photovoltaic solar cells and is a widespread substrate in many photonic devices. More recently, silicon has found new use in the ever-growing research area of terahertz (THz) waves. For example, silicon can serve as a THz photomodulator i.e., when the silicon is illuminated by an above bandgap optical source which renders the

silicon opaque to the THz radiation. The opacity level (modulation depth) and the switching speed between the transparent and opaque states of silicon (modulation speed) are determined by the lifetime of the photoexcited charge carriers in the silicon wafer. For some applications (such as in THz single-pixel imaging) the effective lifetime of silicon is a critical parameter, which must be carefully considered to reach the best trade-off possible between the modulation depth and the modulation speed. However, neither bare silicon (too low) nor routinely surface passivated silicon (too high) yields effective lifetimes that are best suited for such THz applications. Hence we suggest a novel device configuration featuring controlled carrier lifetime modulation of Si-based THz modulators via voltage application across a transparent gate electrode.

In this work, we report the fabrication, characterisation, and implementation in a THz imaging setup of such a photomodulator. We deposited hafnium oxide via atomic layer deposition as the passivation layer on both side of a high-resistivity silicon substrate. The hafnium oxide provides a sufficient electrical insulation and an adequate surface passivation level yielding lifetimes in the hundreds of microseconds. We then coated the hafnium oxide layers with poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) as the conductive layer for the electrical gating. The choice of PEDOT:PSS is particularly relevant for THz photomodulation as it is transparent to both the THz and the visible light. We performed an injection-dependent lifetime characterisation of the photomodulator using standard photoconductance decay (PCD) measurements while a bias voltage in a -10V to +10V range was applied between the PEDOT:PSS top layer and the silicon layer. We observed results for the effective lifetime as a function of the applied bias voltage that are consistent with similar devices previously reported in literature. We also confirmed the applied voltage homogeneity across the whole photomodulator surface by repeating a similar experiment using a photoluminescence imaging technique.

We implemented the electrically tuneable photomodulator in a THz time domain spectroscopy setup (THz-TDS) capable of single-pixel imaging. Similar to the PCD measurements, we first characterised the photomodulator effective lifetime by monitoring the THz radiation decay for a range of photoexcitation intensities and applied bias voltages. The lifetime curves extracted from this THz-TDS photomodulation configuration showed comparable trends with the lifetime curves produced by PCD. To demonstrate the potential of this electrically tuneable THz photomodulator, we performed single-pixel imaging where the photoexcitation source is now spatially structured so that the photomodulator acts as a THz spatial light modulator. We showed that tuning only the bias voltage, which controls the photomodulator effective lifetime, can massively impact the THz imaging. With such silicon-based THz photomodulator, the effective lifetime is not a constraining fixed factor but rather an additional degree of freedom for THz photomodulation.

Toward Solution-Processed UV Photodetectors via Atomically Thin Fluorine-Functionalized Graphene Coupled with Consecutive Carbon Quantum Dots Po-Hsuan Hsiao, Kuan-Han Lin, Tsung-Yen Wu and Chia-Yun Chen; National Cheng Kung University, Taiwan

Heterostructures stand for the artificial structures composed of two or more different solid-state materials. When the dimensionality of materials scales down to nanoscale, the interfaces associated with constitute materials play the dominant role on their materials chemistry, materials physics and even being decisive for the correlated device performances. In this presentation, the photophysical dynamics of fluorine-functionalized graphene (FF-Gra) coupled with carbon quantum dot film (CQDF) is manifested. By probing the involved electronic structures and optical transitions, bound-carrier population and dynamic phenomena is revealed, which exhibit as main features of for the modulation of photophysical origin. All these features implicate the outstanding UV-responsive flexible photodetectors with sound optical transparency, attesting external quantum efficiency (EQE) of $1.68x10^{9}$%, photoresponsivity of $4.66x10^{6}$ A/W and detectivity of $2.92x10^{18}$ Jones based on such nonintuitive quantum-confined hybrid materials. The present photodetector design, along with the mechanism validation was anticipated to be potential for the development of next-generation optoelectronic devices with desired properties.

5:00 PM EL01.03.25
Revealing Gas Sensing Mechanism of PtO_2 Originated from The Structural Equivalence with SnO_2 Seongsu Choi[1], Yeon Sik Jung[1] and Hyeuk Jin Han[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Sungshin Women's University, Korea (the Republic of)

Conventional gas sensing with Pt relies on the spillover effect, where Pt nanoparticles split gas molecules and disperse onto n-type semiconductors such as ZnO, WO_3, and SnO_2. In the presence of PtO, the p-type semiconductor nature of PtO creates an electron depletion region at the heterojunction with n-type semiconductors, which in turn affects the gas sensor resistance and thus provides information about the surrounding gas composition. The gas sensing mechanism of another oxidation state, PtO_2, has conventionally been considered a p-type semiconductor, similar to PtO until now. However, this traditional interpretation does not explain the increased selectivity and sensitivity observed with PtO_2 compared to both PtO and Pt. There is also a lack of research comparing the gas sensing properties based on the different oxidation states of Pt.
In this study, we suggest a novel gas sensing mechanism of PtO_2 when combined with SnO_2, originating from the structural equivalency between PtO_2 and SnO_2. Previously, it has been demonstrated that at elevated temperatures and under high O_2 partial pressure conditions, Pt in PtO_2 can replace Sn in SnO_2 lattice due to their identical rutile structure and oxidation state (4^+) as well as their similar ionic radii. Additionally, PtO_2, known for its strong oxidizing properties, creates oxygen vacancies in a reducing gas atmosphere. These vacancies then become active sites for the adsorption of target gases, significantly enhancing gas sensor performance. To verify the sole influence of the oxidation state of Pt, we designed 3D-aligned Pt decorated SnO_2 nanowires using Thermally-assisted nanotransfer printing(T-nTP). This method improved mass transport, ensured consistent network connections, and increased the surface area, enabling specific focus on the differences originating from the oxidation state of Pt. Via annealing in an air furnace, the oxidation states of Pt were selectively altered while keeping the other conditions, such as the structure of the gas sensor and the state of the supporting material, SnO_2. Specifically, annealing the gas sensor at 900°C results in approximately 99% conversion of Pt into PtO_2. We observed that PtO_2 decoration on SnO_2 exhibited superior sensitivity and selectivity for hydrogen sulfide (H_2S) compared to Pt decoration. PtO_2 showed approximately 60 times greater sensitivity compared to the sample annealed at a lower temperature, achieving response ratios (R_{air} / R_{gas}) exceeding 50 at a concentration of 1 ppm. Overall, this study presents a newly discovered gas sensing mechanism with PtO_2 and demonstrates significantly improved sensitivity and selectivity, particularly in detecting H_2S. Moreover, the gas sensors synthesized via T-nTP offer the potential for comparative analysis of gas sensing properties across different oxidation states of other noble metals.

5:00 PM EL01.03.26
Nanoscale Morphology, Defect Identification and Electronic Spectroscopy of Thin Molybdenum Carbide (α-Mo_2C) Crystals under Ambient Conditions Gokay Adabasi[1], Saima A. Sumaiya[1], Ilker Demiroglu[2], Elif Okay[3], Omer R. Caylan[3], Goknur Cambaz Buke[3], Cem Sevik[4] and Mehmet Z. Baykara[1]; [1]University of California, Merced, United States; [2]Eskisehir Technical University, Turkey; [3]TOBB University of Economics and Technology, Turkey; [4]University of Antwerp, Belgium

The emerging materials family of thin transition metal carbides (TMCs) have garnered significant recent attention due to their distinctive features such as high thermal and chemical resistance, good electrical and thermal conductivity, high hardness, and potential for energy storage as well as electromagnetic shielding. The application potential of thin TMCs will strongly depend on atomic-scale structural and physical-chemical properties. On the other hand, the necessity of high vacuum and low temperatures for atomic-resolution experiments has led to a debate regarding the relevance of such characterization approaches for real-life applications.

Here, we present a nanometer- and atomic-scale characterization study of thin crystals of molybdenum carbide (α-Mo_2C) grown through chemical vapor deposition (CVD). The experiments are performed via conductive atomic force microscopy (C-AFM), under ambient conditions. It is found that the crystal surfaces are partially covered by graphene. Moreover, atomic-resolution imaging, combined with density functional theory (DFT), allows the identification of various defects found on the crystal surfaces. Finally, current vs. voltage spectroscopy performed on the defects provides information about their local influence on surface electronics.

5:00 PM EL01.03.28
Mimicking Positive Aging using Atomic Layer Deposition of Alumina in Quantum Dot Light-Emitting Diodes Haoyue Wan[1], Euidae Jung[1], Pan Xia[1], Benjamin Rehl[1], Ruiqi Zhang[2], Yanjiang Liu[1], Yakun Wang[1], Sjoerd Hoogland[1], Vladimir Bulovic[2] and Edward H. Sargent[1]; [1]University of Toronto, Canada; [2]Massachusetts Institute of Technology, United States

Quantum dot light-emitting diodes (QD-LEDs) frequently exhibit a unique characteristic known as positive aging, where their efficiency improves over time. In this study, we delve into the underlying causes of this behavior. Our findings suggest that the densification of the ZnMgO electron transport layer plays a pivotal role in this process. As the device undergoes shelf-aging, ZnMgO nanoparticles coalesce, leading to a reduction in leakage current and a decrease in surface vacancies within the ZnMgO layer. To expedite the device's performance without waiting for the positive aging effect, we introduced an Al_2O_3 layer via atomic layer deposition between the ZnMgO and the electrode. This modification resulted in red InP QD-LEDs showcasing a remarkable 1.3-fold boost in efficiency and a tenfold enhancement in stability, underscoring the potential of the Al_2O_3 layer in optimizing QD-LED performance.

5:00 PM EL01.03.29
Curvature-Induced Instability in Crystallization of Chiral Liquid Crystals Sepideh Norouzi[1], Jeremy R. Money[1], Jose A. Martinez-Gonzalez[2] and Monirosadat Sadati[1]; [1]The University of South Carolina, United States; [2]Universidad Autónoma de San Luis Potosí, Mexico

Crystallization in curved entities such as viral capsids, Radiolaria, and ice-freezing is ubiquitous in nature, wherein the spatial coordination of constituent materials adjusts to adequately accommodate within curvature, resulting in exotic collective properties. Herein, we investigated the nucleation and growth of blue phase (BPs) soft crystals within curved topological confinement. BPs represent 3D periodic cubic crystals while they have fluidity. They have the potential to assemble into two crystalline symmetries: BPI with a body-centered cubic structure and BPII with a simple cubic structure. These cubic crystal lattices are a few hundred nanometers and show selective Bragg's reflection with rapid sub-millisecond response times, which makes them attractive for sensing and photonic applications. They, however, exist in a very narrow temperature range and generate polycrystalline structures when confined in flat films, preventing their widespread use in most practical applications. Moreover, the growing interest in the integration of these ordered materials into miniaturized, flexible devices brings about the need to understand the effect of geometrical confinement and curved boundaries on the structure of BPs and their stability and photonic responses.
To understand how the interplay of curvature, confinement, and surface anchoring impacts the structural stability and optical response of BPs, we have confined BPs within core-shell and microdroplets with precise size and shell thicknesses. Our observations in shells indicate that increased curvature and strong spatial confinement destabilize BPI promoting its transition into configuration and optical characteristics resembling BPII. Although BPs in shells appeared polycrystalline, the inherent 3D symmetrical curvature in microdroplets facilitated the formation of monodomain crystals, eliminating the need for any specific surface treatments. Moreover, using photo-polymerization technique to stabilize defects in droplets led to an expanded thermal stability range for BPs. Yet, the phase transition temperature in these microdroplets was found to be strongly size-dependent. We have delved into the underlying principles of these molecular arrangements through both experimental and theoretical simulations. These findings can pave the way for designing optically active microstructures, addressing BP-related challenges, offering potential for cutting-edge photonic and sensing applications especially in flexible and wearable devices.

5:00 PM EL01.03.30
Local Defect-Engineering in Monolayer MoS2 through Sulfur Vacancies Controlling with Dip-Pen Nanolithography Jinho Lee, Jeong-Sik S. Jo, Do Wan K. Kim and Jae-Won Jang; Dongguk University, Korea (the Republic of)

Molybdenum disulfide (MoS_2) is a promising layered semiconductor material that can overcome the limitations of conventional silicon-based devices. MoS_2 has a unique characteristic in which the band gap changes depending on the thickness; Monolayer MoS_2 has a direct band gap of about 1.8 eV, while multilayer MoS_2 has an indirect band gap of about 1.3 eV. Therefore, MoS_2 has potential applications in various fields such as optoelectronics, sensors, and catalysis. However, the electrical and optical properties of monolayer MoS_2 are sensitive to defects on its surface. Sulfur vacancies are the most prevalent defects in MoS_2 and they work as electron donors and trap sites. Thus, they create mid-gap states influencing the band structure and the Fermi level of monolayer MoS_2. The charge state and the local environment of the sulfur vacancies can either improve or deteriorate the electrical conductivity, the photoluminescence intensity, and the catalytic activity of monolayer MoS_2. Thus, it is crucial to control the sulfur vacancies in monolayer MoS_2 to optimize its electrical characteristics and device performance. In this study, we propose a method for local defect engineering in monolayer MoS_2. The proposed method controls sulfur vacancies through dip-pen nanolithography (DPN), a tip-based lithography technique that enables direct deposition of molecules or ions onto specific regions of the substrate surface.

5:00 PM EL01.03.31
Understanding Surfaces and Interfaces in Nanocomposites of Silicone and Barium Titanate through Experiments and Modeling Avery Pritchard[1], Vanessa Bartling[1], Heather Fuentes[1], Katrina Nelson[1], Jessica Santosa[1], Albert Dato[1], Todd Monson[2] and Renee Van Ginhoven[3]; [1]Harvey Mudd College, United States; [2]Sandia National Laboratories, United States; [3]Air Force Research Laboratory, United States

Computational and experimental studies into particle surfaces and particle-matrix interfaces in nanocomposites of silicone and barium titanate (BTO) nanoparticles will be the focus of this presentation. BTO is a ferroelectric perovskite that is used in electronic devices and energy storage systems because of its high dielectric constant (up to 7,000). Research has shown that the dielectric constant of BTO drastically increases to 15,000 at a BTO particle diameter of 70 nm, which is an intriguing but highly contested result. Dielectric constants of BTO nanoparticles have been determined by fabricating, characterizing, and modeling surface-functionalized BTO powders incorporated into polymer matrices. These studies have indicated that BTO particle size does impact the dielectric constant of the perovskite. However, more sophisticated modeling and advanced characterization techniques are needed to better understand the nature and complexity of interfaces formed between polymers and BTO, as well as investigate the relationships between interfacial properties, nanocomposite properties, and nanoparticle properties.

Here we present experimental and theoretical research into the preparation, transmission electron microscope (TEM) characterization, and simulation of elastomer-matrix nanocomposites containing BTO nanoparticles with diameters ranging from 50 nm to 500 nm. Methods of functionalizing the surfaces of BTO nanoparticles, preparing nanocomposites of BTO and silicone, and determining the dielectric properties of BTO-silicone nanocomposites will be shown. TEM images of BTO nanoparticles in silicone will provide insight into interface formation and be related to (1) nanocomposite properties, (2)

COMSOL models of the nanocomposites, and (3) density functional theory simulations of the interactions of water with BTO surfaces. The results from this project will advance our understanding of surfaces and interfaces in BTO-polymer nanocomposites, elucidate the particle size dependence of the BTO dielectric constant, and demonstrate an avenue toward manufacturing flexible elastomer-perovskite nanocomposites for wearable electronic devices and energy storage applications.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525. This study was also supported by the National Science Foundation under Grant No. 1943599.

SESSION EL01.04: Area Selective Deposition and Etching II
Session Chairs: Silvia Armini, Santanu Bag, Erwin Kessels and Adrie Mackus
Wednesday Morning, April 24, 2024
Room 348, Level 3, Summit

8:30 AM *EL01.04.01
Plasma Processes for Isotropic and Anisotropic Atomic Layer Etching Adrie Mackus; Eindhoven University of Technology, Netherlands

The development of nanoelectronics towards increasingly complex 3D nanostructured devices requires novel combinations of anisotropic and isotropic etching. Atomic layer etching (ALE) will play an important role in the fabrication of such nanodevices because of its Ångstrom-level control and ability to uniformly etch on complex structures. Previously reported ALE processes can be classified in two main categories: plasma processes for anisotropic etching and thermal chemistries for isotropic etching.
In this contribution, results for both isotropic and anisotropic ALE will be discussed, focusing on the unique opportunities provided by plasmas. The relatively unexplored category of using plasmas for isotropic ALE allows for processing at lower temperatures and higher etch rates, as will be demonstrated for processes involving fluorination with a SF_6 plasma. Recent work also focuses on isotropic ALE based on etching by diketone dosing (e.g., hexafluoroacetylacetone) and plasma cleaning steps. Infrared spectroscopy and simulation studies revealed that the mechanism of etching with diketones involves a competition between etching and inhibition reactions.

9:00 AM EL01.04.02
Atomic Layer Deposition of WO_X-Doped In_2O_3 for High-Performance BEOL-Compatible Transistors Chanyoung Yoo[1,2], Balreen Saini[2], Jonathan Hartanto[2], Cristian Ruano Arens[2], John D. Baniecki[1], Wilman Tsai[2], Baylor B. Triplett[2] and Paul C. McIntyre[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States

Metal oxide semiconductors incorporating In_2O_3 have received significant attention as they possess high electron mobility, can be synthesized at back-end-of-line (BEOL) compatible temperatures, and exhibit excellent transistor characteristics at nanoscale dimensions. Doping In_2O_3 with several mole % tungsten oxide to form "IWO" has been reported to improve the threshold voltage stability of these semiconductor channel materials. However, currently reported film deposition for IWO is limited to sputtering, which does not allow the growth of conformal films with precise thickness and stoichiometry control on topographically complex BEOL surfaces. This limitation becomes critical when utilizing these films as channel materials in gate-all-around structures. A shift toward deposition methods that support 3D structures is necessary to address the increasing demand for high on-current. Consequently, we use the 3D-compatible atomic layer deposition (ALD) method to deposit IWO by adjusting the cycle ratios for In and W precursors and the oxidant co-reactant, enabling precise control over the doped film composition. In addition to facilitating highly conformal film growth, ALD-grown IWO may exhibit different point defect populations and a broader process window for amorphous structure because of the lack of bombardment by energetic species that are present during sputtering. We demonstrate deposition of IWO (1~4 mol% WO_X) films using ALD and fabricate both bottom- and top-gated thin film transistors with a 3-nm thick IWO channel in a BEOL-compatible process with a maximum temperature of less than 250ºC. A transistor with 2 mol% WO_X-doped IWO exhibits exceptional performance characteristics, including a subthreshold slope of 65 mV/decade, a high $I_{D,sat}$ of 70 (W=12 , L=1.5) at V_{DS}=1.0 V and V_{GS}=2.0 V, and remarkable stability under bias stress. The transistor showed negligible hysteresis and maintained a stable threshold voltage (V_{th}) under negative and positive bias stress conditions (ΔV_{th} = -0.06 V and +0.1 V, respectively, at an electric field of 4.2 MV/cm for 1000 seconds). This V_{th} stability under bias stress highlights the reliability of ALD-grown IWO for ferroelectric field-effect transistors and its potential to enable high-performance monolithic 3D integrated devices.
Furthermore, we explored the evolution of long-range order within the IWO films through synchrotron X-ray diffraction. We found that doping In_2O_3 with several mole % of tungsten oxide has a strong anti-correlation with both the ordering and the presence of oxygen vacancies, which are themselves strongly correlated with V_{th}. This work offers an understanding of the impact of W doping and provides insight into the reliability of In_2O_3-based oxide transistors.

9:15 AM EL01.04.03
Understanding The Formation and Evolution of Surface Oxidation Layers in Nb Thin Films Jeffrey Dhas[1,2], Zihua Zhu[1], Peter V. Sushko[1], Mingzhao Liu[3], Ekta Bhatia[4], Jakub Nalaskowski[4], Sandra Schujman[4], Corbet Johnson[4], Tom Murray[4], Satyavolu Papa Rao[4] and Yingge Du[1]; [1]Pacific Northwest National Laboratory, United States; [2]Oregon State University, United States; [3]Brookhaven National Laboratory, United States; [4]NY Creates, United States

Surface oxides formed on metal films have a significant impact on the decoherence and stability of superconducting qubits. Niobium (Nb) exhibits a complex native oxide layer, approximately 10 nm thick, believed to harbor structural and chemical defects contributing to coherence loss in Nb-based devices. In this study, Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) was used to assess the influence of different treatments on the surface oxidation layers of Nb thin films. We employed ToF-SIMS for high-resolution chemical mapping and depth profiling, combined with ex situ $^{18}O_2$ annealing experiments. This allowed us to characterize and evaluate the surface oxidation layers of Nb thin films resulting from chemical mechanical polishing (CMP) and accelerated neutral atom beam (ANAB) treatments, comparing them to native oxides formed through air exposure. By combining ToF-SIMS results with XPS and TEM studies, we revealed the differences in oxidation layer thickness and composition, including Nb_2O_5, Nb_2O_3, and NbO, on the surface. Moreover, we demonstrated that ANAB-generated oxidation layers exhibit enhanced resistance to further oxidation when compared to native oxides. This finding suggests a promising strategy for mitigating surface oxidation and improving the performance of devices based on superconducting metals.

10:00 AM *EL01.04.04
Passivation of Si, Ge and SiGe Surfaces by ALD Nanolayers Erwin Kessels; Eindhoven University of Technology, Netherlands

For many (opto)electronic devices, it is vital to reduce the recombination of charge carriers at the semiconductor surfaces and interfaces. This is becoming more and more challenging due to the ongoing diversification in semiconductor materials to be used in the devices but also due to the increasing surface-to-volume ratio of the (nano)structures employed in electronics and photonics. Surface passivation can be achieved by employing ultrathin films of semiconductor or dielectric materials which often serve other functionalities in the devices too. The underlying mechanism of the surface passivation can be the reduction of surface defect states (i.e., so-called chemical passivation) and/or band bending due to so-called field-effect passivation effect (e.g., due to fixed charges in the film).
In this contribution the surface passivation by some innovative nanolayer approaches prepared by atomic layer deposition (ALD) will be presented. The focus will be on Si and Ge surfaces and also include hexagonal SiGe alloy nanowires which are of interest for nanolasers due to their direct-bandgap [1]. The nanolayers include materials such as Al_2O_3, PO_x and (doped) ZnO as well as stacks thereof [2,3,4,5]. Special attention will be given to the underlying mechanism of the surface passivation achieved as well as its relation to the properties of the nanolayers employed.

10:30 AM EL01.04.05
Substrate Characteristics and Their Impact on Ruthenium Metal Growth via Atomic Layer Deposition (ALD) Amnon Rothman and Stacey F. Bent; Stanford University, United States

Noble metal thin films have attracted significant interest owing to their distinctive properties and structures, which make them ideal for applications in microelectronics, catalysis, energy, and photovoltaics. While several parameters influence the properties of these metals for such applications, the deposition process remains a critical factor. Atomic Layer Deposition (ALD) stands out as a prevalent deposition technique due to its surface-sensitive nature. The ALD process is characterized by its self-limiting surface reactions, promoting a layer-by-layer growth mechanism and allowing for precise control over film thickness and conformality. However, challenges arise in achieving continuous, pinhole-free noble metal ALD layers on oxide surfaces, often resulting in low film quality. These challenges can be traced back to the lack of adequate nucleation sites and the poor wettability of the low-surface energy substrates. We have studied the impact of substrate surface functionalization using organometallic molecules, such as trimethylaluminum (TMA) and diethylzinc (DEZ), on the nucleation and growth of Ru layers. Our results reveal an enhancement in both nucleation density and the average diameter of the Ru nanoparticles deposited, and we attribute these improvements to an increase in both nucleation sites and elevated surface diffusivity. The latter effect is speculated to result from a reduction in the substrate's surface free energy.
We also examine the influence of substrate surface characteristics, including surface termination and crystallinity, on the nucleation and growth of Ru metal via ALD. We utilize a range of substrates, including Si with native oxide, HF-etched Si, quartz, amorphous Al_2O_3, and sapphire, for the Ru metal deposition process. Surface properties such as water contact angle and surface free energy of the examined substrates are measured. The morphologies of the resulting Ru thin films are studied using scanning electron microscopy (SEM), atomic force microscopy (AFM), and grazing incidence small angle x-ray scattering (GISAXS). These analytical results are integrated with an experimental model to elucidate the differences in growth mechanisms observed across substrates. The deposited Ru coverage as well as the Ru island density and average diameter are correlated to the surface free energy of the substrate. The findings underscore the importance of substrate choice in the ALD process and broaden our understanding of Ru metal growth. This research serves as an important step in optimizing the ALD process for various applications by tailoring substrate selection.

10:45 AM *EL01.04.06
Energy Enhanced Atomic Layer Deposition (EEALD) John F. Conley; Oregon State University, United States

Atomic layer deposition (ALD) is based on alternating purge-separated self-limiting surface chemical reactions in which films are deposited in a layer-by-layer fashion. Inherent advantages of ALD include atomic scale controlled growth of high quality highly conformal thin films at relatively low temperatures. A low thermal budget is often critical for BEOL processing, 3D integration, avoiding unwanted diffusion, and maintaining stable effective work functions and threshold voltages in metal/insulator/metal (MIM) and metal/oxide/semiconductor (MOS) devices and well as for deposition on glass or flexible substrates for large area electronics. While advantageous for some applications, the low deposition temperatures common in ALD can lead to incorporation of excess -OH groups or other residual impurities from unreacted ligands and result in poor stoichiometr, which may in turn lead to sub-optimal physical, optical, and electrical properties.

A number of approaches have been used to reduce impurities, increase density, improve stoichiometry and morphology, and achieve the desired properties of ALD films. One obvious approach is to increase deposition temperature. However this may move a process into the CVD regime, negating many of the benefits of ALD. The most common approach to improving film quality is post-deposition annealing (PDA) at elevated temperatures. The PDA temperatures that are typically required, however, can exceed the maximum temperature limitations of the substrate or previously formed electronics.

To maintain low thermal budget while maximizing film properties, performing annealing *during*, rather than after, ALD can be beneficial. An alternate approach to help drive reactions and reduce impurity / ligand incorporation is to add extra energy as part of each (or every few) ALD cycles or supercycles. Methods to date include in-situ rapid thermal (MTA, DADA, etc.) annealing, flash lamp annealing, plasma exposure, UV exposure, etc. I collectedly refer to all of these as energy enhanced ALD (EE-ALD) [1-16]. (Note that these are distinct from plasma enhanced ALD (PEALD), see [17] for excellent review.) Documented benefits of the various forms of EE-ALD include higher GPC, denser films, lower temperature, improved dielectric constant and refractive index, lower leakage, lower residual impurities. A potential downside of energy enhancement is the additional time these steps add to the ALD super-cycle, particularly the cool down time when in-situ annealing is incorporated.

In this invited talk, I will describe, compare, and contrast the various EE-ALD techniques, focusing on mechanisms (thermal vs. chemical), placement in ALD supercycle, benefits, and drawbacks. I will also discuss the challenges to be addressed in finding the ideal EE-ALD technique. Finally, I will introduce an entirely new method of EE-ALD, microwave enhanced ALD (ME-ALD).

11:15 AM EL01.04.07
High Precision Capillary Printing of Polymer Patterns for The Area-Selective ALD of Transparent Conducting Oxide Vincent Jousseaume[1], Marc Pascual[2], Achille Guitton[2], Tony Jullien[1], Luana Golanski[1] and Chloe Guerin[1]; [1]CEA, LETI, France; [2]Hummink, France

Thin films of transparent conducting oxides (TCO) are used as electrodes for optoelectronic devices and microdisplays. However, these oxides are often difficult to pattern with standard lithography and etching processes especially in the case of ZnO, which is very sensitive to water. This problem becomes very limiting when it is necessary to reduce the characteristic dimensions of the devices (typically for structures below 5 mm). An alternative approach is the area selective deposition (ASD) of these oxides. More precisely, one way consists in using polymeric film that can act as ALD inhibiting layer and prevent deposition in certain areas.

In this work, polymeric thin films were printed by an innovative direct nanoprinting technique [1]. This high precision capillary printing (HPCAP) method is directly derived from AFM technologies, replacing scanning probes by nano capillaries. These “nanopens” are filled up with a solution containing the material to deposit and can draw complexes geometries at the surface of the substrate with resolution between 50 nm and tens of µm and positioning precision as low as 20 nm.

Different patterns with poly(methyl methacrylate), poly(vinyl pyrrolidone) or an epoxy-based resist (SU-8) were printed on a silicon substrate. Then, TCO films were deposited on the patterned polymers by low-temperature ALD. The film growth and material structure were analyzed using several characterization techniques including ellipsometry, atomic force microscopy, scanning electron microscopy and energy-dispersive X-ray spectroscopy.

Our results show that it is possible to produce regular micrometric polymer patterns using this HPCAP printing technique. Furthermore, this approach combines with ALD can effectively allow to localize the growth of an oxide such as ZnO. An exclusion zone around the polymer in which ZnO is not deposited is also observed depending of the polymer used. Finally, in the favorable configurations, the polymer can be selectively removed without impacting the ZnO layer. Thus, an array of pixels with 10 mm width has been successfully produced.
In conclusion, a solution combining the direct nanoprinting of a polymer pattern followed by the ALD of a transparent conducting oxide appears to be a promising path toward the realization of a matrix of pixels sub-10 mm.

Atomic Layer Etching of Metals for Microelectronics Robert L. Opila and Omar Melton; University of Delaware, United States

As microelectronics evolves more and more metals are being used. Deposition techniques like atomic layer deposition (ALD) are not always available. As a result, precise, selective etching methods are becoming more and more important. For example, magnetoresistive random-access-memory (MRAM) is a leading option for non-volatile digital data storage and depends upon precise stacking of a variety of magnetic metals. Atomic layer etching (ALE), as a time reversed ALD method, has potential for accurately etching nearly all materials, particularly those that cannot be deposited with precision. Herein, we demonstrate the etching of some transition metals used in MRAM applications, Co, Fe, and CoFeB where the tunneling barrier (MgO) acts as an etch stop. The etch is conducted using a thermal approach (versus plasma), where the film is etched by sequential dosing with to two different chemical moieties, chlorine and acetylacetone (acac). Thus, optimizing kinetic factors to overcome thermodynamic limitations, thereby developing a controlled etch driving towards one atomic layer at a time. Similar techniques demonstrate that Cu is etched under comparatively mild conditions, whereas Pt requires more aggressive temperatures and pressures to facilitate the etch. Etching of candidates for lowermost level metallizations will also be discussed.

Probing the Interfacial Energetics in Organic Semiconductor Blends Anirudh Sharma, Jules Bertrandie, Jianhua Han, Julien F. Gorenflot, Frédéric Laquai and Derya Baran; King Abdullah University of Science & Technology, Saudi Arabia

In the realm of shrinking new-generation electronic and photonic devices, the role of functional thin-film interfaces is pivotal for optimizing device design. For example, the energetics of materials play a critical role in charge transfer at the interface between functional materials with dissimilar properties, as in the case of organic photovoltaics (OPVs).[1] Yet, a clear correlation between material energetics at the donor (*D)* - acceptor *(A)* interface and key device parameters is missing. This is primarily because of a lack of criteria for choosing the most suitable method to determine the ionization energy (*IE*) and electron affinity (*EA*) of organic semiconductors that could precisely predict the energy level alignment at the *D/A* interfaces. Consequently, the development of state-of-the-art donor and non-fullerene acceptor materials has led to contradictory claims about the role of energetic offsets at the *D-A* interface. This makes it difficult to establish design rules for the development of future materials.
In this work, we systematically investigate the frontier molecular orbital energies of organic semiconductors and their molecularly mixed blends, as well as the impact of different solvents and molecular orientation on the resultant energies, via different probing techniques; in particular, low-energy inverse photoelectron spectroscopy (*LE-IPES),* which is a relatively novel and non-destructive technique that enables the direct determination of EA of organic semiconductors with high precision. By characterizing and fabricating thin films and devices based on over a dozen different D/A blends, we demonstrate the significant differences that have been an ongoing debate in the field for energetic losses and device performances.[2]
We show that the *IE* and *EA* values measured using ultraviolet photoelectron spectroscopy (*UPS)* and *LE-IPES* are the most relevant in understanding the charge generation mechanism in OPVs. We further demonstrate how the energy levels of organic semiconductors evolve when blended with energetically dissimilar materials,[3] and the impact of morphology and phase segregation on the resultant energetics. Probing a range of small molecule - small molecule and polymer: small molecule D/A blends, we show that the photovoltaic gap E_{pv} (IE_{donor}-$EA_{acceptor}$) measured from neat materials can be insufficient in some cases, for establishing material-property relationships in solar cells. By controlling the D/A ratio in molecular blend films, we probe the changes induced in E_{pv} of D/A blends as a result of intermixing, intermolecular, and electrostatic interactions between the D/A materials. We rationalize these findings to the resultant photovoltaic parameters and voltage losses in OPVs.
Lastly, from OPVs based on six different *D-A* blends having systematically varying *IE*-offsets (Δ*IE)*, we convincingly demonstrate that Δ*IE* plays a crucial role in charge generation. In contrast to earlier works, we show that a vanishing Δ*IE* is detrimental to device performance.
Overall, these findings establish a solid base for reliably evaluating material energetics and interfacial properties toward interpreting property-performance relationships in solution-processed OPVs.

2:15 PM EL01.05.03
Interface Engineering with Aromatic Diammonium Acetates for Amplifying Hole Extraction in Tin Perovskite Solar Cells Donghoon Song, Yuanze Xu and Qiuming Yu; Cornell University, United States

Perovskite solar cells have emerged as one of the most promising photovoltaic technologies because of their high efficiency, solution processability, and mechanical flexibility, which enables ubiquitous energy harvesting. From device perspective, interfaces play critical roles in charge transport and collection, which turns to be particularly important for tin-based perovskite solar cells. Tin perovskite solar cells (TPSCs) stand at the forefront as toxicity-lean technology, featuring compelling properties such as the large light absorption coefficient, small exciton binding energy, ideal bandgap, slow hot-carrier cooling, and high charge carrier mobility. Especially, tin perovskites are adjustable to a bandgap of ~1.34 eV being optimal for single-junction solar cells according to the Shockley-Queisser limit. Beyond merely a toxicity issue, such superb properties drive TPSCs to an efficiency of power conversion (PCE) close to 15%. To close a gap with that (~26%) of lead counterparts, more attentions have been attracted to tailor tin perovskites to mitigate fast crystallization and Sn(II) oxidation, and to modify their interfaces to attain efficient and stable charge collection. Currently, the inverted p-i-n planar architecture is adopted widely for TPSCs because charge transport is more efficient due to the nature of p-type tin perovskites. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) has been used as hole transport layer (HTL) due to the high-performance and reproducibility in an inverted planar architecture. PEDOT:PSS benefits from the demanding properties for TPSCs including a suitable work function (WF: ~5.0–5.2 eV), decent conductivity, and dopant-free merits. However, ambient annealed PEDOT:PSS thin films are terminated with a thin layer of PSS, which has acidity and is unfavorite for hole collection. We tackle this challenge via interface engineering. Specifically, we treated the surface of PEDOT:PSS using aromatic diammonium acetate salts dissolved in a highly volatile but interactive solvent, which not only modifies PEDOT:PSS itself but also its interface with tin perovskite. The salts are embedded into PEDOT:PSS to bridge and ameliorate its interface with tin perovskite and hence to amplify its hole extraction characteristics. Consequently, we attain a high device efficiency as 12.1% and impressive stability without encapsulation for ~2800 h. The materials and methodologies of our development are extendable to other perovskites- and PEDOT:PSS-based bio, energy, and electronic applications. Moreover, they can expand on surface and interface engineering to gain broader scopes, thereby lying a critical bridging stone on paths to diverse applications.

Evaluation of Bulk and Rear Interface Passivation of Thin Film Photovoltaics by Surface Photovoltage Spectroscopy Nathan D. Rock[1], Michael Scarpulla[1], Adam Phillips[2], Ebin Bastola[2], Ed Sartor[3], Andrea Mathew[3] and Matthew Reese[3]; [1]University of Utah, United States; [2]The University of Toledo, United States; [3]National Renewable Energy Laboratory, United States

Thin film photovoltaics have the potential to dramatically reduce cost and carbon footprint of photovoltaic manufacture. However, current solutions like GaAs are cost prohibitive except for special applications, while more affordable CdTe, SbSe and perovskite devices lag behind silicon in efficiency. To identify and resolve these difficiencies, a fuller understanding of the role of interface and bulk passivation, diffusion length, surface recombination velocity, and band structure is necessary.

We present surface photovoltage (SPV) spectroscopy data on multiple CdTe and SbSe photovoltaic devices, comparing the effects of bulk and surface passivation strategies. The effects of doping, wet etchants, CdCl2 annealing, and surface reconstruction are presented and the results interpretted by advanced modeling which fully describes the device under test.

Traditional methods for interpretting SPV such as the Goodman method, are only valid when diffusion length and absorption depth are both significantly less than the thickness of the sample - a situation which is not applicable to modern devices. In contrast we present analytical and computational modeling which accounts for a full device - including multiple junctions. Analytical models are used to explore the effects of a variety of parameters on SPV in the depetion region, quasi-neutral region and space charge region (SCR). The results are then validated by full device modeling in SCAPS-1D software. The effects of bulk diffusion length, doping, and recombination in each region is explored.

Finally, the understanding of how these effects combine in the final SPV signal allows for SPV to become diagnostic in evaluating the efficacy of new passivation strategies.

3:45 PM EL01.05.05
Non-Equivalent Atomic Vibrations at Interfaces in a Nitride Superlattice Eric R. Hoglund[1,2], Harrison Walker[3], Kamal Hussain[4], De Liang Bao[3], Haoyang Ni[5], Jefferey Baxter[1], Asif I. Khan[4], Sokrates Pantelides[3,3], Patrick E. Hopkins[2] and Jordan A. Hachtel[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Virginia, United States; [3]Vanderbilt University, United States; [4]University of South Carolina, United States; [5]University of Illinois at Urbana-Champaign, United States

The structural and chemical discontinuities at interfaces in III-V material heterostructures are what lead to their emergent electronic properties. However, the spectrum of vibrations in the materials often have large mismatch and large interface thermal resistances can limit device performances. The unique structure and chemistry at interfaces in these materials do not only lead to unique electronic properties, but also unique atomic vibrations. In the case of heterostructures made from AlN-($Al_{0.65}Ga_{0.35}$)N -AlN, the nonequivalence of the two interfaces has long been recognized in that they host different two-dimensional carrier gasses.[1] The nonequivalence of the corresponding atomic vibrations, however, has not been investigated so far due to a lack of experimental techniques with both high spatial and high spectral resolution. Herein we experimentally demonstrate the nonequivalence of AlN-($Al_{0.65}Ga_{0.35}$)N and ($Al_{0.65}Ga_{0.35}$)N-AlN interface vibrations using monochromated electron energy-loss spectroscopy in the scanning transmission electron microscope (STEM-EELS)[2-4] and density-functional-theory (DFT). We demonstrate that angle-resolved STEM-EELS possesses mixed real- and reciprocal-space selectivity of the vibrational response, which enables direct mapping of the nonequivalent interface phonons between materials with different stacking order. The physical origin of the localized and nonequivalent interface behavior is then unraveled through the perspective of DFT. The results have implications on the vibrational properties of heterostructures where interfaces states increase thermal conductivity.[3,5]

Improved Photovoltaic Performance through Ionically Regulated Space Charge Zones in *α*-$FAPbI_3$ Perovskite Solar Cells Jihyun Kim[1], Ji-Sang Park[2], Gee Yeong Kim[3] and William Jo[1,1]; [1]Ewha Womans University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of)

The alpha-phase formamidinium lead triiodide (α-$FAPbI_3$) is considered the most promising photoactive layer material due to its narrow bandgap and superior thermal stability for perovskite solar cells (PSCs). However, interfacial lattice defects created on SnO_2 electron transport layer (ETL) due to its oxygen vacancies (V_O) and hydroxide ions (OH^-) during the fabrication of α-$FAPbI_3$ thin films limit power conversion efficiency (PCE) and increase material degradation rates. Herein, the applied interfacial engineering and the regulation of space charge distribution at the $FAPbI_3/SnO_2$ interface are discussed, both of which are of paramount significance for solar cells. The interfaces were modified using pre-extracted NH_4^+ ions [1], which exhibited a low migration barrier energy of 0.21 eV, as determined from density functional theory (DFT) simulations. Due to the low migration barrier energy of NH_4^+, the $FAPbI_3$ perovskite top surface is p-doped, effectively aligning with hole transport layer interfaces. The redistribution of space charge zones at the $FAPbI_3/SnO_2$ interface is accomplished through the regulation of V_O and OH^-, combined with the application of octyl-ammonium iodide (OAI) perovskite top passivation materials. To substantiate the impact of space charge redistribution on the photovoltaic characteristics at the $FAPbI_3/SnO_2$ interface, parallel conductance measurements were carried out. These measurements entailed the manipulation of $FAPbI_3$ thin film thickness under both dark and illuminated conditions, with the outcomes assessed through D.C and A.C polarization measurements. These results demonstrate that the regulation of space charge zones effectively enhances the modification of bifacial interfaces, leading to improved crystallinity and charge carrier extraction. Ultimately, this approach results in increased PCE up to 24.38% and enhanced operational stability for 1600 hours of PSCs.

***Operando* Electrically Pumped Spectroscopy Analysis of Exciton Dynamics and Parasitic Excitons in Blue Phosphorescent Organic Light-Emitting Diodes** Changmin Lee[1], Hyun Jae Lee[2], Tae Wook Kim[2], Insung Ha[1], P. Justin Jesuraj[1], Chul Hoon Kim[2] and Seung Yoon Ryu[1]; [1]Dongguk University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Understanding exciton dynamics and optimizing device physics in phosphorescent organic light-emitting diodes (Ph-OLEDs) is essential for achieving highly efficient devices with optimal color purity. In this study, we conducted a comprehensive exploration of radiative transitions, including electromer and exciplex, within blue Ph-OLEDs using operando electrically pumped spectroscopy (EPS). EPS served as a versatile tool to simultaneously secure time-resolved electroluminescence and photoluminescence of the electronic device. Our findings revealed that Ph-OLEDs with thin emission layers (EMLs) in the range of 3–5 nm predominantly exhibited primary electromer emissions and minor interface exciplex emissions, resulting in decreased device efficiency. Conversely, thicker EMLs (30–40 nm) promoted exciplex generation at the hole transport layer/EML interface, impacting color purity due to charge balance and redshift (RZ) shift considerations. The operando EPS study detailed the origin of these parasitic excitons in device emissions, elucidating their role in reducing efficiency and color purity. These findings were substantiated through impedance analysis. Optimal efficiency and color purity were achieved with an EML thickness of 20 nm, demonstrating the absence of parasitic excitons as evidenced by EPS. The study investigates the exciton dynamics and presence of parasitic excitons in a typical blue Ph-OLED, providing valuable insights into fundamental mechanisms governing the behavior of molecular excited states. In summary, the operando EPS analysis of blue Ph-OLEDs contributes to understanding exciton dynamics and the generation of parasitic excitons. Logical modifications to the EML thickness (3–40 nm) revealed insights into RZ shifts, TAPC electromer emissions, and exciplex generation. The operando EPS approach presents a promising avenue for uncovering the origin of interface parasitic excitons, facilitating the realization of highly efficient next-generation optoelectronics.

5:00 PM EL01.06.02

Acoustic Nonreciprocity in Compact Acoustic Circulators Generated by Laser Driven Fluid Jiaxin Yang[1], Arup Neogi[1], Yuqi Jin[2] and Zhiming Wang[1]; [1]University of Electronic Science and Technology of China, China; [2]University of North Texas, United States

A circular resonant cavity was designed, using liquid as the medium and driven by laser to move and rotate the fluid. We can control the fluid motion speed by adjusting the laser power. When acoustic signals travel with or against the flow, up to 25dB of acoustic nonreciprocity is observed and faster medium flow implies greater nonreciprocity

1.Background

Acoustic isolation and nonreciprocal sound transmission are highly desirable in many practical scenarios but reciprocal transmission is not always desirable—for example, when one wants to isolate or protect a region of space allowing wave transmission in one direction yet blocking it in the opposite one. But When the fluid rotates in a circular resonates cavity, the sound travels with or against the flow exhibits significant differences.

However, how to make the medium move as quickly as possible without generating noise is a problem. To solve this problem, we have introduced optical flow control technology. When a laser is irradiated on an aqueous solution mixed with gold nanoparticles, a substrate implanted with metal ions, and a metal material, the metal particles will generate ultrasonic waves due to the photoacoustic effect to drive the water flow. We designed a circular cavity to convert this linear motion into rotational motion to cause acoustic nonreciprocity.

2.Method

Design a circular resonant cavity:

The average circumference is an integer multiple of the wavelength of a 100KHz sound wave.

A window for laser incidence.

Two windows A & B for transmitting or receiving acoustic signals

Manufacturing cavity (3D printing technology).

Without laser irradiation, the water inside the cavity remains stationary:

Window A emits ultrasonic signals, while window B receives ultrasonic signals to obtain signal Static1-2.

Window B emits ultrasonic signals, and window A receives ultrasonic signals to obtain signal Static2-1.

With laser irradiation, maintaining a stable flow rate of water in the cavity:

Window A emits ultrasonic signals, while window B receives ultrasonic signals to obtain signal Flow1-2.

Window B emits ultrasonic signals, and window A receives ultrasonic signals to obtain signal Flow2-1.

Compare signal Static1-2,Static2-1,Flow1-2 and Flow2-1, and analyze the acoustic nonanisotropy.

3.Result

According to the experimental requirements, a circular cavity is designed with window Laser used for laser driven fluid motion, and windows A and B used for connecting the ultrasonic transducers. The simulation results show that the maximum nonreciprocity occurs at 101KHz, with an isolation degree of about 25dB; The experimental results show that the maximum nonreciprocity occurs at 70.5KHz, with an isolation degree of about 17dB.

4.Conclusion

1.In the experiment, the rotation of the fluid in the laser driven annular cavity was achieved, and by changing the laser power, the speed of motion from 0mm/s to 40mm/s can be controlled.

2.The higher the flow rate of the fluid in the cavity, the greater the acoustic reciprocity. By controlling the flow rate, approximately 0-25dB of acoustic isolation can be controlled.

3.This technology can be used to design and manufacture acoustic diodes and transistors.

5:00 PM EL01.06.03

Nanoscale Synergetic Effects on Ag-Hyperbolic Metamaterial Substrate for Photoinduced Enhanced Raman Spectroscopy with Ultra-Sensitivity and Reusability Muhammad Shafi[1] and Ahmed Elbanna[2]; [1]Southern University of Science and Technology, China; [2]Nanyang Technological University, Singapore

Multilayer hyperbolic metamaterials (HMM) based SERS substrates have received special consideration owing to the support of different propagating modes such as surface plasmonic polaritons (SPP) and bulk plasmon polaritons (BPP). However, due to its weak electric field enhancement, the SPP resonance has hardly originated in the periodic stack of metal and dielectric layers.The current study introduces an innovative 3D plasmonic structure comprising silver nanoparticles (AgNPs) and HMM (4 periods of Au/TiO_2) to enable highly sensitive and reliable photo-induced-enhanced Raman spectroscopy (PIERS). The use of this hybrid substrate results in an approximate 50-fold enhancement compared to standard surface-enhanced Raman spectroscopy, marking the most substantial PIERS enhancement achieved to date. Moreover, beyond the enhanced Raman signal, the hybrid substrate offers heightened detection sensitivity, possibly owing to its capability for activation with remarkably low UV irradiation and extended relaxation times (prolonged measurement durations). Our research indicates that the localized surface plasmon resonance (LSPR) of silver nanoparticles stimulates SPP, resulting in the creation of intense hot spot zones within the nanogap areas atop the HMM structure. Furthermore, the hybrid substrate showcases exceptional photocatalytic degradation of analytes, enabling its reuse for up to 15 cycles without any decline in PIERS activity. The suggested SERS structure demonstrates the capability for precise thiram quantitative detection, achieving sensitivity limits as low as 10^{-7} M. This potential holds considerable promise in meeting fundamental requirements for environmental conservation and ensuring food safety.

5:00 PM EL01.06.04

Enhancing Perovskites Cell Performance through Alkali Metal Modification of TiO_2: Exploring Electronic Nature and Interface Properties Chittaranjan Das[1,2], Mayank Kedia[1,2], Rajarshi Roy[1] and Michael Saliba[1,2]; [1]University of Stuttgart, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Metal halide perovskite solar cells (PSC) have achieved a remarkable efficiency above 26%, which is comparable to the conventional Si photovoltaics. In the evolution of PSC technology from dye-sensitized solar cells, TiO_2 played a pivotal role in achieving remarkable power conversion efficiency. TiO_2, as a charge extracting layer, efficiently extracts photo-generated electrons and acts as a barrier for holes. Being widely used as a blocking layer, the TiO2 suffers from many fundamental challenges like surface defects, which work as trap states, low electron mobility, and high catalytic activity, collectively contributing to hysteresis and instability in perovskite solar cells. Therefore, to improve the electron transporting properties of TiO_2, various surface modification and doping strategies have been tried. Among various approaches, the alkali metal doping of TiO_2 has proven to be beneficial to achieving overall improvement of the PSCs' performance.
Our research explores how adding lithium (Li), sodium (Na), and potassium (K) to mesoporous TiO_2 affects its electronic properties. We also investigate the chemical interaction between the perovskite layer and TiO_2, as well as the doped TiO_2 with alkali metals. We use soft (XPS) and hard X-ray photoelectron spectroscopy (HAXPES), along with resonance photoemission spectroscopy and X-ray absorption spectroscopy (XAS). Ultimately, we evaluate how alkali metal doping influences the efficiency and stability of the device.
XPS and HAXPES analyses reveal that upon introducing Li, Na, and K to TiO_2, surface Ti^{4+} undergoes reduction to Ti^{3+}, while bulk Ti^{4+} states remain unchanged. The reduction is more pronounced with Li, decreasing from Na to K. This implies Li acts as a dopant, whereas Na and K modify the TiO_2 surface. XAS studies support this conclusion, showing changes in the TiO_2 layers. Resonance photoemission spectroscopy indicates that Li induces more defect states that result from Ti^{4+} reduction. Upon perovskite deposition, these defect states diminish, indicating electron transfer from perovskite to TiO_2, oxidizing it. The reduction of defect states is highest in Li-doped TiO_2. Additionally, Ti2p peak shifts to lower binding energy, indicating upward band bending at the TiO_2/perovskite interface. This band bending is consistent across all TiO_2 types and their perovskite interfaces studied here. Notably, the TiO_2/perovskite interface with Na and K modifications exhibits a higher presence of Pb0 states, suggesting a defective interface. The Li doped TiO_2 based PSCs have higher power conversion efficiency compared to the others. The enhanced power conversion efficiency observed in Li-doped TiO_2-based PSCs can be attributed to the improved conductivity resulting from lithium incorporation. This augmentation facilitates the efficient transportation of photo-generated electrons. However, for sustained and stable PSC performance, Na and K-modified TiO_2 devices exhibit superior characteristics.
The spectroscopic investigation, in conjunction with device performance, shows that there is a favorable upward band bending from TiO_2 to the perovskite, and the defects of TiO_2 are passivated by the perovskite itself. Among used alkalis modifiers, the Li dopes the TiO_2 to increase the electron conductivity and with fewer interface defects, amounting to superior power conversion efficiency. On the other hand, Na and K act as modifiers for the TiO_2 layer, contributing to a more stable device performance. This stability can be attributed to their relatively larger ionic radii compared to Li.

5:00 PM EL01.06.05
Surface Engineering Studies on $CsPbBr_3$ Perovskites Quantum Dots for Optoelectronic Applications Sinyoung Cho[1], Jigeon Kim[2,3], Soon Moon Jeong[1], Min Jae Ko[2], younghoon kim[3] and Jong-Soo Lee[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]Kookmin University, Korea (the Republic of)

Lead halide perovskite quantum dots have been considered as the most promising materials for next-generation optoelectronics because of their high light absorption, narrow emission, and excellent photophysical and optoelectronic properties. Organic ligands with long hydrocarbon chains used as ligands in quantum dot synthesis should be exchanged to short organic/inorganic ligands for improving the charge transporting in optoelectronic device applications. However, previous research related to surface ligand exchange for solar cell application have been largely focused on iodide-based $CsPbI_3$ perovskite quantum dots so far. For various solar cell applications such as tandem solar cell and Building-integrated photovoltaics (BIPVs), ligand exchange studies on bromide- and chloride-based perovskite quantum dots should be performed. Herein, we demonstrate that surface ligand exchange studies of green-emitting $CsPbBr_3$ perovskite quantum dots, utilizing several materials such as NaOAc. Improved charge transporting property within $CsPbBr_3$ perovskite quantum dot thin films contribute to the electroluminescent solar cell applications with high open-circuit voltage of 1.6 V and power conversion efficiency of 3.9 %. Also, quantum dot light-emitting diodes with synthesized $CsPbBr_3$ perovskite quantum dots was fabricated via interfacial engineering, showing 6.5% of EQE and 22.5 cd/A of current efficiency.

5:00 PM EL01.06.06
Towards Improved Device Performance: A Study on Defects and Interfaces in MHP Devices using Electron Spin Resonance Spectroscopy Jose A. Delgado[1,2], Ross Kerner[2], Joseph Luther[2] and Joseph Berry[1,2]; [1]The University of Colorado Boulder, United States; [2]National Renewable Energy Laboratory, United States

Electron spin resonance (ESR) spectroscopy has been identified as a powerful method for nondestructively probing intrinsic defects and interfaces in metal halide perovskite (MHP) devices. Key challenges in MHP devices stem from defects originating from synthesis, interface reactions, lattice strain, energy level mismatches, and other interfacial issues. Furthermore, intrinsic perovskite defects, which tend to propagate post-device deployment [1–3], have substantial implications on device stability. Traditional approaches, like photoemission, often fall short in accurately characterizing these defects due to their constraints at near-surface regions. To circumvent these limitations, nondestructive methods with an acceptable probing depth and sensitivity are needed. In our study, UV and visible light sources were applied to MHP samples to analyze degradation dynamics. We acquired both ex situ and in situ EPR spectra from MHP single crystals, precursor powders, and perovskites interfaced with transport materials. The results provide valuable insights into defect origins and degradation pathways, further emphasizing the importance of a comprehensive understanding to improve MHP-based device longevity and performance.

5:00 PM EL01.06.07
Linear Stark Shift of Two-Dimensional Ga via AC Electric Double Layer Gating Nader Sawtarie[1], Jonathon Schrecengost[2], Krishnan Ananthanarayanan[2], Nithil Manimaran[3], Ke Xu[3], Joshua Robinson[2], Noel C. Giebink[4] and Susan Fullerton[1]; [1]University of Pittsburgh, United States; [2]The Pennsylvania State University, United States; [3]Rochester Institute of Technology, United States; [4]University of Michigan–Ann Arbor, United States

2D polar metals (PMets) synthesized via confinement heteroepitaxy (CHet) consist of 1-3 atomic layers of metal intercalated between a SiC substrate and graphene that are theorized to have an out-of-plane permanent electric dipole moment resulting from the non-centrosymtmetric interface between each layer. 2D PMets, such as bilayer Ga, exhibit unique optical absorption attributed to a quantum-confined interband transition (~1.9 eV). In this work, 2D Ga optoelectonic devices were gated using electric-double-layer (EDL) side gating with polyethylene oxide (PEO):$CsClO_4$. The EDL gating technique induces large (i.e., ~MV/cm) electric fields, and in this case, AC EDL gating (5 Hz) is successfully demonstrated to enable the use of a lock-in amplifier to measure small changes in reflectivity. COMSOL modeling confirms an RMS field strength of 1.36 V/nm, which agrees with the ~5% RMS channel current modulation that is detected. These high fields induce a measurable electroreflectivity ($\Delta R/R \sim 10^{-4}$) resulting from a ~1.5 meV linear Stark shift. The Stark shift resembles the first derivative lineshape of the reflectivity, corresponding to 0.05 Debye change in the permanent dipole moment. These results validate the theoretical model by providing the first direct experimental evidence for the presence of a permanent ground state dipole moment in 2D PMets, as well as demonstrate a powerful new technique to safely deploy large time varying electric fields to 2D materials in the form of AC EDL-gating.

5:00 PM EL01.06.08

Interfacing Durable Materials to Enable Structural Electronics Georgia Kaufman[1], Mychal Taylor[1], David Boese[1], Emily Huntley[1], Samuel Leguizamon[1], Michael Gallegos[1], Leah Appelhans[1], Randy Schunk[1] and Bryan Kaehr[1,2]; [1]Sandia National Laboratories, United States; [2]Center for Integrated Nanotechnologies, United States

In-mold structural electronics (IMSE) is a manufacturing approach to integrate devices into any architectural form factor, providing design freedom and device simplification while delivering advantageous size, weight and power. IMSE typically links integrated circuits and discretes by screen-printing nanoparticle-based inks onto flat, thermoplastic substrates that are molded into 3D forms—material sets/processes with widely variable interfaces that are woefully suited for demanding environmental applications. Our project seeks to demonstrate the application of more robust and reliable materials, compatible in extreme environments, such as metal foils for circuit patterning and moldable thermosets. We have explored patterning of copper foils onto b-staged and dual cure epoxies that are subsequently formed into test coupons to study interface delamination, encapsulation and environmental stability. Additionally, we have adapted the chemistry of frontal ring-opening metathesis polymerization (FROMP) of dicyclopentadiene (DCPD), a rugged thermoset material, to be compatible with IMSE. Foil patterned pre-forms are vacuum molded into devices such as 3D RF circuits, battery interconnects, and capacitive touch panels that are subsequently locked into shape at ambient temperature using FROMP. This represents a breakthrough for IMSE technologies, enabling 3D device integration into challenging environmental architectures.

5:00 PM EL01.06.09
Thermal Stability of Metastable GeSn Nanowires Anis Attiaoui[1,2], John Lentz[1], Jarod Meyer[1], Kunal Mukherjee[1] and Paul C. McIntyre[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The (Si)GeSn semiconductor material system is highly desired as a potential candidate for optical interconnects and monolithic photonic integration on Si. The demonstrated fundamental direct band gap of this complementary metal-oxide-semiconductor (CMOS) compatible semiconductor has sparked great interest due to its unique properties. Unfortunately, the low solid solubility of gray-Sn (α-Sn) in Ge (1 at.%) and the large lattice mismatch between α-Sn and Ge of approximately 14%, make it difficult to maintain its thermal stability. In fact, rapid thermal annealing (RTA) at temperatures above 400 °C leads to Sn segregation and island formation for $Ge_{0.9}Sn_{0.1}$ [1]. Moreover, the low temperature growth of GeSn (<350 °C) can promote the formation of many point defects (mostly divacancies) and act as *p*-type background impurities [2]. An often-observed background *p*-type doping of ~10^{16}-$10^{18}$$cm^{-3}$ leads to strong electric field leakage in devices due to high parallel conductance. Consequently, it is highly desirable to enhance the thermal stability of this material. Herein, we present a method to counteract annealing-induced surface segregation of Ge core/GeSn shell nanowires grown by previously reported methods [3]. Surface passivation significantly improves the thermal stability of GeSn alloys through the atomic layer deposition (ALD) of a very thin Al_2O_3 oxide layer (< 5 nm). Next, annealing the ALD-coated NWs at different temperatures (300°C, 350°C, 400°C, 450°C, and 520°C), above the growth condition of the NWs (~275°C) was systematically investigated. First, structural characterization (X-ray diffraction and scanning electron microscopy (SEM)) demonstrated the unchanged strain state and morphology after annealing (9±1 at. % Sn composition). Second, low-temperature (80K) infrared photoluminescence spectroscopy was undertaken on the annealed NWs to better quantify the recombination mechanisms after annealing. Interestingly, two key findings were observed: an average of 5-fold increase in the PL integrated intensity after annealing, and a blueshift of the band-to-band optical transition. This blueshift suggests that deep level traps are not a potential mechanism for such bandgap shift, as a bandgap contraction would be expected in that case. Understanding the mechanism behind such a blueshift is still an ongoing work. However, a plausible hypothesis can be linked to the nature of the short-range ordering in these materials, as it has been shown theoretically to be the case [4]. Third, single NW devices were fabricated to measure the resistivity variation before and after annealing. The resistivity increases from 0.28±0.02 Ω-cm for an as-grown NW to 0.42 ± 0.08 Ω-cm, when annealed at 450°C. The resistivity increase suggests a modest decrease in the p-type carrier density of the NW. The effect of annealing on the structural and optoelectronic properties of the GeSn NW are explored in this work. Further results on the optical bandgap and resistivity changes will be reported.

5:00 PM EL01.06.11
Magnetic Assembly of Vertical Nanogaps for Highly Sensitive Electrical Biosensors. Hoang Minh Nguyen[1,2], Jae Sung Yoon[2,1], Do-Hyun Kang[2], Yeong-Eun Yoo[2,1] and Kwanoh Kim[2]; [1]University of Science & Technology, Korea (the Republic of); [2]Korea Institute of Machinery & Materials, Korea (the Republic of)

Nanogap biosensors have emerged as potential tools for the detection and analysis of minuscule quantities of biomolecules, offering unparalleled sensitivity, a low limit of detection (LOD), and enhanced output signals. However, their potential is often limited by the intricate and labor-intensive processes required to precisely engineer the the tiny gap between electrodes. In this work, we present an innovative fabrication method to obtain vertical nanogap platforms for electrical biosensing. Leveraging magnetic attraction, we facilely construct 40 nm gaps by assembling antibody-tagged nanowires onto a nanodisk positioned between a pair of microelectrodes. An electrically conductive bridge is established when gold nanoparticles, conjugated with targeted antigen, are captured within the gaps. This results in a substantial amplification in the output current across the electrodes. Our platforms demonstrate an LOD of 18 pM with a linear dynamic detection range up to 150 pM. This approach offers a versatile biosensing platform with potential integration into a myriad of applications, from lab-on-chip systems to biomedicine and point-of-care diagnostics.

5:00 PM EL01.06.12
Adsorption Kinetic Approximation of a Mixed Alkylamido-Cyclopentadienyl Hafnium Precursor in HfO_2 Atomic Layer Deposition Nhat-Minh Phung[1,2], Min-Seong Kong[1], Si-Young Bae[1], Soonil Lee[2] and Seong-Min Jeong[1]; [1]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of); [2]Changwon National University, Korea (the Republic of)

In this study, the growth kinetics of HfO_2 via the atomic layer deposition (ALD) using a mixed alkylamido-cyclopentadienyl hafnium precursor are proposed based on experimental data. The hydroxyl concentration on the targeted surface, which is sensitive to the surface condition prior to the ALD, governs the saturated growth per cycle (GPC) values. Moreover, we found that the bulkiness of remaining ligands on adsorbed species hinders the adsorption of $CpHf(N(CH_3)_2)_3$ (Cp-Hf) molecules.
Considering this phenomena, we proposed a kinetic model by calculating the energetic terms to quantify the “steric hindrance effect” of the first elementary surface reaction of precursor Cp-Hf. The targeted Si substrates were hydroxylated at several levels to evaluate the reliance of saturated GPC and steric hindrance effect on the nature of the surface. According to the experimental ALD process, the film growth was found to be influenced by the steric hindrance factor, especially at the temperature range from 150 ºC to 250 ºC, but the hindrance effect decreases with increasing temperature and disappears at 300 ºC. The effective activation energy of the adsorption of Cp-Hf molecules on Si substrates was estimated to be 0.2 eV. Although our present model is limited to the ALD of HfO_2, we foresee that the kinetic model could potentially assist the study of metal oxide ALD which utilizes a wide range of

precursors.

5:00 PM EL01.06.13
Forming Solid Films Containing Potassium Ferricyanide for Achieving Vibrational Strong Coupling Roba Rashed[1,2], Rena Klipper[1,2] and Yaakov Tischler[1,2]; [1]Bar Ilan, Israel; [2]BINA, Israel

The phenomenon of vibrational strong coupling (VSC) presents an opportunity to exert control and to manipulate the characteristics of materials and light-matter interactions at the quantum level. Within this domain, the interaction between light and matter becomes exceedingly amplified relative to dephasing processes, rendering the light and matter sub-systems inseparable. Consequently, a novel hybrid lightmatter system forms, exhibiting properties that are distinct from those of the constituent sub-systems. It has been demonstrated that VSC possesses the capability to alter the reactivity of a molecule or a catalyst for a chemical reaction and to make new sources of IR light. We choose to work with Potassium ferricyanide K3Fe(CN)6 because it is a material with a very narrow absorption spectrum even at room temperature. Ferricyanide is a strong oxidizing agent, it is a very important reference material for electrochemistry, which is very well characterized and studied, and it has even been used for VSC [S. R. Casey and J. R. Sparks, The Journal of Physical Chemistry C (2016) 120 (49), 28138-28143.]. Until this point in time, all of the research reports on VSC using ferricyanide and the molecules that resemble it such as Tungsten hexacarbonyl W(CO)6 have been performed in solution and not in solid form. This can be a problem for some applications, namely in liquid it can be more difficult to tune the cavity resonance and to apply voltage on the solution for generating IR light emission. Here, we succeeded to form solid films containing ferricyanide where the molecules are doped into a PVA matrix that we deposit via spin coating. Initially, we tried to prepare “neat films” of potassium ferricyanide from different solvents such as water, DMSO, and methanol, using a variety of deposition techniques such spin-coating, drop-casting, and even using UV-light, but these methods resulted in rough films, strange absorption peaks or wider absorption bands. We then tried to dope ferricyanide into various polymer matrices with different solvents, such as PMMA. In the end, we observed that the combination of ferricyanide in PVA, all dissolved in water, yielded smooth thin films, of controllable thickness ranging from 1.5 to 3.7 microns, depending on concentration in solution and spin-speed. We also observed a pronounced absorption peak at 2100 cm-1 and a narrow absorption spectrum of 6 cm-1 . Using these thin films, we can achieve VSC in high-Q DBR-based microcavities, by growing a “bottom” DBR composed of 2.5 pairs of Ge and ZnS layers, then spin-coating a thin film of ferricyanide doped into a PVA-matrix, and completing the microcavity with a top DBR.

Thermal Transport and Mechanical Stress Mapping of a Compression Bonded GaN/Diamond Interface for Vertical Power Devices William Delmas, Amun Jarzembski, Matthew Bahr, Anthony McDonald, Wyatt Hodges, Ping Lu, Julia Deitz, Zachary T. Piontkowski and Luke Yates; Sandia National Lab, United States

In the last 20 years Gallium Nitride (GaN) electronics have outstripped conventional silicon devices in both efficiency and breakdown voltages. This enhanced performance of GaN devices comes at the cost of increased operating temperatures, kindling a need to develop more robust thermal management schema for such technologies. One such design proposes taking advantage of passive heat diffusion by bonding the GaN device to a high thermally conductive substrate, such as diamond. This would allow the heat generated in the GaN to flow into the diamond, reducing operating temperatures. To test this design, GaN and diamond die were bonded under 2 kN of force via an Ar activated intermetallic bonding layer of Ti/Au. The total bonding area of GaN/diamond stacks was quantified through confocal scanning acoustic microscopy (C-SAM), revealing both bonded and unbonded areas. These areas were confirmed to be bonded/unbonded using a combination of Focused Ion Beam milling and Transmission Electron Microscopy, with the unbonded regions being identified as a delamination at the Ti/diamond layer. Raman microscopy revealed a uniform compressive stress of <80 MPa in the well bonded areas in addition to, stress oscillations where the sample transitions from being bonded to unbonded, corresponding to a net stress differential of up to Δ100 MPa. The thermal properties of the GaN/diamond stack were measured through spatially resolved frequency-domain thermoreflectance (FDTR), with the bonded area boasting a thermal boundary conductance (TBC) of > 100 MW/m^{2}K. FDTR also revealed the presence of micron-scale unbonded regions that showed up as fully bonded under C-SAM. Furthermore, Co-Local Raman/FDTR mapping was demonstrated for the first time with the mapping of a micron-scale unbonded region, showing that stress differentials border the low TBC region. Overall, our work demonstrates a new method for thermal management in vertical type GaN devices that maintains low intrinsic stresses while boosting thermal boundary conductances. As the delaminations seen in these samples are on the order of a possible device (200 microns), more needs to be done to mitigate their formation during initial device fabrication and to spot them post fabrication with more sensitive techniques than C-SAM, such as FDTR.

Spectroscopic Analysis of Polymer and Transition Metal Dichalcogenide Interface for Photodetection Applications Christine McGinn[1], Daniel M. Harrington[1,2], Edwin J. Heilweil[1] and Christina Hacker[1]; [1]National Institute of Standards and Technology, United States; [2]Tufts University, United States

Two-dimensional transition-metal dichalcogenides (2D TMDs) have been extensively studied for photodetection applications due to their strong optoelectronic behavior in the visible range and tunable band gap. [1] However, the optoelectronic properties of 2D TMDs can deteriorate due to surface defects and exposure to air and water. [2] Researchers have used a variety of materials to combat this degradation and passivate the surface, but polymers are ideal for passivating 2D TMDs for photodetection applications as many are transparent in the visible range. [3] Researchers have used polymers to perform significant modulation of the optoelectronic properties of hybrid devices via doping, passivation, dielectric screening, and capacitive effects. [4] These schemes illustrate that polymers can contribute multiple mechanisms to the polymer/2D TMD interface. In this work, the 2D TMD and polymer interface is assessed spectroscopically for three common polymers to evaluate the efficacy of each polymer in passivating the MoS_2 surface for photodetection applications. Evaluating this interface with spectroscopic methods, especially with ultrafast and dynamic pump probe measurements, mimics the physics occurring during photodetection operation and thus provides a clearer understanding of the fundamental physics at play.

For this study, a representative group of three commonly available polymers were chosen to understand the relative passivation effects: parylene N (Pa-N), polymethyl methacrylate (PMMA), and polyvinylidene difluoride-trifluoroethylene (PVDF-TrFE). Pa-N is an extremely inert polymer used frequently in organic electronics as a dielectric and biomedical devices as a chemical barrier. [5] PMMA is an electron beam photoresist frequently used to encapsulate 2D TMD devices for passivation. [6] PVDF-TrFE is an electroactive polymer that has been shown to be piezoelectric, pyroelectric, and ferroelectric, and as a result, is widely applied for flexible sensors. [7] PMMA and PVDF-TrFE have functional groups containing oxygen and fluorine that would be expected to better fix sulfur vacancies or provide doping than Pa-N.

Spectroscopic measurements including Raman spectroscopy, photoluminescence spectroscopy, and time-resolved terahertz spectroscopy (TRTS) were performed on these samples to observe the effect of polymer passivation on a MoS_2 monolayer. The photoluminescence measurements were done with a hyperspectral microscope to facilitate greater averaging of the photoluminescence response across the sample surface. The results of the Raman and photoluminescence spectroscopy show an n-doping effect on the MoS_2 spectra after coating with Pa-N and PMMA through a downshift in the Raman

peaks and a redshift in the photoluminescence peak. In the TRTS measurements, the peak of the response was higher for all polymer samples, which suggests more charge is generated in polymer passivated samples upon excitation either from doping or successful passivation. For PVDF-TrFE, the lifetime of the carriers was longer than any other sample. These results indicate that unpoled PVDF-TrFE best passivates the surface of the MoS_2 of the polymers tested. Further work is being done to understand the exact mechanism by which it passivates the surface, but it is suspected that the fluorine present in the PVDF-TrFE contributes electrons that help to fill the sulfur vacancies. This effect could be used successfully in photodetection to help improve the detectivity.

5:00 PM EL01.06.16
Improving Hazardous Gas Detection Behavior with Palladium Decorated SnO_2 Nanobelts Networks Cleber A. Amorim[1,2], Estacio P. Araújo[3], Murilo P. Paiva[2], Lucas A. Moisés[4], Kate C. Blanco[5] and Adenílson J. Chiquito[4]; [1]Universidade Estadual Paulista, Brazil; [2]University of São Paulo State–UNESP, Brazil; [3]Brno University of Technology, Czechia; [4]Universidade Federal de São Carlos, Brazil; [5]Universidade de São Paulo, Brazil

Transparent Conductive Oxides (TCOs) have been widely used as sensors for various hazardous gases. Among the most studied TCOs is SnO_2, due to tin being an abundant material in nature, and therefore being accessible for moldable-like nanobelts [1]. Sensors based on SnO_2 nanobelts are generally quantified according to the interaction of the atmosphere with its surface, changing its conductance [2]. The present study reports on the fabrication of a nanobelt-based SnO_2 gas sensor, in which electrical contacts to nanobelts are self-assembled, and thus the sensors do not need any expensive and complicated fabrication processes. The nanobelts were grown using the vapor–solid–liquid (VLS) growth mechanism with gold as the catalytic site [3]. The electrical contacts were defined using testing probes; thus, the device is considered ready after the growth process. The sensorial characteristics of the devices were tested for the detection of CO and CO_2 gases at temperatures from 25 to 75 °C, with and without palladium nanoparticle deposition in a wide concentration range of 40–1360 ppm. The results showed an improvement in the relative response, response time, and recovery, both with increasing temperature and with surface decoration using Pd nanoparticles. These features make this class of sensors important candidates for CO and CO_2 detection for human health.

5:00 PM EL01.06.17
Tunable Ordering of 2D Tin on Silicon Caitlin V. McCowan and Shashank Misra; Sandia National Laboratories, United States

The optical and electronic properties of binary alloys can depend on atomic scale, site-to-site correlations. This is clearly illustrated in group IV alloys of tin, silicon, and germanium, where a direct bandgap is theoretically predicted in the random alloy, but an indirect bandgap is experimentally observed and thought to result from short range order (SRO). The balance between the deposition rates, temperature, and templating by the substrate influences the atomic-scale organization within thin films in intertwined ways, which is doubly challenging due to the atomic-scale characterization required for visualization. Here, we combine the ability to deposit materials with sub-monolayer coverage, apply heat in a separate controlled step, and *in situ* atomic-scale imaging of each discrete step with scanning tunneling microscopy (STM), to visualize the growth of Sn:Si.
The fundamental goal of our work is to systematically characterize SRO, to better understand its impact of electronic properties of a material. Existing STM work on Sn monolayers deposited on Si and Ge, in both 100 and 111 orientations, has shown the nucleation of different long-range surface reconstructions. How this influences growth is an open question, as Sn also surface segregates at moderate growth temperatures. By analyzing growth in discrete steps, comprised of Sn deposition, annealing, followed by Si deposition, and further annealing, using STM *in situ*, the dynamic nature of the thin film growth at the substrate interface can be better understood. This talk will focus on analyzing the STM data of different growth and heating combinations to reveal the forces driving ordering and surface segregation. This step-by-step mode of growth enables the creation of metastable configurations that manipulate the degree of order itself, which, in the future, can help in better understanding the relationship of order to optical and electronic properties.

Fabrication of Gold Nanohole by Scanning Probe Lithography using a Sacrificial Layer and Its Applications Jeong-Sik S. Jo, Jinho Lee and Jae-Won Jang; Dongguk University, Korea (the Republic of)

Fabrication of a highly controlled gold nanohole (Au NH) is demonstrated through the use of a sacrificial layer (a tip-crash buffer layer) during scanning probe lithography. As the sacrificial layer, a poly(methyl methacrylate) layer is applied on an Au film to reduce scratches during nano-indentation by scanning probe lithography. Due to the relatively small scratches on the Au film, sub-50 nm Au NH and 15 nm gap between the Au NHs are obtained and the size of the Au NHs can be more precisely controlled compared to the Au NHs fabrication without the use of the sacrificial layer. Additionally, a multi-tip probe array was employed to showcase the mass production potential of the Au NH array. To demonstrate the applications of the Au NH array, MoS_2 hole array and conical-shaped silicon nanostructures are fabricated by using the Au NH array as a dry etching mask and a catalyst of metal-assisted chemical etching, respectively. Moreover, the Au nanoparticles trapped in Au NH shows a strong electric field by coupling between electromagnetic waves focused by the Au NH and enhanced by the Au NPs; the enhancement factor of surface-enhanced Raman scattering of 1.5×10^8 is obtained.

5:00 PM EL01.06.19
Novel Rapid Reprecipitation with Passivation Engineering for Fast Responsive and Durable Perovskite Photodetectors Byung Gi Kim, Woongsik Jang, Ji Yun Chun, Jin Young Kim, Jihyun Lim, Zhao Yang, Suyeon Kim, Junmin Lee and Dong Hwan Wang; Chung-Ang University, Korea (the Republic of)

To develop the perovskite formation process, it becomes necessary to explore the fabricating principles underlying the photosensitive layers. To this end, various aromatic solvents with different functional groups (such as methylbenzene and chlorobenzene (CB)) are selected and analyzed during perovskite crystallization [1]. This demonstrates the excellent detectivity and fast response speed of the perovskite photodetector treated with CB, owing to its enhanced interfacial affinity with ETL and improved charge dynamic behavior. Thus, this showcases the optimization of morphological affinity and the realization of a fast and highly sensitive photodetector via selective use of anti-solvents. Meanwhile, the strategy of a highly sensitive photodetector fabrication is introduced via the relaxation effect of perovskite intermolecular exchangers [2]. Chloronaphthalene (CN) is utilized to fabricate high-quality photosensitive layers in a perovskite nucleation environment due to the unique properties of CN, such as its high boiling point and bulky naphthalene ring. Steric hindrance is thereby induced in the perovskite adduct step, delaying intermolecular interactions and creating a stable perovskite nucleation environment which promotes grain growth. Accordingly, higher crystallinity and larger grains are found in CN treated thin films. Based on this, photodetector performance is greatly improved due to the development of long grain boundary lengths as grain size increases. This is because the increase in shunt resistance and ohmic shunt within the device are suppressed, leading to improved charge transfer and recombination properties. This demonstrates improved device stability, with photodetector parameters observed for approximately 1000 hours. An advanced method for controlling the adduct phase of perovskite via 1,8-octanedithiol additive (1,8-ODT) engineering is presented [3]. In this process, 1,8-ODT is utilized as an anti-solvent additive, forming a coordination bond with Pb^{2+} ions and facilitating rapid perovskite phase conversion. The optimized photodetector exhibits low dark current density, as well as high responsivity and detectivity at 680 nm. Based on this, stability test reveals that the performance remains at approximately 90% even after approximately 260 hours. The properties of stable and recoverable perovskite photodetectors are introduced via moisture trap engineering [4]. Perovskite decomposition mechanism by moisture and the effect of moisture trap introduction are specifically proposed. The degree of hydration and perovskite photodetector characteristics are compared via solubility changes based on each H_2O content. As a result, stable photodetector driving characteristics are reproducibly observed despite moisture content when moisture trap engineering is introduced. Finally, we propose a highly sensitive photodetection strategy via passivation engineering, specifically silica nanocrystal encapsulation [5]. We designed quantum dots (QD@APDEMS) based on silane barriers with hydrophobic ligands. These quantum dots exhibit excellent dispersibility and durability, facilitating an effective film formation. This approach is applicable to bulk perovskite photosensitive layers. As a result, the introduction of QD@APDEMS leads to an improvement in charge dynamics, attributed to perovskite grain expansion and the formation of films with fewer defects. This effect can be attributed to grain boundary passivation via QD@APDEMS. Furthermore, the deep HOMO level of QD@APDEMS effectively suppresses hole charge carrier injection and shunt leakage.

Anchoring Hydroxyl Groups on Tin Oxide Nanowires Cleber A. Amorim[1,2], Estacio P. Araújo[3], Ariano d. Rodrigues[4] and Adenílson J. Chiquito[4]; [1]University of São Paulo State–UNESP, Brazil; [2]Universidade Estadual Paulista, Brazil; [3]Brno University of Technology, Czechia; [4]Universidade Federal de São carlos, Brazil

The nanowire functionalization process often takes place due to the need to have functional groups that enable or facilitate the chemical bonding between the inorganic material and the one intended for functionalization. In this study, we report two methods for anchoring hydroxyl groups: *i*) through nanowire growth using the vapor-solid (VS) approach, followed by treatment at various pH levels with sodium hydroxide (NaOH), and *ii*) nanowires grown using the vapor-liquid-solid (VLS) method in the presence of water vapor. Structural characterization was conducted through various techniques, including X-ray diffraction, scanning electron microscopy, UV-visible spectroscopy, Raman, and FTIR spectroscopy. Consequently, we observed the presence of OH groups on the material's surface that induced a variation in the material's bandgap when grown in the presence of water vapor. Furthermore, X-ray diffraction analysis revealed no significant alterations in the SnO_2 structure.

5:00 PM EL01.06.21
Analysis of Buried Interfaces for Device Technology by Soft and Hard X-Ray Photoelectron Spectroscopy Jennifer Mann; Physical Electronics, United States

X-ray photoelectron spectroscopy (XPS) has long been favored for its precision and reliability in discerning nanometer-thick overcoats on silicon surfaces. However, a challenge arises when using surface sensitive soft X-ray sources, as the areas of interest are often concealed beneath metal electrodes or oxide layers. While higher energy X-ray beams have enabled the detection of photoelectron signals from deeper layers, most of this analysis has been conducted at synchrotron radiation facilities. Recent advancements in lab-based hard X-ray photoelectron spectrometers (HAXPES), such as the PHI *Genesis*, have opened new accessible avenues for the routine examination of subsurface layers of technologically significant devices.

Angle-resolved or angle-dependent XPS and HAXPES (ADXPS/ADHAXPES) represent a potent, non-destructive method for providing a quantitative chemical composition depth profile for thin film structures, with thicknesses falling within the XPS or HAXPES sampling depth. This depth typically ranges from under 5-10 nanometers for an Al K alpha soft X-ray source to approximately 15-30 nanometers for a Cr K alpha hard X-ray source. Using *StrataPHI* analysis software, non-destructive XPS/HAXPES depth profiles can be reconstructed from angle-dependent photoelectron spectra. In the latest development of this software package (*StrataPHI 2.0*), spectra from both hard and soft X-ray sources can be combined. If the layer identity, order, and approximate thicknesses, are known, *StrataPHI* will recommend the X-ray source and transition to use for angle resolved measurements, reducing the overall data acquisition time.

This poster will highlight current cutting-edge and potential future directions for the integration of HAXPES and XPS in the investigation of semiconductors and nanoelectronics. It will underscore the advantages of utilizing hard X-ray sources in combination with a high-throughput, fully automated spectrometer located in a laboratory setting. These advantages encompass the ability to investigate concealed interfaces, such as electronic layers positioned beneath surface capping layers, and compositional studies within the bulk of materials and interfaces beyond the limited probing depth of soft X-rays.

5:00 PM EL01.06.22
Bismuth Surfactant Enhancement of Low-Temperature MBE-Grown GaSb Thin Films Pan Menasuta, John H. McElearney and Thomas E. Vandervelde; Tufts University, United States

Homoepitaxial growth of GaSb is crucial for applications in mid-IR optoelectronics, such as thermal imaging, optical communication, LEDs, and thermophotovoltaic cells. At cold growth temperatures, the surface of GaSb degrades and can result in surface defects and device performance degradation. Yet, lower growth temperatures are favorable for reasons ranging from compatibility with other layers that require low-temperature growth to lowered bulk

mobility to prevent defects. Recently, we have demonstrated that bismuth surfactancy can lead to a smoother surface morphology of low-temperature-grown GaSb films. In this work, we examine the effects of bismuth surfactant at varying fluxes on the film quality of GaSb(100) grown at a cold temperature of 290 degee Celcius using molecular beam epitaxy (MBE).

A series of 200nm thick GaSb is grown via MBE in a Veeco GENxplor system in otherwise identical growth conditions except for the variation of the bismuth surfactancy flux used during growth. All films are grown at the stoichiometric point at ~0.4 monolayer (ML) per second. Bi:V flux as measured by the beam flux monitor (BFM) is varied from 0, no bismuth, to 0.2, where we have found an observable (1%) Bi incorporation. The effects of bismuth surfactant on the GaSb surface are characterized by atomic force microscopy (AFM). Raman spectroscopy is used to characterize and compare the film quality. Scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDS) are used to analyze film surface and surface composition. High-resolution X-ray diffraction (HRXRD) was performed to confirm the bismuth incorporation into the films.

We concluded in our previous findings that bismuth substantially increases the two-dimensional Erlich-Schwöebel (ES) potential barrier of atomic terraces, inducing an upward adatom flux that contributes to surface smoothing. This work examines the effects of such bismuth surfactancy over a wide range of bismuth fluxes from none to some incorporation to understand how bismuth surfactancy can enhance the surface morphology and film structure of low-temperature grown GaSb. Furthermore, this research can potentially improve the growth of other homoepitaxial III-V semiconductor systems under non-ideal conditions and will contribute to the understanding of the bismuth surfactancy effects in dilute GaSbBi alloys.

5:00 PM EL01.06.23
Resolving and Engineering the Surface Chemistry of Superconducting Quantum Circuits Mingzhao Liu; Brookhaven National Laboratory, United States

Superconducting qubits have emerged as one of the leading hardware platforms for realizing a quantum processor. Consequently, researchers have made significant effort to understand the loss channels that limit the coherence times of qubits made with superconducting materials. A major source of loss has been attributed to two level systems (TLS) that are present at the material interfaces in superconducting qubits. Recently, it has been shown that by substituting the superconductor niobium with tantalum, coherence times of superconducting qubits can be improved significantly. In this talk, we will discuss our studies on resolving the surface/interfacial chemical profiles at the metal-air and metal-substrate interfaces of superconducting tantalum films, to identify possible sources of TLS losses. The talk will cover the study of surface oxidation of tantalum using a combination of Hard X-ray Photoelectron Spectroscopy (HAXPES) and scanning transmission electron microscopy - electron energy loss spectroscopy (STEM-EELS), from which we can quantatively determine the oxidation profile and atomic motifs across the ~3 nm-thick native oxide layer. We will also discuss the study of interfacial diffusion at the metal/substrate interface by synchrotron X-ray reflectivity. In the end, we will discuss a few surface and bulk engineering techniques that are used to achieve more perfect interfaces for less contribution to TLS loss.

Pd-Decorated SnO_2/CuO Composite Nanofiber Heterostructure as a Low ppm H_2S Gas Sensor Shaik Ruksana; Indian Institute of Technology Hyderabad, India

Hydrogen sulphide (H_2S) sensing is crucial in various industrial and environmental contexts, including chemical processing, safety applications, and environmental monitoring. In this research, we introduce a hydrogen sulphide sensing structure composed of Pd-doped SnO_2/CuO composite nanofibers. The core innovation in our approach lies in the synergistic combination of electrospinning and DC sputtering techniques. Electrospinning offers nanofibers with a high surface area, tunable morphology, and enhanced gas diffusion, which significantly boosts the sensitivity of gas sensors. The XRD peaks depict the high crystalline nanofibers show rutile and monoclinic structures of SnO_2 and CuO present in the nanofibers. The surface roughness explained in FESEM analysis is the key feature for gas sensing as the diameter of the fibre reduced from 552 nm to 385 nm. The bare SnO_2/CuO nanofibers exhibited a response (Ra/Rg) of 6.95 when exposed to 50 ppm of H_2S gas at 200 °C. Pd sputtering acts as a catalyst that plays a dual role in enhancing sensitivity. Firstly, it catalytically splits hydrogen sulphide (H_2S) into SH and H radicals on its surface. This process liberates electrons, resulting in an abundance of charge carriers and significantly improving the sensor's response to H_2S. Secondly, Pd has the remarkable ability to split oxygen (O) molecules on its surface without the need for external energy. This process creates additional active sites on the sensor's surface, further enhancing its capacity to interact with gas molecules and leading to improved gas sensing performance. The presence of Pd (sputtered for 9 s) catalyses the metallization of SnO_2/CuO heterojunctions, leading to an increase in 8.5 response to 50 ppm of H_2S gas at 200 °C. This dual approach, combining the benefits of electrospinning and Pd sputtering, results in the exceptional sensitivity observed in our nanofibers. The unique properties of Pd-doped SnO_2/CuO nanofibers, such as their extraordinary sensitivity even for 0.5 ppm (response of 2.6) and selectivity for H_2S gas, make them valuable tools for various applications where the precise detection of hydrogen sulphide is paramount.

5:00 PM EL01.06.25
Enhanced Optoelectronic Properties of Green Perovskite Light-Emitting Diodes by Amino Acid-Doped PEDOT:PSS Joonseok Kim, Min-Gi Jeon, Artavazd Kirakosyan, Subin Yun and Jihoon Choi; Chungnam National University, Korea (the Republic of)

Halide perovskites are promising materials for light-emitting diodes (LEDs) applications owing to their excellent optoelectronic properties such as long carrier diffusion length, high quantum yield, and facile bandgap tunability. Additionally, poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) is commonly used as hole transport layer (HTL) in perovskite electronic devices owing to its high hole mobility, solution processability, and optical transparency. However, PEDOT:PSS can potentially degrade the adjacent layers owing to its acidic nature arising from a sulfonic acid group. Furthermore, the electrical conductivity and light emission characteristic of upper perovskite layer decrease due to phase transition from the crystalline phase to an undesired hydrated phase and decomposition of perovskite caused by the moisture absorbed by PSS chains from environment. Therefore, the acidic and hygroscopic properties of PEDOT:PSS reduce the operational stability and lifetime of perovskite LEDs (PeLEDs).
Herein, we report the pH neutralization of PEDOT:PSS by adding basic amino acids, which are arginine, lysine, and asparagine. The addition of amino acids can not only modulate the pH of PEDOT:PSS, but also provide nucleation sites to perovskite crystals, and passivate the defects at the interface of PEDOT:PSS and perovskite. Thus, the addition of amino acids results in enhanced stability and photoluminescence quantum yield of the perovskite nanocrystalline layer. When the amino acid-doped PEDOT:PSS is adopted as HTL layer in PeLEDs, the external quantum efficiency (EQE) of green-emitting PeLEDs (λ=518 nm) is improved from 8.99 to 11.96 % without a shift of electroluminescence spectrum. These results demonstrate that the aforementioned disadvantages of PEDOT:PSS can be overcome, expanding the scope of application of PEDOT:PSS as HTL.

5:00 PM EL01.06.26
Enhanced NIR Photoresponce in Nanostructured Sb_2Se_3 Film on Micro-Pyramidal Silicon Substrate Yogesh Singh[1,2], Avritti Srivastava[1,2], Sanjay K. Srivastava[1,2] and Vidya Nand Singh[1,2]; [1]Academy of Scientific and Innovative Research, India; [2]CSIR- National Physical Laboratory, India

The increasing demand for high responsiveness in imaging technology and optical communication has driven the development of photodetectors with

enhanced performance. Plasmonic sensor technologies have shown promise, but they often suffer from low optical absorption and inefficient charge carrier transport. Addressing these challenges, we present a novel approach utilizing Sb_2Se_3, a light-sensitive material with a high absorption coefficient, in the design of a near-infrared (NIR) photodetector.
We have developed an efficient, scalable, and cost-effective NIR photodetector by depositing a nanostructured Sb_2Se_3 film onto a p-type micro-pyramidal silicon substrate, fabricated through a wet chemical etching process. Pump-probe spectroscopy was employed to investigate the impact of annealing on Sb_2Se_3 films, shedding light on their suitability for advanced photodetector applications. We excited both annealed and unannealed samples near the band gap at 650 nm (1.9 eV) with an average power of 1mW, probing the near-infrared (NIR) region spanning 800-1400 nm. The recorded kinetics at various probe wavelengths which provides crucial insights into the behavior of these materials.
The transient absorption kinetics were captured over an extended time window ranging from 0 to 6 nanoseconds. The entire spectrum is blue-shifted, a phenomenon attributed to lattice heating induced by the femtosecond laser—a well-known effect termed the Burstein-Moss shift. A negative band, centered around 850 nm, represents photoluminescence (PL) emission spectra with a longer duration due to defects within the band structure, as evidenced by a time constant (τ4) exceeding 5 nanoseconds, accounting for nearly half of the carrier concentration. Notably, a broad photo-induced absorption (PIA) region spanning 910-1150 nm is observed, characterized by rapid decay within 1 or 2 picoseconds. The fastest time constant (τ1) of approximately 1 picosecond is attributed to the thermal relaxation of carriers within the conduction band and the associated surface states, while a subsequent time constant (τ2) of around 25 picoseconds adds further depth to our understanding. This study underscores the importance of annealing in optimizing the properties of Sb_2Se_3 films and contributes valuable insights into the dynamics of carrier relaxation and the role of defects in these materials. These findings are instrumental in advancing the development of high-performance photodetectors and related technologies.Our findings reveal that at the optimized thickness of the Sb_2Se_3 layer, the micro-pyramidal silicon substrate significantly enhances responsivity, achieving nearly double the performance compared to Sb_2Se_3 deposited on flat silicon or glass/ Sb_2Se_3 samples at a wavelength of 1064 nm (power density = 15 mW/cm^2). Notably, the micro-pyramidal silicon-based device operates at zero bias voltage, paving the way for self-bias devices.
We report the highest specific detectivity of 2.25×10^{15} Jones at a power density of 15 mW/cm^2 and a bias voltage of 0.5 V. This superior performance is attributed to the field enhancement provided by the Kretschmann configuration of the silicon pyramids, creating "hot spots" at the Si/Sb_2Se_3 junction. With a remarkable responsivity of 47.8 AW^{-1}, our design demonstrates its suitability for scalable and cost-effective plasmonic-based NIR photodetectors, addressing the need for high responsiveness in advanced imaging and optical communication applications.

Dark Current Suppression based on Theorical and Experimental Investigation of Barrier Energy between Transparent Anode and Photosensitive Layer via Material Design in Organic Photodetector Woongsik Jang and Dong Hwan Wang; Chung-Ang University, Korea (the Republic of)

Organic semiconductor-based photodetectors (OPDs) have attracted a variety of attention attraction as a substitute for photodetectors with conventional inorganic materials for image sensors with high sensitivity. The organic semiconductor has tunable optical, electrical and mechanical properties by designing their structure. OPDs are evaluated by both dark current and photocurrent. However, research to investigate the causes of dark currants has been insufficient.
Herein, we introduce non-fullerene acceptors which have opened new avenues with regard to improve the figure of merits of OPDs including wide absorption and fast response. [1] To investigate the effect of electron acceptors on dark current, OPDs are fabricated according to the types of acceptors in photosensitive layers, because anodic charge injection to acceptors has a major role of dark current under an applied reverse bias, which influences the performance of organic photodetectors. [2] The origin of dark current generated in an organic photodetector is observed through the modeling between current and voltage. To elucidate the dominant mechanism, the barrier energies in anodic contact are set from 0.6 to 1.0 eV using photosensitive layers composed of different acceptors. The current density–barrier energy characteristics measured under reverse bias strongly suggests the main source of dark current. The linear relationship observed in the current density–voltage characteristics also confirm tunnelling effects rather than thermionic emission. Consequently, the non-fullerene acceptor-based OPDs show a high detectivity and a faster response time, because of the excellent dark current suppression of the carrier injection and the low trap density of non-fullerene acceptor. Eh-IDTBR (ethylhexyl-rhodanine-benzothiadiazole-coupled indacenodithiophene) has been employed in OPDs and the results have been compared with fullerene derivatives ($PC_{71}BM$), in combination with electron donor PBDTTT-EFT material. eh-IDTBR based OPDs has shown excellent detectivity in comparison to $PC_{71}BM$ based OPDs due to suppressed injected carriers and trap density. Furthermore, morphological and electrical changes depending on thermal and electrical stress have been investigated in the two different acceptor systems.
Carbon nanotubes (CNTs) have attracted huge attention owing to their outstanding flexibility, transparency, and conductivity, so that CNTs can replace an indium-tin oxide (ITO) for efficient curved and flexible photodetectors. Especially, CNTs-based electrode with high chemical resistance is the excellent candidate for organic photodetectors (OPDs), because the devices have been fabricated through solution process. In addition, The OPDs require dense nanotubes arrays to form top layers suitably to enhance the performance. The CNT electrode with high transmittance reduces dark current below pA level and exhibits the higher detectivity than that of ITO-based devices owing to its deep work function related with the high electron injection barrier energy. [3] The flexible OPDs fabricated utilizing the CNT electrode stably operate after 500-bending tests. By investigating the charge injection mechanism according to barrier energy between transparent anode and photosensitive layer in organic photodetector, This work can help devise an effective strategy to suppress dark current for effective organic photodetector device implementation with increase of process yield and reduction of unit prices.

Printable Self-Powered Electrochemical Oxygen Sensor Tianyi Liu, Vijaya Kayastha, Chandler Murray, Brock Morris, David Taggart and Jiadeng Zhu; Brewer Science, United States

Oxygen sensors have a wide range of applications, from monitoring respiration and oceanography to food and pharmaceutical industries. These sensors measure the oxygen concentration in a gas or liquid, typically air or exhaust gases, and play a crucial role in improving efficiency, reducing emissions, and ensuring safety and environmental compliance. Screen printing is a widely adopted method for producing energy storage devices, especially in printed electronics. It creates patterns of conductive materials, such as electrodes and current collectors, on various substrates. In this work, an electrochemical

sensor was fabricated using printing technology for O_2 detection at room temperature. This design consists of zinc metal as an anode and carbon-based material as a cathode. The oxygen concentration can be observed in terms of electrical signals. A complete product development process has been demonstrated, including material screening, hardware design, and sensor tests. The resultant sensor exhibits a fast response (T_{90} ~2.7 s) and high sensitivity. Furthermore, the sensor fabrication is an environmentally friendly process with minimized consumption of toxic materials, such as Pd, and release of pollutants.

8:15 AM EL01.07.02
Efficiency Enhancement of Bifacial Sb_2Se_3 Photovoltaic Devices with Cu_2O Back Buffer: A Modeling Study Sanghyun Lee; University of Kentucky, United States

Thin-film solar cells based on an Antimony Selenide (Sb_2Se_3) absorber layer have been emerging as third-generation photovoltaic devices with promising properties. A Sb_2Se_3 absorber has 1.1 eV bandgap, a high absorption coefficient at visible light (>10^5 cm^{-1}), good carrier mobility (<15 cm^2/Vs), long carrier lifetime (<67 ns), and simple binary compound with high vapor pressure and low melting point (550 °C).
Due to the versatility of Sb_2Se_3 thin-films, Sb_2Se_3 has been studied by varying compositions and concentrations of incorporated elements for various applications. In particular, Ge-incorporated Sb_2Se_3 thin-films (hereafter, Ge- Sb_2Se_3) have been reported as a good polycrystalline absorber candidate with Ge concentration <15 %.
To further improve the efficiency of polycrystalline Sb_2Se_3 devices, both front and rear-side illumination could be captured by utilizing the bifacial device configuration of Sb_2Se_3 devices. However, developing bifacial devices has stagnated in thin-film photovoltaic technologies due to the short carrier lifetime (<100 nS) as compared to polysilicon counterparts. For instance, the record efficiency of rear-side illumination is reported as 9.2 % for CIGS, 8.0 % for CdTe, and 9.0 % for Kesterite solar cells, respectively. Designing a bifacial photovoltaic structure has been studied by several research groups and recently, a few studies of thin-film devices with a thin absorber (<2 um) such as CIGS, CdTe, and Kesterite have been reported. By carefully selecting a transparent back buffer layer coupled with a transparent conducting back contact, a bifacial device configuration needs to be optimized in thickness and doping concentration to maximize a bifaciality factor, which is the ratio of rear-to-front efficiency to the same irradiation.
In this contribution, we have theoretically studied bifacial Ge Sb_2Se_3 devices after fabricating Ge Sb_2Se_3absorber thin-films, followed by characterizing the optical properties. The optical properties of a Ge- Sb_2Se_3 absorber layer were used as input parameters for modeling and numerical simulation of the bifacial device configuration. For our analytical simulation, we have used in-house MATLAB modeling suites that have been developed in our group. We have proposed new bifacial devices to improve the overall device performance and optimized developed device models with various parameters. With a Cu_2O back buffer layer, the best efficiency of front-side illumination is 19.7 %, Voc (744.4 mV), Jsc (40.14 mA/cm2), and FF (66.1 %). For the rear-side illumination, the performance is 13.0 %, Voc (724.5 mV), Jsc (31.6 mA/cm2), and FF (56.7 %). Consequently, the bifaciality factor is 66 %.

8:30 AM *EL01.07.03
$Hf_{0.5}Zr_{0.5}O_2/Al_2O_3$ Bilayer Ferroelectric Tunnel Junctions: Investigations of The Chemistry of Interfaces and Films by HAXPES Wassim Hamouda[1], Ines Haeusler[2], Muhammad Hamid Raza[1], Keerthana S. Nair[1,3], Adnan Hammud[4], Christoph Koch[2], Veeresh Deshpande[1], Christophe Schluter[5] and Catherine Dubourdieu[1,3]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]Freie Universität Berlin, Germany; [4]Fritz-Haber Institute of The Max-Planck Society, Germany; [5]DESY, Germany

The discovery of ferroelectricity in hafnium dioxide-based ferroelectrics has revived the research on ferroelectric devices. In particular, the $H_{f0.5}Zr_{0.5}O_2$ (HZO) solid solution compound provides an opportunity for back-end-of-line integrable devices due to its low crystallization temperature (< 450°C). Among the different ferroelectric-based devices, ferroelectric tunnel junction (FTJ) memories are well suited for emerging neuromorphic applications due to their low power consumption, non-volatile nature, and potential to achieve multiple resistance states through domain partial switching of domains. As the conventional metal-ferroelectric-metal FTJ stack requires an ultra-thin ferroelectric layer (1-3 nm), it is quite challenging to fabricate with a polycrystalline $Hf_{0.5}Zr_{0.5}O_2$ (HZO) layer. With a bilayer stack architecture based on HZO/Al_2O_3, a thicker HZO can be used (10 nm) and can still provide a high ON current as the tunneling occurs through the thin dielectric layer (~3 nm) [1]. The performance of such devices rely on the ability to stabilize a large switchable ferroelectric polarization in HZO, which is interfaced - on one side - with a dielectric and not a metal. The remanent polarization and the overall device performance also depends strongly on the nature of the bottom and top electrodes, on the presence of interfacial layers (whether intentional or not), and on the oxygen vacancies' content and distribution.
In this study, we discuss the role of processing conditions on the ferroelectric polarization and device performance of TiN / 10 nm HZO / 3 nm Al_2O_3 / W FTJs. The HZO is crystallized at 400[endif]-->C for full CMOS back-end of-line compatibility. As observed in the electrical characterization, the annealing conditions of the ultrathin Al_2O_3 tunneling barrier plays a key role in the ability to stabilize and switch the polarization in the HZO layer. Hard X-ray photoelectron spectroscopy (HAXPES) was used to probe the bonds and chemistry of the different buried interfaces and layers in the stack and to quantify the oxygen vacancy content. Measurements at different synchrotron beam angles were performed to probe various depths of the HZO layer. The top Al_2O_3/W layers were investigated by combining laboratory XPS with low energy Argon ion sputtering. Complementary information was gained from scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS). A strong difference in the oxygen vacancy profiles in HZO is found depending on the stack fabrication conditions. The dependence of the remnant polarization with the voltage pulse width points to the major role of charge traps in minimizing the depolarizing field. We will discuss the influence of the processing conditions on providing the needed traps for screening charges, which is essential in stabilizing the ferroelectric polarization in bilayer HZO-based FTJs.

Current-Voltage Versus Time: How Metallic Coatings affect Conductive Atomic Force Microscopy Interpretation on Resistive-Switching Metal Halide Perovskites Holland Hysmith[1], Neus Domingo Marimon[2], Sabine M. Neumayer[2], Stephen Jesse[2] and Mahshid Ahmadi[1]; [1]University of Tennessee Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Metal halide perovskites (MHPs) are commonly studied for their solar cell applications yet are a potentially effective switching medium in memristors. A memristor by design can remember its state after external excitation is removed. This function is helpful in reducing the von Neumann bottleneck in computing by creating more powerful and compact environments for the modern world. However, MHPs are limited by their lack of commercial scaling and puzzling material phenomena that are not easily understood by scientists. To address this, using techniques like atomic force microscopy (AFM) to study MHP thin film mechanisms can help understand, quantify, and optimize MHP efficiency.

When using AFM techniques like conductive AFM (c-AFM), valuable information such as photocurrent, dark current and I-V hysteresis can be uncovered in MHP films. Although, when measuring surface morphology with an AFM tip, many factors have been reported to influence the perception of its findings: surface charges, artifacts, charge injection, wearing of the tip, etc. The AFM tip metal coating can also create undesirable and unpredictable interactions with the sample surface, especially for volatile organics such as perovskites. Therefore, we measured how cyclic voltammetry changes over time as a function of AFM metallic tip coatings on resistive-switching $FACsPbI_3$ thin films. This approach of c-AFM coupled with heterodyne kelvin probe

force microscopy (KPFM) and time-of-flight secondary ionization mass spectrometry (ToF-SIMS) reveals the local electrical, potential, and chemical changes in the film.

Common AFM metallic coatings for c-AFM applications like platinum, diamond, and iridium were used in this study. I-V maps showed changes in the Schottky barrier with each respective tip coating and alterations to resistive switching qualities over time. Disruptions during scanning shows the potential for dragging surface charges (e.g. I_2^-) and affecting the magnitude of current measured. KPFM was measured after c-AFM to demonstrate changes in local potential among different applied sample voltages and tip coatings. Lastly, ToF-SIMS revealed multi-dimensional chemistry at the film scanning sites. The use of tools such as AFM is vital for improving the future of MHP memristors, but understanding the limitations from data interpretation and application is important for comprehending what is found.

Enhanced Sub-Band Gap Photosensitivity by an Asymmetric Source-Drain Electrode Low Operating Voltage Oxide Transistor Utkarsh Pandey; Indian Institute of Technology (BHU), Varanasi, India

Electrical characteristics of a thin film transistor (TFT) can be tuned by using an asymmetric work function source-drain (S-D) electrode. However, to realize the effect of this asymmetric S-D electrode, a low operating voltage TFT is required. On the other hand, sub-bandgap photosensitivity of a photodetector required a suitable material interface engineering. In this work, an asymmetric S-D electrode has been used to enhance the photosensitivity of a solution processed low voltage driven metal oxide TFT. An ion-conducting $LiInSnO_4$ thin film has been used as the gate dielectric of this TFT that limits the operating-voltage of this TFT within 2 V whereas ZnO has been used as the channel semiconductor. This asymmetric S-D electrode of TFT allows a selective carrier (electron or hole) injection and collection from the channel. As a consequence, the On/Off ratio and photosensitivity of the device improve significantly. The On/Off ratio of asymmetric TFT is 10^2 times greater than symmetric TFT. More interestingly, the subthreshold swing (SS) of this asymmetric S-D electrode TFT (210 mV/decade), was reduced more than four times than that of the symmetric electrode (975 mV/decade) device. The $LiInSnO_4$/ZnO interfaces states which has been identified in the UV-Vis absorption of $LiInSnO_4$/ZnO thin film is capable to generate sub-band gap photocurrent in the devices. As a consequence, this ZnO based phototransistor can detect light efficiently ranging from 400 to 800 nm. Overall, photosensitivity of this asymmetric S-D electrode TFT has been enhanced by ~ 405 and ~ 377 times under red and blue illumination respectively with respect to the symmetric S-D electrode TFT whereas the detectivity of the device increases by ~10 and ~4 times

Precision Colloidal Synthesis: How Far Can it take us in Realizing Advanced Quantum Light Sources? Jennifer Hollingsworth and Eric Bowes; Los Alamos National Laboratory, United States

Core/shell heterostructuring of semiconductor quantum dots (QDs) provides a convenient platform for exploring the limits of synthetic control over quantum optical properties. Even “simple” control of component composition and feature size in a nano-heterostructure affords opportunities for band-structure engineering, which leads to altered photoluminescence properties, including emission color, lifetime, photostability, etc. More interestingly, however, colloidal synthesis provides possibilities for nearly-atomically precise manipulation of the core/shell interface. This can include alloying, introduction of defects or dopants, and selective facet growth. Here, I will describe several examples of how advanced colloidal synthesis can be used to finely tune nanoscale heterostructure to realize novel properties: dual-color emission, charged-state versus excitonic emission, and resistance to photobleaching by either dimming or catastrophic failure. First, we show that adventitious or intentional introduction of hole traps at the InP/CdSe QD interface, as well as arm length and arm diameter tuning in CdSe/CdS core/arm tetrapods, can provide conditions for realizing two-color excitonic or multi-excitonic emission, respectively, both potentially characterized by suppressed blinking. Second, we assign for the first time the synthesis-structure-function correlations for non-blinking CdSe/CdS core/shell QDs to define the limits of “on-demand” single-photon production under thermal or high-photon-flux

stress. The new insights show, e.g., the relationships between shell defects and charged-state emission and between interfacial alloying and photobleaching resistance, each precisely controlled by synthesis conditions. Taken together, the different nano-heterostructure systems reveal the opportunity for achieving designed quantum optical properties through synthesis, while the remaining limitations expose where alternative strategies might be needed to realize, e.g., transform-limited, ultrafast single-photon emitters.

Soft-Electronic Quantum Dot Light-Emitting Diodes Taeghwan Hyeon[1,2] and Dae-Hyeong Kim[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

We demonstrated a wearable red-green-blue (RGB) colloidal quantum dot light-emitting diode (QD LED) array with high resolution using a novel intaglio transfer printing technique (*Nature Commun.* **2015**, 6, 7149). We also reported transparent QD LEDs with extremely high luminance and transmittance (*Adv. Mater*. **2018**, *30*, 1703279). We reported a novel device design and fabrication method using metal-based etch-stop layers and a laser-assisted patterning for 3D foldable QD LEDs (*Nature Electronics* **2021**, *4*, 671). Shape-tunable multiplexed phototransistor array was fabricated using an intrinsically stretchable and color-sensitive semiconducting nanocomposite consists of size-tuned quantum dots, blended in a semiconducting polymer within an elastomeric matrix (*Nature Nanotech.* **2022**, 17, 849). We report novel material and device strategies for the intrinsically-stretchable quantum dot light-emitting diode (*is*-QLED) (*Nature Photon.* In revision). We reported on the design and synthesis of highly stable, photoluminescent, and catalytically active suprastructures of $(CdSe)_{13}$ nanoclusters (*Nature Mater.* **2021**, *20*, 650).

11:30 AM *EL02.01.03
Engineered Colloidal Quantum Dots as Universal Optical Gain Media for Solution- and Solid-State Lasers and Laser Diodes Victor I. Klimov; Los Alamos National Laboratory, United States

Colloidal quantum dots (QDs) are attractive materials for applications in laser technologies. In addition to being compatible with inexpensive and easily scalable chemical techniques, they offer multiple advantages derived from a zero-dimensional (0D) character of their electronic states. These include a size-tunable emission wavelength, low optical-gain thresholds, and high temperature stability of lasing characteristics.

So far, all validated reports on colloidal QD lasing employed optically excited close-packed solid-state QD films. Two classes of QD lasers that are yet to be realized are liquid-state optically pumped devices and electrically pumped solid-state lasers (laser diodes). In both cases, a principal obstacle is very fast Auger recombination of optical-gain active multicarrier state. One consequence of fast Auger decay is the existence of a minimal (critical) QD concentration required for lasing. Due to solubility limits, this concentration is difficult to attain with liquid-state samples. Therefore, up to now, QD lasing devices have employed high-density solid-state films. Fast Auger delay also creates a serious problem when one tries to realize lasing with electrical pumping. In particular, it mandates the use of prohibitively high current densities for maintaining QDs in the inverted multicarrier state.

Here we describe how we overcome the challenge of fast Auger recombination using meticulously engineered hetero-QDs. To impede Auger decay, we modify an optical gain state so as to reduce the number of available Auger pathways. Further, we employ compositional grading of the QD interior to smoothen carrier confinement potentials and whereby suppress the strength of individual Auger transitions. As a result, our engineered QDs exhibit long optical gain lifetimes (nanosecond time scales) while still maintaining strong 3D quantum confinement.
We use our novel QDs to demonstrate new types of lasing devices including prototype laser diodes and widely tunable dye-like liquid-state lasers.

SESSION EL02.02: Magic-Sized Clusters and Atomically Precise Structures
Session Chairs: Grant Dixon and Hao Nguyen
Tuesday Afternoon, April 23, 2024
Room 347, Level 3, Summit

1:30 PM *EL02.02.01
Prenucleation Clusters of Colloidal Semiconductor CdTe Quantum Dots Kui Yu; Sichuan University, China

The synthesis of colloidal semiconductor quantum dots (QDs) keeps developing during the past 40 years, with limited attention paid to the evolution of prenucleation clusters. With CdTe as a model system from a non-injection-based approach, we show that prenucleation clusters form and isomerize prior to the nucleation and growth of QDs. We propose that the prenucleation clusters evolve via chemical self-assembly of Cd and Te precursors. The prenucleation clusters are relatively optically transparent, which are covalent inorganic polymers. They can transform to absorbing magic-size clusters (MSCs). Thus they are called precursor compounds (PCs) of MSCs. We placed prenucleation-stage samples obtained at 25, 45, or 80 °C into a mixture of cyclohexane (CH) and octylamine (OTA) at room temperature. We observed the presence of MSC-371, MSC-417, or MSC-448 which displayed optical absorption peaking at 371, 417, or 448 nm, respectively. Based on our experimental data, we thus hypothesize that in the reaction PC-371 forms at 25 °C, and isomerizes to PC-417 at 45 °C and to PC-448 at 80 °C. These PCs and MSCs form a group of (quasi) isomers. Our findings suggest that a multi-step non-classical model shall be taken into account to understand the nucleation and growth of colloidal QDs, instead of the one-step classical LaMer model. Furthermore, the PC-assisted transformation is the underlying cause for the step-wise spectral shift for MSCs instead of a continuous pattern.

2:00 PM EL02.02.02
The Isomer Chemistry of Magic-Sized Clusters Youngjae Ryu; Pohang University of Science and Technology, Korea (the Republic of)

Magic Sized Clusters (MSCs) are small sized inorganic nanoparticles which are less 2 nm in size with a thermodynamically stable structure. Their highly surface-dependent properties facilitate the existence of various types of isomers. Particularly, isomers which exhibit dissymmetric circular dichroism signals, also known as optical isomers, are of great importance. Chiral MSCs with large circular dichroism signals will be discussed as compared to other chiral semiconductor nanocrystals. To investigate the chiroptical origins of our chiral MSCs, characterizations including XRD and Raman were conducted to explore ligand geometry and structural properties. By surface characterizations including FT-IR and TGA, we have found that particular mode of surface ligand binding is critical for the chirality. Low crystal symmetry of MSCs is thought to induce the large transition dipole moment of MSC, which in turn yields high chiroptical activity. In contrast, similar sized QDs showed silent chirality presumably due to the high crystal symmetry and the consequent low transition dipole moment. Propagation of chirality using chiral MSCs as the building block will be also addressed. We believe that unique characteristics of MSCs may open a new avenue in designing and synthesizing unprecedented chiroptical materials.

2:15 PM EL02.02.04
Atomically Precise Indium Arsenide Magic-Sized Cluster Mahnmin Choi[1], Jibin Shin[1], Doeun Shim[2], Joongoo Kang[2] and Sohee Jeong[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]DGIST, Korea (the Republic of)

In the domain of atomically precise nanoscale science, clusters serve as intermediate assemblies of atoms or molecules, stabilized with organic ligands. These formations, distinctly larger than a single atom yet considerably smaller than bulk materials, exhibit physicochemical properties divergent from established material systems. The elucidation of their structure is paramount because these clusters provide an ideal platform to clarify the intricate relationship between structure and physicochemical properties. Recently, magic-size clusters (MSCs) were discovered; these are atomically precise semiconductor clusters, and their structures have been unveiled. To clarify the relationship between the structure and physicochemical properties, the synthetic method, isolation, and characterization techniques must be refined. The Indium arsenide (InAs) quantum dot has emerged as a promising material for various infrared applications. During the synthesis of the InAs quantum dot, the presence of InAs MSC, as indicated by distinctive absorption peaks, was investigated. However, the isolation and characterization of InAs MSC have not been reported until now.
Herein, we synthesized and isolated atomically precise InAs MSCs to scrutinize their structure. With the optimal synthetic temperature, the InAs MSC revealed two distinct optical transitions. To gain a theoretical understanding, we modeled the InAs MSC using density functional theory (DFT) calculations, identifying a structure with notable stability. This model displayed two optical transitions, from HOMO to LUMO, consistent with the optical transitions we observed. The X-ray diffraction spectrum also aligned with the simulation results. For a deeper atomic-level understanding, we employed X-ray absorption spectroscopy and characterized the cluster using X-ray absorption fine structure (XAFS) techniques. By comparing with an InAs quantum dot, which is larger than the InAs MSC, we noted increases in the In-As peaks and decreases in the In-O peaks, attributable to size-dependent surface-to-volume ratios. Furthermore, spectral intensity offered insights into coordination numbers. Our fitting analysis of the XAFS spectrum enabled precise estimations of coordination numbers for various bonds. Notably, the coordination number for the In-As bond in MSC agreed with our computational predictions. Collectively, these results not only validate our theoretical model but also deepen our understanding of the structural and optical properties of InAs MSCs.

2:30 PM EL02.02.05
Structure and Reactivity of Atomically-Precise III-V Nanoclusters Soren Sandeno[1], Kyle Schnitzenbaumer[2], Sebastian Krajewski[1], Ryan Beck[1], Dylan Ladd[3], Kelsey Levine[3], Damara G. Dayton[3], Michael Toney[3], Werner Kaminsky[1], Xiaosong Li[1] and Brandi M. Cossairt[1]; [1]University of Washington, United States; [2]Transylvania University, United States; [3]University of Colorado Boulder, United States

Advances in the synthesis of III-V quantum dots, including InP and InAs, have led to their development for current- and next-generation solid-state lighting, wide color gamut displays, and infrared optoelectronics. The most widely adopted synthesis of these III-V quantum dots involves indium carboxylates and $E(SiMe_3)_3$ (E = P, As) and is understood to proceed through the formation of metastable, atomically-precise intermediates that are often referred to as clusters. In this work, we report that the surface chemistry of $In_{37}P_{20}(O_2CR)_{51}$ can be leveraged to modify the core structure and control the reactivity of the clusters. Bulkier surface ligands hinder $P(SiMe_3)_3$ diffusion and allow for the stabilization and isolation of $In_{26}P_{13}(O2CR)_{39}$, which has been characterized by single-crystal X-ray diffraction. When employing $As(SiMe_3)_3$ in an identical synthesis, no cluster forms and instead the inclusion of an L-type phosphine ligand is required to isolate an atomically-precise material. The surface and core of the InAs cluster are characterized, revealing important contrasts with InP with implications for understanding the landscape of accessible binary semiconductor clusters.

3:15 PM *EL02.02.06
Exploring The Chemical Paths to Doped II-VI Magic Size Clusters Kevin Kittilstved, Hyunggu Kim and Jillian Denhardt; University of Massachusetts Amherst, United States

The introduction of targeted, substitutional chemical dopants in a semiconductor lattice is a useful strategy to impart new functionality and in some instances emergent phenomena when synthesized at the nanometer lengthscale. One major challenge in the quantum dot field has been overcoming the thermodynamic penalty associated with introducing an impurity ion into the critical nucleus, which typically leads to an undoped core and dopants only doped in the shell or surface of the nanocrystal. The role of metastable magic size clusters in the synthesis of various quantum-confined nanostructures including doped nanostructures has received much attention in the past decade. In this talk, we will explore the common routes to prepare (doped) magic-size nanoclusters and introduce an alternate method that employs (doped) molecular clusters as single-source precursors.

3:45 PM *EL02.02.07
Doped InP Magic-Sized Clusters Sungjee D. Kim; POSTECH, Korea (the Republic of)

Magic-sized clusters (MSCs) can be isolated as intermediates in quantum dot (QD) synthesis, and they provide pivotal clues in understanding QD growth mechanisms. Two families are introduced that have chlorine or zinc incorporated InP MSCs. In each family line, different MSCs could be either directly synthesized or could be converted from one to another. As the conversion proceeded, evolution from uni-molecule-like to QD-like characters was observed. Early stage MSCs showed active interstate conversions in the excited states, which is characteristics of small molecules. Later stage MSCs exhibited narrow photoinduced absorptions at lower-energy region like QDs. The crystal structure also gradually evolved from polytwistane to more zinc-blende. Other halide doped InP MSCs and Ga doped MSCs will be also discussed. MSCs show many interesting properties such as isomerization induced by adsorption of small molecules. Reversible and dramatic isomerization of MSCs will be introduced. Chiral properties of MSCs will be also discussed.

4:15 PM *EL02.02.08
Steering Doping Polarity from Synthesis Onset: Using II-V Clusters in InAs Colloidal Nanocrystals for Infrared Optoelectronics Sohee Jeong; Sungkyunkwan University, Korea (the Republic of)

In the realm of nanocrystal-centric optoelectronic devices, control over the carrier type control is essential, however, integrating foreign atoms into semiconductor nanocrystal lattices remains challenging. A recent standout in this semiconductor lattice domain, Indium Arsenide (InAs) colloidal nanocrystals, has been in great attention due to their promising prospects, especially in near to short-wavelength infrared optoelectronics.
In this presentation, we introduce a novel methodology where doping polarity in InAs nanocrystals is innately steered from the synthesis onset. By harnessing the capabilities of II-V clusters as reaction precursors, we offer a pathway that not only addresses existing challenges but also achieves versatile control over doping polarity with the right parameter adjustments. Our exploration underscores the robust realization of p-type doping in InAs nanocrystals, indicating their integration in state-of-the-art printed electronic architectures.

SESSION EL02.03: Synthesis of Nanocrystals and Discovery of Novel Nanomaterials
Session Chairs: Grant Dixon and Nayon Park
Wednesday Morning, April 24, 2024

Synthesis, Interconversion and Photophysical Properties of CdSe Magic-Sized Cluster Polymorphs towards Atomically Precise Emitters Hunter Ripberger[1], Kyle Schnitzenbaumer[2], Lily K. Nguyen[1], Dylan Ladd[3], Kelsey Levine[3], Damara G. Dayton[3], Michael Toney[3] and Brandi M. Cossairt[1]; [1]University of Washington, United States; [2]Transylvania University, United States; [3]University of Colorado Boulder, United States

Cutting-edge applications of quantum dots (QDs) as next generation emitters require a precise understanding of their synthesis and structure, since atom-scale differences between individual nanoparticles can result in particle-to-particle variation in their optoelectronic properties. A strategy to synthesize atomically precise QD ensembles utilizes magic-sized clusters (MSCs), which are kinetically stable, atomically defined intermediates along the QD reaction potential energy surface. The synthesis of cadmium selenide MSCs is well precedented, and recent work has established two different structural motifs: a cation-rich, "zincblende-like" tetrahedron and a "wurtzite-like," quasi-spherical cluster with a stoichiometric inorganic core. However, the wide range of protocols used to access these species has made the direct comparison of their structure, surface chemistry, and optoelectronic properties difficult. Additionally, the physical and chemical relationship between these MSC polymorphs has yet to be established. Here, we demonstrate that both cation-rich and stoichiometric CdSe MSCs can be synthesized from identical reagents and can be interconverted through the addition of either excess cadmium or selenium precursor. The structural and compositional differences between these two polymorphs can be contrasted using a combination of ^{1}H-NMR spectroscopy, x-ray diffraction, pair distribution function (PDF) analysis, inductively coupled plasma optical emission spectroscopy, and UV-vis transient absorption spectroscopy. The subsequent polymorph interconversion reactions are monitored by UV-vis absorption spectroscopy, with evidence for an altered cluster atomic structure observed by powder x-ray diffraction and PDF analysis. This work helps simplify the complex picture of the CdSe nanocrystal landscape and provides a method to explore structure-property relationships in colloidal semiconductors through atomically precise synthesis. Furthermore, an understanding of polymorph structure allows us to tune the optoelectronic properties of the MSC using surface chemistry, with emission energy and quantum yield affected by the identity of the ligands.

The Dream of The Perfect Nanocrystal David J. Norris; ETH Zürich, Switzerland

Quantum dots are nanometer-sized crystallites of semiconductor that have a roughly spherical shape. Due to extensive research, quantum dots are now commercially used as a robust fluorescent material in displays and lighting. However, even with our best procedures, state-of-the-art samples still contain particles with a distribution in size and shape. Because this causes variations in their optical properties, their performance for applications is reduced. This leads to a fundamental question: can we achieve a sample of semiconductor nanocrystals in which all the particles are exactly the same? In this talk we will discuss this possibility by examining two classes of nanomaterials. First, we will consider thin rectangular particles known as semiconductor nanoplatelets. Amazingly, nanoplatelet samples can be synthesized in which all crystallites have the same atomic-scale thickness (e.g., 4 monolayers). This uniformity in one dimension suggests that routes to monodisperse samples might exist. After describing the underlying growth mechanism for nanoplatelets, we will then move to a much older nanomaterial—magic-sized clusters (MSCs). Such species are believed to be molecular-scale arrangements (i.e., clusters) of semiconductor atoms with a specific ("magic") structure with enhanced stability compared to particles slightly smaller or larger. Their existence implies that MSC samples can in principle be the same size and shape. Unfortunately, despite three decades of research, the formation mechanism of MSCs remains unclear, especially considering recent experiments that track the evolution of MSCs to sizes well beyond the "cluster" regime. Again, we will discuss the underlying growth mechanism and its implications for nanocrystal synthesis. Finally, we will present an outlook if perfect nanomaterials can be obtained.

9:15 AM EL02.03.03
Sizing Up The Electronic Structure of Atomically Precise Semiconductor Nanoparticles Eimear Madden and Martijn Zwijnenburg; University College London, United Kingdom

Empirically the effect of reducing the characteristic size of semiconductor materials on their optical and by extension electronic properties is well known. Similarly, the fact that this change with size can at least be qualitatively understood in terms of spatially constraining the excited-electron and hole pair to a volume smaller than what it would occupy in the bulk. However, when reducing the size of a semiconductor material more changes than just simply the characteristic size. The role of the surface and the nature of its termination become more important, the dielectric screening changes often reduce as more field lines travel around rather than through the semiconductor, as well as the (electronic) structure can become different to that of the bulk. This is especially true for atomically precise nanoparticles,[1] which typically are on the smaller side of the size spectrum.

To properly understand the effect of reducing the size of semiconductor materials and predict the properties of atomically precise nanoparticles of such materials one needs to perform electronic structure calculations on true nanoparticles. Such calculations should ideally consider the possible surface chemistry of the nanostructures and not assume that any of their properties, other than perhaps their internal structure, is the same as the bulk. Luckily such calculations have become tractable now, both using time-dependent density functional theory (TD-DFT) and the many-body perturbation theory combination of GW and solving the Bethe-Salpeter Equation (GW-BSE).[2-4]

In our contribution we will compare and contrast the results of calculations on ligand-capped cadmium sulfide nanoparticles, perhaps the archetypical atomically precise semiconductor nanoparticles, and their hydrogen terminated silicon counterparts, the c. elegans of computational nanoparticle research. Both ligand-capped binary semiconductor nanoparticles and hydrogen terminated silicon nanocrystals are interesting from an application point of view,[5,6] but also are derived from bulk materials that are both structurally similar but electronically different. We will discuss not only how the optical and electronic properties differ between the two classes of particles and how they change with particle size but also how these changes are linked to the particles' surface chemistry and changes in the dielectric screening and the fundamental electronic structure of the particles with particle size. An example of the latter being the onset of band-like behaviour.

Indium Coordination as a Handle for Controlling Indium Phosphide Quantum Dot and Nanowire Nucleation and Growth Helen Larson and Brandi M. Cossairt; University of Washington, United States

Indium phosphide (InP) is a less toxic semiconductor with exciting nanoscale applications in LED displays, bioimaging, and single-nanowire transistors and optoelectronics. However, colloidal InP synthesis lacks mechanisms for precursor reactivity-based size control, and standard synthesis methods rely on hazardous precursors that require high energetic input. To address these challenges, we have taken inspiration from natural biomineralization to expand control over nucleation and growth, focusing on modulating the indium coordination environment. We examined the effect of a strongly chelating anion on the nucleation and growth of InP QDs synthesized using aminophosphine chemistry. Increasing the equivalents of metal-chelating aminopolycarboxylic acid EDTA ($[CH_2N(CH_2CO_2H)_2]_2$) (0–0.75 equivalents per indium) was found to decrease the final diameter of InP QDs from 4.5 to 2.3 nm by lowering the initial InP growth rate. This size trend was rationalized by invoking a continuous nucleation model in which the suppressed initial growth rates are attributed to a competitive decrease in reactivity caused by indium EDTA complexation and a lower effective concentration. In opposition to strong indium chelation by EDTA, the weak indium-binding ligands trifluoroacetate and trifluoromethanesulfonate allow the aminophosphine-based InP chemistry to access nanowires through a solution-liquid-solid mechanism. Slow phosphorus reactivity is identified by ^{31}P NMR spectroscopy which, along with the weak indium-ligand interactions and the overall reducing environment, are proposed to allow access to the indium metal necessary for nanowire growth. Transmission Electron Microscopy identifies unusual nanoribbon morphologies of zinc-blende InP. Altogether, we identify that controlling indium coordination provides a versatile handle and access to new chemistries for the nucleation and growth of InP nanocrystals.

Solution Synthesis Empowers Control in Inorganic Thermoelectric Materials Maria Ibáñez, Tobias Kleinhanns, Mariano Calcabrini, Christine Fiedler, Sharona Horta and Daniel Balazs; ISTA, Austria

Thermoelectricity is the process of directly converting heat into electricity and vice versa, offering an environmentally sustainable means to generate electricity from wasted heat. To enhance the efficiency of this conversion, it's essential to precisely control various structural aspects beyond just the crystal structure. These aspects include defects, grain size, orientation, and interfaces. Conventional solid-state methods have limitations in achieving such precise control.

In recent years, solution-based techniques have garnered significant interest as a cost-effective and easily scalable approach for manufacturing high-performance thermoelectric materials. In this method, a powdered material is first prepared in a solution and then subjected to purification and thermal processing to produce the desired dense polycrystalline material. Unlike traditional methods, solution-based syntheses offer an exceptional level of control over various particle properties, including size, shape, crystal structure, composition, and surface chemistry. This precise control over the properties of the powder creates distinct opportunities for crafting thermoelectric materials with precisely tailored microstructural characteristics.

Throughout our research, we will illustrate various instances where exercising control over distinct nanoparticle characteristics, such as surface attributes or stoichiometry, directly influences specific properties of the dense material, thereby enabling us to fine-tune its performance optimally. Our focus will be particularly directed towards Ag_2Se, a thermoelectric material of great significance, especially in applications near room temperature.

10:45 AM EL02.03.06
HF-Free Synthesis of Colloidal A_2BF_6 Nanocrystals Eden A. Tzanetopoulos, Julie Schwartz and Daniel R. Gamelin; University of Washington, United States

Fluoride-based lattices are widely studied due to their low toxicity, high photostability, and optical transparency. These properties, along with their generally low phonon energies compared to oxides, make fluoride lattices attractive hosts for luminescent impurities. In particular, A_2BF_6 (A = Na, K, Cs, NH_4; B = Si, Ti, Zr, Ge) compounds doped with Mn^{4+} in the B^{4+} site are leading candidates for narrow-line red emitters in display and lighting technologies.[1] Solution-processability of these materials would enable additive manufacturing of next-generation classical and quantum photonic structures or devices, but fluoride lattices containing tetravalent cations are essentially entirely unexplored as colloidal nanomaterials, in large part because of the current reliance upon concentrated hydrofluoric acid (HF) in nearly all doped A_2BF_6 syntheses. This talk will describe results from a versatile new synthesis[2] developed to eliminate the handling of HF entirely. Colloidal nanocrystals of several A_2BF_6 lattices ($(NH_4)_2ZrF_6$, Cs_2ZrF_6, $(N[CH_3]_4)_2ZrF_6$, K_2SiF_6) have now been prepared for the first time. *In-situ* A-site cation exchange has also been demonstrated in these materials, allowing the post-synthetic conversion of, *e.g.*, $(NH_4)_2ZrF_6$ nanocrystals into Cs_2ZrF_6 nanocrystals. Under some conditions, a nanoscale Kirkendall effect occurs that yields hollow A_2BF_6 nanostructures. Recent results showing nanocrystal size and shape control will also be discussed. These results highlight the versatility of this bottom-up synthesis for preparing a wide variety of previously inaccessible colloidal fluoride nanostructures.

11:00 AM EL02.03.07
Colloidal Synthesis of P-Type Zn_3As_2 Nanocrystals Seongchan Kim, Jaeyoung Seo, Namyoung Gwak, Seungki Shin and Nuri Oh; Hanyang University, Korea (the Republic of)

Zinc pnictides (Zn_3Pn_2, where Pn represents P, As, or Sb) are compound II–V semiconductors composed of earth-abundant elements belonging to the II and V groups of the periodic table. These materials exhibit exceptional properties, such as high carrier mobility, low effective mass of charge carriers, anisotropic charge transport characteristics, and narrow band gaps. Notably, Zn_3As_2, which has a band gap of approximately 1.0 eV, has significant potential for optoelectronic applications across a wide range of wavelengths. Given the substantial advantages and opportunities associated with intrinsically p-type nanomaterials, particularly considering the abundance of well-established inorganic n-type nanomaterials, Zn_3As_2 is a highly promising material owing to its inherent p-type characteristics and appropriate bandgap.
Colloidal synthesis of nanocrystals (NCs) from compound semiconductors offers precise control over their size, resulting in a wide range of tunable electrical and optical properties. These colloidal NCs, such as Zn_3As_2 NCs, exhibit characteristics that make them highly suitable for low-cost large-area processing, opening up diverse applications in fields such as solar energy harvesting and photodetection spanning the visible to infrared regions. However,

despite the outstanding properties of colloidal Zn_3As_2 nanocrystals, research in this area is lacking because of the absence of suitable precursors, the occurrence of surface oxidation, and the intricacy of the crystal structures. Zn precursors such as diethylzinc, or As precursors such as tris(trimethylsilyl)arsane exhibit high reactivity but yield Zn_3As_2 NCs that are too small. Also, previously reported Zn_3As_2 NCs have exhibited low crystallinity, which was primarily attributed to the difficulty in achieving precise stoichiometry during their formation.
In this study, a novel and facile solution-based synthetic approach is presented for obtaining highly crystalline p-type Zn_3As_2 nanocrystals with accurate stoichiometry. By carefully controlling the feed ratio and reaction temperature, colloidal Zn_3As_2 nanocrystals are successfully obtained. Moreover, the mechanism underlying the conversion of As precursors in the initial phases of Zn_3As_2 synthesis is elucidated. Furthermore, these nanocrystals have been employed as active layers in field-effect transistors that exhibit inherent p-type characteristics with native surface ligands. To enhance the charge transport properties, a dual passivation strategy is introduced via phase-transfer ligand exchange, leading to enhanced hole mobilities as high as 0.089 $cm^2 V^{-1} s^{-1}$. This study not only contributes to the advancement of nanocrystal synthesis, but also opens up new possibilities for previously underexplored p-type nanocrystal research.

11:15 AM *EL02.03.08
The Chemistry of Tin Halide Perovskite Nanocrystals Loredana Protesescu; University of Groningen, Netherlands

Metal halides perovskites with nanoscale geometries have revolutionized the field of solution-processed photovoltaics and light-emitting devices due to their strong absorption and exceptional photoluminescence properties combined with a remarkable tolerance to structural defects. However, the further development of these materials to practical commercialization is hindered by their toxic components like lead and their inherent structural lability. Moreover, we still have little understanding of their crystallographic structures, chemical and physical interactions, and surface chemistry at a fundamental level.

The chemical design of metal halide perovskites proved to be the key to addressing those issues. In this work, I will discuss the physical and chemical parameters which can help us to achieve a stable, tunable and monodisperse $CsSnX_3$ perovskite nanocrystals with defined optical features. Pertaining to the formation energies of nanostructures, the interplay of the 2D Ruddlesden-Popper ($L_2Cs_{n-1}Sn_nX_{3n+1}$) phases with 3D $CsSnX_3$ nanocrystals is apparent with respect to ligand combinations (ammonium, carboxylate, phosphinate), precursor ratios and temperature when SnX_2 salt is used as a precursor. X-ray diffraction and scattering studies conjoined with optical spectroscopy and electron microscopy helps us in acquiring the useful insights into directing the chemistry of Sn-halide perovskites at nanoscale. This research work showcases the insistent necessity for the development of mechanistic understanding to design efficient synthetic routes to achieve high-quality tin-halide perovskite nanocrystals.

11:45 AM EL02.03.09
Tin Chalcogenide Colloidal Quantum Dots for Infrared Photodetection Barbara Y. Martin, Jianying Ouyang, Neil Graddage, Jianping Lu, Nathan Yee, Tyler Davidson-Hall, Jianfu Ding, Tao Ye and Patrick Malenfant; National Research Council Canada, Canada

Printable, flexible and low-cost photodetectors with sensitivity in the near-infrared (NIR, 700-2500nm) window are in high demand. Much research on infrared active colloidal quantum dots (CQDs) have been conducted based on lead or mercury chalcogenides. However, environment-friendly alternatives with tunable sensitivity in the NIR and high performance should be investigated to better protect our environment. We have developed silver chalcogenide CQDs and demonstrated their application in NIR photodetection, including Ag_2Se and Ag_2Te QDs with detection up to 1.2 µm and 1.4 µm[1,2]. To further push the sensitivity to longer wavelength, we have been developing tin telluride (SnTe) CQDs. SnTe QDs possess good optical properties in the range of 1.5-2.5 µm. So far, only a few studies were reported; the reaction mechanism is poorly understood, the synthesis is challenging and the products are prone to oxidation.

Our SnTe CQDs were synthesized with tin precursors that are less toxic, less expensive and less susceptible to oxidation than that commonly used (Bis(bis(trimethylsilyl)amino tin(II))[3]. The reaction was optimized by tuning different parameters (ligands, temperature, tin precursor, etc.) to reduce the oxidation and obtain monodispersed CQDs. We were able to obtain CQDs of 12 nm with an optical sensitivity up to 2.5 µm and good stability (weeks) under air. Additionally, SnTe CQDs can be coated to obtain more stable CQDs under air. The absorbance wavelength can also be tuned with this doping from 1.2 µm to 2.5 µm with a good control by changing the reaction time.

Our developed SnTe CQDs can offer a low-toxicity route for low-cost solution-processable fabrication of high-performance infrared photodetectors with sensitivity up to 2.5 µm.

SESSION EL02.04: Scalability in Synthesis, Characterization and Integration of Colloidal Nanocrystals
Session Chairs: Emily Miura and Nayon Park
Wednesday Afternoon, April 24, 2024
Room 347, Level 3, Summit

1:30 PM *EL02.04.01
Sustainable, Additive, Scalable Nanomanufacturing of Quantum Materials at The Attoscale John D. MacKenzie[1,1,2]; [1]University of Washington, United States; [2]Washington Clean Energy Testbeds, United States

Conventional semiconductor processing has made immense progress in the 70 years since its introduction, pushing progress in performance, critical dimension and functionality per unit cost forward at an unparalleled rate. Even though the roadmap to single nanometer devices is still being set, it is highly likely that this field will continue to innovate given the need for increasing information processing, storage and transfer in virtual reality, artificial intelligence and the integration of electronics with virtually every aspect of our lives. At the same time, there are global concerns about climate and sustainability and, here, the future for conventional manufacturing is less certain. Whether applied to optoelectronics, microelectronics or emerging areas such as optical quantum devices, conventional approaches are dominated by cycles of subtractive and high waste lithographic processing and energy intensive and increasingly complex sets of materials that run counter to a goal of sustainable, lower carbon footprint and lower environmental impact. We

will show here that advances in solution-processable materials and corresponding additive manufacturing approaches can provide alternative, and even more capable processing routes not feasible with conventional processing.
An overview of additive nanomanufacturing will be presented along with progress towards applying electrohydrodynamic (EHD) printing as a fully additive pathway towards quantum optical devices and integrated photonics. Although nanoscale 3D printing via processes like two photon stereolithography can produce submicron structures, this is largely limited to passive materials that require subsequent subtractive processing to render functional elements. Techniques like pressure driven inkjet printing, such as piezoelectric or thermal evaporation actuated printing common to consumer inkjet systems, can digitally deposit functional materials from nanoparticle and reactive precursor inks. These types of printing have also been scaled industrially in applications such as flat panel displays. The surface energy and decreasing inertia bottlenecks for ink droplets of decreasing size and increasing surface/volume ratio leads to size and positioning accuracy limits of around 10 microns. Unfortunately, this is two or more orders of magnitude too large for applications at the leading edge of micro- and opto-electronics. Leveraging the flexibility and dynamic range inherent to electric fields, EHD printing has been shown to overcome the droplet size limitations of mechanical jetting to deterministically position functional material inks additively with zero moving part actuation.
It will be shown here that direct printing of functional materials and precursors using EHD can be pushed to deterministic positioning of quantum dots and nanocrystal precursors at the nanoscale. This includes our ability to additievly pattern high index dielectrics for optical metasurfaces and shelled luminescence II-IV QDs at resolutions <100 nm from attoliter scale droplets. Our work on heterointegration of perovskite nanocrystals and QDs with photonic cavities, including selective deposition of quantum dots on free-standing close-spaced cavity pairs that demonstrate optical cross coupling will also be outlined. This demonstrates an exceptional example of heterointegration on optical structures at ambient pressures and temperatures that cannot be readily achieved by any conventional approach (e.g. semiconductor epitaxy, lithography or stochastic coating demonstrations). We will conclude with results of additive single QD deposition for devices such as single photon emission sources via dilute QD ink deposition, and formation of nanocrystals from in-situ attoliter scale reactions in printed reagent ink droplets. This will show that the resolution of techniques such as electron beam lithography can be surpassed in an additive, wasteless, sustainable scalable nanomanufacturing process.

2:00 PM EL02.04.02
Nondestructive High-Resolution Direct Optical Lithography of Colloidal Emissive Nanocrystals Himchan Cho; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

High-resolution precision patterning is a crucial requirement in the fabrication of immersive near-eye displays that incorporate high-color-purity emissive nanocrystals such as colloidal quantum dots and perovskite nanocrystals as color filters or electroluminescence (EL) emission layers in the form of an RGB matrix.[1)] Direct optical lithography, which involves a photochemical reaction of photosensitive ligands or additives, offers a new platform for patterning colloidal nanocrystals, providing high pattern uniformity with a simple procedure.[2)] However, a significant decrease in photoluminescence (PL) quantum yield during the patterning process has been a major challenge. To address this challenge, we have developed direct, scalable, and nondestructive methods for high-resolution patterning of colloidal emissive nanocrystals without sacrificing their luminescent properties. With photochemically activated reactions, leading to *in situ* exchange[3-4)] or crosslinking[5)] of long-chain organic ligands, we have demonstrated uniform PL and EL patterns of red, green, and blue quantum dots and perovskite nanocrystals with feature sizes as small as sub-1 μm, while preserving their structural, electronic, and emissive properties. The underlying patterning mechanisms were identified by investigating the photochemical transformations of surface ligands and additives at each step of the process. Our approach provides a promising solution for patterning of colloidal emissive nanocrystals, which can be implemented in next-generation augmented reality displays and other optoelectronics applications.

Data-Driven Exploration of Silver Nanoplate Formation in Multidimensional Chemical Design Spaces Huat Thart Chiang, Kiran Vaddi and Lilo D. Pozzo; University of Washington, United States

Artificial Intelligence (AI) driven closed systems, which are usually composed of an AI agent to plan experiments, robots to perform experiments, and a high throughput characterization method to evaluate experiments have recently shown to be successful in optimizing structural properties of colloidal nanoparticles. However, a limitation of these kinds of systems is that they have only been demonstrated in constrained design spaces which is where the targeted structure has a high probability of being formed. In addition, while many samples are being synthesized and characterized, minimal amounts of information on the relationship between experimental design parameters and the structure of the nanoparticles is obtained from the experiment. To solve these problems, we introduce a novel AI driven closed system and test it with a model system of silver nanoparticle synthesis with the objective of synthesizing nanoplates. Our method first searches the design space for silver nanoplates based on UV-Vis spectroscopy curves, which are autonomously classified into “plates” or “not plates” using a distance metric. This information is then used to train a gaussian process classifier which then iteratively suggests experimental parameters for a new batch of samples that are likely to be nanoplates. After the chemical design space is constrained to contain mostly nanoplates, we then use small angle x-ray scattering characterization to obtain size/shape parameters. This information is used to train a gaussian process regressor, from which we can extract design rules such as the effect of the composition of the reagents on the obtained size/shape parameters.

3:30 PM *EL02.04.04
Precision Synthesis and Accelerated Optimization of Colloidal Quantum Dots with Self-Driving Fluidic Labs Milad Abolhasani; North Carolina State University, United States

Despite the intriguing physicochemical properties and widespread applications of colloidal quantum dots (QDs) in energy and chemical technologies, their discovery and synthesis optimization are still based on Edisonian techniques. Existing QD discovery and development strategies using batch reactors with irreproducible and uncontrollable heat/mass transport rates very often fail to comprehensively explore the vast synthesis and processing space of QDs. These limitations necessitate the development and implementation of new strategies to accelerate the pace of QD discovery and development. Recent advances in reaction miniaturization, automated experimentation, and data science provide an exciting opportunity to reshape the discovery, development, and manufacturing of QDs. In this talk, I will present a *Self-Driving Fluidic Lab* (SDFL) for accelerated discovery, optimization, and manufacturing of colloidal QDs with multi-step chemistries, through the integration of flow chemistry, online characterization, and machine learning (ML). [1-5] I will discuss how modularization of different synthesis and processing stages in tandem with a constantly evolving ML-assisted QD synthesis modeling and decision-

making under uncertainty can enable resource-efficient navigation through high dimensional experimental design spaces. Example applications of SDFLs for the autonomous precision synthesis of metal halide perovskite, II–VI, and III–V QDs will be presented to illustrate the potential of autonomous labs in reducing QD development timeframe from >10 years to a few months. Finally, I will present the unique reconfigurability aspect of SDFLs to close the scale gap in nanomanufacturing research through on-demand switching from reaction exploration/exploitation to smart nanomanufacturing mode.

Autonomous Synthesis and Characterization Platforms for Parameter Space Mapping for Quantum Dots Paul Kenis and Jeff Xu; University of Illinois, United States

Controlling composition, structure, and thus properties of nanomaterials continues to be of importance to numerous fields, with potential and realized applications for colloidal nanomaterials ranging from quantum dots for displays and bioimaging, to metal nanoparticles for (electro-) catalytic conversions. The vastness of synthesis parameter space, in combination with limited understanding of the nucleation and growth mechanisms for many nanomaterials still hampers progress in identifying nanomaterials with desired properties for existing and newly envisioned purposes. Furthermore, the identification of optimal synthesis recipes for these nanostructures remains a major hurdle. To no surprise, many research efforts have been devoted to these challenges over the past 20+ years.

This presentation will focus on our efforts to develop and apply a number of enabling capabilities achieved through reactor engineering, focusing on the synthesis and characterization of quantum dots. We have demonstrated how the use of *automated flow reactors* not only helps in run-to-run reproducibility but also in uncovering mechanistic information. Examples include reactors with dedicated nucleation, growth, and shell formation zones, and investigation that revealed mechanistic insight of how water concentration affects QD synthesis outcome. In subsequent work, we employed an autonomous flow reactor system to map synthesis parameter space of specific QD systems, a project that relied on fast, fully automated in-situ characterization using UV-vis in combination with multi-step machine learning workflows The utility of flow reactors, however, is limited when considering chemistries with longer reaction times. Hence, more recently we developed a fully *automated batch reactor* for parameter space mapping of QD synthesis via hot injection, the most frequently used method in both QD research and in QD production at scale. This batch platform is being augmented with purification capabilities, to address some of the challenges of in-line, in-situ characterization of raw reaction mixtures, and to enable using advanced optical and structural characterization methods to provide insight into the actual structure of the QD materials.
In summary, we developed an integrated approach for the rapid synthesis, purification, and characterization of QDs to determine structural properties, with ongoing work focusing on structural mapping of QD synthesis.

4:30 PM EL02.04.07

Continuous Flow Synthesis of Lead Sulfide Quantum Dots for NIR/SWIR LED Applications Pierre Machut[1,2], Anna Karina Antonini[1], Céline Rivaux[1], Gabriel Mugny[2] and Peter Reiss[1]; [1]CEA, France; [2]STMicroelectronics, France

The development of new industrial applications in fields such as cell phones and automobiles depend on the ability to produce low-cost LEDs emitting in the NIR/SWIR range. A method for synthesizing large quantities of PbS/CdS core/shell quantum dots, known for their high photoluminescence, would enable this development.
Since the first synthesis of PbS quantum dots (QDs) using the hot-injection method in 2003,[1] many efforts have been employed to develop monodisperse PbS quantum dots. Nowadays, the use of bis(trimethylsilyl) sulfide (TMS_2S) as sulfur precursor still remains very attractive due to the narrow size distribution giving rise to precise absorption/emission features in the NIR/SWIR region. However, scaling up this synthesis remains a challenge due to the difficulty of handling and the high toxicity of the H_2S gas released during synthesis using this sulfur precursor.
Various sulfur precursors have been utilized to prepare PbS QDs, including elemental sulfur[2] and substituted thioureas[3]. The latter show a great potential as the reaction rate can be adjusted over several orders of magnitude by altering their substituents, which gives access to precisely controlled particle sizes in a wide range. Moreover, there are approximately 10^4 different thioureas that can be synthesized in simple reactions using commercially available chemicals.
To enhance the reproducibility of the syntheses and scale them up to larger quantities, continuous flow synthesis is an appealing alternative to widely used batch synthesis. Among other advantages, the strongly enhanced heat and mass transfer in small tubular reactors combined with controlled pressure can be cited. On the other hand, flow synthesis comes with several restrictions, which require in most cases an adaptation of the synthesis protocol. In particular, both the lead and sulfur precursors should be perfectly soluble at room temperature to avoid clogging, and the injected volumes should be balanced to keep consistent flow rates.
In this study, we developed new synthesis conditions affording monodisperse PbS QDs via flow synthesis exhibiting identical optical properties as with classic batch synthesis, with excitonic peak to valley ratios >3. Moreover, the excitonic peak position could be adjusted with the residence (=reaction) time, in contrast to batch reactions.
The flow synthesis of highly luminescent PbS/CdS core/shell QDs was also achieved using ex-situ prepared cadmium oleate via the cation exchange method.
Summarizing, the developed flow process gives access to grams of high-quality of PbS/CdS core/shell QDs in a couple of hours and in a highly reproducible manner, at wavelengths of particular interest for NIR QLEDs.

Resonant Tunneling Transistor based on Single PbS Quantum Dot Retno D. Wulandari[1,2,3], Yin Dongbao[2], Ricky D. Septianto[4], Yoshihiro Iwasa[1,5], Yutaka Majima[2] and Satria Bisri[1,3]; [1]RIKEN, Japan; [2]Tokyo Institute of Technology, Japan; [3]Tokyo University of Agriculture and Technology, Japan; [4]RIKEN CEMS, Tokyo Institute of Technology, Japan; [5]The University of Tokyo, Japan

The growing need for high-performance computing continues to drive circuit and device technologies to improve in terms of speed and power. Device dimension scaling will be the most effective strategy for meeting circuit performance requirements and reducing power consumption. Colloidal semiconductor quantum dots (QDs) are highly suitable to support device miniaturization by solution processability and as platforms for quantum information science[1]. The consideration of quantum mechanical effects is crucial in designing nanometer-scale electronic devices (i.e., transistors) that involve single QD. On the other hand, challenges related to the fabrication of such devices require radical solutions. Therefore, developing a bottom-up approach to enable the fabrication of high-quality single QD transistors based on the colloidal process that can easily be contacted electrically is an essential strategy that must be explored.

Here we demonstrate a resonant tunneling transistor (RTT) based on single lead sulfide (PbS) QD as a Coulomb island anchored by ligand molecules that are attached to the Au nanogap electrodes. We are utilizing two different alkane dithiol ligands which have different ligand chain length[2]. We specifically use PbS due to its well-established synthesis process and large electron Bohr radius, thus providing stronger and more stable quantum confinement at the given QD diameters and the well-defined formation of the discrete energy levels[3]. We develop nanogap electrodes by combining both electron beam lithography and electroless gold plating (ELGP)[4] to create a robust platform for the single QD device. The robust heterostructure ELGP nanogap electrode provides the capability to apply large voltage bias to the single PbS QD transistor across the two Au electrodes (the source and the drain) without breaking the device, which leads to an excellent yield. It enables us to tune the chemical potential of the PbS QD in and out of resonance with the given band energy. Consequently, we can clearly observe multiple regions of negative differential resistance (NDRs) in the current-voltage (I-V) characteristics of PbS QD devices. In addition, these NDRs can be additionally tuned by the application of a gate electric field. NDR is among the key features that can be used in modern electronic and logic circuits, which are expected to play essential roles in quantum and neuromorphic electronics[5]. This demonstration of single PbS-QD-based RTTs paves the way for the future development of solution-processable quantum electronic devices.

5:00 PM EL02.05.02
Multi-Facet Passivated $AgBiS_2$ Colloidal Quantum Dot for Efficient Lead-Free Optoelectronic Dongeon Kim[1], Gaeun Cho[1,2], Yun Hoo Kim[3], Ji Hyun Kwon[1], YeonWoo Oh[1], Minjung Yang[1], Seungin Jee[1], In Suh Lee[1], Min-Jae Si[1], Yujin Jung[4], Ho Yeon Yang[1], Changjo Kim[5], Han Seul Kim[6] and Se-Woong Baek[1]; [1]Korea University, Korea (the Republic of); [2]Korea Institute of Science and Technology Information, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of); [4]National University of Singapore, Singapore; [5]Los Alamos National Laboratory, United States; [6]Chungbuk National University, Korea (the Republic of)

Silver bismuth sulfide ($AgBiS_2$) colloidal quantum dots (CQD) are promising lead-free light absorbing materials for CQD optoelectronic due to their low cost, earth-abundant element, and high absorption coefficients. However, $AgBiS_2$ CQD photovoltaics are hampered by low open-circuit voltage (V_{oc}) due to the complication of passivating charge neutral (100) surface of $AgBiS_2$. Here, we propose a ligand combination for solution ligand exchange to passivate the (100) facet of the $AgBiS_2$ with improved ink stability. We demonstrated that incorporating alkali metal ions can enhance the ink stability of solution ligand exchanged CQD ink and surface ligand coverage ratio. We revealed the synergetic passivating mechanism of cation ligands on $AgBiS_2$ CQD surface through density functional theory. This multi-facet passivated $AgBiS_2$ CQD solid possessed low trap density and Urbach tail. Consequently, fabricated multi-facet passivated $AgBiS_2$ optoelectronics showed power conversion efficiency (PCE) of 8.1 %, detectivity of over 10^{11} around 400-930 nm, and response time of 400 ns. Which is the highest PCE and fastest response time among published solution ligand-exchanged $AgBiS_2$ optoelectronics showing promise for lead-free optoelectronics.

5:00 PM EL02.05.03
Colloidal InSb Quantum Dot Ink Enables III-V Group Bulk-Heterojunction Shortwave Infrared (SWIR) Photodetector Seungin Jee, Min-Jae Si, Dongeon Kim and Se-Woong Baek; Korea University, Korea (the Republic of)

Infrared (IR) optoelectronics have become important owing to their various applications, such as recognition, autonomous driving, and quantum communications. Specifically, IR detection in the shortwave IR (SWIR) spectrum (i.e., 1550 nm) is significantly important for eye safety and long-range communications. To date, the II-VI and IV-VI (e.g., HgTe, PbSe, and PbS) groups of CQDs have been widely applied to SWIR optoelectronic devices, but the use of toxic elements such as Pb and Hg limits their commercial viability. Group III-V colloidal quantum dots (CQDs) (e.g., InAs, InSb) have recently attracted significant interest as SWIR materials due to their narrow bulk bandgap and lack of toxic elements such as Pb and Hg. Herein, we synthesized of InSb CQD using the modified continuous injection method approach. This approach enables for facile tuning of bandgap at a SWIR wavelength of up to 0.9 eV with diffusion growth via monomer flux. In addition, the surface of the InSb CQD was effectively passivated and a stable CQD ink was obtained through solution-phase ligand exchange using halides and thiolates. Finally, we demonstrated a bulk heterojunction (BHJ) structure using n-type and p-type III-V CQDs. The BHJ CQD solids exhibited broad absorption up to 1600 nm and a 6-fold higher responsivity compared to the pristine InSb CQD device due to efficient charge transport.

5:00 PM EL02.05.04
Precise Doping Control of InAs Quantum Dots Using II-V Clusters Seongmin Park, Eunji Jang, Mahnmin Choi and Sohee Jeong; Sungkyunkwan University, Korea (the Republic of)

Colloidal InAs quantum dots (QDs) have tunable band gaps across the near-infrared (NIR) and short-wave infrared (SWIR) spectra, making them attractive

candidates for IR optoelectronic applications such as IR photodetectors, bio-imaging, and telecommunications. Previous studies on InAs QDs for application in optoelectronic devices have extended the size of QDs and achieved narrow size distribution based on synthetic pathways and growth mechanisms discovered through various precursors and synthesis methods. Subsequently, manipulating the electrical properties of InAs QDs through doping control has emerged as an important aspect. In particular, converting the carrier type from n-type to p-type plays a crucial role in expanding application fields. Recently, post-treatment method has been proposed that utilizes heterogeneous elements such as Zn^{2+} or Cd^{2+} precursors to lead to substitutional doping with In atoms. However, when diethylzinc or Zn-oleate was used as a p-dopant precursor, it was reported that Zn-doped p-type InAs QDs could be obtained only by highly reactive diethylzinc. Understanding the doping mechanism is essential to modulate the electrical properties of InAs QDs through doping control. Although many results of altering the carrier type have been reported, there has not yet been a clear discussion on the doping mechanism of QDs.
In this study, to understand the doping mechanism, we developed the II-V cluster as a p dopant precursor that can precisely control doping and synthesized InAs QDs with uniform size. In particular, by continuously supplying Zn-As clusters, the carrier type of the InAs QDs was gradually switched from n-type to ambipolar and eventually to p-type. This demonstrates that Zn-As clusters are effective precursors for finely controlling the carrier type. EXAFS analysis was performed to confirm the bonding between Zn and As in the InAs QD lattice, and Zn-As bonding was found only in InAs QDs showing p-type characteristics. This indicates that Zn-As clusters can be incorporated into InAs QDs by alternative doping of In with Zn under appropriate supply. To demonstrate the versatility of the II-V cluster-mediated synthesis system, Cd-doped p-type InAs QDs were also successfully synthesized using Cd-As clusters. As a result, our study provides valuable insights into the doping mechanism of InAs QDs by establishing systematic doping control conditions using II-V clusters for the first time.

5:00 PM EL02.05.05
Direct Photocatalytic Patterning of Colloidal Perovskite Nanocrystals Seongkyu Maeng, Sun Jae Park, Jaehwan Lee, Hyungdoh Lee, Jonghui Choi, Jeung Ku Kang and Himchan Cho; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

Abstract:
Perovskite nanocrystals (PeNCs) are emerging materials with significant potential for various optoelectronic applications, especially in LED technologies. For their integration into AR/VR displays, precise patterning technologies are crucial [1]. However, current techniques face challenges in fabricating high-resolution PeNC patterns while preserving their unique emissive properties, due to the inherent instability of these materials. To address this challenge, we develop a direct photocatalytic patterning that can completely preserve the optical characteristics of perovskite nanocrystals (PeNCs). Solubility change of PeNCs is achieved mainly by a photoinduced thiol-ene click reaction between surface ligands and a dual-role reagent, pentaerythritol tetrakis(3-mercaptopropionate) (PTMP), where the thiol-ene reaction is enabled at a low light intensity dose (~ 30 mJ cm^{-2}) by the strong photocatalytic activity of PeNCs. The photochemical reaction mechanism was investigated using various analyses at each patterning step. The PTMP also acts as a defect passivation agent for the PeNCs and even enhances their photoluminescence quantum yield (by ~5%) and photostability. Multicolor patterns of cesium lead halide ($CsPbX_3$) PeNCs were fabricated with high resolution (<1 mm). Our method is widely applicable to other classes of nanomaterials including colloidal cadmium selenide–based and indium phosphide–based quantum dots and light-emitting polymers; this generality provides a nondestructive and simple way to pattern various functional materials and devices [2].

5:00 PM EL02.05.06
Doped CeO2 as a Probe of Active Site Speciation for Organophosphate Degradation Emily Miura[1], Ashley Oregon[1], James J. De Yoreo[2], Chun-Long Chen[2] and Brandi M. Cossairt[1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Organophosphate degradation is an important reaction for decomposing environmentally harmful compounds and recovering phosphate ions in biological molecules.1,2 CeO2 nanocrystals have been well-studied for dephosphorylation via hydrolysis due to their stable Ce3+ and Ce4+ oxidation states. However, there is ambiguity regarding which defect properties of the CeO2 surface (Ce3+/Ce4+ oxidation state, oxygen vacancies, faceting, and dopants) are responsible for efficient hydrolysis.1,3,4 Trivalent (M3+) dopants have been used as a tool to control the defects, such as the concentration of Ce3+ and oxygen vacancies, and hence the hydrolytic activity of CeO2.5 Herein, we used trivalent transition metals and rare earth metals (M = Y3+, Cr3+, In3+, and Gd3+) to tune the active sites on the CeO2 nanocrystal surface and observed the impacts of the respective metal dopant on the cerium oxide active sites for organophosphate hydrolysis. We synthesized M-doped CeO2 via hydrothermal synthesis to yield colloidally dispersed nanoparticles that we annealed to prime the nanocrystal surface for catalysis. We characterized their properties by powder X-ray Diffraction (PXRD), X-ray photoelectron spectroscopy (XPS), and Raman spectroscopy. Finally, we evaluated the catalytic ability using organophosphate dimethyl-*p*-nitrophenol phosphate (DMNP) and UV-visible absorption spectroscopy to monitor the degradation to p-nitrophenol over time. While we observed successful doping of CeO2 by all of the dopants, their characteristics have revealed that M3+ dopants can both positively and negatively impact CeO2 in our system. We propose that the CeO2 is extremely sensitive to dopants that cause excessive lattice strain, Ce3+ ions, and oxygen vacancy defects. Thus, CeO2 requires a delicate balance where the active sites are an ensemble of defects in ideal concentration and orientation on the nanocrystal surface to reach high catalytic efficiency.

5:00 PM EL02.05.07
Compositionally Engineered Ternary PbS_xSe_{1-x} Quantum Dots Active in Short-Wavelength Infrared Region Seohee Park[1,2], Yongwoo Jeon[1,2], Sung Nam Lim[1], Shin Ae Song[1], Kiyoung Kim[1], Sohee Jeong[2] and Ju Young Woo[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Lead chalcogenide Quantum Dots (QDs) possess versatile attributes, primarily due to their large exciton Bohr radius and extensive infrared radiation

absorption capabilities. Among them, PbS and PbSe QDs have been integrated into various optoelectronic devices, such as solar cells and photodetectors, showcasing superior performance. Notably, their excellent absorption properties in the SWIR region underscore their potential in LiDAR systems. Although PbSe QDs display superior mobility characteristics compared to PbS,[1] they have a lower chemical yield. Furthermore, lead chalcogenide QDs exhibit size-dependent air-stability,[2] with PbSe showing significantly compromised air-stability, especially in the SWIR region. PbS_xSe_{1-x} QDs might provide an alternative solution to overcome these critical shortcomings.

Long Hu et al. highlighted enhanced mobility in FETs and better PCE in solar cells through the simple admixture of PbSe with PbS.[3] Wanli Ma et al. described PbS_xSe_{1-x} QDs that exhibited improved J_{sc} compared to PbS and enhanced V_{oc} relative to PbSe.[4] Despite the potential of PbS_xSe_{1-x} QDs in photovoltaic applications, a deeper investigate into their air-stability and other material properties remains essential. Additionally, studies to date have not conclusively explored properties concerning compositional shifts, primarily because inevitable wavelength alterations occur with changes in the anion ratio.

We successfully synthesized PbS_xSe_{1-x} QDs active in the SWIR region through a simple synthesis method by injecting a mixture of anion precursors. The QDs, synthesized uniformly, were compositionally engineered to absorb within a consistent wavelength range. Compared to the chemical yield observed in PbSe QDs, there was a marked enhancement for our PbS_xSe_{1-x} QDs with the yield being approximately three times greater. Under ambient conditions, the blue shift phenomenon resulting from oxidation is reduced and surface analysis provided evidence that the formation of Se oxide (either SeO_2 or SeO_3^{2-}) was notably diminished. The mobility in FETs was improved compared to that of PbS QDs and PbS_xSe_{1-x} QDs ink was produced for the first time through a ligand exchange from long chain to short. Moreover, PbS_xSe_{1-x} in the NIR region demonstrated solar cell efficiencies exceeding 10%, the highest on record. These findings emphasize the promising future of PbS_xSe_{1-x} QDs in infrared optoelectronic applications.

5:00 PM EL02.05.09

π-SnS Colloidal Quantum Dots for Field-Effect Transistors Thanyarat Phutthaphongloet[1,2,3], Ricky Dwi Septianto[1], Retno Miranti[1], Nobuhiro Matsushita[2], Yoshihiro Iwasa[1] and Satria Bisri[1]; [1]RIKEN CEMS, Japan; [2]Tokyo Institute of Technology, Japan; [3]Tokyo University of Agriculture and Technology, Japan

Significant progress in QD optoelectronic devices and energy devices has been made mainly by Pb-based, Hg-based, and Cd-based binary compounds, or the involvement of rare noble metal alloys. While some have reached commercial markets, their high degree of toxicity is the primary concern for practical applications. We recently developed a rapid one-pot method to synthesize a novel phase of tin monosulfide quantum dots (QDs), π-SnS[1]. This cubic QD phase exhibits a larger band gap bandgap (1.53–1.69 eV) than the other SnS phase (the orthorhombic α-SnS), and more thermodynamically stable. This method yields QD radii below 10 nm, allowing us to explore the quantum confinement effect, which can be utilized for high-performance photodetector devices. Despite these prospects, obtaining the scalable synthesis of this SnS QD phase with good monodispersity is still challenging. On the other hand, the electronic transport properties of this material have never been investigated, which will directly impact the design of its practical uses for electronic or optoelectronic device applications.
Here we report a controllable synthesis of monodispersed π-SnS QDs and demonstrate the field-effect transistors of colloidal π-SnS QD assemblies. We can synthesize the SnS QDs with diameters ranging from 5 nm to 8 nm and better air stability through synthesis protocol optimizations than the previously reported method. Furthermore, by performing the integration of synthesis and optical absorption measurement, we could fine-tune the synthesis methods so that we can obtain the synthesis condition boundary to obtain either π-SnS QDs or α-SnS. Synthesis temperature is found to become the critical factor that can lead to different end results. The π-SnS phase was generated at a specific injection temperature range.
We are able to fabricate field-effect transistors of the π-SnS by adapting the methods of performing ligand exchange in the solid-state phase during the layer-by-layer deposition of the QD monolayers.[2,3] The oxide-gated π-SnS QD FETs exhibit p-type characteristics with charge carrier mobility values comparable to the early development of many other metal chalcogenides QDs. This investigation will provide insights into the factors influencing the formation of different phases of SnS QDs. Furthermore, the first success of demonstrating transistor operation of π-SnS QD assemblies presents new opportunities to investigate their charge carrier transport for developing environmentally friendly QD electronics.

Chemically and Electronically Active Metal Ions on InAs Quantum Dots for Infrared Detectors Jaeyoung Seo, Seongchan Kim, Namyoung Gwak, Seungki Shin and Nuri Oh; Hanyang University, Korea (the Republic of)

Indium arsenide (InAs), one of the III-V compound semiconductors, has a relatively small carrier effective mass, direct bandgap, and small exciton binding energy, which are attractive properties for state-of-the-art electronic and optoelectronic applications. Due to the quantum confinement effect, the nano-sized crystals of InAs can possess additional benefits, including tunable optical bandgap ranging from near-infrared (NIR) to short-wave infrared (SWIR) and versatile solution processability. Given these advantages, the IR-responsive InAs quantum dots (QDs) can be integrated as a thin solid form into various IR photosensors, enabling to apply machine vision, imaging sensors, and telecommunications. For high performance of QD-based photodetectors, it is important to obtain highly monodisperse InAs QDs and control the surface defects that can enhance the charge transport properties in QD films.
The synthesis of InAs QDs is not, however, as simple as the ionic compound semiconductor nanocrystals, because of their strong covalent bonding nature and the lack of group 15 precursors. Previous researches using continuous injection and seeded growth methods have been focused on reactivity control of highly reactive silylated or germylated arsenic precursors, which have difficulty handling to some extent due to toxicity and pyrophoric properties of the precursors. Meanwhile, co-reduction methods with commercially available arsenic precursors are another facile approach for InAs QD synthesis. The simple heat-up process along with reducing zinc and arsenic precursors together simultaneously, may be suited for large-scale production, but it normally requires a subsequent size selection process because of a broad size distribution. Additionally, as the nanoscale III-V semiconductors suffer from the oxidative defects, the surface of InAs QDs is also prone to oxidation. It is required to eliminate the oxidative defects so that the QDs are electronically connected for efficient charge extraction without charge trapping.
In this work, we propose the synthesis approach to improve monodispersity of InAs QDs based on the co-reduction method. We introduce zinc halide

precursors as a form of coordination complex into the indium and arsenic reaction mixtures. During the synthesis, the zinc ions are chemically passivating the surface of InAs QDs, allowing to induce size-focusing as well as to remove surface defects. The surface oxide-free InAs QDs are stable enough as a colloidal form even with weakly bound ligands to facilitate the follow-up process. When InAs QDs are integrated into the infrared photodiode as an IR absorber, the surface zinc ions can electronically modulate the energy levels and carrier concentrations. The IR photodiodes with InAs:Zn QD layers exhibit higher IR sensitivity and faster response than the bare InAs QDs. We anticipate that the unique synthesis approach for InAs QDs with electronically active zinc ions should inspire QD research into a new direction for NIR and SWIR applications.

5:00 PM EL02.05.11
Interface Stoichiometry Control of InP Heterostructure Quantum Dots for Efficient Light-Emitting Diodes Seungki Shin, Nuri Oh and Jina Na; Hanyang University, Korea (the Republic of)

Colloidal quantum dots (QDs) have garnered extensive attention in optoelectronic applications due to excellent optical and electrical properties. A significant characteristic of colloidal QDs is the size-dependent optical properties. The band gap can be tuned by adjusting the particle size, enabling QDs to cover the entire visible light spectrum and near-infrared region which allows the QDs as a light-emitting diodes (LEDs), bio-imaging, photodetector, and solid-state lighting. The unique size-dependent characteristic of QDs is originate from quantum confinement effect which is observed when the QDs have smaller diameter than exciton Bohr radius. For example, the exciton Bohr radius of InP is 15 nm and 5.3 nm for CdSe. The size limitation of QDs compels the sophisticated synthesis of the emissive core materials on a nanometer scale. However, there is a rise in the surface-to-volume ratio when the size of the particles diminishes, leading to a significant increase in surface imperfections.

Indeed, the InP core exhibits photoluminescence quantum yields (PLQYs) under 1 % due to the surface defects. Forming a core/shell heterostructure in nanocrystals helps the core materials emit photons effectively. Epitaxially grown shells passivate the surface defects, such as dangling bonds, and provide the better confinement of electron/hole wavefunctions with type I band alignment. This strategy allows the InP-based QDs, which have heavy metal-free composition, to achieve near-unity PLQY. For a shell material, group II-VI materials such as ZnSe and ZnS are widely employed because they possess the wide energy band gap and low lattice mismatch with InP core. However, there is a fundamental interface misfit between the III-V composition of the InP core and the II-V composition of the shell materials. The heterogeneity between the III-V core and II-VI shell could impede radiative recombination or charge carrier transport.

In this study, we investigate the effects of interface stoichiometry in InP-based core/shell structure QDs on optical and electrical properties. We control the chemical composition at interface of InP core/shell QDs to improve the charge carrier injection efficiency in QD-based LEDs (QD-LEDs) by in-situ selenium treatment. This strategy allows the excess indium and zinc ions to be anchored on the surface during the InP core synthesis, resulting in the formation of In/Zn thin alloy layer. The surface stoichiometry of the in-situ Se-treated InP core can be tuned by controlling the feed ratio of indium and zinc precursor. The change of binding energy of selenium depending on the In/Zn feed ratio in X-ray photoelectron spectroscopy (XPS) analysis confirmed the formation of In/Zn alloy layer. Photoluminescence (PL) analysis showed that the InP core with In/Zn alloy layer exhibit higher PLQYs than InP core with Zn-rich interface even after thick shell growth. Ultraviolet photoelectron spectroscopy (UPS) analysis revealed that the in-situ Se treatment modifies the energy band alignment, leading to an enhanced charge carrier balance in QD-LEDs. As a result, the QD-LEDs based on the Se-treated InP QDs show peak current efficiency as 31.5 cd/A and a maximum luminance of 26370 cd/m^2 for green emission.

Luminescence and Covalency in Yb^{3+}-Doped CrX_3 (X = Cl, Br, I) Van der Waals Compounds Thom Snoeren, Kimo Pressler, Kelly M. Walsh and Daniel R. Gamelin; University of Washington, United States

The layered 2D van der Waals ferromagnets CrX_3 (X = Cl, Br, I) are some of the most promising and well-studied materials for spintronics and related quantum systems. Despite potential applications in quantum sensing and as single-photon sources, investigations on the optical properties of CrX_3, characterized by broad *d-d* photoluminescence (PL), are severely lacking. The incorporation of carefully designed atomic defects such as lanthanides opens up a pathway to modulate the overall electronic and magneto-optical properties. Here we report preparation, structural characterization, and spectroscopic studies of all three CrX_3 compounds doped with the optical impurity Yb^{3+}. 4 K PL measurements show efficient sensitization of Yb^{3+} luminescence upon photoexcitation into lattice absorption bands for all three compounds, converting their nondescript broadband *d-d* PL into sharp *f-f* emission. The PL of $CrCl_3$:Yb^{3+} and $CrBr_3$:Yb^{3+} occur at energies typical for $[YbX_6]^{3-}$ with these halides, with PL decay times of 0.5 – 1.0 ms at 4 K, but CrI_3:Yb^{3+} displays anomalously low-energy Yb^{3+} emission and an unusually short PL decay time at 4 K. Data analysis and angular overlap model (AOM) calculations show that Yb^{3+} in CrI_3:Yb^{3+} has a lower spin-orbit splitting energy than reported for any other Yb^{3+} in any other compound. We attribute these observations to exceptionally high covalency of the Yb^{3+} *f* orbitals in CrI_3:Yb^{3+} stemming primarily from the shallow valence-shell ionization potentials of the iodide anions. These results provide rare fundamental insights into the electronic structure and luminescence of the remarkably underexplored $[YbI_6]^{3-}$ motif.

5:00 PM EL02.05.13
Thermally-Induced Isomerization of Prenucleation Clusters during the Prenucleation Stage of CdTe Quantum Dots Zhe Wang and Kui Yu; Sichuan University, China

The evolution of prenucleation clusters in the prenucleation stage of colloidal semiconductor quantum dots (QDs) has remained unexplored. With CdTe as a model system, we show that substances form and isomerize prior to the nucleation and growth of QDs. Called precursor compounds (PCs), the prenucleation clusters are relatively optically transparent and can transform to absorbing magic-size clusters (MSCs). When a prenucleation-stage sample at 25, 45, or 80 °C is dispersed in a mixture of cyclohexane (CH) and octylamine (OTA) at room temperature, either MSC-371, MSC-417, or MSC-448 evolves with absorption peaking at 371, 417, or 448 nm, respectively. We propose that PC-371 forms at 25 °C, and isomerizes to PC-417 at 45 °C and to PC-448 at 80 °C. The PCs and MSCs are quasi isomers. Relatively large and small amounts of OTA favor PC-371 and PC-448 in dispersion, respectively. The present findings suggest the existence of PC-to-PC isomerization in the QD prenucleation stage.

Ligand Boosting of $CsPbBr_3$ Nanoplatelets for Highly Stable Efficiency Blue LED Subin Yun, Artavazd Kirakosyan, Min-Gi Jeon, Joonseok Kim and Jihoon Choi; Chungnam National University, Korea (the Republic of)

Perovskite light-emitting diodes (PeLEDs) with an external quantum efficiency (EQE) exceeding 20% have been achieved in both green and red emissions. On the other hand, the efficiency of blue perovskite materials has lagged far behind, with EQEs of 12.3% emitting the sky blue (wavelength at 475~490 nm) and 8.8% emitting the blue (wavelength at 460~475 nm). Several strategies have been proposed for the synthesis of blue-emitting perovskite nanocrystals such as (i) mixed halide perovskites and (ii) low-dimensional nanoplatelets (NPLs). Whereas the mixed halide perovskites show a variable energy bandgap, they have critical drawbacks such as a deep trap state in the bandgap owing to the formation of Cl^- vacancies and phase segregation arising from ion migration. In $CsPbBr_3$ NPLs, the emission wavelength can be controlled depending on the number of $[PbBr_6]^{4-}$ layers. However, the high density

of surface defects in 2D perovskite nanocrystals results in a low photoluminescence quantum yield (PLQY), which imposes challenging issues. Here, we demonstrate that the PLQYs of $CsPbBr_3$ NPLs could be significantly enhanced by adopting inorganic ligands, which can effectively passivate the surface defects. To boost the PL and PLQY of NPLs, several organic/inorganic ligands (such as $PbBr_2$, $C_8H_{12}BrN$, and N_2H_3Br (HZBr) are used. The PLQY of $CsPbBr_3$ NPLs is significantly enhanced from 34% to 90% when HZBr is used as the ligand can be effectively coordinated at the surface defects of the $CsPbBr_3$ NPLs. In addition, we conducted the cryogenic PL spectroscopic measurement. Interestingly, in the HZBr-treated sample, the activation energy for carrier trapping is increased from ~180 to 290meV indicating that the surface vacancies and the associated defect states are well passivated. Furthermore, the exciton-longitudinal optical (LO) phonon coupling coefficient and LO phonon energy are reduced from ~280 to 100meV and from ~30 to 20meV, respectively. It suggests that the contribution of exciton-LO coupling to the broadening of PL became weaker.

Chemical Modification of CdSe Nanomaterials through Carborane Ligand Exchange Eugenia S. Vasileiadou, Victoria Rubio, Elijah Cook, Tasnim Ahmed, Alexander Spokoyny and Justin Caram; University of California, Los Angeles, United States

Inorganic nanocrystals capped with surfactant-like organic ligands exhibit a broad range of properties that emerge from the combination of the individual inorganic-organic components. By expanding towards functional organic ligands that are bounded on the nanocrystal surface, the charge-transport and biocompatibility of nanocrystals are enhanced, thus achieving greater chemical control of nanomaterials for targeted applications. Herein, we functionalize CdSe nanocrystals through binding with electron-donating carborane ligands ($C_2B_{10}H_{12}$). The synthetic preparation for CdSe quantum dots (QDs) and CdSe nanoplatelets is developed where variable concentration ligand exchange of the CdSe nanomaterials with the carborane ligands leads to changes in the photoluminescence (PL) intensity. Post-synthetic ligand exchange of the native oleate capping ligands for carborane results in a red-shift of the optical band gap of the studied CdSe QDs, while their colloidal stability is maintained based on TEM imaging. Fourier-transform infrared (FTIR) analysis demonstrates the successful incorporation of the carborane ligands onto the CdSe surfaces with the characteristic B-H resonances at 2600 cm^{-1} and 1250-600 cm^{-1} in the spectrum. Furthermore, we explore tuning the surface dipole of the CdSe core from a non-functional oleate ligand to functional carborane dipole, where the carborane dipole enables long-range ordering and higher control on the electronic properties of the resultant CdSe core/carborane shell. Altogether, this work illustrates the unique aspects of functional surface carborane ligands in controlling the optoelectronic and dipole properties of CdSe nanocrystals, which could advance their potential applications in solid-state device and bioimaging applications.

Structural Transformations of Group III-V and II-VI Magic-Sized Clusters Driven by Atomic-Bond Exchanges Joongoo Kang; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Multistep nucleation and growth of quantum dots (QDs) involves the utilization of kinetically persistent, small inorganic clusters, specifically magic-sized clusters (MSCs), as intermediates. Therefore, understanding and control of the reactivity (or stability) of MSCs is essential to such non-classical QD synthesis. In this talk, using *ab initio* molecular dynamics (AIMD) simulations, we reveal the destabilization process of a carboxylate-ligated $In_{37}P_{20}$ MSC, induced by a surface ligand network modification beyond a critical limit.[1] At elevated temperatures, the release of three $In(O_2CR)_3$ subunits triggers the sudden loss of stability in the remaining $In_{34}P_{20}$ core, leading to structural transformations through In–P bond breaking and rearrangement. This isomerization manifests as an In–P bond exchange between a pair of In atoms, resulting in a “rupture” on the cluster surface. The structural disruption in the InP cluster causes noticeable changes in the simulated UV–vis absorption spectra and XRD patterns, which agree well with experimental findings[2] on MSC destabilization induced by reactions with primary amines at low temperatures. Our analysis elucidates that the MSC instability is driven by the intricate interactions between the surface ligand network and the inorganic core of the group III-V MSC. Finally, we discuss the fundamental differences in the isomerization of the InP MSC and a related CdS cluster of similar size,[3,4] highlighting the distinct nature of surface ligand networks in the group III–V and II–VI cluster systems.

9:15 AM *EL02.06.03
The Surface Chemistry of Colloidal Semiconductor Quantum Dots Ivan Infante; BCMaterials - Basque Center of Materials, Spain

Despite significant progress in recent years in understanding the chemical reactions occurring on the surfaces of II-VI, III-V, and lead halide perovskite quantum dots (QDs), there are still fundamental questions that remain unanswered regarding the nature of QD surfaces, QD-ligand interactions, and the formation of trap states. Addressing these aspects is crucial for enhancing the optoelectronic efficiency of QDs.

In this study, we present a pioneering multiscale modeling approach that combines Density Functional Theory and Molecular Dynamics simulations. Our approach encompasses QDs ranging from small to real-sized QDs passivated with oleate ligands and immersed in organic solvents. Through this methodology, we gain invaluable insights into the surface characteristics and the binding energies of ligands under different experimental conditions. This methodology not only provides a deeper understanding of the intricate behavior of colloidal semiconductor nanocrystals but also paves the way for future advancements in their diverse applications.

9:45 AM EL02.06.04
Engineering The Surface Chemistry of Colloidal InP Quantum Dots for Charge Transport Tianshuo Zhao[1,2], Qinghua Zhao[2], Jaeyoung Lee[2], Shengsong Yang[2], Han Wang[2], Ming-Yuan Chuang[2], Yulian He[3], Sarah M. Thompson[2], Guannan Liu[2,3], Nuri Oh[2], Christopher B. Murray[2] and Cherie R. Kagan[2]; [1]The University of Hong Kong, Hong Kong; [2]University of Pennsylvania, United States; [3]Yale University, United States

Colloidal InP quantum dots (QDs) have emerged as potential candidates for constructing nontoxic QD-based optoelectronic devices. However, charge

transport in InP QD thin-film assemblies has been limitedly explored. Herein, we report the synthesis of ~8 nm edge length (~6.5 nm in height), tetrahedral InP QDs and study charge transport in thin films using the platform of the field-effect transistor (FET). We design a hybrid ligand-exchange strategy that combines solution-based exchange with S^{2-} and solid-state exchange with N^{3-} to enhance interdot coupling and control the n-doping of InP QD films. Further modifying the QD surface with thin, thermally evaporated Se overlayers yields FETs with an average electron mobility of 0.45 $cm^2 V^{-1} s^{-1}$, ~10 times that of previously reported devices, and a higher on–off current ratio of 10^3–10^4. Analytical measurements suggest lower trap-state densities and longer carrier lifetimes in the Se-modified InP QD films, giving rise to a four-time longer carrier diffusion length.

10:30 AM *EL02.06.05
Photogenerated Spin states in Quantum Dot – Molecule Conjugates Jacob Olshansky; Amherst College, United States

The inherent spin polarization in photogenerated spin-correlated radical pairs makes them promising candidates for quantum computing and quantum sensing applications. Notably, these states are spin-polarized (non-Boltzmann populated) at moderate temperatures, and can therefore be initialized in well-defined quantum states. This feature allows them to be probed and manipulated using microwave pulses within standard electron paramagnetic resonance spectrometers equipped with pulsed lasers. Quantum dot – molecule conjugates offer a tunable platform for hosting these spin-correlated radical pairs. We have therefore designed a series of quantum dot – molecular systems that can produce photogenerated spin-polarized states. The molecules are chosen for their ability to undergo efficient charge separation, and the nanoparticle materials, ZnO quantum dots, are chosen for their promising spin properties. Transient and steady state optical spectroscopy performed on ZnO quantum dot–molecular conjugates shows that reversible photogenerated charge separation is occurring. Transient and pulsed electron paramagnetic resonance experiments are then performed on the photogenerated radical pair, which demonstrate that (1) the radical pair is polarized at moderate temperatures and well modeled by existing theories, (2) the spin states can be accessed and manipulated with microwave pulses, and (3) the spin system can be tuned with quantum dot size and molecular linker length. This work opens the door to a new class of promising qubit materials that can be photogenerated in polarized states and hosted by highly tailorable inorganic nanoparticles.

11:00 AM EL02.06.06
Erbium Spin Defects in Colloidal Ceria Nanocrystals with Near Microsecond Spin Coherence Joeson Wong[1,2,1], Arashdeep Thind[3], Jasleen Bindra[2], Jiefei Zhang[2,2], Gregory Grant[2,1], Christina Wicker[1], Yuxuan Zhang[1], Jens Niklas[2], Oleg Poluektov[2], Robert F. Klie[3], F. Joseph P. Heremans[2,1,2], David Awschalom[1,2,2] and Paul Alivisatos[1,1,1]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States; [3]University of Illinois at Chicago, United States

We experimentally demonstrate spin coherence times approaching a microsecond in erbium doped ceria nanocrystals with an ensemble average level of a single erbium per nanocrystal. To achieve these spin coherence times, ceria was chosen as a host material with a low natural abundance of nuclear spins. As a result, we observe population lifetimes that approach a millisecond, suggesting substantial improvements to the spin coherence should be possible. We postulate that the spin coherence is limited by the nuclear spin bath of hydrogen atoms from the oleic acid ligands on the surface of the nanocrystal. Quantum beats are observed which correspond to the Larmor frequency of hydrogen, which further suggests the erbium ions are sensitive to the nearby hydrogen nuclei. Scanning transmission electron microscopy measurements combined with electron energy loss spectroscopy further show that Ce^{3+} and O vacancies are prevalent on the surface of the nanocrystal, likely playing a role in the observed spin coherence and lifetime. Nonetheless, the spin coherence already demonstrated suggests that spin defects in nanocrystals are a promising materials platform for quantum information processing.

11:15 AM *EL02.06.08
Colloidal Atomic Layer Deposition enables Synthesis of Nano-Heterostructures with Atomic Layer Precision Dmitri V. Talapin; University of Chicago, United States

In contrast to molecular systems, which are defined with atomic precision, nanomaterials generally show some heterogeneity in size, shape, and composition. The sample inhomogeneity translates into a distribution of energy levels, band gaps, work functions, and other characteristics. The lack of atomistic control during nanomaterial synthesis also limits our ability to perform “total-synthesis” of sophisticated nano-heterostructures with precisely arranged multiple components and fine-tuned properties. We discuss a general synthetic strategy which largely circumvents these limitations of traditional colloidal synthesis. Colloidal Atomic Layer Deposition (c-ALD) allows significant reduction of inhomogeneity for nanomaterials without compromising their structural perfection. We report a novel realization of c-ALD step sequence which significantly improves synthetic control and quality of synthesized nanomaterials. In traditional gas-phase ALD, the substrate and gaseous reactants act as the stationary and mobile phases, respectively. Such distinction facilitates removal of unreacted precursors by pulsing inert gas after each half-reaction. For c-ALD, we inverted the stationary and mobile phases – reactants form the stationary phase while the substrate is moved in and out of the reactor as the mobile phase. This approach brings c-ALD closer to traditional ALD and is expected to make it a similarly powerful and versatile technique. Our improved c-ALD enables synthesis of epitaxial nano-heterostructures of unprecedented complexity, ultimately enabling bandgap and strain engineering in colloidal nanomaterials synthesized with close-to-atomistic accuracy. Improved synthetic control elucidates the effects of quantum confinement and strain on the properties of semiconductor nanostructures.

11:45 AM EL02.06.09
Illuminating the Impact of Solvent and Particle Properties on Optical Manipulation of Colloidal Nanomaterials Brandon Reynolds and Matthew Crane; Colorado School of Mines, United States

The precise control over the placement of colloidal nanomaterials has led to enticing emergent phenomena including transport through superlattices, strong coupling with optical cavities for quantum applications, and hybridization when different colloidal materials are interfaced. These applications and many more require precise spatial placement of nanoparticles as well as precise control over orientation. As an example, defects in wide-band gap nanomaterials or spins in semiconductor nanomaterials offer promising solutions for quantum technologies that are inaccessible to bulk materials, if the colloidal materials can be precisely positioned in an optical cavity. This requires a tool that acts on a single colloid in three dimensions, controls the angle of the colloid, and is applicable to a variety of particles and a variety of solvents. Optical manipulation methods such as optical trapping provide a unique platform that addresses these criteria, by trapping a particle in three dimensions and allowing for orientation control through polarization. However, we have limited understanding of how optical manipulation may change in the environments necessary for colloidal nanomaterials – *i.e.* organic solvents, ligands, or high refractive index materials. Here, we investigate the impact of particle composition, geometry, and size as well as solvent identity on optical trapping forces using a combination of experiments and multiphysics simulations. We investigate the impact of key variables such as viscosity and refractive index on optical trapping strength. Combining these results, we identify key relationships between solvent and colloidal nanomaterials to manipulate and orient nanomaterials and suggest guidelines to further improve optical manipulation.

SESSION EL02.07: Surface Chemistry, Electronic and Optical Properties of Semiconducting Nanocrystals II
Session Chairs: Emily Miura and Hao Nguyen
Thursday Afternoon, April 25, 2024
Room 347, Level 3, Summit

1:30 PM *EL02.07.01
Dopants and Defects in Colloidal Nanocrystals Daniel R. Gamelin; University of Washington, United States

Colloidal inorganic nanocrystals offer new opportunities for studying, cultivating, and exploiting electronic and optical effects at the nanoscale. New forms of magnetic materials at the nanoscale can reveal new behaviors relevant to high-density spintronics, spin-photonics, or related technologies, and new emissive nanostructures can open opportunities for additive manufacturing of conventional or quantum optoelectronics. This talk will describe the synthesis and physical properties of colloidal semiconductor and insulator nanostructures integrating dopants and defects as a route to controlling photonic functionality. The talk will describe the synthetic development, optical, and electronic-structural properties of these materials.

2:00 PM *EL02.07.02
Hot Electrons and Coherent Photons from Strongly Quantum-Confined Lead Halide Perovskite Nanocrystals and Their Assemblies Dong Hee Son; Texas A&M University, United States

Imposing strong quantum confinement in lead halide perovskite nanocrystals enhances the electronic interactions between charge carriers and dopants within each nanocrystal and promotes the delocalization of the exciton wavefunction in the closely packed assemblies of these nanocrystals. We investigated: (i) the generation of hot electrons via exciton-to-hot electron upconversion in strongly quantum-confined cesium lead bromide ($CsPbBr_3$) nanocrystals doped with Mn^{2+} and (ii) the coherent photon emission from the superlattices of $CsPbBr_3$ quantum dots, where strong quantum confinement plays a significant role. The enhanced exciton-dopant interaction in the more strongly confined $CsPbBr_3$ nanocrystals proved beneficial for hot electron upconversion and allowed for the utilization of the long-lived dark exciton in such processes at low temperatures. The closely-packed QD superlattice of the strongly confined CsPbBr3 quantum dots, which are 4 nm in size, exhibited superfluorescence from excitons delocalized across many quantum dots, rather than from an ensemble of electronically non-coupled quantum dots, especially as the temperature decreased. Positioning the superlattice within the micro-ring resonance cavity further amplified the coherent emission from the interconnected quantum dots.

2:30 PM EL02.07.03
Assessing Photoinduced Carrier and Heat Transfer in Tin-Doped Indium Oxide Nanocrystals Sara Russo, Lauren Cisneros and Matthew Crane; Colorado School of Mines, United States

Degenerately doped semiconductor nanocrystals exhibit tunable localized surface plasmon resonances with strong optical absorption cross sections and band gaps. Upon excitation, these materials produce non-equilibrium carrier distributions that rapidly relax, presenting a brief window for utilization. These features mark plasmonic nanocrystals as promising candidates for new applications that require efficient light absorption and highly directed energy and carrier utilization, such as photodetectors, photovoltaics, and photocatalysts, if we can understand and engineer efficient transport mechanisms. Here, we investigate hot carrier and heat transfer from prototypical tin-doped indium oxide (ITO) nanocrystals to adsorbates as a model system for harvesting and utilizing light in plasmonic semiconductor nanocrystals. Using transient absorption spectroscopy, we track carrier and energy transfer from ITO nanocrystals to adsorbates and evaluate the impact of aliovalent dopant concentration, wavelength, and energy level alignment. We find that these variables strongly impact carrier transfer to adsorbates. Utilizing local temperature reporters, we simultaneously quantify heat transfer from ITO nanocrystals into their environment. Combining these results, we suggest general design rules to optimize carrier energy transfer from plasmonic semiconductors.

3:15 PM *EL02.07.04
Anion Exchange in Discretely Grown Semiconductor Nanomaterials Yalei Deng, Xinke Kong, Lin Ru and Yuanyuan Wang; Nanjing University, China

Ion exchange is emerging as a powerful post-synthetic strategy to engineer unprecedentedly high-quality nanomaterials by tuning chemical composition, crystal phase, doping, and morphology. Several heterostructured nanocrystals have been prepared through cation exchange (CE) reactions. However, in contrast to CE, the study of anion exchange (AE) processes is still in its infancy. Since the larger size and slower migration rate of anions, the exchange process usually requires high reaction temperatures, which leads to the reconstruction of the original frameworks, thus causing structural changes or collapse. Here, we used magic size clusters (MSCs) and nanoplatelets (NPLs), two discretely grown nanomaterials, as model systems to study the AE. We showed that two different AE pathways exist in the transition of MSCs, which are determined by the MSCs' compositions and structures. In addition, we achieved AE in two-dimensional nanocrystals, by which either type I or type II NPLs can be obtained without the Kirkendall effect. The heterostructured NPLs show improved optical properties. For example, the quantum efficiency of CdSe-CdS NPLs at 462 nm can be increased from 13.63% to 63.68%.

3:45 PM EL02.07.05
High Mobility and Low Trap Density in 3D PbS Quantum Dots Superlattices by PbI_2 Passivation Jacopo Pinna[1], Elisa Pili[1], Razieh Mehrabi Koushki[1], Dnyaneshwar S. Gavhane[1], Francesco Carlà[2], Bart J. Kooi[1], Giuseppe Portale[1] and Maria Antonietta Loi[1]; [1]University of Groningen, Netherlands; [2]Diamond Light Source, United Kingdom

Lead chalcogenide colloidal quantum dots (CQDs) are one of the most promising materials to revolutionize the field of optoelectronics. This is due to their unique optical properties, namely the bandgap tunability in a wide wavelength range (800 – 3000 nm). Even if the past two decades of research resulted in significant development of this technology, these materials still show moderate mobility and high trap densities, which are a limitation for their applications. Most of the problems stem from the disordered nature of the deposited films and poor control over the ligand exchange (LE). It is predicted that ordered assemblies of CQDs, the so-called superlattices (SLs), should display mobilities up to four orders of magnitude higher than the disordered counterparts. Recently, we demonstrated mobilities above 270 cm^2/Vs in 3D SL of PbSe CQDs[1], when surface traps are filled using an ionic-gel gate. Nevertheless, using PbSe CQDs is undesirable for applications due to its tendency to oxidise very easily. On the other hand, PbS shows much higher stability even in air when proper passivation strategies are adopted. While there are several reports in the literature on PbS-based superlattices, the focus has been on structural characterisation and often transport properties are not measured. A recent report on 2D square SL with PbS CQDs demonstrated electron mobilities of 15 cm^2/Vs with ionic liquid gating.

Here we demonstrate for the first time highly ordered 3D SLs of electronically coupled PbS CQDs and an effective trap passivation with iodide-based

ligands. To be suitable for photodetection, we grow films up to 220 nm of thickness with outstanding coherent ordering, both in-plane and along the thickness, as proved by electron microscopy and advanced x-ray scattering techniques. To achieve electronic coupling, we perform LE with ethylenediamine which, despite the noticeable thickness, removes the oleic acid ligand. We finally test the transport properties with an ionic-gel gated field-effect transistor and observe n-type transport, high conductance, and modulation. The measured electron mobilities achieve a maximum of 220 cm^2/Vs, which is one order of magnitude above the state-of-the-art for PbS SLs with comparable gating, proving how the 3D structures outperform the 2D ones thanks to the better ordering. Finally, a passivation treatment with PbI_2 is shown to reduce the surface trap density as demonstrated by a significant reduction of the subthreshold swing. The combination of strong absorption in the short-wavelength infrared range and the record charge mobilities make these metamaterials an excellent candidate for fast-response photodetector in a wavelength range where traditional semiconductors perform poorly despite the high cost. We also demonstrate how surface trap passivation will be a key element to control in order to implement these 3D SLs in optoelectronic devices.

4:00 PM EL02.07.06
Optical and Electrical Investigations to Unveil Charge Storage and Transport Mechanisms in ITO Nanocrystals . Anjana P. Muraleedharan[1,2], Nicolo Petrini[1], Sidharth Kuriyil[1], Luca Rebecchi[1], Priyadarshi Ranjan[1], Mukesh Kumar Thakur[1], Andrea Rubino[1], Nicola Curreli[1] and Ilka Kriegel[1]; [1]Italian Institute of Technology, Italy; [2]University of Genova, Italy

Transparent conducting oxide (TCO) zero-dimensional (0D) nanocrystals (NCs) such as Indium-Tin-Oxide (ITO) are of special importance for opto-electrical devices because of their unique features of optical transparency in the visible region and controllable electrical conductivity. In order to fully realize the potential of these materials to integrate them into useful devices, greater understanding of the charge transport in nanocrystal thin films along with a deep insight into the charge storage mechanism in solution is necessary[1]. Doped metal oxide nanocrystals (MO NCs) are potential candidates for accumulating multiple electrons through the light induced doping process termed 'Photodoping'. It has been demonstrated recently that metal oxide (MO) nanocrystals can act as nanocapacitors when coupled with a suitable system acting as hole or electron acceptor, storing the charges that are generated upon illumination with photon energy above the MO bandgap[2].ITO NCs with different In_2O_3 (IO) shell thicknesses are charged using a UV LED in a controlled and inert atmosphere, simultaneously monitoring the changes in the absorption spectra over time with time resolution of few seconds. In this way we extract information on the dynamics of the light-driven charging process of a set of ITO/In_2O_3 core/shell (ITO/IO) NCs with "artificial" depletion regions.[3] In addition, we leverage a metal-insulator-metal device configuration to probe the electronic transport in Tin doped Indium Oxide nanocrystals (ITO nanocrystals) to understand the electrical effects of photodoping.[4] The electronic conduction in ITO NC thin film is studied in dark and light (UV) conditions in order to understand light- induced charge generation. ITO, being a wide bandgap material with high native doping levels, manifest electronic conduction that resembles semiconductor behaviour.

The Role of Colloidal Er-Doped SiO_2 Thin-Film Interfaced with Czochralski Silicon on Enhanced Bandgap Emission for Optoelectronic Applications Sufian Abedrabbo[1], Anthony T. Fiory[2] and Nuggehalli M. Ravindra[3]; [1]Khalifa University, United Arab Emirates; [2]Integron Solutions LLC, United States; [3]New Jersey Institute of Technology, United States

Colloidal silica bulk glass and coatings have been studied extensively for many years. In this work we report a new optoelectronic phenomenon introduced by interfacing Er-doped sol-gel silica on Czochralski silicon (Cz-Si). The discovery is noteworthy on two aspects: (i) strong enhancement of bandgap emission, and (ii) modeling the observed luminescence spectra reveals strong dominance of correlated electron-hole (e-h) radiative recombination. Colloidal interfacial reactions with Cz-Si surface are known to introduce random interfacial strain fields that favors the radiative recombination interactions. The modeling of the room-temperature photoluminescence spectra exhibit attenuates a strong attenuation of the shorter tail of the emission spectra; thus, amplifying the excitonic e-h. The presentation will also include a comparative study of the bandgap emission of thermally oxidized Cz-Si with the colloidal prepared spin-coated silica on Cz-Si to highlight the discovery.

SESSION EL02.08: Poster Session II: Towards Atomically Precise Colloidal Materials for Conventional and Quantum Optoelectronics II
Session Chairs: Brandi Cossairt, Hao Nguyen and Gillian Shen
Thursday Afternoon, April 25, 2024
Flex Hall C, Level 2, Summit

5:00 PM EL02.08.01
Surface-Mediated Photomultiplication based on Colloidal InAs Quantum Dots enabled by Dual-Ligand Passivation Min-Jae Si[1], Seungin Jee[1], Minjung Yang[1], Dongeon Kim[1], Yongnam Ahn[1], Seungjin Lee[2] and Se-Woong Baek[1]; [1]Korea University, Korea (the Republic of); [2]Korea Institute of Energy Technology, Korea (the Republic of)

For next-generation infrared (IR) detection in various applications, such as virtual reality, recognition, and quantum communication, solution-processed low bandgap semiconductors are essential for both absorption and emission of IR light. Colloidal quantum dots (CQDs) of the III-V group are of particular interest as non-toxic, band-gap-tunable materials that are suitable for IR absorbers; however, their device performance is still inferior to that of Pb-based devices. Here, we present a universal surface passivation method for InAs CQDs enabled by intermediate phase transfer (IPT). IPT is a preliminary process that exchanges native ligands with aromatic ligands on the CQD surface, yielding a highly stable CQD ink and resultant uniform film. We fabricated CQD near-infrared (NIR) photodetectors fabricated by IPT process. The precise control of surface ligands enabled by IPT allows tuning of trap state densities and surface-mediated photomultiplication, resulting in significant gain control up to ~10 with fast rise/fall response time (~12/36 ns). The optimal CQD photodiodes yield one of the highest FOM's among all previously reported solution-processed nontoxic semiconductors, including organic, perovskite, and CQD, in the NIR wavelength range considering EQE versus response time (or -3 dB bandwidth).

5:00 PM EL02.08.02
Exploiting Cation Exchange to Synthesize Well-Defined Three-Component $CuInS_2$ Nanocrystals Ji Tianmeng; Peking University, China

Cation exchange has emerged as a compelling strategy for crafting nanocrystals with intriguing compositions and structures, overcoming limitations inherent in direct-synthesis approaches. However, well-defined synthesis of multi-component nanocrystals with a single phase by finely tuning cation exchange kinetics remains challenging. Multi-component nanocrystals, such as $CuInS_2$ and $CuInSe_2$, have attracted significant interest owing to their diverse applications in optics, electronics, and catalysis. Utilizing $Cu_{2-x}S$ nanocrystals as the host precursors and In^{3+} as the exchange cation, we successfully synthesized monodisperse $CuInS_2$ nanocrystals with tunable size, morphology, and near-infrared luminescence properties. An in-depth exploration into the impact of size variations and Cu vacancies of host nanocrystals on cation exchange kinetics was conducted. Larger-size $Cu_{2-x}S$ nanocrystals exhibit reduced vacancy density, leading to a slower rate of cation exchange and facilitating the formation of heterostructures during the cation exchange process. Comparative analysis with directly synthesized $CuInS_2$ nanocrystals highlighted the controllability achieved through cation exchange. This work provides valuable insights for synthesizing multi-component nanocrystals with attractive properties.

5:00 PM EL02.08.03
Synergistic Passivation of $AgBiS_2$ Ternary Colloidal Quantum Dots: A Strategy for Enhancing Stability and Performance Investigated with First Principles Calculations Gaeun Cho[1,2], Dongeon Kim[1], Han Seul Kim[3] and Se-Woong Baek[1]; [1]Korea University, Korea (the Republic of); [2]Korea Institute of Science and Technology Information, Korea (the Republic of); [3]Chungbuk National University, Korea (the Republic of)

Solution-processed semiconductors, including perovskites, colloidal quantum dots(CQDs), and conjugated polymers, have gained significant attention for their potential applications in energy conversion and optoelectronics. Such semiconductors are characterized by their printability, low cost, and large form factors. CQDs, in particular, exhibit unique physical properties, such as quantum confinement effects, which allow for tuning of optical bandgaps across the visible to infrared spectrum. The lead-chalcogenide (PbS) CQDs have the ability to tune the bandgap to the infrared (~1800 nm) range. This unique feature allows for the realization of low bandgap solar cells when used as back cells in multi-junction structures. The best outcomes were achieved by introducing heavy metals, such as lead (Pb), into CQD compounds. However, due to the toxicity of these metals, the commercialization of related devices was limited.
$AgBiS_2$, which is a ternary compound, has attracted significant attention owing to its high absorption coefficients, tunable bandgap, and environmental stability. Various strategies have been proposed to enhance the device performance of thin-film $AgBiS_2$ CQD solar cells, resulting in a promising current density even under ultrathin conditions. Despite these efforts, $AgBiS_2$ CQD solar cells demonstrate a relatively low power conversion efficiency (PCE) compared to lead-based CQD solar cells. The main drawback of solution-processed $AgBiS_2$ is attributed to the use of long-chain hydrocarbon ligands during the synthesis process, which impedes charge transport in practical applications. Consequently, the exchange of surface ligands emerges as a promising strategy to overcome this limitation. Nevertheless, the theoretical understanding of the surface properties of $AgBiS_2$ CQDs is still lacking, which can potentially influence the exchange kinetics in the synthesis process.
In this presentation, an effective passivation of $AgBiS_2$ CQD surface is proposed by designing a synergistic passivation strategy with $[AgI_2]^-$, $[AgBr_2]^-$, and Na^+ based on density functional theory (DFT) calculations. Utilizing (111) and (100) facets which are expected to be the primary components of CQDs, single-ligand passivation calculations on each surface demonstrated that individual cations do not effectively adhere to the (111) surface. On the other hand, the simulation revealed that the synergistic ligand approach was shown to be complementary to selective surface passivation. It was found that the initial covering of the metal halide anion reconfigures the surface, leading to subsequent cation passivation. Moreover, it was also demonstrated that the synergistic exchange can easily passivate both (111) and (100), providing a uniform passivate strategy for multiple facets. Furthermore, the experiments have demonstrated the feasibility of the theoretically suggested synergistic passivation and the improvement in performance. In particular, XPS measurements indicated that stable $AgBiS_2$ CQD ink were realized through synergistic passivation mechanism as suggested by the simulation. Finally, the solar cell that was fabricated based on our CQD ink achieved a power conversion efficiency (PCE) of 8.14%, which is 11% higher than the previous best report.
In conclusion, our synergistic uniform passivation strategy successfully mitigates the issue of selective surface passivation of a single ligand. By uniformly passivating the CQD surface, our strategy provides a route to significantly enhance the stability and suppress the trap states. Based on this high-quality CQD solids, we also experimentally demonstrated that ink stability, short response time, and PCE of $AgBiS_2$ CQD-based optoelectronic devices were significantly improved. Additionally, we anticipate that such a synergistic ligand strategy will serve as a universal approach for the development of high-performance CQD-based optoelectronic devices.

5:00 PM EL02.08.04
Toward Semiconductor Lasering Cooling Using $CsPbBr_3$ Nanocrystals Yang Ding, Zhuoming Zhang, Jeffrey W. Peng and Masaru Kuno; University of Notre Dame, United States

Lasering an emissive material could induce refrigeration. This counter-intuitive phenomenon requires near-unity emission quantum yields (QYs) as well as efficient single-photon anti-Stokes photoluminescence (SP-ASPL) process. $CsPbBr_3$ nanocrystal (NC) emerge as a promising candidate due to the readily attainable near-unity QYs and high SP-ASPL up-conversion efficiency. Herein, we developed a repeatable synthetic approach that consistently yields NCs with near-unity QYs. Subsequent systematic nuclear magnetic resonance studies unveil a close-packing surface as origin of the near-unity QYs. Additionally, the synthesized NCs also manifest a near-unity SP-ASPL up-conversion efficiency, displaying non-Arrhenius behavior. This could be rationalized by our developed polaron model. Our studies of QY and ASPL performance in $CsPbBr_3$ NCs lays the foundation for advancing laser cooling in this material.

5:00 PM EL02.08.05
Additive Manufacturing of Nanostructures Enabled by Ligand-Salt Stabilized Polar Nanocrystal Inks Rayne T. Anderson, Stephen L. Gibbs, Daniel R. Gamelin and John D. MacKenzie; University of Washington, United States

Solution-processable semiconductor nanocrystal (NC) materials can enable the sustainable manufacturing of NC-enabled devices such as QD displays, nanophotonics, and optical quantum devices using techniques such as inkjet printing and large-area coating. A current limitation for deposition and nanoscale resolution solution-based additive manufacturing of NCs is a common requirement for nonpolar solvent systems to sufficiently stabilize NC suspensions for effective use as NC inks. In conventional printing, such as piezoelectric or liquid vaporization-based inkjet printing, non-polar inks are ejected from micromachined inkjet nozzles. In these techniques, stable printing of minimum drop volumes on the picoliter scale and printed feature dimensions down to ~10 microns are enabled in part by the low surface energy of the apolar inks. Due to the small zeta potential that the NCs have in solution; the practicality of these inks, however, is often hindered by the concentration limits of NCs in the solvent. To move towards emerging nanoscale additive nanomanufacturing with functional materials such as single NC quantum dot (QD) heterointegration or high resolution QD microdisplay fabrication. QD inks will require finite ink polarizability to enable true nanoscale deterministic positioning and attoliter scale deposition volumes. Here, we have utilized a nitrosonium tetrafluoroborate salt to ligand exchange shelled CdSe/CdS NCs to a polar solvent, N'N Dimethylformamide (DMF), that allows for high printability at low concentrations (M-10) to additively manufacture nanoscale structures.
CdSe NCs in polar DMF were utilized in electrohydrodynamic ink jet (EHDIJ) printing to additively manufacture nanostructures with <100 nm dimensions with high reproducibility. The nanoparticles were stabilized in the polar solvent through tetrafluoroborate ions via ligand exchange with nitrosonium tetrafluoroborate salt. Although the photoluminescent properties of the CdSe NCs were significantly degraded after ligand exchange, shelled CdSe/CdS NCs retained their high PL quantum yields and resulted in exceptionally stable NC/DMF suspension inks for EHDIJ at attoliter and sub-100nm feature sizes. These polar NC inks also allow for high printability at lower NC concentrations of NCs than typical non-polar inks such as octane/hexadecane mixtures. This work supports polar NC inks as a pathway towards additive manufacturing of integrated single NC quantum devices leveraging electrohydrodynamics to extract droplets 104 times smaller in volume than in conventional inkjet printing using simpler, zero moving part inkjet heads where droplet size is decoupled from the mechanical orifice size..
Electrohydrodynamic inkjet printing is a promising additive manufacturing method for fabricating nanostructures for electromagnetic enhancements and optical devices. Currently, subtractive electron beam lithography is a widely used method for generating nanoscale features. However, the requirement for conductive substrates, high cost, and high fabrication time limits the adoption of this method for research environments. We demonstrate here that sub 100nm additive nanomanufacturing of functional materials and single quantum dot printing of dilute polar NC inks is now possible.

5:00 PM EL02.08.06
Kinetically Controlled Synthesis of Quasi-Square $CsPbI_3$ Nanoplatelets with Excellent Stability Mengyun Chen and Feng Gao; Linkoping University, Sweden

Nanoplatelets (NPLs) share excellent luminescent properties with their symmetric quantum dots counterparts, and entail special characters benefiting from the shape, like the thickness-dependent bandgap and anisotropic luminescence. However, perovskite NPLs, especially those based on iodide, suffer from poor spectral and phase stability. Here, we report stable $CsPbI_3$ NPLs obtained by accelerating the crystallization process in ambient-condition synthesis. By this kinetic control, we tune the rectangular NPLs into quasi-square NPLs, where enlarged width endows the NPLs with a lower surface-area-to-volume ratio (S/V ratio), leading to lower surficial energy and thus improved endurance against NPL fusion (cause for spectral shift or phase transformation). The accelerated crystallization, denoting the fast nucleation and short period of growth in this report, is enabled by preparing a precursor with complete transformation of PbI_2 into intermediates (PbI_3^-), through an additional iodide supplier (*e.g.*, zinc iodide). The excellent color stability of our materials remains in the light-emitting diodes under various bias stress.

5:00 PM EL02.08.07
Highly Stable Blue QLEDs through Energy Level Control with Air-Stable ZnSeTe/ZnSe/ZnS Quantum Dot Seongwoo Cho[1,2], Sung Nam Lim[1], Shin Ae Song[1], Kiyoung Kim[1], Sohee Jeong[2] and Ju Young Woo[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Next-generation high-performance displays will be made using quantum dots (QDs) with adjustable band gaps, their superior optical properties, and ease of processing in solutions. Achieving long operational lifetimes and near-theoretical-maximum external quantum efficiency (EQE) has been realized in red and green InP-based quantum dot light-emitting diodes (QLEDs) [1,2]; however, an alternative solution is necessary to cover the blue region, such as employing a ternary ZnSeTe alloy structure with a band gap around 460 nm to replace cadmium-free blue-emission quantum dots.
While semiconductor quantum dots made of ZnSeTe have recently shown extremely high photoluminescence quantum yield (PL QY) and EQE, the well-known methods of highly toxic hydrofluoric acid (HF) in their synthesis have hindered their commercialization.[3] Additionally, the PL QY in ZnSe/ZnSe/ZnSe/ZnS quantum dots rapidly decreases under ambient conditions despite having double shells due to rapid oxidation. Furthermore, QLEDs made with these QDs have high driving voltage and short operational lifetime, which are difficult to use in practical applications.
We have developed a non-toxic synthetic method that completely eliminates the need for toxic HF in the synthesis of ZnSeTe/ZnSe/ZnS heterostructure quantum dots suitable for QLED applications. Instead of using HF, we introduced excessive metal halides, resulting in significantly improved PL QY. Importantly, we have demonstrated highly stable ZnSeTe/ZnSe/ZnS quantum dots in both the solution and the solid state through a straightforward ligand exchange process, which enhances surface binding via thiolate functional groups.
In QLED devices, we investigated how the Te ratio and the size of ZnSeTe QDs affect the EQE and stability. In addition, to alleviate hole transport layer (HTL) degradation, which has an adverse effect on stability in the inverted structure, the band alignment between EML and HTL was adjusted through ligand exchange in the EML. ZnSeTe QDs, stable in both material and device, make it possible to achieve complete electroluminescent QLEDs.

Superatom Clusters of Bi-Icosahedral Gold: An Optical and Electrochemical Study Mary Sajini Devadas, Benjamin Raufman, Catherine Connolly, Zara Freeland and Zaid Qureshi; Towson University, United States

Gold nanostructures have been the focus of research over the past two decades because of their potential as excellent two-photon absorbers, which make them good sensors and imaging agents. This is due, in part, to their size-specific properties. Of particular interest are a class of gold nanostructures called superatoms, or magic numbered clusters, that exhibit quantum confinement effects. These structures are also referred to as nanomolecules (AuNCs). They have small enough optical band gaps to absorb in the near infrared I (near IR) region (700-900 nm) which is beneficial for biological applications. One of the most investigated superatom clusters is $Au_{25}L_{18}$ (L = alkyl or aryl thiols) in the icosahedron geometry. Its properties have been characterized both

experimentally and theoretically. $Au_{25}L_{18}$, where L = hexanethiol exhibits luminescence efficiencies of ~2.5×10^{-4} in the nearIR region with cross-sections of 2700 GM at 1290 nm which can be useful for two-photon imaging with IR light. Doping the AuNC metal core with foreign atoms is considered a powerful method for transforming $Au_{25}L_{18}$ into stable clusters with different electronic structures resulting in increased luminescence. In addition, this can induce magnetism which is important for magnetic imaging, and computing applications. The electronic states of these clusters can further be manipulated by adding ligands containing a chromophore or possessing redox capability. While these effects are documented, the mechanisms involved remain controversial and little work has been done with respect to its bi-counterpart. The results of this study will offer more insight to better designed AuNCs with bi-icosahedral geometrical structures that are doped (Pt, Ag, Cd, Hg) for use as novel nonlinear optical materials (NLO). The electrochemical band gap and brightness factors will also be presented.

5:00 PM EL02.08.09
Magic-Sized InP Clusters as Platforms for Core-Only Emitters with Narrow Linewidths Grant Dixon and Brandi M. Cossairt; University of Washington, United States

Colloidal quantum dots (QDs) excel at converting light or electricity into bright, tunable, color-pure luminescence, a property that promises a future of display technology that can reproduce the range of spectral hues discernable to humans. While several materials are disqualified due to hazardous substance restrictions, indium phosphide (InP) is energetically qualified and not RoHS restricted. Imparting synthetic control over the resultant photophysical properties of InP is an outstanding challenge, however. Our efforts have focused on developing the synthesis of atomically precise InP magic-sized clusters that show unique and distinct photophysical behavior from their larger QD counterparts. Importantly, these clusters demonstrate exceptionally narrow emission linewidths and long-term ambient stability, making them a promising platform for emissive materials. This is achieved by exchanging carboxylic acid ligands for phosphonic acids, employing reaction additives, and exploring post-synthetic atomistic surface modifications. Despite exhibiting exceptionally narrow ensemble linewidths, the as-synthesized clusters suffer from low photoluminescence quantum yield. Low brightness is remedied by including phosphine oxides in the synthesis, which affords highly monodisperse InP nuclei demonstrating improved photoluminescence intensity and lifetimes. Ongoing and future efforts are focused on exploring the formation, physical structure, and the role of ligands and extraneous additives on modulating the surface chemistry and resultant photophysical behavior of phosphonic acid-capped InP magic-sized clusters.

5:00 PM EL02.08.10
Scalable Nanomanufacturing of Quantum Dot Heterointegrated Nanophotonic Cavities Gregory G. Guymon[1], Theodore A. Cohen[1], David Sharp[1], Purbita Purkayastha[2], Stephen L. Gibbs[1], Shaun M. Gallagher[1], Arnab Manna[1], Eden A. Tzanetopoulos[1], David S. Ginger[1], Edo Waks[2], Daniel R. Gamelin[1], Arka Majumdar[1] and John D. MacKenzie[1,1]; [1]University of Washington, United States; [2]University of Maryland, United States

Nanophotonic structures are a foundation for the emerging field of light-based quantum networks and devices. These nanoscale structures act through their ability to couple with and manipulate photons. Colloidal quantum dots (QDs) are uniquely suited to complement this range of devices due to their solution-processability, broad tuneability, and near-unity photoluminescence quantum yields, in some cases. Here we have used electrohydrodynamic inkjet (EHDIJ) printing as a highly precise and scalable nanomanufacturing method for digital deposition of attoliter-scale QD droplets to bridge the heterointegration gap between QDs and nanophotonics. EHDIJ printing is an electrophoretic additive manufacturing process that uses applied electric fields to overcome surface energy barriers to selectively deposit charged droplets and deterministically position functional materials, including QDs, down to nanoscale resolutions.

For monolithic substrate-coupled SiN nanophotonic cavities, we have shown that $CsPbBr_3$ QDs can be deterministically patterned over large arrays and with sub-micrometer precision using EHDIJ printing. Additionally, we collected the first high-resolution STEM images of EHDIJ printed structures, showing that the original QD structure is preserved post-printing. Furthermore, we found that QDs within these printed structures can self-assemble into superlattice domains and that ~200 nm diameter printed features containing ≤200 QDs can be produced with this technique.

Building on this capability, EHDIJ printing has been expanded to encompass heterointegration of structures that are challenging or impossible to create by conventional subtractive semiconductor processing. An example of this is the coupling of QD emitters to substrate-decoupled nanoscale resonant structures. We have demonstrated the first successful application of EHDIJ printing for the integration of colloidal CdSe/CdS QDs with suspended nanophotonic cavities, achieving selective single-cavity deposition for cavity pairs as close as 100 nm apart. PL characterization of the as-printed cavities confirmed EHDIJ printing's ability to manufacture QD-cavity and inter-cavity coupled devices, at nanoscale spacings. This broadens the horizon for new hybrid integrated device architectures that were previously considered impossible from a materials integration standpoint.

To demonstrate this broad applicability, we have also begun to apply strategies learned from these previous demonstrations onto bullseye cavity structures. These consist of semi-complete suspended concentric rings of alternating dielectrics, SiN and air. Bullseye cavities offer increased Purcell enhancement and the unique ability to direct emission from photon sources into the far field. Using EHDIJ printing, we are integrating $CsPbBr_3$ QDs into 500 nm diameter cavity-centered targets, while tuning the colloidal solution's concentration and chemistry to minimize the number of QDs integrated into the devices towards single QD and single photon systems.

We believe these results will motivate the development of future suspended heterointegrated devices that utilize EHDIJ printing as a sustainable, additive, and scalable method for quantum photonics nanomanufacturing.

5:00 PM EL02.08.11
Bright Colloidal Deep-Blue-Emissive Europium Halide Nanocrystals Jaeyeong Ha, Seongbeom Yeon, Hyungdoh Lee, Jaehwan Lee and Himchan Cho; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

Halide perovskite nanocrystals (PNCs) are gaining significant attention as light-emitting materials due to their high color purity and facile color tuning, coupled with the ease of solution-based processing. However, a significant limitation for industrialization lies in the toxic nature of Pb-based perovskites. Additionally, the photoluminescence quantum yield (PLQY) and stability of blue-emitting PNCs have lagged behind compared to the red and green counterparts.
To address these challenges, europium (Eu)-based nanocrystals, which emit deep-blue light, have been proposed as a key eco-friendly alternative. However, the inherent properties of Eu precursors: (i) low solubility and (ii) strong organic coordination, present significant obstacles for colloidal synthesis of Eu-based nanocrystals. So far, reported colloidal Eu-based PNCs have not achieved a high PLQY exceeding 6%.
In this study, we present a systematic synthetic strategy of colloidal Eu-based nanocrystals with high PLQYs. We controlled the chemical interaction between the precursors and ligands, along with modulation of reaction temperature and duration. These controlled reactions led to successful synthesis of deep-blue-emitting Eu^{2+}-doped CsBr, Cs_4EuBr_6/CsBr and $CsEuBr_3$ nanocrystals. Notably, the synthesized colloidal $CsEuBr_3$ nanocrystals exhibited a high PLQY of ~40% and a narrow spectral linewidth. Furthermore, we investigated the chemical reactions between the precursors and ligands in-depth, suggesting the synthetic mechanisms of the colloidal Eu-based nanocrystals. This study introduces great potential of Eu-based nanocrystals for solution-

processable non-toxic blue light emitters exhibiting both high PLQY and high color purity.

5:00 PM EL02.08.12
Characterization of Photogenerated Spin Qubit Pairs in Various Dye Derivative - ZnO QD Conjugates Autumn Y. Lee and Jacob Olshansky; Amherst College, United States

Previously, we have shown that upon photoexcitation of a dye molecule - quantum dot conjugated system a charge separated state can be induced. This charge separated state possess two formerly spin-paired electrons that reside in spatially separated sites, nominally labeled as spin-correlated radical pairs (SCRPs). SCRPs, also referred to as spin qubit pairs (SQPs), have unique properties which are applicable to quantum information science. These systems can act as quantum bits, qubits, operating at moderate temperatures with well-defined quantum states. In this work, we aim to expand our understanding regarding the effect that distance between dye and quantum dot (QD) has on the presence and lifetime of SQPs. We examine this causal relationship by utilizing various linker lengths, allowing us to examine a range of distances between the QD and the dye. The specific system we have chosen to study involves various carboxylate dye molecules, perylene and BPEA derivatives, and ZnO QDs. We first study their chemical interactions using absorption isotherms and then measure the photophysics of these conjugates using both steady-state and time-resolved photoluminescence spectroscopy. Swift photoinduced electron transfer from the dye derivatives to the ZnO QD is observed, and a long-lived (> 7 ns) charge separated state is generated. This charge separated state is then analyzed using laser induced time-resolved electron paramagnetic resonance spectroscopy to fully characterize the spin dynamics of the photogenerated SQPs.

5:00 PM EL02.08.13
Nonthermal Plasma Synthesis of Water-Dispersible and Photoluminescent Silicon Quantum Dots for Bioimaging with Near Infrared Emission Yeonjoo Lee[1], Mihee Kim[2], James H. Werner[2], Jinkyoung Yoo[2] and Uwe R. Kortshagen[1]; [1]University of Minnesota, United States; [2]Los Alamos National Laboratory, United States

Silicon quantum dots (Si QDs) are considered as attractive probes for bioimaging applications because of their earth-abundance, and size-tunable optical properties, nontoxicity, biocompatibility and biodegradability. In this study, one-step synthesis of water-dispersible and red-emitting Si QDs is investigated using nonthermal plasma. Nonthermal plasma is popular to produce Si QDs with superior size and shape uniformities, high purity and crystallinity which are important to obtain decent and well-controlled optical properties. The one-step synthesis method is a simplified approach to produce surface-passivated Si QDs by combining QD synthesis and surface passivation processes. Therefore, it does not require additional treatments involving high temperatures and toxic chemicals; it can save energy as well as time and reduce hazardous chemicals. We prepared water-dispersible and red-emitting Si QDs using the one-step synthesis method for the first time. Si QDs were synthesized using silane as a precursor, and their surfaces were passivated by acrylic acid. In order to improve water dispersibility, oxygen gas or water vapor was added into the passivation stage. We estimated Si QDs' size from X-ray diffraction (XRD) patterns, and the estimated diameter was 4 nm. The XRD patterns also showed the Si QDs are crystalline. The hydrodynamics diameters of QDs were measured by dynamic laser diffraction to investigate water-dispersibility. 10 to 11 nm of hydrodynamic diameters meant Si QDs can disperse well enough to be used as bioimaging probes; for instance, QDs smaller than 20 nm can cross the blood-brain barrier. The Si QDs excited by ultraviolet light (400 nm) emitted red light (peak position at ~830 nm) with 30% of photoluminescence quantum yield. Since skin, fat, tissue, and blood are relatively transparent in the red-to-NIR range, red-emitting Si QDs can offer deeper tissue penetration resulting in improved bioimaging quality. We conducted bioimaging using 3T3 cells cultured with the Si QDs and demonstrated the Si QDs existed inside the cells emitting red light. This result showed that our water-dispersible Si QDs enables bioimaging in NIR range. Thus, this study shows that the one-step Si QD preparation method is an energy- and time-saving as well as less hazardous route for fabricating water-dispersible and photoluminescent Si QDs which are promising materials as probes for bioimaging applications as well as diagnostic tools.

5:00 PM EL02.08.14
Synthesis and Chracterization of Single-Grain Epitaxially-Fused PbSe Quantum Dot Superlattices Alex Abelson[1,2], Caroline Qian[2] and Matt Law[2]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Irvine, United States

Epitaxially-fused superlattices of colloidal quantum dots (QD epi-SLs) may exhibit electronic minibands and high-mobility charge transport, but electrical measurements of epi-SLs have been limited to large-area, polycrystalline samples in which superlattice grain boundaries and intragrain defects suppress/obscure miniband effects. In this talk, I will first discuss the synthesis of large-grained PbSe QD SLs, including detailed analysis of their chemical and physical structure. Next, I will discuss the mechanism by which a ligand-capped PbSe QD SL is converted into an epi-SL. Finally, I will present systematic measurements of charge transport in individual, highly-ordered PbSe QD epi-SL grains. One technical challenge in making these devices is the inherent mismatch in using traditional microfabrication techniques to make single-grained devices of air-sensitive materials. Here, we demonstrate the air-free fabrication of microscale field-effect transistors (μ-FETs) with channels consisting of single PbSe QD epi-SL grains (~ 1 -10 μm grain sizes) and analyze charge transport phenomena in these samples. The devices exhibit *p*-channel or ambipolar transport with a hole mobility as high as 3.5 $cm^2 V^{-1} s^{-1}$ at 290 K and 6.5 $cm^2 V^{-1} s^{-1}$ at 170–220 K, one order of magnitude larger than that of previous QD solids. Device hysteresis at higher temperatures makes the true mobility–temperature curve uncertain and evidence for miniband transport inconclusive.

SESSION EL02.09: Classical and Quantum Light Sources and Other Devices from Colloidal Quantum Dots I
Session Chairs: Hao Nguyen and Gillian Shen
Friday Morning, April 26, 2024

8:45 AM EL02.09.01
Colloidal Quantum Dots-Based Shortwave Infrared Photodetector: From Materials to Devices Se-Woong Baek; Korea University, Korea (the Republic of)

The detection of infrared (IR) light is crucial for realizing various future applications, including recognition, bio-imaging, spectroscopy, and object inspection. In particular, utilizing photons beyond the silicon absorption band-edge (i.e., 1550 nm) becomes important to demonstrate long-range communications and quantum technologies. Colloidal quantum dots (CQDs), semiconducting nanocrystals, are promising alternative materials due to their quantum-confined bandgap tunability across visible to shortwave-infrared (SWIR) wavelengths. However, CQD-based IR optoelectronics currently face two challenges: the use of toxic elements such as Pb, Cd, and Hg, and lower performance compared to epitaxial semiconductors.
This talk showcases how to build IR devices using non-toxic CQD materials, including III-V, I-VI, and beyond. Various short-ligand passivation strategies

enable stable CQD ink, thereby rendering high-quality conductive solids. We reveal that the extent of ligand passivation yields a surface-mediated photomultiplication effect, boosting the responsivity of devices. Furthermore, we have demonstrated an efficient avalanche breakdown in the CQD multiplication layer, achieving a fast response time below the nanosecond level with a notable gain of up to ~10^4. This represents a record gain x bandwidth product among all prior solution-processed IR photodetectors operated at 1550 nm.

9:00 AM EL02.09.02
Atomistically Tailored Surface states of Indium Phosphide Quantum Dots for Shell-Less Light-Emitter Namyoung Gwak, Seungki Shin, Seongchan Kim, Jaeyoung Seo and Nuri Oh; Hanyang University, Korea (the Republic of)

The surface complexity of III-V compound QDs has been progressively elucidated through surface etching and passivation using various surface ligands. Regardless of the synthetic routes, the surfaces of highly covalent InP QDs are prone to the formation of oxidative species due to their high oxygen affinity. These surface traps act as local energy minima that hinder or delay electron-hole recombination, consequently reducing luminous efficiency. Ideally, if the surface oxides of InP QDs can be effectively removed and the exposed DBs can be passivated with additional ligands, InP cores without a pristine shell could potentially exhibit sufficient luminescent efficiency.
As part of this research endeavor, the utilization of Lewis acidic Z-type ligands for partially coupling surface atoms has shed light on the significance of surface stoichiometry and undercoordinated surface sites in the luminescence of QDs. Z-type ligand passivation has proven effective in treating the surfaces of various InP QDs, yielding consistent outcomes irrespective of their types. Recently proposed combinational ligand passivation strategies offer safer chemical routes than HF and have shown high photoluminescence quantum yield (PLQY) for InP cores without any shells, achieving 85% PLQY with the combination of $ZnCl_2$ and InF_3, and 60% PLQY with the combination of $ZnCl_2$-TOP and Zn-oleate. These approaches address the challenge of eliminating the remaining undercoordination despite the effective passivation of a significant number of surface DBs using Z-type ligands. Additionally, the introduction of gallium ions in a post-synthetic process of InP QDs has provided further insights into tackling surface complexity. While the enhancement of InP core luminescence has been reported through GaP shell formation, Ga cation exchange, In-Ga alloying, and additional coordination at the InP/ZnSe interface, the specific role of Ga-based ligands in altering the surface chemical state remains unclear. Overall, achieving defect-free and DB-free InP QD surfaces without shell formation while maintaining excellent luminescent properties for applications like electroluminescent (EL) devices remains an unexplored possibility. Although matching factors such as surface coordination of cations and anions and charge neutralization hold promise for eliminating surface defects in compound semiconductor QDs, further research is needed to realize the full potential of defect-free InP QDs with pristine surfaces.
To address this challenge, our novel approach focuses on controlling InP QD surface stoichiometry and coordination without the conventional growth of a complete shell. Through atomic-level modification involving proportional surface passivation using gallium chloride and zinc carboxyl groups, we successfully reduce the density of surface defect states, resulting in remarkably stable luminescence with near-unity PLQY (up to 95%). Theoretical models have offered guiding principles for identifying the chemical composition and quantity of surface traps, which can be verified through spectroscopic analysis. Remarkably, our core-only InP QDs, even without a shell, demonstrate sufficient electroluminescence in conventional LED architectures for the first time. Our findings provide valuable insights into the role of surface chemistry in controlling luminescence and present a novel strategy for developing bright and stable QDs without the necessity of a complete shell.

9:15 AM EL02.09.03
Towards Non-Blinking Strongly Confined Perovskite Quantum Dots Yitong Dong, Chenjia Mi and Matthew Atteberry; The University of Oklahoma, United States

Quantum information science has shown its capabilities to enable secure quantum communications. Single photon emitters (SPEs) emit photons one at a time and are fundamental elements of such transformative technologies. Quantum dots (QDs), an atom-like solid-state light source, can emit photons with high efficiency and thus become promising SPE materials. Colloidal cesium lead halide ($CsPbX_3$, X=Br, I) perovskite QDs are ideal for next-generation SPEs because of their high room-temperature luminescence efficiency and low-cost, scalable syntheses. Unfortunately, individual perovskite QDs show insufficient photostability and severe photoluminescence (PL) intensity fluctuations. These fluctuations, also called blinking, can lead to spectral shifts, change the fluorescence dynamics, and reduce the structural stability of perovskite QDs. This has greatly limited the spectroscopic studies for SPE developments. Unlike conventional CdSe QDs, due to the highly ionic crystal structure of perovskites, there is not yet an approach to produce a homogeneous Type-I core-shell structure for perovskite QDs that can efficiently suppress blinking.

One challenge of studying the ionic perovskite QDs is their relatively low ligand binding affinities. When preparing individual perovskite QD samples, QD colloids often need to be diluted, and the ligand can detach from the QD, introducing defects. As a result, individual perovskite QDs often show rapid PL intensity fluctuations accompanied by photodegradation. Many significant advances have been made to search for ligands that bind strongly with the surface of perovskite QDs, such as zwitter ionic and didodecyldimethylammonium bromide ligands. However, perovskite QDs, especially for strongly size confined QDs, are still experiencing severe PL blinking with large PL “OFF” occurrences.

Here we discovered a method that can significantly suppress PL blinking and improve photostability of strongly confined $CsPbBr_3$ Perovskite QDs. $CsPbBr_3$ QDs with tunable sizes from ~ 3.5 nm to 7 nm are synthesized using the thermodynamic-equilibrium-controlled method and annealed at elevated temperatures to form a bromide rich surface. Diluted QD colloids are then used as antisolvent and nucleation centers to form a polycrystalline thin film consisting of phenethylammonium bromide (PEABr) salts. The bromide rich surface will be epitaxially anchored onto the PEABr matrix and therefore be passivated. Individual strongly confined $CsPbBr_3$ QDs embedded in the PEABr show nearly non-blinking behavior under both pulsed and *cw* aser excitations (non-resonant) at room temperature. Power-law analysis of the blinking traces of thes perosvkite QDs show very different “ON” and “OFF” powers (0.85 and 1.9). These QDs remain photostable for more than one hour under laser excitations and show very high singe photon purities (> 95%). Additionally, $CsPbBr_3$ QDs with sizes from 3.5 nm to 7 nm can all be passivated and stabilized using our method and show nearly non-blinking behaviors. We anticipate that these QDs will result in more accurate and detailed studies of exciton dynamics and structural-optical property relationships in strongly confined perovskite QDs.

9:30 AM EL02.09.04
Feasibility of Quantum Dot Superradiance Serguei Goupalov[1] and Mikhail O. Nestoklon[2]; [1]Jackson State University, United States; [2]TU Dortmund, Germany

Superradiance is the collective spontaneous emission of a system of many radiative dipoles [1]. Recently, behaviors characteristic for superradiance have been reported for arrays of closely packed self-assembled colloidal lead halide perovskite quantum dots (QDs) [2,3]. The main obstacle which hinders formation of a superradiant state is the inhomogeneous broadening of the optical transitions implying variances of the resonant frequencies from one emitter to another. At first glance, in order to form a superradiant state, variances of the resonant frequencies for participating emitters should be within the radiative linewidth, which for exciton transitions in lead halide perovskite QDs is on the order of few micro-eV. However, along with the long-range interaction through the transverse electro-magnetic field, exciton radiative dipoles are subjects of short-range dipole-dipole interaction. We show that this

interaction allows one to relax the strict resonant conditions for formation of the superradiant state. Yet, we demonstrate that the dipole-dipole interaction between excitons in lead halide perovskite QDs is at least two orders of magnitude weaker than reported in literature [3] and, for closely packed QDs, amounts few tenths of a meV. We further show that retardation effect inhibits superradiance and limits the number of emitters participating in the superradiant state. This number also depends on the configuration and dimensionality of the array.

Programmable Quantum Nanophotonics Arka Majumdar; University of Washington, Seattle, United States

Analog quantum simulators rely on programmable quantum devices to emulate Hamiltonians describing various physical phenomenon. Photonic coupled cavity arrays are a promising platform for realizing such devices. Using a silicon photonic coupled cavity array made up of high quality-factor resonators and equipped with specially designed thermo-optic island heaters for independent control of cavities, we demonstrate a programmable device implementing tight-binding Hamiltonians with access to the full eigen-energy spectrum. We report a reduction in the thermal crosstalk between neighboring sites of the cavity array compared to traditional heaters, and then present a control scheme to program the cavity array to a given tight-binding Hamiltonian. Finally, I will talk about use of colloidal materials to provide strong nonlinearity in this platform.

10:45 AM *EL02.09.06
Luminescence of Colloidal Quantum Dots in The Mid-Infrared and Beyond, and Implications for Detectors and Emitters Philippe Guyot-Sionnest; University of Chicago, United States

This talk will discuss the challenges and motivations to create bright colloidal quantum dots in the mid-infrared and beyond. At all infrared wavelengths, colloidal quantum dots show enormously superior luminescence compared to organic dyes, by many orders of magnitude in the short-wave infrared. However, this talk will show that the luminescence of colloidal quantum dots is still very poor in the mid-infrared and beyond. The possible reasons will then be described, as well as some tentatives to improve the situation. Then the applications of quantum dots to detectors and emitters, in the mid-infrared and beyond, will be presented, emphasizing the connection to the challenge of luminescence.

11:15 AM EL02.09.07
Single PbS Colloidal Quantum Dot Transistors Kenji Shibata[1], Masaki Yoshida[1], Kazuhiko Hirakawa[2,2], Tomohiro Otsuka[3,3,3], Satria Bisri[4,5] and Yoshihiro Iwasa[4,2]; [1]Tohoku Institute of Technology, Japan; [2]University of Tokyo, Japan; [3]Tohoku University, Japan; [4]RIKEN Center for Emergent Matter Science, Japan; [5]Tokyo University of Agriculture and Technology, Japan

Colloidal quantum dots (CQDs) are small semiconductor crystals with a diameter of several nanometers [1]. CQDs exhibit excellent light emission/absorption characteristics, and their optical bandgaps are widely tunable by adjusting their size. CQDs can be treated by liquid processes, and their functionality can be controlled by selecting suitable ligands [2]. These properties make CQDs attractive candidates for use as transport channels in single-electron transistors (SETs) operating at high temperatures. However, there have been only a few evaluations of carrier transport through single CQDs in transistor geometries because of the technical difficulties in electrically accessing single CQDs prepared by bottom-up methods.

In this work, we report the first demonstration of single-CQD transistors based on commercially available high-quality PbS CQDs with oleic acid as a ligand. We made electrical contact to a single CQD using nano-gap metal electrodes and measured single-electron tunneling through the CQDs. The transport characteristics measured at 4 K strongly depend on the quantum dot size; a few-electron regime is observed in small PbS CQDs, while a many-electron regime is observed in large CQDs. From the orbital-dependent electron charging energy and conductance, we demonstrate that the tunneling barrier in this system is formed not only by the capping material but also by the intrinsic gap between the electron wavefunction in the CQDs and electrodes. Analysis of the excited states observed in the Coulomb stability diagram indicates that the confinement potential of electrons in CQDs is strongly affected by the external electric field induced by gate and source-drain voltages, suggesting the tunability of the effective confinement size of electrons and the bandgap in CQDs by the external electric field. Moreover, spin-correlated coherent carrier transport (the Kondo effect) has been observed for the first time in the CQD system; this indicates strong coupling between the electrodes and the CQDs despite the use of long-chain insulating oleic acid ligand. These results provide nanoscopic insight into carrier transport through CQDs at the single quantum dot level, which is essential for developing CQD applications in optoelectronic devices, such as solar cells and photodetectors.

Furthermore, the large charging energy in small CQDs enables SET operation at high temperature. While there is a tendency for the noise to increase at higher temperatures, we obtained diamond-like Coulomb stability diagrams even at room temperature, confirming that the devices operate as SETs at room temperature [3]. This is the first demonstration of room-temperature SET operation in semiconductor nanocrystal systems. Considering that PbS CQDs are excellent emitters and absorbers of light, our device is a platform for room-temperature SETs with good optical properties, increasing the functionality and versatility of single-electron devices. This will bring about innovation in quantum information technology.

11:30 AM EL02.09.09
Mid-Infrared Cascade Intraband Electroluminescence with HgSe/CdSe Core/Shell Colloidal Quantum Dots Xingyu Shen, Ananth Kamath and Philippe Guyot-Sionnest; University of Chicago, United States

Efficient infrared light sources are needed for applications like gas sensing, environmental monitoring, and spectroscopy. In the visible, electroluminescence from colloidal quantum dots is highly efficient, wavelength-tunable, and cost-effective, which inspires using the same approach in the infrared. Despite the promising performances of colloidal quantum dots light-emitting diodes in the near-infrared, mid-infrared devices show quantum

efficiencies of about 0.1% due to the much weaker emission. Moreover, these devices exclusively relied on the interband transition, restricting the possible materials.

Here, we show electroluminescence at 5 microns using the intraband transition between 1Se and 1Pe states within the conduction band of core/shell HgSe/CdSe colloidal quantum dots. With a three-monolayer CdSe shell thickness, the electroluminescence efficiency is about 50-fold larger than in a device that uses the interband transition of similar-sized core-only mid-infrared HgTe colloidal quantum dots. The device showed an EQE of 4.5% at 2 A/cm^2 while the power efficiency was 0.05%. The quantum efficiency approaches that of commercial epitaxial cascade quantum well light-emitting diodes. The high emission efficiency and the electrical characteristics support a similar cascade process where the electrons, driven by the bias across the device, repeatedly tunnel into $1P_e$ and relax to $1S_e$ as they hop from quantum dot to quantum dot.

The efficiency of the device could be further enhanced through the improvement of the colloidal quantum dots synthesis and film processing. Moreover, similar intraband transitions exist in many other materials, and the cascade mid-infrared electroluminescence design could then be extended to lower toxicity systems.

11:45 AM EL02.09.10
Acceleration of Near-IR Emission through Efficient Surface Passivation and Doping of Cd_3P_2 Quantum Dots Logan Smith[1], Kathryn E. Harbison[1], Nickie Tiwari[1], Benjamin T. Diroll[2] and Igor Fedin[1]; [1]The University of Alabama, United States; [2]Argonne National Laboratory, United States

Fast near-IR (NIR) emitters are highly valuable in telecommunications and biological imaging. Colloidal synthesis is a potent method that produces a few NIR-emitting materials, but they suffer from long photoluminescence (PL) times. These long PL times are intrinsic in some NIR materials (PbS, PbSe) but are attributed to emission from bright trapped carrier states in others. We develop the colloidal chemistry of an overlooked II–V semiconductor cadmium phosphide (Cd_3P_2) — an alternative promising near-IR material that offers a high bandgap tunability. It is a unique material that bridges III–V and II–VI semiconductors and combines the best of both worlds: near-IR emission with solution processability. We show that as-synthesized Cd_3P_2 QDs possess substantial trap emission with radiative times $>10^1$ ns. With the help of intelligent surface passivation through shell growth or Lewis coordination, or through cationic doping, we manage to accelerate the NIR emission from Cd_3P_2 QDs by decreasing the amount of trap emission. This finding brings us one step closer to the application of colloidally synthesized QDs as quantum emitters.

Toward Ultrathin and Intrinsically Stretchable Optoelectronic Devices Moon Kee Choi; Ulsan National Institute of Science and Technology, Korea (the Republic of)

In recent years, deformable electronic devices have garnered significant attention for their potential in various applications, ranging from flexible displays to wearable technology. However, their mechanical rigidity and relatively large size often preclude seamless integration into flexible, curved, or dynamic environments. We explore the capabilities of ultrathin and intrinsically stretchable optoelectronic devices, such as light-emitting diodes (LEDs) and photodetectors, enabled by the synergistic incorporation of advanced nanomaterials like quantum dots and perovskites, along with cutting-edge printing techniques. The ultrathin architecture facilitates the deployment of high-definition, energy-efficient perovskite LEDs as skin-attachable electronic tattoos, as well as the use of heavy-metal-free photodetectors in wearable photoplethysmogram (PPG) sensors. Moreover, the intrinsic stretchability of displays represents a significant milestone in the design and realization of next-generation soft optoelectronic systems that can adapt to a diverse range of form factors.

1:45 PM EL02.10.02
Exploring Optoelectronic Properties of Heterostructures of Thin Films and Magic-Sized Clusters of Metal Halide Perovskites Asmitha Mekala[1], Jorge Arteaga[1], Heng Zhang[2], Jin Zhang[2] and Sayantani Ghosh[1]; [1]University of California, Merced, United States; [2]University of California, Santa Cruz, United States

The broad spectrum of potential applications presented by metal halide perovskites (MHPs), coupled with their straightforward manufacturing procedures, has captured considerable interest in recent years. Considerable effort has been invested in enhancing the charge transport and extraction efficiencies of MHP thin films for applications in photovoltaics and in refining the film surface quality for usage in sensing. One approach is leveraging heterostructure engineering of MHPs, and prior studies have demonstrated improved photoluminescence (PL) and emission tunability via the adaptation of this method. In our previous work, we have documented how heterostructures comprising thin films of $CH_3NH_3PbI_3$ (methylammonium lead iodide, or MAPI) and metal halide perovskite quantum dots (PQDs) result in improved stability, defect passivation, increased charge carrier lifetimes, and increased charge extraction efficiency in the MAPI films. This work focuses on charge and energy transfer in heterostructures of MAPI thin films and perovskite magic-sized clusters (PMSCs). Magic-sized clusters refer to small, well-defined stable clusters of atoms or molecules that have unique physical and optoelectronic properties, and our PMSCs are 1 – 3 nm in diameter, smaller than the typical PQDs of equivalent composition. Owing to this higher surface-to-volume ratio, PMSCs have greater potential of higher charge and energy transfer efficiencies and higher PL quantum yield. Furthermore, one of the causes affecting the quality of the MHPs films are point defects at the film surface and at grain boundaries. These defects are in the sub-nanometer spatial scale, which could be addressed better by adding the PMSCs to the MHPs film rather than PQDs.
We have conducted a comparative study of heterostructures comprising MAPI films with colloidally synthesized PMSCs and PQDs. The deposition was carried out two ways: the first, by spin coating $MAPbBr_3$ (methylammonium lead bromide) MSCs or $MAPbBr_3$ PQDs on annealed MAPI films; the second, by adding the PMSCs or PQDs to the precursor of MAPI and annealing them together. Scanning electron microscopy and X-ray diffraction were employed to get insights into the morphological and structural characteristics of the films with PMSCs and PQDs. Confocal microscopy, PL spectroscopy and time-resolved PL measurements while varying sample temperature and excitation wavelengths were utilized to understand the energy and charge transfer mechanisms between the coated MAPI films and the PMSCs or PQDs.

2:00 PM EL02.10.03
Multimodal Strategies for Novel Material Discovery and Enhanced Halide Perovskite Emitters Alexander S. Urban[1], Nina A. Henke[1], Carola

Lampe[1], Kilian Frank[1], Stefan Martin[1], Ioannis Kouroudis[2], Milan Harth[2], Patrick Ganswindt[1], Markus Döblinger[1], Alessio Gagliardi[2] and Bert Nickel[1]; [1]LMU Munich, Germany; [2]Technical University Munich, Germany

To meet the current and future global energy demands, we must implement a dual strategy of increased renewable energy conversion and reduced energy consumption. This will require us to substantially optimize current materials or discover and develop entirely new ones, for example, for solar cells and light-emitting diodes. A material with vast potential for these applications is nanocrystalline halide perovskite. However, one of the difficulties in improving perovskites is that the fabrication can be too fast to investigate with conventional approaches, and optimizing the resulting NCs can be an extremely tedious task. In this talk, I will discuss our new multimodal approaches to determine the structure and synthesis dynamics of highly confined 1D and 2D halide perovskite nanocrystals, tailor them to specific applications, and enhance their efficiency and stability.[1,2] I will also highlight our approach to incorporate a machine-learning process to optimize syntheses with minimal data demand. Importantly, many of these novel approaches can readily be applied to other systems, greatly benefitting material discovery and development.

Metal Halide Perovskite Nanocrystals for Advanced Display Technologies Tae-Woo Lee; Seoul National University, Korea (the Republic of)

Metal halide perovskites (MHPs) have gained recognition as potential candidates for next-generation display technologies, given their high color purity, cost-effectiveness, and facile processing attributes. While several techniques have been pursued to magnify their luminescence performance and stability, they have not yet eclipsed the benchmarks set by conventional organic or inorganic quantum dot-based LEDs. In this talk, we will delve into the unique advantages and strategies involved in MHPs for display technologies using meticulously designed nanomaterials. First would be a comprehensive material strategy aimed at inhibiting defect generation in atomically precise colloidal perovskite nanocrystals (PNCs), thereby elevating their luminescent efficiency. By incorporating guanidinium (GA^+) cations into formamidinium lead bromide ($FAPbBr_3$) PNCs, we could achieve a significant surge in luminous efficiency coupled with decreased amount of defect sites. [1] In addition, the incorporation of the bromine-incorporating molecule, 1,3,5-tris(bromomethyl)-2,4,6-triethylbenzene (TBTB), effectively addressed the halide vacancies. In terms of scalable manufacturing, we have pioneered a modified bar-coating process capable of producing large devices on par with the efficiencies of spin-coated counterparts at small device size. [2] In-situ type of core/shell PNC synthesis methodology on substrate will also be discussed, which facilitated the realization of perovskite LEDs with high efficiency, brightness, and stability at the same time. [3] By fragmenting large 3D crystals into nanoscale counterparts and surrounding them using covalently-bonded compact acidic organic ligands, we achieved outstanding charge confinement without compromising charge mobility. Collectively, these advancements underscore the potential of MHPs as the vanguard of self-emissive display materials.

2:45 PM BREAK

3:15 PM EL02.10.05
The Role of Inorganic Ruddlesden-Popper Planar Faults in $CsPbBr_3$ Perovskite Nanocrystals and Their Performance in LEDs Mariia V. Goriacheva[1], Alec Pickett[2], Payal Bhattacharya[3], Suchismita Guha[4] and Yangchuan Xing[4]; [1]University of North Dakota, United States; [2]Intel Corporation, United States; [3]MKS Instruments, United States; [4]University of Missouri–Columbia, United States

Ruddlesden-Popper (RP) planar faults composed of organic layers were shown to significantly enhance stability and overall opto-electronic performance of lead-halide perovskite nanocrystals (PNCs). The observed phenomena have been mainly attributed to the moisture-repellant and electronically insulating nature of long carbon chains allowing them to shield perovskite domains from moisture while confining excitons. Similar performance enhancement is seen in PNCs with all-inorganic RP layers – insulating in nature, yet highly soluble in water. Here we attempt to define the role of CsBr RP-faults in $CsPbBr_3$ nanocrystals by performing a comparative analysis of nanocrystals with and without RP layers. The nanocrystals are studied as stand-alone colloids and thin films as well as emissive layers in light-emitting diodes. We find that $CsPbBr_3$ PNCs with RP faults possess both higher exciton binding energies and longer exciton lifetimes. The former is ascribed to a quantum confinement effect in the PNCs induced by electronically insulating CsBr layers. The latter is attributed to a plausible spatial electron−hole separation across the RP faults. A striking difference is seen in the up-conversion photoluminescence response from $CsPbBr_3$ PNCs with and without RPs. For the first time, all-inorganic $CsPbBr_3$ PNCs with RP faults are tested in light-emitting devices and demonstrated to significantly outperform non-RP $CsPbBr_3$ PNCs.

3:30 PM *EL02.10.06
Priming InP-Based Quantum Dots for On-Chip LED Color Conversion Zeger Hens and Pieter Schiettecatte; Ghent University, Belgium

InP-based quantum dots have emerged as an alternative for CdSe-based materials for luminescent color conversion in the visible. At the same time, color-conversion approaches are shifting from remote phosphor on-chip configurations, which implies exposure to higher light intensity and increased operation temperature. In this contribution, we discuss recent progress in the synthesis of InP-based core/shell quantum dots, reaching near unity photoluminescence quantum yield across the visible spectrum and the formation of monochromatic LEDs by means of on-chip color conversion through InP-based quantum dots. In addition, we address in detail the properties of the core/shell interface and the termination of the quantum dot outer surface that made this result possible and discuss different mechanisms of failure - leading to a deterioration of the color conversion efficiency - from an atomistic perspective.

4:00 PM EL02.10.07
Understanding Electrical Excitation Dynamics in Quantum-Dot Light-Emitting Diodes: From Steady-State to Temporal Behaviors Yunzhou Deng[1] and Yizheng Jin[2]; [1]University of Cambridge, United Kingdom; [2]Zhejiang University, China

Light-emitting diodes based on colloidal quantum dots (QDs) promise a new generation of color-pure, cost-effective, and flexible light sources. Despite of the tremendous advances in the synthesis of QDs, the electroluminescent (EL) properties of QDs generally lag behind their photoluminescent (PL) properties. These EL-PL gaps originate from the essential difference in the charge dynamics of electrical excitation with respect to optical excitation. Here, we report our recent advances in understanding the electrical-excitation dynamics of QDs in active quantum-dot light-emitting diodes (QLEDs) in both steady-state operations, long-term evolutions, and transient EL dynamics under pulsed excitations.
First, we unraveled how the dynamic charge balance can be achieved in the steady-state operation of red, green, and blue QLEDs, leading to high-performance devices with near-limiting efficiencies [1,2]. Key to this is the sequential charge injection at single-nanocrystal level and effective blocking of

electron leakage at the polymer/QD interface. Then, we address an anomalous efficiency-elevation phenomenon induced by operational degradation. Comprehensive in-situ characterizations reveal that this is caused by the ligand migration between the electron-transport layer and the cathode, which in turn improves the charge balance in long-term operation. Finally, we report the excitation-memory effects in the transient EL dynamics of QLEDs modulated by deep-level trap states. By utilizing this unique process, we demomstrate 100 MHz modulation and data transmission based on micro-QLEDs.

8:00 AM *EL02.11.01
Photo-Crosslinkable Ligands for High-Density Patterning of Perovskite Nanocrystals Zhi Kuang Tan; National University of Singapore, Singapore

The patterning of luminescent quantum dots and nanocrystals into micron-sized pixels is required for applications in electronic color displays. In the recently-developed QD-OLED technology (Quantum Dot Organic Light-Emitting Diode), semiconducting quantum dots are deposited onto blue OLED display pixels by inkjet printing methods to enhance the color quality of the displays. However, inkjet printing is prone to alignment and clogging issues, which impacts the manufacturing yield of these devices. In this talk, I will discuss the development of new crosslinkable ligands that would allow high-density patterning of perovskite nanocrystals or quantum dots by photolithography techniques. Our new ligands attach to the nanocrystals via an entropy-driven ligand exchange process. The resulting nanocrystals could be deposited onto substrates and be patterned by a photo-initiated polymerization process, similar to well-established photolithography protocols that are used in the semiconductor industry.

8:30 AM *EL02.11.02
A Path Toward Making Mid-Wave Infrared Sensing a Ubiquitous Technology Dong Kyun Ko, Mohammad Mostafa Al Mahfuz, Junsung Park and Rakina Islam; New Jersey Institute of Technology, United States

Reducing the size, weight, power consumption, and cost of infrared detectors can make the use of infrared sensing ubiquitous. In the technologically important spectral region of mid-wavelength infrared (MWIR = 3 - 5 μm), commercially available detectors suffer from the high cost associated with epitaxial growth and hybridization as well as the stringent requirement for cryogenic cooling, limiting their use to defense and space applications. The colloidal quantum dot is one of the potential materials candidate to overcome these limitations due to the availability of low-cost synthesis and wafer-scale device fabrication via solution processing. Infrared sensors based on colloidal quantum dots have been studied for decades, and harnessing the interband transition in these quantum-confined nanostructures has been the mainstream theme in optoelectronic research. More unique photophysical properties can be harnessed by utilizing the transitions within the conduction levels or valence levels, known as intraband (intersubband) transitions. In this presentation, we discuss the progress, challenges, and opportunities of MWIR sensors fabricated from Ag_2Se intraband colloidal quantum dots, a heavy metal-free colloidal nanomaterial that has merits for wide-scale adoption in consumer and industrial sectors.

9:00 AM EL02.11.03
Doubling Photoluminescence of Red-Emitting Quantum Dots by Direct Transfer from Hexane into Water Without Adding Extra Reagents Tohid Baradaran Kayyal and Marie-Christine Daniel; University of Maryland, Baltimore County, United States

The demand for converting hydrophobic nanoparticles (NPs) into water-soluble NPs, specifically red-emitting quantum dots (QDs) synthesized in organic solvents, has led to extensive research. However, the current methods for transferring these NPs face challenges related to their efficiency and a decrease in their photoluminescence quantum yield (PLQY). In this study, a remarkably facile and efficient technique was utilized to transfer oleic acid (OA)-coated CdSe/CdS core-shell QDs into water without the need for additional chemicals or agents. This process results in an unexpected increase of over 100% in PLQY upon transfer into basic water (pH 8). The transfer method is highly reproducible and can be extended to other oleic acid-based particles like magnetic NPs. The process is a straightforward method using ultrasonic assistance completed within only 4 hours at room temperature, involving the rearrangement of OA ligands at the QD surface, leading to the formation of a 'mixed' monolayer. This innovative configuration exposes approximately half of the carboxylic acid moieties to the QD surface and directs the remaining towards the aqueous medium. Density-functional-theory (DFT) calculations corroborate this rearrangement, indicating its favorable energetic state in aqueous media. The behavior of the transferred QDs was investigated and compared to that of the original QDs in hexane through absorption spectroscopy, fluorescence spectroscopy, and transmission electron microscopy. Regarding DFT calculations, Quantum ESPRESSO was utilized and CdS surfaces were generated to mimic core-shell quantum dot surfaces. This discovery can open promising avenues for employing NPs especially conventional QDs synthesized in organic solvents for applications in aqueous media. The ease of transferring QDs into a water environment will also facilitate a variety of assembly methods that rely on aqueous surface chemistry, and applications in the field of biomedical imaging.

Unravelling Nanocrystal Surface Structures with Relativistic DFT Calculations of Cadmium and Selenium Solid-State NMR Spectra of CdSe Nanocrystal Surfaces Rana Biswas[1,2], Yunhua Chen[1,2], Javier Vela[2,1] and Aaron Rossini[2,1]; [1]Iowa State University, United States; [2]Ames Laboratory, United States

Semiconductor nanocrystals (NCs) offer novel tunable electronic and optical properties that depend on their size, shape and surface passivation. Semiconductor NCs exhibit multiple exciton generation and are appealing for next-generation solar cells. Surface ligands and surface sites on NCs control their nucleation, growth, colloidal stability, chemical reactivity and optical/electronic properties. However direct experimental probes of the molecular structure of NC surfaces are lacking. Solid-state nuclear magnetic resonance (SSNMR) is a powerful tool to determine the structure of NC surfaces and sites on the surface where ligands can bind.
Using CdSe as a prototypical example, SSNMR spectra have been measured to probe the structure of these nanocrystals and develop detailed models of their surface structures. DFT-optimized cluster models that represent probable molecular structures of carboxylate coordinated surface sites have been proposed. However, to the best of our knowledge, ^{113}Cd and ^{77}Se chemical shifts have not been calculated for these surface models. We performed relativistic DFT calculations of cadmium and selenium magnetic shielding tensors on model compounds with previously measured solid-state NMR

spectra, with (i) the 4-component Dirac-Kohn-Sham (DKS) Hamiltonian, and (ii) the scalar and (iii) spin-orbit levels within the ZORA Hamiltonian. Molecular clusters with Cd and Se sites in varying bonding environments were used to model CdSe (100) and CdSe (111) surfaces capped with carboxylic acid ligands. Our calculations identify the observed ^{113}Cd isotropic chemical shifts δ(iso) of –465 ppm, –318 ppm and –146 ppm arising from $CdSeO_3$, $CdSe_2O_2$, and $CdSe_3O$ surface groups respectively, with very good agreement with experimental measurements. The ^{113}Cd chemical shifts linearly decrease with the number of O-neighbors. The calculated spans ($\delta_{11} - \delta_{33}$) encompass the experimental values for $CdSe_3O$ and $CdSe_2O_2$ clusters but are slightly larger than the measured value for $CdSeO_3$ clusters. Relativistic DFT calculations predicted a one-bond ^{113}Cd-^{77}Se scalar coupling of 258 Hz, in good agreement with the experimental values of 250 Hz. With a dense coverage of carboxylic acid ligands, the CdSe (100) surface shows a distribution of Cd-Se bond lengths and J-couplings. Relativistic DFT simulations aid in interpretation of NMR spectra of CdSe nanocrystals and related nanomaterials, and offer new insights into the complex structures at nanocrystal surfaces.

9:30 AM EL02.11.05
Optimising Spectral Quality of Ternary Copper Dichalcogenide Core-Shell Nanoparticle Luminescent Down-Shifting Films in Controlled Environments Stefan C. Ghany and Richard A. Taylor; The University of the West Indies, St. Augustine Campus, Trinidad and Tobago

The development of luminescent down-shifting films (LDS) for spectral adaptation in controlled environment agriculture systems (CEAs) towards improved crop yields has been of tremendous focus in recent years. Due to their tunable nature, they can better utilise the sun's energy for effective light transmittance, down-shift emission into photosynthetically active radiation (PAR), while also reducing unwanted wavelengths which contribute to the generation of excessive heat within the CEAs; detrimental to crops grown in hot climates.

Copper-based dichalcogenide quantum dots (QDs) are regarded as environmentally benign materials that display desirable optical properties resulting in their use in LDS films in CEAs. In this project, a facile hot-injection colloidal synthetic protocol is employed. Highly luminescent copper indium sulphide (CIS) nanoparticles synthesised between 180 – 240 °C and excited at 525 nm emit between 619 – 639 nm (orange – red light) of varying luminescent intensities, FWHM between 79 – 90 nm, and peaking at 230 °C after 25 minutes of growth. Particle size is largest at 10 nm under the 240 °C protocol, with triangular morphology and high crystallinity due to their sharp edges and clearly defined uniform inter-particle distances indicative of effective binding of 1-dodecanethiol and oleic acid surfactants.

Energy dispersive spectroscopic (EDS) analysis reveals that at lower synthetic temperatures between 180 – 200 °C an off-stoichiometric copper-deficient particle with respect to indium ($Cu_{0.59}In_{0.94}S_{2.46}$ at 180 °C), produces negligible to low orange – red luminescence with direct bandgaps between 2.31 – 2.13 eV respectively after 30 minutes of growth. At higher synthetic temperatures between 220 – 240 °C, however, the EDS data indicate a copper-rich particle with respect to indium ($Cu_{1.26}In_{0.65}S_{2.09}$) with the highest red luminescent intensity at 230 °C. Direct bandgaps decreased from 2.06 to 2.03 eV after 30 minutes of growth. Further characterization using X-ray photoelectron spectroscopy, Raman spectroscopy and time-resolved photoluminescence spectroscopy implicate several defects such as copper vacancies and interstitials influencing the remarkable luminescent properties of CIS.

Additionally, surface shelling the CIS core particles with zinc sulphide (ZnS) further tunes their optical properties for effective spectral adaptation by not only increasing the luminescent intensity through surface passivation and decreasing surface defects, but by blue-shifting its emission by cation-exchange mechanisms at the core's surface with CIS emission from 634 nm (FWHM 79 nm) at 220 °C, to 620 nm (FWHM 72 nm) CIS/ZnS shell growth at 210 °C for 30 minutes.

The highly luminescent nanoparticles will be embedded into transparent polymers of either poly(lauryl methacrylate-co-ethylene glycol dimethacrylate) (P(LMA-co-EDGM)) or poly(ethylene-vinyl acetate) (P(EVA)) to form LDS films of effective thickness to effect the desired optical properties which can enhance crop yield. The nanocomposite LDS films will be used as a prototype solar window element to evaluate the effectiveness of the QDs to spectrally adapt the solar spectrum to improve certain crop yields under controlled conditions in CEAs.

9:35 AM EL02.11.06
Green" Cu@ZnInSe/ZnSeS Core/Composition Gradient Shell Quantum Dots for Boosted Photoelectrochemical Hydrogen Production Kokilavani Shanmugasundaram[1], Lei Jin[1], Gurpreet S. Selopal[2] and Federico Rosei[1]; [1]Institut National de la Recherche Scientifique, Canada; [2]Dalhousie University, Canada

Colloidal quantum dots (QDs) are considered building blocks for solar energy devices due to their promising optoelectronic properties, such as size/shape/composition-dependent absorption and emission spectrum and high absorption coefficient. However, well-performing QDs in solar energy conversion technologies (i.e. photovoltaics or clean fuel production) are typically containing toxic heavy metals (e.g., Cd and Pb), which restricts their commercial applications. In this context, eco-friendly Cu-doped ZnInSe QDs emerged as a promising alternative due to their unique merits, including the long lifetime of charge carriers and suitable band structure for charge injection. Nonetheless, the sensitivity of the plain Cu:ZnInSe QDs may induce surface defects that act as charge recombination centers, leading to a severe deterioration of the photoelectrochemical (PEC) performance. The growth of suitable shell material is a promising approach for effective suppression of surface related defects/traps states and obtain a tailored optical response of QDs. Here, we report the synthesis of Cu:ZnInSe/ZnSeS core/composition gradient shell with tuneable shell thickness to understand the influence on optoelectronic properties, consequently PEC performance for hydrogen production. An optimized thick composition gradient shell obtained with low Se/S ratio (n = 2 and r =0.05) showed broader absorption toward longer wavelength and high PL quantum yield. Resulting PEC device based on the Cu@ZnInSe/ZnSeS core/shell QDs with n =2 and r = 0.05 exhibited an excellent saturated photocurrent density of 11.7 mA/cm^2 (at 1 V vs RHE) under one sun illumination (AM 1.5 G, 100 mW/cm^2), which is 96% higher than the achieved value of bare Cu@ZnInSe QDs. The investigation and its findings will be presented in detail, exploring how controlled composition gradient shell thickness influences surface passivation and carrier dynamics. In addition, the significance of composition gradient shell layer to achieve enhanced device performance will be discussed, highlighting its great potential for future eco-friendly core/shell QD-based solar energy technologies.

Binary and Ternary Intermetallics for Advanced Interconnect Metallization Jean-Philippe Soulie[1], Nancy Heylen[1], Kiroubanand Sankaran[1], Jeroen E. Scheerder[1], Claudia Fleischmann[1,2], Johan Swerts[1], Zsolt Tokei[1] and Christoph Adelmann[1]; [1]IMEC, Belgium; [2]KU Leuven, Belgium

In the recent past, alternatives to Cu metallization have elicited much interest for advanced interconnect applications due to increasing intrinsic limitations of line resistance and reliability at line widths below 20 nm [1,2]. Elemental metals with short mean free path (MFP) such as Co, Mo [3] or Ru [4] were first proposed to replace Cu and to improve line resistance and reliability. The effort has been recently extended to include binary and ternary compounds [5, 6].
Amongst binary compound metals, only certain ordered intermetallics show low bulk resistivities with values that are potentially of interest for interconnect applications. The study of binary metals for interconnect applications has therefore focused completely on intermetallic ordered compounds. *Ab initio* screening (by assessment of the $\rho_0 \times \lambda$ figure of merit together with calculations of the cohesive energy [7]) indicated that especially binary aluminides show promise for alternative metallization. The most promising materials include NiAl, CuAl, $CuAl_2$, RuAl and $ScAl_3$. Thin films of these aluminide intermetallics were then studied experimentally to assess their properties and their potential for interconnect metallization. Low thin film resistivities have been obtained for NiAl, CuAl, $CuAl_2$ and $ScAl_3$ [8, 9]. Despite different crystal structures and constituents, binary aluminide intermetallics share common properties and challenges such as crystalline order, point defects, composition control, composition uniformity, secondary phase formation, agglomeration, (interface) reactivity, or non-stochiometric surface oxidation. These common challenges will be discussed in detail, highlighted by multiple experimental examples. We show by atom probe tomography that stochiometric NiAl films are prone to local compositional variations on nm scales, which are difficult to detect with other techniques. For thicknesses below ~15nm, the thin film resistivity strongly increased, and the effect of annealing was reduced. Resistivity modelling found that the resistivity of thin NiAl films below ~ 15 nm was dominated by grain boundary scattering due to small grain sizes, with little impact of surface scattering. To mitigate this issue, the grain size for a given film thickness was increased by back thinning of thicker films (with larger grains) using ion beam etching (IBE) or chemical mechanical polishing (CMP). The resistivity of NiAl could be further optimized at small thicknesses by combining the back thinning experiments with epitaxial deposition: a resistivity as low as 11.5 μΩcm at 7.7 nm for epitaxial NiAl on Ge (100) has been demonstrated [10], which outperforms PVD Ru and Cu at comparable thicknesses and thermal budget. We discuss prospects of such approaches for integration.
Finally, we discuss ternary compounds as replacement for Cu in advanced metallization schemes. We will discuss potential classes of materials (e.g. MAX materials) and their prospects. We introduce a materials complexity index for alternative metals to reflect the complexity of the material control. The index can also be used to develop mitigation activities to reduce complexity.

Formation of Surface Sulfide Layer on Liners for Reducing Interface Scattering of Ruthenium Interconnect Yu-Lin Chen, Kai-Yuan Hsiao, Dun-Jie Jhan, Ming-Yen Lu, Pei Yuin Keng and Shou-Yi Chang; National Tsing Hua University, Taiwan

Ruthenium with a low bulk resistivity, a high melting point and a short mean free path of electron is of great potential to replace copper as the next-generation metallization for low-resistance interconnects. However, the drastic resistivity scaling with the continual decrease of linewidth due to the scattering of electrons at the interfaces with dielectrics or liners needs to be minimized. Much specular scattering is expected when a layer of two-dimensional materials such as disulfides is applied to the interface, retaining the original electron density of state of the metals. Hence in this study, three types of liner materials (tantalum-titanium alloy, nitride and oxide) were deposited on silicon substrates by physical vapor deposition. Instead of complicated transfer process, sulfurization was applied onto the surface of the liner layers in a tube furnace at different temperatures, simply by using sulfur vapor or hydrogen sulfide gas, to form an ultrathin sulfide layer. Thin ruthenium films with different thickness were then deposited on the sulfurized liners for investigating the influence of the sulfide layer on interface scattering. The microstructure, chemical composition and bonding configuration of the sulfurized surface were characterized, and the resistivity scaling of the ruthenium films was examined with implementation of the Fuchs-Sondheimer and Mayadas-Shatzkes models. Experimental results indicate that, with the sulfur vapor and particularly the hydrogen sulfide gas at an appropriate temperature, an ultrathin sulfide layer of only a few nanometers thick was successfully formed on the top surface of the liners and changed the binding states from a metallic, nitride or oxide state to a sulfide state with altered binding energy. Microscopic observations revealed a crystalline structure of tantalum-titanium binary sulfide being formed, similar to the structure of two-dimensional sulfide materials. With the surface sulfide layer on the liners, the interface diffuse scattering was effectively reduced to elevate the permeability of electrons from 0.2 to 0.9, and the resistivity scaling was accordingly lessened for at least 40% at a ruthenium film thickness of below 10 nm, without a significant loss of interfacial adhesion strength.

11:15 AM EL03.01.03
In Depth Study of In-Plane Thermal Conductivity of Thin Diluted AlCu Alloy Films as Metallic Interconnects Sara Makarem[1], Daniel Hirt[1], Giovanni Steves[2] and Patrick E. Hopkins[1]; [1]The University of Virginia, United States; [2]Sandia National Laboratories, United States

Understanding the thermal conductivity trends in metallic thin films has attracted tremendous interest over the past decades due to their wide applications as interconnects in integrated circuits of electronic devices. As the dimension of the metallic interconnects has decreased comparable to the electron mean free path, size effects on the thermal transport process becomes of high importance. Reduction in size also leads to a reduction in thermal conductivity of the thin metallic films. Such a reduction will then worsen the heat transfer in the circuits and, in most cases, lead to the burnout of the circuit following by the device failure. Upon reduction in size, thermal and electrical conductivity of these interconnects are governed by emerging phenomena that challenge our understanding of the thermal and electrical conductivity of bulk materials. Matthiessen's rule combines all the non-ideal effects together through a summation rule to calculate the electronic mobility and thermal conductivity of systems subject to multiple scattering sources. Therefore, it can be readily applied to estimate the relative magnitude of different scattering mechanisms. Matthiessen's rule has been widely used to predict the phonon thermal conductivity of dielectric solids and the electrical conductivity or electronic thermal conductivity of metallic materials.
In this work we address the limitations of Matthiessen's rule in estimating thermal conductivity of $Al_{99.5}Cu_{0.5}$ (AlCu) films at nanometer length scales and as a result of alloying. We employ ultrafast laser spectroscopic techniques such as time-domain thermoreflectance (TDTR) to directly measure the in-plane thermal conductivity of AlCu films ranging from 24 to 175 nm. We investigate the in-plane thermal conductivity trend with film thickness down to thicknesses comparable to the electron mean free path of Al which is ~19 nm. In principle, one can attribute deviations from Matthiessen's rule to three causes: (a) changes in the band structure and the phonon spectrum due to alloying (b) additional temperature-dependent scattering processes associated with solute atoms, in particular phonon-assisted impurity scattering processes, where electrons and phonons are scattered by solute atoms, and (c) the "two-band" effect where two or more groups of electrons and phonons with different relaxation times contributing to the conductivities. In addition to the experimental thermal conductivity measurements and in order to gain a better understanding of the role of electron-phonon scattering in total thermal conductivity, we measure scattering rate with IR-VASE, an spectroscopic ellipsometry technique. All the provided characterization techniques enable us to validate the contributing share of the electron-electron, electron-phonon, or electron-system boundaries scattering in total thermal conductivity of these films.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

11:30 AM EL03.01.04
Quasi-2D Materials for Ultra-Low Resistance Electrical Interconnects Bilal Azhar, Tobias Schwaigert, Qi Song, Cameron Gorsak, Yacob Melman, Darrell G. Schlom and Hari Nair; Cornell University, United States

The dramatic increase in the resistivity of interconnect lines with decreasing dimensions presents a significant bottleneck for further downscaling of integrated circuits.[1] This is because current interconnects use 3-dimensional metals which experience increased interface electron scattering as the interconnect dimensions approach their electron mean free path. A possible solution is to use metals with much lower electron mean free paths such as: W, Mo, and Ru. Metallic delafossite oxides are an alternative solution because of their inherent advantages over traditional metals such as, ultra-low room temperature resistivity, potential mitigation of interface/surface scattering due to their 2D Fermi surface, potentially decreased likelihood of electromigration, and potentially better compatibility with low-K oxide dielectrics. Metallic delafossite can prove to be a disruptive new material for ultra-scaled electrical interconnects.

Delafossites are layered oxides with the formula ABO_2 where A is a metal cation that forms 2D sheets separated by the BO_2 transition-metal oxide octahedra. In this study we focus on metallic delafossites $PtCoO_2$ and $PdCoO_2$ because of their ultra-low room temperature resistivity of 2.1 μΩ.cm and 2.6 μΩ.cm, respectively, which is comparable to the current semiconductor industry standard interconnect metal, Cu.[2] The metallic delafossite structure has an anisotropic nature with resistivity along the c-axis a factor of 1000 higher than resistivity within the Pt/Pd sheet. Due to the layered crystal structure, the Fermi surface of the metallic delafossites is cylindrical as for a 2D metal. This quasi-2D crystal structure can potentially mitigate interface and surface scattering since the electron Fermi velocity does not have components perpendicular to the Pd/Pt sheets. This can potentially overcome the resistivity penalty encountered by conventional 3D metals in ultrathin films (< 20 nm). Additionally, the unique Fermi surface topology allows for an electron-phonon coupling constant that is a factor of 3 lower than copper.[3]

In this study we investigate the structural and electrical properties of MBE-grown $PdCoO_2$ delafossite films. High-resolution X-Ray diffraction (HRXRD) confirms that the films are phase-pure. XRD phi scans, however, reveal in-plane twinning in these films, and the lateral size of the rotational twin domains are ~17 nm based on skew-symmetric rocking curves. We measured the resistivity of the films using a van der Pauw geometry and modelled the resistivity scaling with film thickness using Fuchs-Sondheimer (FS) and Mayadas-Shatzkes (MS) model. The upshot is that a 50 nm thick $PdCoO_2$ film has a resistivity of 5 μΩ.cm. Based on our resistivity fitting we find that the twin boundaries have a very low electron reflection coefficient of ~5%. This is extremely encouraging since atomic layer deposition (ALD) which is a back-end-of-the-line (BEOL) compatible synthesis technique will likely yield highly twinned delafossite thin films.

Ballistic Thermal Transport in TiN/TiC Multilayers due to Interfacial Elastic Modulus Enhancement Md. Rafiqul Islam[1], Elie Azoff-Slifstein[2], Sean King[3], Daniel Gall[2] and Patrick Hopkins[1]; [1]University of Virginia, United States; [2]Rensselaer Polytechnic Institute, United States; [3]Intel Corporation, United States

The scale of microelectronics is gradually reducing towards dimensions comparable with the electron mean free path. Since there is a need to dissipate ever increasing amounts of waste heat in microelectronic applications the increased device and interface density is highly undesirable. Thus, the approach of engineering materials with high densities of interfaces to achieve desirable thermal conductivity solids requires a fundamental understanding. In this work, we report on the thermal conductivity of a series of crystalline multilayers composed of alternating layers of titanium nitride and titanium carbide with varying interface densities.We deposit titanium nitride and titanium carbide superlattice films on MgO(001) by reactive magnetron sputtering in an ultra-high vacuum chamber. The alternating nitride carbide layers are formed using reactive mixtures of Ar/N and Ar/CH_4, respectively. The 1 um thick samples are deposited at 1100 °C with alternating layer thicknesses between 1.5 and 15 nm. We directly measure the thermal conductivity of these films via the time-domain thermoreflectance technique. We find that the thermal conductivity increases with an increasing interface density indicating that the heat carriers are scattering less in the interfaces of the multilayers. This finding contradicts the traditional theory and conventional understanding. The role of interfacial nonidealities and disorder on thermal transport across interfaces is traditionally assumed to add resistance to heat transfer. The increase in thermal conductivity could be related to their increase in their elastic modulus which was measured by picosecond acoustic and nanoindentation techniques. The increase in interface density leads to a monotonically increasing elastic moduli imply a high quality of interface formation which usually results in a higher thermal conductivity. Our results demonstrate a path toward engineering thermal conductivity, thus providing a novel approach to dissipate the ever-increasing amounts of waste heat in microelectronic devices and alleviate the concern for the continuation of Moore's law.

SESSION EL03.02: Metallization II
Session Chairs: Silvia Armini and Eiichi Kondoh
Tuesday Afternoon, April 23, 2024
Room 346, Level 3, Summit

1:30 PM *EL03.02.01
Interconnect Technology for Superconducting Devices and its Interface Properties Masahisa Fujino[1], Yuuki Araga[1], Hiroshi Nakagawa[1], Katsuya Kikuchi[1] and Noboru Miyata[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Comprehensive Research Organization for Science and Society (CROSS), Japan

Superconducting devices, such as superconducting tunnel junction (STJ), qubits, etc. can be manufactured by the current Si-based semiconductor manufacturing processes. However, circuits should be superconducting material such as Nb (T_c=9.29 K), Pb (T_c=7.2 K), In (T_c=3.4 K) , etc.
In current technology, these devices are arranged in monolithic structures and processes, and each device should wire to control and read signal lines in the same plane. When a large number of devices and/or high-density devices are integrated, these wires would be too constrained, and several problems would be actualized, such as wiring for devices located at the chip center, crosstalk among wiring, and so on.
3D integration of qubits with interposer chips by flip-chip bonding is the proof-of-concept of large-scale qubit integration. The 3D integration approaches for qubit-based devices are the same as conventional electronic devices, including the through silicon via (TSV) process for interposers and micro bump flip-chip bonding.
3D integration for STJ would acquire the high density of sensing top electrodes for detecting x-rays from far away.
Also, the signal integrity for qubits is much better than having qubits at short distances from the control circuitry by 3D integration.

However, they use superconducting metals instead of copper and other non-superconducting materials. Most flip-chip microbump bonding processes require thermal compression bonding (TCB)at over 170 °C. Superconducting elements are easily degraded by heat.
Consequently, we apply TCB around 100 °C using In-Pb alloy.
Surface activated bonding (SAB) was also applied for room temperature bonding of Nb-Nb as superconducting metal.
Both bonding processes succeeded in confirming the superconducting interconnect.

Additionally, we discuss the superconducting interface of direct bonded Nb-Nb by T_c, and also the interfacial structure measured by polarized neutron reflectometry (PNR). The results show clear spin asymmetry in the superconducting state, as splitting is observed in the fringes of the parallel neutron (neutron spins parallel to the external magnetic field 0.1 T) reflection R^+ and the antiparallel (neutron spins antiparallel to it) reflection R^-, where the latter has become larger. This well-known effect is related to the flux penetration in the superconducting state. Therefore, unique information about the superconducting state of the buried thin film can be measured by using the polarized neutron beam. For this project, the major advantage of PNR will be to characterize the superconducting state at the deeply buried Nb interfaces sandwiched between the two substrate wafers, which would be infeasible using alternate techniques.

2:00 PM EL03.02.02
A Meta-Analysis of Non-Copper Nanowire Resistivities Sean King; Intel Corp, United States

Innovations in back-end-of-line (BEOL) interconnects over the past several decades have been driven primarily by both Moore's law mandated dimensional scaling of Cu wiring and permittivity scaling of low dielectric constant (i.e. low-*k*) interlayer dielectrics (ILDs) to mitigate increased resistance-capacitance (RC) delays. However, due to the demand for continued dimensional scaling, the industry now faces an exponential rise in interconnect metal line resistance created by both increased Cu resistivity size effects and limitations in thickness scaling for the Cu diffusion barrier materials needed for yield and reliability considerations. This has created an intense interest for identifying new conductors that exhibit reduced resistivity size effects and / or that require no or reduced thickness diffusion barriers. To support the identification of potential copper replacement conductors, we share a benchmarking Meta-analysis of nanowire resistivities publicly reported in the scientific literature for numerous metals including those currently under active consideration (i.e. Cobalt, Tungsten, Ruthenium, and Molybdenum) as well as up and coming metals (Iridium, Rhodium) and other potentially

overlooked metals. We will conclude by examining the supply chain challenges that may ultimately play a role in the selection of future copper replacement conductors and discuss research needed to address these challenges.

2:15 PM EL03.02.03
Highly Textured (100)-Oriented and (111)-Oriented, Cobalt Mono Silicide Nanoribbons: Material Growth and Device Fabrication Guy M. Cohen, Peter Kerns, Leonidas Ocola, Nathan Marchack, John Bruley, Franco Stellari, David Rath, Christian Lavoie and Ching-Tzu Chen; IBM T.J. Watson Research Center, United States

Topological conductors with protected surface conduction states are candidates for scaling beyond copper interconnects. The topological semimetal CoSi is used here to study the properties of this class of materials because of the well-separated surface and bulk bands in its band structure. Highly textured CoSi nanoribbons were fabricated by sputtering Co on a hot Si (111) oriented facet. The as-grown CoSi nanoribbons showed a (100) surface orientation. A further annealing resulted in rearranging the CoSi surface orientation to (111). Devices for electrical testing of the nanoribbons were fabricated by patterning (100)-oriented silicon-on-insulator (SOI) into bars, then using TMAH etching for forming (111) sidewall facets on both edges of the SOI bars. A diluted HF (DHF) clean was used to strip the native oxide and H-passivate the Si (111) facets prior to cobalt deposition. The unreacted cobalt in the field region was selectively etched leaving isolated nanoribbons on the Si (111) facets. The nanoribbons were encapsulated by a dielectric and tungsten contacts to the nanoribbons completed the device fabrication. Initial electrical characteristics of nanoribbons with a width down to 20 nm and thickness of ~3 nm were measured.

2:30 PM *EL03.02.04
Size Effects on The Electron and Phonon Scattering and Thermal Conductivity of Thin Metal Films and Multilayers for Metal Interconnects: Looking Beyond Copper Patrick E. Hopkins; University of Virginia, United States

The progressive reduction in the characteristic length scales of logic technology nodes in very-large-scale integration (VLSI) has led to the need to find replacements for copper being used as interconnects. Both the thermochemical and thermomechanical stability of Cu at these length scales, along with the strong reduction in both electrical and thermal conductivity due to length scales reducing to those less than its electronic mean free path has led to underperformance, which in part can be ascribed to deleterious heating effects. While Ru and W interconnects are currently being evaluated, a range of additional metals and metallic systems (alloys, eutectics and multilayers) are also of note due to their potential mechanical and thermal properties that are superior to Cu at the < 100 nm length scale. In this presentation, I will discuss our recent efforts in measurements of thermal conductivity and electron-phonon scattering rates of thin metal films for interest as next-generation metal interconnects, including Ru, W, Ir, Pt, Mo, Co and Ta. First, I will discuss the use of steady state thermoreflectance (SSTR) as a measurement platform to measure the in-plane thermal conductivity (k) of thin metal films. This measurement of in-plane allows for direct comparison to k derived from electrical resistivity measurements and application of the Wiedemann-Franz (WF) Law. We find that in most cases, the application of the WF law with the low temperature value of the Lorenz number does not sufficiently predict the total thermal conductivity. To understand the mechanisms that drive the thermal transport of these metal films, we use both infrared pump-probe measurements (< ps) and infrared variable angle spectroscopic ellipsometry (IR-VASE) the measure the electron scattering rates, demonstrating the relatively thickness independent scattering processes in these films, providing strong promise in the scaling of these metals to technology node length scales. Finally, I will talk about classes of multilayer metal/metal and metal nitride/metal carbides in which interfaces do not scatter electrons and phonons strongly enough to impact the thermal resistance, thus introducing a series of “interface transparent” metal multilayers that do not exhibit traditional size effects in their thermal conductivity. I will conclude by commenting on new thermal metrologies that can provide truly nanoscale thermal resistance measurements and the elucidation of new mechanisms of interfacial thermal transport.

Pixel Pitch Hybrid Bonding and Three Layer Stacking Technology for BSI Image Sensor Kazumasa Tanida, Shigeru Suzuki, Toshiki Seo, Yasunori Morinaga, Hayato Korogi, Michinari Tetani, Masakazu Hamada, Ryuji Eto, Takeshi Yamashita, Yasuhiro Kato, Naoaki Sato, Tadami Shimizu, Tetsuro Hanawa, Hiroko Kubo, Fumitaka Ito, Yoshihiro Noguchi, Masayuki Nakamura, Ryuji Mizukoshi, Masahiko Takeuchi, Masakatsu Suzuki, Naoto Niisoe, Isao Miyanaga, Atsushi Ikeda and Susumu Matsumoto; Tower Partners Semiconductor Co., Ltd., Japan

Abstract
We have developed a pixel pitch (1.35 µm) hybrid wafer bonding technology and successfully demonstrated three layer stacked backside illuminated (BSI) image sensor fabrication with full hybrid Cu-Cu direct bonding process. We found that plasma activation condition on the bonding wafer surface is a key factor of Cu-Cu contact yield improvement for smaller size Cu contacts. Optimized pixel pitch hybrid bonding shows good electrical and reliability performances. For three layer stacking, we developed through Si via (TSV) process. The second hybrid bonding process was adapted on the first hybrid bonded wafers and it shows good electrical performances. This three layer stack technology with pixel pitch hybrid bonding is promising for many different applications.
1. INTRODUCTION
Nowadays, hybrid wafer bonding with Cu-Cu connection is a major production technology of two layer stacked backside illuminated (BSI) image sensor applied for several applications [1]. In addition, three layer stacked BSI image sensor with through Si via (TSV) connection has been introduced to high performance cameras [2]. Furthermore, three layer stacked BSI with pixel pitch Cu-Cu connection will be required in order to realize much higher performance and multi functionality image sensors. In this paper, we developed key technologies for three layer stacking. One is pixel pitch hybrid wafer bonding with minute Cu-Cu connection, the other is three layer stacking process including TSV for middle layer and the 2nd hybrid wafer bonding. Finally, three layer stacking process was demonstrated by adapting these technologies.
2. PIXEL PITCH HYBRID BONDING
Cu-Cu contact with conventional hybrid wafer bonding conditions was studied utilizing the test element group (TEG) structure of Cu-Cu connection. The Cu-Cu contact pitch is 4.00 to 1.35 µm, and Cu electrode size is 1.25 to 0.42 µm square. As the results, Cu-Cu contact yield decreased as the contact pitch and pad size became smaller. The failure was Cu-Cu open mode with small gap between upper and lower Cu electrode. Cu-N compound layer on Cu

electrode surface was identified after plasma surface activation by wafer bonder. It indicates that Cu-N compound layer was formed because Nitrogen was dosed into Cu surface during plasma activation. We considered that the Cu-N compound layer formed on both upper and lower minute Cu electrode was not broken by compressive stress of Cu thermal expansion during post annealing. Therefore, the Cu-N layer acted as a barrier, and Cu-Cu metal bonding between minute electrodes was not achieved.
N/Cu ratio of Cu electrode surface was decreased with lowering N dose of plasma condition and 1.35 µm pitch Cu-Cu contact yield (438k chains TEG) was improved. The Qual test of 1.91 µm pitch Cu-Cu contact (0.60 µm sq.) namely, electro migration (EM), stress migration (SM), temperature cycling (TMCL) and I-V, were passed.
3. THREE LAYER STACKING DEMONSTRATION
Three layer stacking was demonstrated following flow; The middle layer is bonded to the top layer by the 1st hybrid bonding with 1.91 µm pitch Cu-Cu connection. After the middle layer Si thinning, the Cu-TSV and the backside BEOL are formed. Then the 2nd hybrid bonding is done in order to bond the backside of the middle layer to the bottom layer with Cu-Cu connection. Finally, top layer Si is thinned and Al-TSV through top layer Si is formed. The stack chain TEG (10 chain circuit through Al-TSV, the 1st hybrid pixel pitch Cu-Cu, Cu-TSV, back BEOL and the 2nd hybrid Cu-Cu) shows the small resistance distribution. As the results, good electrical path of three layer stacking was established.

Direct Metal Etch of Ruthenium: Enabling Sub 20nm Pitch Interconnects Gayle Murdoch, Giulio Marti, Stefan Decoster, Souvik Kundu, Anshul Gupta, Ankit Pokhrel, Seongho Park and Zsolt Tokei; IMEC, Belgium

The realisation of Moore’s law, which predicts that the number of transistors in an integrated circuit will double every 2 years, has been achieved by countless innovations in the semiconductor industry over the last 60 years. As device dimensions shrink the innovation in transistor design often grabs the headlines but of course this must be supported by innovation in the interconnect technology as the minimum metal line pitch shrinkage follows that of the gate.

Around 25 years ago the semiconductor industry made the radical transition from subtractive aluminium patterning to copper damascene, which required significantly different materials and fabrication techniques. This transition was necessary to increase the processing speed of the microchips; as the resistivity of Cu is 40% lower than Al, the RC delay is reduced, which is the performance indicator in BEOL.

In the present day, we are approaching the end of Cu damascene scaling and thus there is the requirement for another disruptive technology change to keep the RC delay at acceptable levels. Below 2nm node it is predicted that the minimum metal pitch will be < 20nm, at which point Cu damascene is not an option; even if it were possible to fill 10nm lines with Cu, the need for a metal barrier means the resistance would become too high. Therefore, we must look for an alternative interconnect material. One strong candidate is Ru, which has the convenience of having low resistivity and can be used without a barrier, giving an immediate resistance benefit for line dimensions below 12nm. Another advantage is that it can be patterned subtractively, giving access to higher aspect ratio lines than can be achieved with damascene integration schemes.

In this talk we will discuss how the subtractive patterning of Ru can realise the semi-damascene scheme which is proposed by imec as the alternative to Cu damascene at advanced logic nodes.

Thickness-Dependent Optical Properties of Metallic Thin Films and Their Correlation with Thermal Conductivity Saman Zare[1], Md. Rafiqul Islam[1], Sean King[2], Christopher Jezewski[2], Colin Landon[2], Rinus Lee[3], Kandabara Tapily[3], Colin Carver[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Intel Corporation, United States; [3]TEL Technology Center, United States

The semiconductor industry stands as a cornerstone of modern technology, and its relentless pursuit of miniaturization, efficiency, and performance hinges upon the precise control and understanding of materials used in electronic devices. Within this context, the study of thin films of metals takes on paramount significance. These films play a pivotal role in various semiconductor applications, as they are utilized not only as fundamental components in electronic devices but also as essential elements in the thermal management of these devices. As electronic components become increasingly compact and powerful, the efficient dissipation of heat generated during operation has become a critical challenge. Understanding the optical and thermal properties of thin metal films is instrumental in addressing these challenges, as it offers valuable insights into their potential as heat-dissipating materials and their influence on the performance and reliability of semiconductor devices.
In this study, we perform precise spectroscopic ellipsometry measurements on thin films of several metals that are of unique importance for electronic devices, including copper, iridium, ruthenium, and tungsten. Using these measurements, we determine the optical properties of these metallic thin films across a broad spectral range throughout the infrared and UV-Vis region. Through meticulous analysis involving the Drude free-electron model, we quantify variations in relaxation times and plasma energies in relation to film thickness. Furthermore, our investigation extends to exploring the intriguing interplay between size-dependent relaxation times, as derived from the Drude model, and the thermal conductivity of these metallic thin films, as measured using a thermoreflectance-based thermal conductance and ultrafast pump-probe technique. Our findings are instrumental in enhancing our understanding of these materials' behavior, with potential implications for the development of advanced electronic components.

SESSION EL03.04: Memory

Embedded non-volatile memories (eNVMs) are an essential component of modern microelectronics technologies, providing a reliable and cost-effective solution for storing critical data and program code in a wide range of applications. Microcontrollers, in particular, have shown a regular increase of their market, overpassing 20 Billions dollar by year with two digits growth in the last period. They benefit from the persuasion of microelectronics intelligent products in modern life, from the automotive and industrial sector, smartcards, to the communication grid and global interconnection growing needs. From a technological point of view, Mature Floating Gates technologies are progressively replaced by new back end of the line solutions, more compliant with High K / metal technology and density increase constraints. Spin Torque Transfer Magnetic Random Access Memories (STT MRAM), Oxide Based resistive Memories (OXRAM) as well as Phase change Memories (PCM) have been introduced in the last years and are nowadays qualified in production on different nodes by majors players. Different physics and architecture involved might lead to different memory characteristics and products best suited for each technology.
Developing memories for embedded microcontrollers requires to sustain very aggressive mission profiles for memory reliability, and its introduction in the Back end of integrated circuits adds up important technology limitations. In this presentation the author will describe the constraint of eNVM for microcontrollers, both from the application and the integration side. A comparison of the different BEOL memories technologies will be done in regard to device level performance and architecture, reliability mission profiles, memory point architecture versus integration, and technology cost. A special emphasis will be applied on ePCM technology, with description of device, process flow and materials optimization involved to fulfill aggressive product requirement with competitive solutions. Lastly, emerging memory solutions for storage memories as well as working memories in “In Memory Computing” approach will be discussed, highlighting the main challenges for each competitor (FeRAM, FeFET, OTS, RERAM).

9:15 AM EL03.04.02
Experimental Characterization and 1D KMC-Based Simulation of the Reliability of 28nm BEOL Integrated VCM ReRAM Nils Kopperberg[1], Stefan Wiefels[2], Karl Hofmann[3], Jan Otterstedt[3], Dirk Wouters[1], Rainer Waser[1,2] and Stephan Menzel[2]; [1]RWTH Aachen, Germany; [2]Forschungszentrum Jülich GmbH, Germany; [3]Infineon Technologies AG, Germany

Valence change memory (VCM) cells are promising candidates for non-volatile memory applications and neuromorphic computing [1]. Typically, they consist of a simple metal-insulator-metal (MIM) structure, where the insulating oxide layer can be manipulated by an externally applied voltage. Thereby, oxygen vacancies can be incorporated and redistributed in a way that the resistance of the oxide layer can be switched between a high resistive state (HRS) and a low resistive state (LRS). These states can be read out non-destructively and switched very fast. Furthermore, the cells show a great scalability, CMOS (complementary metal-oxide-semiconductor) compatibility and low power consumption [2,3].

Despite their excellent characteristics, a few questions and challenges concerning the key parameter reliability are still open. During the experimental characterization of the generally great endurance of 2Mbit VCM cells, we found a rare failure mechanism in a few ppm of the cells after about 500k cycles, where the cells could not be switched back into the HRS (RESET) [4]. The investigated cells are integrated back-end-of-line (BEOL) in a 1-transistor-1-resistor (1T1R) configuration in a 28nm CMOS technology.

Based on the JART VCM 1.0 model of La Torre [5], we developed a 1D KMC simulation model to physically explain the observed failure mechanism. We show that the interplay of the transistor and the VCM cell plays an important role. In rare cases of a combination of a high resistive transistor and a very low resistive cell, the voltage dropping over the cell is not sufficient to originate the RESET. Additionally, we experimentally investigate the RESET kinetics and their dependence on the used transistor. Here again, we can explain our findings with the help of the developed 1D KMC simulation model. In conclusion, we want to point out the importance of the interplay of transistor and resistor and its understanding for the improvement of the reliability.

Colloidal Syntheses of Novel Sb_2S_3 and Bi_2S_3 Cubic Phases for Phase Change Memory Applications Zach Wylie[1], Soohyung Lee[1], Vyvyan Dao[1], Jade Paranhos-Lopes[2], Nicolas M. Gaillard[2] and Vincent C. Holmberg[1]; [1]University of Washington, United States; [2]University of Hawai'i, United States

Phase change memory (PCM) is a developing technology that is set to position itself as the bridge between fast, volatile, dynamic random-access memory (DRAM) and slow, non-volatile, NAND flash storage which have become the workhorses of device architecture. To store non-volatile information, PCM typically utilizes the difference in resistance between the amorphous and metastable cubic phases of pseudo-binary GeTe-Sb_2Te_3 which undergoes a fast and reversible phase transformation. This phase change, which can occur in nanoseconds in thin films, allows for access times that can be a full order of magnitude faster than NAND flash. Despite seeming stoichiometrically imbalanced, the metastable cubic phase in Sb_2Te_3 and its alloys do not fall immediately into the more stable layered orthorhombic phase due to stabilization from a high concentration of cation site specific defects (>30%) which decreases the antibonding characteristics around the Fermi level. These defects are also responsible for the unique disorder-induced localization of states which accounts for a majority of the phase’s resistance. A noteworthy computational study by Xu et al. has predicted several other metal chalcogenides that could theoretically share a similar metastable cubic phase.[1] Here, we present a direct, scalable, colloidal synthesis route for two of these previously undiscovered defect rich cubic phases for Sb_2S_3 and Bi_2S_3 nanocrystals. Solution syntheses such as these will prove invaluable for studying these and other metastable phases for use in PCM technology that would be otherwise inaccessible by other synthetic routes.

Boron in The Back-End: Advances in Boron-Based Solids for Interconnect Applications Michelle M. Paquette; University of Missouri-Kansas City, United States

Playing a less glamorous yet critically important role, the interconnect system requires relentless innovation to support more complex and higher-density device architectures. To meet future demands, we require a constant supply of novel and better materials, material fabrication methods, and material combinations. Known for their robust mechanical, chemical, thermal, and electrical properties, boron-based solids are a compelling alternative to silicon-based solids for a range of interconnect material needs, to include low-dielectric-constant (low-*k*) dielectrics, etch stops, diffusion barriers, hard masks, spacers, capping layers, and other patterning-assist layers. This talk with cover advances in boron-based solids, including BC and BN, for state-of-the-art interconnect applications, touching on fundamental materials science, layer-by-layer deposition techniques, and functional and patterning applications.

10:45 AM *EL03.05.02
Porous Thin Films for Advanced Dielectrics using Molecular and Atomic Layer Deposition Nick C. Strandwitz; Lehigh University, United States

Atomic and molecular layer deposition (ALD, MLD) techniques boast precise control of film thickness, conformal growth, and a wide range of material compositions. Generally, ALD and MLD thin films are non-porous, yet introduction of porosity would enable a wide range of uses ranging from catalysis to low-k dielectrics for electronics. Here, we have examined the purposeful inclusion of organic molecules including bifunctional and monofunctional alcohols during the MLD/ALD process and their subsequent removal using thermal and/or UV treatment to induce porosity. We examined the evolution of various physical and electrical properties with thermal treatment as well as the composition of these films. We found that the density and dielectric constant of these materials are smaller than the parent dense ALD oxides. This strategy is thus promising for tailor made dielectrics based on sequential self-limiting surface reactions characteristic of the ALD and MLD processes. This development parallels other methods for forming porous inorganic oxides such as terpinene inclusion in silicon-based dielectrics or block copolymer templating of inorganic solids.

11:15 AM EL03.05.03
Surface Converted Interconnected Tetrapodal Zinc Oxide for Selective Sensing Application Barnika Chakraborty[1,2], Ajay Padunnappattu[1], Jürgen Carstensen[1], Rainer Adelung[1], Norbert Stock[1] and Leonard Siebert[1]; [1]Kiel University, Germany; [2]Katholieske University, Belgium

Gas sensors, a longstanding presence in the market, have yet to reach their full potential. They lack the necessary precision for specific gas measurements. For instance, while one gas may lead to cancer and another gas might be linked to tuberculosis, a conventional metal oxide gas sensor detects both indiscriminately, failing to identify the exact gas or its concentration. This leaves ordinary consumers unable to discern the particular gas or disease they may be exposed to, even after investing in a gas sensor. Thus, achieving selectivity is paramount for gas and Volatile Organic Compound (VOC) sensors. This is where porous chemical frameworks like Metal Organic Frameworks (MOFs) or zeolites enter the scene. These materials possess defined pore sizes and selective diffusivity, allowing them to filter some gases while obstructing others, contingent on the size of the gases and the pores in MOFs/zeolites. The challenge, however, lies in their predominantly insulating nature, posing an obstacle in creating chemiresistive sensors. Therefore, for effective sensor response detection, we have opted for the well-established conducting n-type semiconductor zinc oxide.

Zinc Oxide (ZnO) is renowned for its diverse morphology, adaptable properties, and versatile applications across various fields including sensing, battery technology, catalysis, and filtration. Among the established morphologies, the tetrapodal form (t-ZnO) synthesized through flame transport synthesis is of particular interest due to its single-crystalline structure and adjustable oxygen vacancies. A versatile method of applying different metal hydroxides/oxides to coat t-ZnO in an organized manner, creating a core@shell structure of t-ZnO@$M(OH)_x$ (where M represents metals like Cu, Co, Al, Fe, Ni, Ti, etc.) derived from a suitable metal precursor is also studied. Subsequently, we interconnect the arms of the tetrapods using a photochemical process. This development of interconnections is particularly intriguing from a sensor application perspective, as it forms stable bridge-like structures between morphologies, even those that may not conduct electricity, such as MOFs or zeolites.

The surface of t-ZnO@M(OH)x can undergo conversions to adopt alternative structures based on the same metal framework. For example, a $Cu(OH)_2$ shell can give rise to a Cu-based MOF like HKUST-1, a $Co(OH)_2$ layer can yield a Co-based MOF like ZIF-67 and $Al(OH)_3$ can either convert to Al-based MOFs or serve as a source for zeolite. Likewise, t-ZnO can be readily surface converted to a Zn-based MOF, such as ZIF-8. This technique facilitates the solvothermal growth of MOFs based on any metal framework utilizing ZnO as the sensing material, all while preserving the morphology, thus enhancing selectivity towards various gases or VOCs. The interconnects grown can be precisely tailored with respect to the desired material growth, growth areas, thickness, and proximity of the self-organized flakes achieved. The ultimate objective is to create selective, sustainable, lightweight, and portable indoor gas sensors for VOCs.

In this talk, I represent how interconnected porous chemical frameworks like tetrapodal ZnO or corresponding MOFs and zeolites show promising selective filtration based on pore sizes by applying these structures to zinc oxide, a versatile semiconductor to enhance sensor selectivity, ultimately aiming to create indoor gas sensors with the capacity to detect VOCs.

Keywords: Photochmical Interconnects, Volatile Organic Compounds(VOCs), Metal-Organic Framework(MOFs), selectivity, Zinc Oxide(ZnO), Metal Coating, Indoor gas sensors, Bridge-like tunable interconnects.

11:30 AM *EL03.05.04
Interplay of electrical and mechanical behaviors in dielectrics Fabien Volpi, Morgan Rusinowicz, Chaymaa Boujrouf, Muriel Braccini, Guillaume Parry and Marc Verdier; Université Grenoble-Alpes, France

Dielectric films are widely integrated into advanced devices for both their functional and mechanical properties. In terms of functional properties, dielectrics are essentially expected to prevent electrical leakages, sustain large electric fields, limit capacitive coupling… In terms of mechanical properties, dielectrics contribute to the stiffness of device architecture but, like all ceramics, they are also preferential loci for crack nucleation/propagation. Consequently, understanding the interplay between the mechanical and electrical behaviors of dielectric films is essential to predict the lifetime of functional devices.
Nanoindentation is a powerful technique to probe the mechanical behavior of small-scale systems. When combined to electrical measurements, electrical-nanoindentation can be used to assess this mechanical-electrical interplay.
In the first part of this presentation, we will show how a mechanical stress can modify the electrical conduction mechanism in an ultra-low-k dielectric

(nanoporous SiOCH film deposited on a silicon substrate). Experimentally, electrical leakage was monitored in-situ during nanoindentation with a Berkovich indenter. These experiments reveal a counterintuitive electrical conduction drop under high mechanical stresses. This phenomenon is reproduced numerically (by FEM analysis) by correcting the Poole-Frenkel conduction law with a strain-dependent factor, and described analytically in terms of space-charge build-up induced by the trapping of holes at the mechanically-generated defects. A threshold strain is identified as the keystone linking this strain-dependent conduction to the current line distribution within the dielectric.
In the second part, we show how an electrical stress can degrade the mechanical properties of dielectrics. Experiments were carried out on a wide panel of dielectric systems: high-k and low-k dielectrics, thin and thick films, with or without bottom electrodes… Thanks to the fine in-situ coupling of mechanical and electrical monitoring, a mechanical collapse of the film is observed after the application of an electrical stress. Various origins of this collapse were first ruled-out (electrostatic force, local heating…), before it was finally demonstrated that the injection of electrical charges drives this mechanical collapse. Numerical modelling (FEM analysis) is used to discuss which film property is actually modified: stiffness or hardness. This phenomenon appears to be universal, since it is observed on all kinds of dielectric systems assessed in this study.

Pathfinding in Optical Critical Dimension Metrology George A. Antonelli; Onto Innovation, Inc., United States

Semiconductor manufacturing has long relied upon optical methods for non-destructive high volume critical dimensional metrology. Optical reflectometers, ellipsometers, and interferometers from the deep ultraviolet to near infrared are essential engines of discovery. The underlying architecture and operating principles of many modern optical metrology tools are directly related to their progenitor instruments. Increased complexity and continued scaling of logic and memory devices offer new metrology challenges and force the continued evolution of these tools and the introduction of new architectures. High aspect ratio and buried structures are two general areas of concern for future devices which optical metrology must address. High aspect ratio structures >100:1 have become an integral part of many semiconductor devices in a variety of applications. Conventional optical critical dimension metrology tools can address a subset of this need but fall short in some use cases. One potential solution lies in the extension of these techniques into the mid-infrared range.

The shift to a three-dimensional paradigm for transistor and interconnect geometries has led to an increase in the use of conformal and gap filling techniques to address reentrant features. Both random and systematic void formation are common defect modes in these processes. In some process flows, an opaque metal layer disrupts the conventional lithographic layer alignment requiring a different approach. Photoacoustic methods can be applied to address both issues. It is also possible to use photoacoustics to perform sub-optical resolution dimensional metrology of buried features.

In this talk, we shall briefly discuss optical methods capable of addressing these challenges. The physical principles of the proposed approaches and hardware implementation will be reviewed. Several examples drawn from memory and logic process flows will be shared.

2:00 PM *EL03.06.02
Characterizing Highly-Confined Heat Flow, Elastic, and Structural Properties of Nanostructured Semiconductors and Dielectrics using Ultraviolet Light Sources Joshua Knobloch, Brendan McBennett, Albert Beardo, Emma Nelson, Travis Frazer, Jorge N. Hernandez-Charpak, Begoña Abad Mayor, Henry C. Kapteyn and Margaret Murnane; STROBE, JILA, University of Colorado Boulder, United States

Next-generation nanoelectronic, energy, and quantum devices rely on the discovery, integration, and optimization of novel complex and nanostructured materials. As the critical dimensions of these devices shrink below 10-nm, the complex 3D geometries and physical properties—including, mechanical, thermal, and surface/interface quality—of new materials govern device efficiency and performance. However, as the complexity increases and scale decreases, conventional models fail to accurately predict the functional properties, and traditional metrology tools cannot probe the relevant behaviors on their intrinsic length- and time-scales. By harnessing tabletop sources of coherent extreme ultraviolet (EUV) light[1], novel metrology tools can characterize the elastic, thermal, and structural properties of ultrathin dielectric films and nanostructured semiconductors.
Optimized ultrathin low-*k* interlayer dielectric films are critical materials to improve the speed and efficiency of nanoelectronic devices. However, precise characterization of films with thickness <<100nm is challenging for traditional methods. Using a tabletop dynamic EUV scatterometry technique, we nondestructively extract the full elastic properties of single- and bilayer a-SiC:H and a-SiOC:H ultrathin films with thicknesses down to <5 nm—revealing surprising results[2,3]. By simultaneously extracting both Young's modulus and Poisson's ratio in a series of hydrogenated ultrathin films, we observe an unforeseen trend in the compressibility: in the presence of strong hydrogenation which reduces the bond coordination past a critical threshold, the films undergo a transition from brittle to ductile[2]. Additionally, we find that not only doping but also surfaces/interfaces can drastically alter the mechanical properties of ultrathin films. In very thin bilayers (<5 nm) with low-hydrogen doping, surface effects induce a substantial increase in compliance—by almost an order-of-magnitude—compared with identical thicker films, an effect not observed in highly-doped systems[3].
Using our dynamic EUV scatterometry technique, we also nondestructively characterize the elastic properties, thickness, porosity, and thermal behavior of thin silicon metalattice layers[4-6]—artificial 3D solids that are periodic on the sub-100 nm length scale. By monitoring the dispersion of hypersonic surface acoustic waves, we extract the Young's modulus and thickness of silica-filled and empty-pore silicon metalattice films with 14 – 35 nm periods, agreeing well with nanoindentation and electron microscope images[4,5]. Moreover, we nondestructively probe the porosity and interconnectivity in an empty-pore re-infiltrated metalattice and validate with electron tomography[5]. Using these characterized properties, we can subsequently analyze the exotic thermal behaviors of these nanostructured silicon materials. By tracking the cooling of laser-excited metallic nanostructures, we observe a diffusive-like heat transport behavior with an apparent thermal conductivity two-orders-of-magnitude below bulk silicon[6], which is not predicted by traditional analytical models. To describe this behavior, we derive an analytical expression for the apparent thermal conductivity based on an analogy to rarefied gas flow in porous media[6]. We find that the physics can be separated into two components: a geometry-dependent permeability and a geometry-independent viscous component which scales universally with porosity. This analytical expression describes not only transport in silicon metalattices but also nanomeshes, nanowire networks, and porous nanowires.

Electrical and Reliability Characteristics of Low-K SiCOH Dielectrics with Metal Integration Seonhee Jang, Rajib Chowdhury and Thomas Poche; University of Louisiana at Lafayette, United States

In modern microelectronic devices, copper (Cu) and low dielectric constant (low-k) dielectric materials have been used in the back-end-of-line (BEOL) interconnects. However, the migration and diffusion of Cu into the low-k films become challenging during the integration of Cu/low-k interconnects, causing degradation of electrical performance and reliability. A metal barrier is introduced between Cu and low-k dielectrics to prevent Cu diffusion. With further scaling of technology node, the resistance of Cu metal lines significantly increases because of Cu surface and grain boundary scattering and additional metal barrier. To decrease the line resistance, the thickness of the metal barrier should be reduced. To reduce the surface and grain boundary scattering effect, different metals with low resistance can be employed. Potential candidates to replace Cu can be determined by lower product value of bulk resistivity and electron mean free path than that of Cu. Based on this criteria, cobalt (Co) and molybdenum (Mo) were selected. In this study, the integration of Co or Mo with the low-k materials was conducted and electrical and reliability characteristics were investigated.
Low-k SiCOH thin films were fabricated on p-type Si (100) wafer by plasma-enhanced chemical vapor deposition (PECVD) of tetrakis(trimethylsilyloxy)silane precursor at ambient temperature. To investigate electrical and reliability characteristics of low-k SiCOH dielectrics with metal integration, metal-insulator-silicon (MIS) structures were fabricated. Four different metals Al, Cu, Co, and Mo were deposited on the low-k SiCOH films using a sputtering deposition or electron beam evaporation methods. Thickness of each metal was approximately 120-130 nm. The fabricated MIS capacitors were then annealed in N_2 atmospheres at 400 °C for 1 h. The electrical characteristics of the MIS structures were measured from capacitance-voltage (C-V) and current-voltage (I-V) curves using a semiconductor parameter analyzer. The C-V curves of Al-gate, Cu-gate, Co-gate, and Mo-gate MIS capacitors were compared before and after thermal stress. The typical C-V curves were obtained with accumulation, transition, and depletion regions from the negative to positive bias application. Depending on the type of metal-gate, the accumulation capacitance was different, suggesting that the deposition of metal gate may affect the capacitance of the underlying low-k film. The thermal annealing reduced the accumulation capacitance of the MIS capacitors. An increase in the k-value suggests that the low-k thin film was damaged by plasma during metal sputtering deposition. After annealing, the k-values were reduced, indicating that plasma-induced damage to the film could be recovered by annealing process. The shift in the C-V curve was the evidence of the diffusion of metal ions into the low-k film by annealing process. An increased leakage current after annealing demonstrates that the diffusion of metal ions occurred in the low-k film. The elemental composition including Si, O, and C was investigated by X-ray photoelectron spectroscopy (XPS). Metal diffusion into the low-k film at the interface between the low-k film and each metal after annealing affected C-V and I-V characteristics. Effects of different metals on the electrical properties and reliability of the low-k SiOCH films under thermal stress were compared in this study.

Stretchable High-Resolution Multifunctional Displays Jisu Yoo, Gwang Heon Lee and Moon Kee Choi; Ulsan National Institute of Science & Technology, Korea (the Republic of)

Internet of things (IoT) technology urged the development of displays, which serve as fundamental human-machine interfaces by visualizing information for the user, in order to accommodate the expanding demand of electronic systems in daily life. For this reason, multifunctional displays, instantly representing non-visible stimulation as optical information, have been actively investigated to conduct diverse remarkable electronic applications. Sound generating displays, which have only lately been highlighted, are designed as single device without additional circuitry elements, while concurrently satisfying high degrees of deformation for wearable and/or attachable device applications.
Alternative current electroluminescent (ACEL) devices are one of the promising candidates as deformable optoelectronics owing to their simple device construction, facile fabrication, mechanical robustness, stable emission, and exceptional deformability. Among them, thin-film type ACEL devices are constructed with two electrodes sandwiching emissive layer that comprises phosphors and dielectric matrix. Under AC bias, thin-film ACEL device can be operated as both EL device and dielectric actuator speaker, originated from their structural similarity, making them optimal candidates as stretchable multifunctional displays. For practical application, patterning techniques also need to be applied to ACEL device. However, existed patterning methods of ACEL device were constrained to low-resolution EL operation (pattern size > 2 mm) and reduced brightness below the industrial standard (> 100 cd/m^2). Hence, it is necessary to develop effective way to achieve high-resolution multicolor patterning of devices.
Herein, we report a stretchable high-resolution multifunctional display that can work both as an input and output device. Silver nanowires (AgNWs) and conductive polymer (PEDOT:PSS) embedded in thermoplastic polyurethane (TPU) are used as stretchable electrodes, and high dielectric constant particles ($BaTiO_3$)-inorganic electroluminescent phosphors (ZnS:Cu)-polydimethylsiloxane (PDMS) composite is adopted as emissive layer. Through surface engineering of both stamp and the top of emissive layer, transfer printing technique for emissive layer was developed. This technique facilitates the high-resolution and multicolor patterning of emissive layer for stretchable multifunctional displays that can be stably operated under dynamic and static deformation. Owing to clear and high-resolution patterning ability, we suggested the multifunctional displays that can work both as input and output device.

4:15 PM EL03.07.03
Optimization of Reliable and Reproducible Growth of Carbon Nanotube Forests and Microstructures based on The Machine Learning-Assisted Control of Catalyst Nanoparticle Morphology Kwangjun Kim, Yongtae Kim, Minwook Kim, Rahul S. Ingole and Jong G. Ok; Seoul National University of Science and Technology, Korea (the Republic of)

Recently, the realm of carbon nanotube (CNT) applications has been expanding in accordance with the rapid growth of cutting-edge industries including secondary batteries, semiconductors, sensors, and so on. For instance, CNTs are actively used in a powder or solution form as a conductive agent for both the anodes and cathodes of secondary batteries, which, however, typically entails various physical and chemical post-treatment processes. Utilizing the CNT forests and lithographically patterned CNT microstructures in their as-grown forms may obviate the labor for harvesting (off the substrate) and subsequent post-treatment (e.g., solution preparation) and may provide more functional frameworks with controlled 3D morphology, density, and aspect ratio. This can be achieved by optimizing the morphology of catalyst nanoparticles that are converted from the thin-film catalyst layer during the annealing step of the chemical vapor deposition (CVD)-based CNT growth process. Each catalyst nanoparticle offers a growth site of each CNT, suggesting that the catalyst nanoparticle's size and density control the diameter, density, and degree of alignment of the resultant CNT forests – and thus their physical,

chemical, and electrical properties. Here we propose a machine learning-based thermal and fluid interaction analysis for the control of catalyst nanoparticle morphology during the CVD process through thermal energy-driven Ostwald ripening and subsurface diffusion. We use the thermal fluid-structure interaction (TFSI) method to analyze the heat transfer characteristics of the catalyst layer system ($Fe/Al_2O_3/SiO_2$). We pay more attention to the micropatterned catalyst system which exhibits considerably different heat transfer characteristics depending on the micropattern geometry as compared to the non-patterned thin-film catalyst system. Additionally, we conduct machine learning to optimize the CVD parameters for reliable growth of CNT forests on micropatterned catalyst systems with various geometries. This optimization is based solely on preprocessed SEM images of the catalyst nanoparticles. The morphological data (density, diameter, and roundness) of catalyst nanoparticles are learned, and the global optimum values for CVD parameters - temperature and time during the annealing step, as two factors dominating catalyst nanoparticulation - are proposed. The experimental growth results are presented as a validation. We demonstrate that such a reliable and reproducible CNT growth – either to a forest or microstructure - realized by taking the global optimum values can be utilized in several cutting-edge applications including neural signal recording (using 3D CNT microelectrode arrays) and stretchable strain sensors (using one-directionally aligned CNT thin films engineered from microscale CNT blade patterns).

PEDOT:PSS-Based Nanofibrous Electrodes for Flexible Transparent Electronics Xenofon Karagiorgis[1,2], Dhayalan Shakthivel[2], Gaurav Khandelwal[2], Rebecca E. Ginesi[1], Peter Skabara[1] and Ravinder Dahiya[3]; [1]Joseph Black, United Kingdom; [2]James Watt, United Kingdom; [3]Northeastern University, United Kingdom

The demand for flexible and transparent electronics requires electrodes capable of concurrently maintaining high conductivity, flexibility, and optical transparency. Conventional metal electrodes, such as indium tin oxide (ITO), are inadequate for this purpose due to their inherent brittleness and the scarcity of indium. Furthermore, when subjected to bending conditions, ITO on flexible substrates is prone to delamination and cracking. These challenges have urged researchers to explore alternative Transparent Conductive Electrode (TCE) materials exhibiting properties similar to ITO. These targeted characteristics include (1) high conductivity and transparency, (2) exceptional flexibility and stability under various mechanical deformations (4) large area processability, (4) cost-effective, (5) room temperature (RT) processing, and (6) readily available: i.e., abundant supply.

Our work addresses these challenges by introducing a single-step electrospinning process with post-treatment to create highly conductive, flexible, and transparent PEDOT:PSS-based fibers suitable for interconnects and electrodes. These fibrous electrodes exhibit a sheet resistance of 7 Ω/sq and electrical conductivity of 354 S/cm, which is comparable to traditional rigid and metal electrodes, such as copper, silver, and ITO (0.1 to 10 Ω/sq) all while maintaining exceptional optical transparency of 77 % at 550 nm wavelength and excellent flexibility. The previous research has explored PEDOT:PSS and PEDOT:PSS/Ag nanowires fibers with sheet resistance in the range of 600 kΩ/sq and electrical conductivity in the range of 10^{-12}-10^{1} S/cm which is very low and has no potential to replace the conventional electrodes. The electrospun nanofibers were also deposited onto different substrates with varying levels of roughness and subjected to cyclic bending tests. The fibers on the poly(caprolactone) (PCL) substrate performed best under 1000 bending cycles with a slight change in sheet resistance from 7 Ω/sq to 8 Ω/sq, while on cotton fabric and Kapton film, a slight increment was observed.

The nanofibers were demonstrated as interconnects in a simple circuit for powering a light-emitting diode (LED). Even after 1000 bending cycles, the fibers were still able to turn on the LED at the same applied voltage of 2V, despite the slight changes in their sheet resistance. The potential of electrospun nanofibers for replacing metal electrodes was evaluated by fabricating a triboelectric nanogenerator (TENG). The TENG employing the metallic electrode achieved an output voltage of 73.9 V and an output current of 6.7 μA. When the copper electrode on one side was replaced with the nanofibers, the electrical performance of the TENG showed a notable improvement, reaching 77.9 V and 7.1 μA. This work stands out due to the significantly lower sheet resistance and stability under bending cycles which is attributed to the organic-inorganic interactions of our nanofibers, positioning them as ideal for applications including touch interfaces, OLEDs, interactive displays, energy storage, and harvesting. etc.

IoT-Enabled Pd-Anchored CuO/SnO_2 Hybrid Thin Films via RF Sputtering for H_2S Gas Sensing Amit Kumar; Indian Institute of Technology Jodhpur, India

The advancement of various fields, including Industry 4.0, Big Data, and Machine-to-Machine technologies, is significantly influenced by the integration of the Internet of Things (IoT) and Machine Learning (ML). These technologies play a crucial role in continuously collecting and analyzing information related to parameters such as temperature, speed, pressure, health data, environmental conditions, and consumption. The development of high-performance toxic gas sensing devices is essential for public safety, environmental control, industrial operations, and other applications, contributing to improved living standards. In this context, a novel fabrication method has been devised for H2S gas sensor prototypes. These sensors utilize noble metal-functionalized metal oxide semiconductor (MOS) chemiresistors. The fabrication process involves the growth of CuO/SnO2 hybrid nanostructures sensing thin film on SiO2/Si substrates using the RF sputtering method. Subsequently, Pd nanoparticles, known for their excellent gas-sensing catalyst properties, are functionalized onto the CuO/SnO2 hybrid films using DC sputtering, with varying sputtering times of 3, 6, 9, and 12 seconds. The resulting nanostone morphology enhances gas absorption, enabling the capture of more target molecules. Notably, a 9-second Pd sputtering time significantly improves H2S sensing compared to other gases. The CuO/SnO2 film with Pd exhibits the highest response, registering a 74.7% response to 50 ppm H2S and detecting concentrations as low as 0.5 ppm. These promising results are achieved at the optimal working temperature of 150 °C. Following the optimization of parameters, the technology is transferred to the development of a sensor module with IoT integration. The prototype sensor seamlessly connects to a NODEMCU-ESP8266 Wi-Fi module, establishing a link with a smartphone through a mobile hotspot. This integration enhances the real-time monitoring and data transmission capabilities of the sensor, contributing to efficient and connected systems for diverse applications.

Improvement of Bending Failure in DRAM Capacitors through The Utilization of EUV Patterning Seungjin Kim; Sungkyunkwan University, Korea

(the Republic of)

As the size of the dynamic random access memory(DRAM) continues to shrink, the difficulty of patterning has become increasingly challenging. Among them, the capacitor pattern, an essential element for data storage, possesses the structure with the highest aspect ratio in DRAM. Consequently, difficulties in securing yield arise due to the chronic defects such as bending and pattern collapse of the pillar-type capacitor node, impeding the overall manufacturing process. Bending of the capacitor node, generating bridges in the bottom electrodes, serves as a disruptive factor that hinders the normal operation of the memory. The bending of the capacitor occurs due to stress induced by bottom electrode oxidation during the deposition of the dielectric layer after the deposition of the bottom electrode. To prevent this, a supporter structure is being introduced. The supporter is composed of a nitride layer and is patterned for the deposition of the dielectric layer on the bottom electrode. The impact on capacitor bending varies depending on the patterning of this supporter. In this research, the improvement in capacitor bending was confirmed through the application of all cell open(ACO) supporter patterning using extreme ultraviolet(EUV). Through this, we suggests the ultimate patterning fabrication process for DRAM capacitors to overcome the scaling limits of DRAM, opening up the inevitable possibility of the EUV era, ensuring the realization of sub-10nm patterns with high guarantee.

***In-Situ* Multi-Chip Integration of Ultra-Thin-Silicon Interposer via Transfer Printing** Uhyeon Kim, Seungbeom Kim, Junhyung Kim, Sangyeop Lee, Agha A. Jan and Seok Kim; Pohang University of Science and Technology, Korea (the Republic of)

2.5D heterogeneous integration packaging based on interposer technology has emerged as a key technology driving 'Beyond Moore' advancements in semiconductor miniaturization. However, conventional carrier wafer techniques and flip-chip processes pose limitations when handling extremely thin components (<30μm) that can be easily distorted. In this study, an innovative In-Situ bonding process was developed using shape memory polymer (SMP) stamp-based transfer printing technology to reliably transfer ultra-thin silicon interposers at high speeds within 3 minutes.
The ultra-thin silicon interposer was designed with transferable ink using transfer printing and thermal processing techniques. By predefining copper TSVs (Through-Silicon Vias) and Cu-Sn solder bumps on an SOI (Silicon On Insulator) wafer to a specific thickness, and separating the Box Layer, an independent ultra-thin interposer of 15μm thickness was manufactured. This interposer was precisely and securely transferred to the receiver substrate using an SMP (Shape Memory Polymer) stamp, designed to transfer through thermo-mechanical property. Subsequently, a low-temperature bonding method (~230°C) suitable for Cu-Sn fusion conditions was employed, successfully achieving rapid coupling for the fragile components' multi-layer integration. The bonded interposer exhibited distinct characteristics such as FIB (Focused Ion Beam) and IV curve. This ultra-thin integration technology holds promise for the utilization of brittle ultra-thin DRAM integration, specifically in applications like HBM (High Bandwidth Memory).

Economical Flexible Electronics Incorporating All-Solution-Processed Transistors on Paper Chengmin Zhang[1], Do Hoon Lee[2] and Byung Yang Lee[1]; [1]Korea University, Korea (the Republic of); [2]Hokkaido University, Japan

Paper electronics is receiving great interest because it is one of the best candidates for next-generation devices with many useful features such as low cost, disposability, and flexibility. However, the rough and porous surface of standard paper accelerates the spreading of liquid ink, limiting the manufacture of solution-processed paper electronics. Here, we use extremely rough and absorptive paper substrate without any treatment with an overall average RMS roughness much higher than that of general-purpose paper. The AgNW network acting as a gate electrode was formed on the paper surface by absorbing the AgNW solution (1 wt% in DI water) into the filter paper using a home-made screen printer screen printed gate electrode with low sheet resistance (9±5 Ω/sq) and low root mean square (RMS) roughness of 130±10 nm was obtained after drying for 30 min under ambient air without heating treatment. Then, the PVDF-HFP (Poly(vinylidene fluoride-co-hexafluoropropylene)) solution (20 wt% dissolved in DMF (N, N-Dimethylmethanamide)) is injected onto the surface by screen printing. In the vacuum state at a pressure of 0.002 atm for 5 min, a certain amount of PVDF-HFP solution is filtered in the AgNWs network layer and most of the solution is absorbed. As a result, a dielectric layer of less than 10 μm is cured thinly on the surface of the AgNW-assembled paper. The solution-processed flexible FETs on paper exhibit electrical performance with charge carrier mobility of 0.053 $cm^2 V^{-1} s^{-1}$, and a current on/off ratio of 7×10^2. We report the development of zinc oxide nanowire (ZnO NW) field-effect transistors (FETs) on paper with facile, low-cost, and large-area manufacturing. By utilizing simple equipment such as a vacuum filter and a homemade pulling system, we could produce outstanding FETs that are desirable for cheap flexible electronic applications.

Electrochemical Deposition of Polyetherimide (PEI) Thin Films from Aqueous Emulsions for Structured Substrates: Towards Advanced Integrated Capacitors in Power Electronics Alexandre Seurot, Antoine Hoang, Vincent Jousseaume and Paul-Henri Haumesser; CEA LETI, France

In the pursuit of miniaturized high-power electronic devices, the demand for robust high-power capacitors capable of withstanding electric fields in the range of several hundred volts across micrometric dielectric layers has emerged. To miniaturize these capacitors, one possibility is to create 3D structures in a silicon wafer to maximize capacitance density by expanding the dielectric surface area. However, this approach encounters difficulties when trying to combine it with conventional inorganic dielectrics (such as SiO_2), due to the mechanical stress induced by thick films. Among suitable dielectric materials to build such devices, polyetherimide (PEI) is highly promising due to its exceptional chemical resistance and thermal stability up to 170°C. The conventional technique of spin-coating for polymer thin film deposition, however, falls short in achieving conformal deposits on 3D-structured substrates with large developed surface area. To address this limitation, we explore an electrochemical deposition process for PEI, employing an aqueous emulsion of organic droplets containing the polymer as the electrolyte.[1]
In this study, we grafted N-methylpiperazine onto the imide groups of raw PEI polymeric chains within a solvent mixture. The grafting reaction is confirmed to be quantitative through FTIR and NMR measurements. The addition of an aqueous lactic acid solution, followed by ultrasonic mixing, led to the formation of emulsions encompassing modified PEI organic droplets. These droplets exhibited an approximate diameter of 40 nm, as observed through Cryo-TEM, and zeta potentials exceeding 50 mV. These emulsions were diluted by a factor of 10 with the addition of deionized water, and were stable for at least several weeks.
Deposition experiments were conducted within a 3-electrode electrochemical cell, under mild conditions (room temperature, pH ranging from 3 to 4), utilizing Cu metal surfaces. A pulsed DC waveform with an amplitude below 2 V/SCE was employed to mitigate hydrogen evolution. Within a timeframe of 600 seconds, a PEI coating with a thickness of a few micrometers was successfully obtained.
Remarkably, our results demonstrate comparable film thickness to existing literature [1], despite using an emulsion with 20 times dilution and voltages 40 times lower. Our comprehensive investigation into the influence of deposition factors on coverage and uniformity has revealed the significant impact of hydrodynamic conditions and the pivotal role played by the pulse/tension combination in achieving distinct morphology and thickness. SEM inspection showcased a uniform film at the center with iridescence.
Following deposition, the film was thermally cured under vacuum conditions to eliminate solvents and restore the imide groups of PEI.[1] FTIR analyses confirmed excellent agreement between IR spectra of the cured and pristine polymers, as well as the elimination of amide (I and II) peaks.
This work establishes the feasibility of electrochemically depositing insulating polymeric films under mild conditions, enabled by the formation of stable emulsions containing charged polymeric droplets. This innovative electrodeposition process holds immense promise for coating substrates with complex

3D structures, contrasting with conventional dielectric deposition techniques. Importantly, this original methodology presents a potential avenue for fabricating integrated capacitors on silicon wafers, paving the way for the next generation of power electronics devices.

Investigating TDDB Reliability in Next-Generation Packaging Technology: Nano-Twinned Cu RDL Yoongu Lee, Hongik Kim, Gaeun Song, Young-Chang Joo and In-Suk Choi; Seoul National University, Korea (the Republic of)

Due to the performance improvement and miniaturization of semiconductor devices, the size of input/output (I/O) has decreased while their number has rapidly increased, surpassing the capacity of conventional printed circuit board (PCB) substrates. To address this issue, recent advanced packaging technology for 2.5D integration has applied a redistribution layer (RDL), which enables a larger number and smaller size of I/O, significantly improving signal process performance. However, as RDL becomes increasingly fine-pitched, the interlayer dielectric spacing between RDLs decreases rapidly, resulting in an increased effective electric field and raising concerns about potential dielectric breakdown. Notably, since the dielectric in RDL is organic dielectric polyimide (PI) instead of the SiO_2-based inorganic dielectric used in the conventional backend-of-line (BEOL), it is expected to be more vulnerable to time-dependent dielectric breakdown (TDDB). Therefore, this presentation will showcase the TDDB assessment of fine-pitch RDL interconnect for different RDL linewidth/space (L/S) and RDL line patterns. In particular, we compare the TDDB of interconnect with random microstructures to that with nanotwinned Cu interconnect, which is known to possess superior strength, ductility, thermal conductivity, and electromigration (EM) resistance due to its microstructure that incorporates a few nanometers thick twin boundaries within grains. Interestingly, we observed a clear difference in TDDB results between random Cu interconnect and nanotwinned microstructure. We will also discuss the cause of the difference in TDDB reliability according to the microstructure, based on the analysis of the leakage current conduction mechanism through voltage-ramping dielectric breakdown (VRDB) tests at various temperatures.

Keywords: 2.5D/3D integrated circuit (IC) integration, redistribution layer(RDL), Time-dependent dielectric breakdown (TDDB), Nano-twinned Cu

Sustainable Printing Processes for Chip Scale Interconnect and RF Structures on Flexible Substrates Henry Lei[1,2] and John D. MacKenzie[1]; [1]University of Washington, United States; [2]NoiseFigure Research, United States

This work demonstrates the use of multiple types of sustainable high resolution additive manufacturing processes such as EHDIJ (electrohydrodynamic inkjet) and piezoelectric inkjet to create chip scale interconnect and RF structures on both rigid and flexible substrates. Different types of metal based nanoparticle inks such as silver and gold are printed using a variety of methods such as direct write or drop on demand to create the desired conductive pattern. The techniques described are additve and in direct contrast to both semiconductor and PCB (printed circuit board) based metal patterning processes where metal is substractively removed. These additive manufacturing methods may be completed in atmospheric conditions thus saving energy as vacuum is not required, unlike ebeam evaporation or other metal deposition methods in semiconductor manufacturing, nor do they require toxic chemicals, such as ferric chloride, a common copper etchant used in the fabrication of PCBs. Trace widths and spacings that range from 80 microns down to 40 microns on both rigid and flexible substrates were achieved, demonstrating these techniques' viability to create structures for chip level fan out. These techniques' capability to manufacture structures that operate at RF frequencies is shown via both a single antenna and an 1x3 antenna array that operate at the 3.6 GHz 5G n48 band. The functional antenna modules demonstrate the feasibility of these additive processes in manufacturing and prototyping for the current generation telecommunication protocols.

5:00 PM EL03.08.09
Gecko-Inspired Adhesive Conductive Film for Flexible Electronics Auriane Despax-Ferreres[1], Pascal Tiquet[1], Jean-Charles Souriau[2], Julia De Girolamo[1] and Vincent Jousseaume[2]; [1]University Grenoble Alpes, CEA, Liten, France; [2]University Grenoble Alpes, CEA, LETI, France

A large number of flexible electronic applications are envisioned among them, wearable electronics and bio-electronics applications. One of the main challenges in this field is to integrate semiconductor devices on unconventional substrates subject to mechanical stress (bending and stretching). Interconnect technologies must be implemented at low pressure and low temperature to avoid damaging the substrate. They must also be able to withstand slight deformation, like a medical patch in contact with the skin. Currently, the solutions for interconnecting electronic components with their active face facing on substrates are mainly based on metallic soldering. These solutions are not ideal for flexible substrates as the soldering is rigid and irreversible. The used of a thin stretchable anisotropic conductive adhesive that can be used as a conductive film between the silicon device and the substrate could solve these issues.
In this work, we have developed gecko-inspired adhesive based on an arrays of microscale pillars made of polydimethylsiloxane (PDMS), a biocompatible and low-cost polymer. The pillars have mushroom-shaped tips known that are known as the most efficient form of contact. First, mushroom-shaped molds with varying geometries were fabricated in a silicon-on-insulator wafers (SOI) with typically a 2 µm-thick buried oxide layer and a thick Si top layer ranging from 15 to 25 µm. The mushroom molds were realized by standard photolithography and etching process and the surface of the molds was then covered with a hydrophobic thin film using a vapor phase process. Then, gecko-inspired films were performed using a solution of PDMS poured into the molds and spread out by spin-coating. The spin-coating parameters were adjusted to obtain films with a backing layer thickness of approximately 190 µm. Finally, the gecko-inspired films were cured at 100°C and peeled from the SOI molds. This method allow to produce microstructured films with very few defects. To make these films locally conductive, composites based on high aspect ratio multi-walls carbon nanotubes (1 wt%, mean aspect ratio of ~830) and PDMS were used. The localization of the conductive composite was performed by screen-printing. CNT-PDMS composite was deposited through a stencil composed of holes of 300 µm diameter directly on the SOI molds. After screen-printing, the CNT-PDMS was thermally cured and pristine PDMS was deposited by spin coating, cured and demolded.
The adhesion performances of the different mushroom-shaped microstructured films were characterized by compression and pull-off tests on glass and on silicon. For both surfaces, adhesion forces higher than 6 $N.cm^{-2}$ can be obtained depending on the geometry. However, the shape of the mushrooms needs to be carefully designed, as some configurations (particularly when aspect ratios are too high) are not leading to high adhesion forces. Preliminary results show also that a slight degradation of the adhesion (by a factor ~3) is observed with conductive mushrooms. This results could be related to the difference of elastic modulus induced by the presence of CNT fillers in the composite and by a difference of the surface state of the films. The electrical conductivity obtained for microstructured films is evaluated at 10^{-2} $S.m^{-1}$ which is lower than the bulk conductivity of the composite (by one order of magnitude). The surface state of the conductive film may also be at the origin of this result, inducing a high contact resistance.

Advancing Precision in Transfer Systems with Shape Memory Polymers Han Jun Park, Minsu Kim, Dokyung Kyeong, Ga-in Lee and Moon Kyu Kwak; Kyungpook National University, Korea (the Republic of)

Shape memory polymers (SMPs) belong to a unique category of smart materials capable of retaining a "permanent shape" via the shape memory effect and

transitioning into a "temporary shape" under the influence of specific stimuli like heat, electricity, light, or a magnetic field. In the case of thermally triggered SMPs, they typically exist in a rigid state with a fixed permanent shape initially. However, when exposed to temperatures above their glass transition temperature (T_g), their elastic modulus decreases, enabling temporary deformation in response to an external force. Upon cooling, the elastic modulus of SMPs returns to its initial value, effectively preserving the deformed state as the temporary shape even after the removal of the external force. A defining trait of SMPs is their ability to regain their original shape and mechanical properties when subjected to thermal stimulation after adopting a temporary shape. One of the most promising applications involves utilizing the shape memory effect of SMPs in transfer systems for achieving high-precision pickup and release of delicate substrates.
Transfer system is a pivotal process in the manufacturing of displays and semiconductors, demanding the ability to transfer objects with varying surface profiles. As the demand for thinner and larger substrates continues to rise, the necessity for efficient transfer systems becomes more critical. Achieving high efficiency in pick-and-place systems necessitates both strong adhesion forces for pickup and weak adhesion forces for placement. Recent efforts have focused on dry adhesives that rely on van der Waals interactions for achieving the required adhesion switching. Dry adhesives are appealing due to their cost-effectiveness, mechanical robustness, and they are increasingly finding applications in the pick-and-place industry. Nonetheless, challenges persist in achieving stable detachment during the adhesion switching process. Several research studies have explored various strategies for designing such systems using SMPs, which include double-layer structures, surface microstructures, and dry adhesives. However, the manufacturing process of SMP-based adhesives remains time-consuming, largely due to the need for multiple material combinations and lengthy thermosetting times.
In this study, we present the design and development of a novel SMP dry adhesive that achieves highly reversible heat-actuated adhesion switching systems using Norland Optical Adhesive 63 (NOA 63). Notably, NOA 63 offers the flexibility to program the T_g based on curing conditions, facilitating the rapid and straightforward manufacture of SMP-based adhesives through UV irradiation. UV curing induces a transition in NOA 63 from a rubbery to a glassy state, reducing polymer chain mobility and diffusion. Subsequent temperature increases prompt the polymer chains to revert to the rubbery state, resuming residual reactions and elevating the material's T_g. The fabricated SMP dry adhesive exhibits outstanding adhesion performance to substrates with varying surface topographies, thanks to its ability to transition to the rubbery state above the T_g. Additionally, introducing a micro-lens pattern on the SMP dry adhesive's surface enhances both adhesion and detachment. The shape memory effect of the SMP dry adhesive facilitates the recovery of the micro-lens pattern's shape, simplifying substrate detachment. By altering the curing conditions of NOA 63, different T_g values can be programmed, resulting in varying adhesive performances at different temperatures. Furthermore, the SMP dry adhesive demonstrates remarkable mechanical durability even after repeated adhesion cycle tests. To assess its practicality, a pick-and-place experiment employing a Peltier element was conducted, confirming the feasibility of continuous fabrication through the convenient UV curing process of NOA 63 in a roll-to-roll system.

5:00 PM EL03.08.11
Vacuum- and etch-free mechanical fabrication of metal wire microtrenches interconnected by ZnO nanowires for flexible bending-sensitive optoelectronic sensors Minwook Kim, Kwangjun Kim, Rahul S. Ingole, Yongtae Kim and Jong G. Ok; Seoul National University of Science and Technology, Korea (the Republic of)

In recent years, there has been expanding interest in developing optoelectronic transducers using micro- and nanoscale materials and structures in compact, lightweight, and flexible forms. Specifically, optoelectronic micro- and nanoarchitectures composed of micropatterned electrodes connected by semiconductor nanowires (NWs) such as ZnO NWs (ZNWs) have gained considerable attention due to their good sensitivity to incident light. However, traditional methods for fabricating micropatterned electrodes often involve difficult and time-consuming processes such as vacuum deposition, optical lithography, and etching, often preventing scalability and widespread application. Additionally, synthesizing ZNWs, usually dependent on high-temperature seed sintering or chemical vapor deposition, can interrupt their practical use on flexible substrates. One tactful approach to overcoming these challenges is to create a micropatterned electrode via mechanically machining microtrenches and filling the metal wires therein, and then growing ZNWs selectively on the trench-embedded metal wires via a metal-mediated low-temperature hydrothermal process. Working on this novel strategy, we develop a vacuum- and etch-free method for the fabrication of metal-wire-embedded microtrenches interconnected by ZNWs. Our method involves the continuous mechanical inscribing of linear microtrench patterns (micrograting) on a substrate, followed by the doctor-blade-assisted embedding of solution-processable metal wires within those trenches. We then undertake the low-temperature metal-mediated hydrothermal growth of ZNWs selectively onto the metal wires, finalizing the ZNW-interconnected micrograting electrode structure. The entire process can be carried out at a low temperature without resorting to vacuum, lithography, and/or etching steps, thereby enabling the use of flexible polymer substrates of scalable sizes. The resulting flexible device can function as a bending-sensitive optoelectronic sensor with high sensitivity, as the number of ZNWs interconnecting the trench-embedded micrograting electrodes changes upon mechanical bending.

Novel Patterning Solutions For Scaling Interconnects Beyond 2030 Gurpreet Singh; Components Research - Intel Corp, United States

In addition to improved transistors, interconnects, and advanced packaging, scaling is a major factor in the improvement of semiconductor product performance. Scaling improves product performance by enabling lower capacitance and lower power systems, by enabling more functionality per logic block through use of additional transistors and by enabling either more cores or memory capacity per chip. Scaling is enabled by innovations in patterning, power delivery and transistor architecture. Stacked transistor architecture is expected to follow gate-all-around architecture for continued improvement in performance and density. Such an architecture could reduce the cell size by approximately 50% due to cell height reduction. However, to efficiently route an aggressively scaled cell with stacked transistors, the metal and interconnect pitch must be scaled to levels that are difficult to achieve with conventional patterning techniques. Variation control is the key challenge to pitch scaling as the edge placement margin of error is small and the large number of features required for modern circuits implies stochastics sampling in the greater than 7 sigma regime. Solutions are needed to address each component of variation, such as line roughness and size variation, via size variation, line-end pullback and overlay. One example of a powerful complementary lithography technique with superior variability control is directed self-assembly (DSA). DSA offers a fundamental advantage over conventional lithography since the line and space CDs are chemically encoded into each molecule with unprecedented accuracy. We will report on recent progress made for a process flow based on DSA that rectifies complex, multi-pitch and multi-CD EUV patterns with low integrated defects, robust electrical yield, and compatibility with standard design rules.

Selective Processes to Enable Scaling: Progress, Challenges and Opportunities Dina H. Triyoso, Robert Clark, Kandabara Tapily, Nathan Antonovich, Lior Huli, Ainhoa Romo-Negreira, Ryota Yonezawa, Cory Wajda and Gert Leusink; TEL, United States

Selective deposition has been used in microelectronics industry for many years. These processes are mostly done at high temperature. As scaling continues, device architecture has evolved from planar to FinFET, gate all around and vertically-stacked-Complementary Field Effect Transistors (CFETs). With the stacking of devices, it is desirable to enable low temperature selective processes. In this paper we discuss three examples of selective processes which are used to help extend scaling: (1) Dielectric on Metal (DoM) to enable advanced interconnect, (2) Dielectric on Dielectric (DoD) to enable Fully Self-Aligned Via (FSAV), and (3) Combining selective deposition and etch to extend EUV scalability. These three processes are well established and not too far from high volume manufacturing (HVM). Beyond these processes, challenges in selective deposition on similar surfaces and high aspect ratio structures will be discussed.

9:15 AM EL03.09.03
Mechanisms of Area Selective- Atomic Layer Deposition and Their Impact on Feature Sizes Katherine T. Young[1], Andy Hsiao[1] and Chris Yang[2]; [1]Georgia Tech Research Institute, United States; [2]Georgia Institute of Technology, United States

As devices have continued to scale down in size, fabrication of smaller features using novel methods has become a necessity. Strict requirements of location and alignment are often necessary and difficult to achieve with prior techniques, which has led to studies of area selective deposition. Area selective deposition, such as area selective-atomic layer deposition (AS-ALD), can be achieved by manipulating deposition preferences for different materials. A material is deposited selectively at certain locations based on the interaction of the precursors with different surfaces, so etching is not usually necessary and sometimes lithography is not necessary. AS-ALD can take advantage of the preferential deposition of the ALD precursors onto different types of materials like oxides or metals, etc. In fact, these techniques can sometimes be the only option for patterning different materials if the geometry of the surface or substrate cannot be patterned with lithography. Also, some SAM or polymer masks that have very low deposition can be patterned onto a surface so that AS-ALD can be used to pattern a single material (since the mask is later removed). This technique is especially useful for patterning materials or substrates that may be sensitive to etching. However, the selectivity between two different materials under certain deposition parameters limits the use of some materials and ALD precursors. Thus, a deeper understanding on the mechanism of area selective deposition is necessary to understand limitations on feature sizes.
This study describes the mechanisms for area selective- atomic layer deposition of common oxide materials (e.g., TiO_2 and HfO_2) on PMMA and Si and the effects of these deposition mechanisms on feature sizes. PMMA was patterned onto Si using electron beam lithography with feature sizes ranging from 5 µm down to 60 nm. ALD of TiO_2 and HfO_2 were studied to understand the selectivity of the deposition on Si vs PMMA and how that selectivity affected feature size dimensions and film thickness. The mechanisms of deposition were studied by characterizing the extent of ALD deposition before and after PMMA removal. TiO_2 was not detected on the surface of the PMMA, but after PMMA removal there was a very small amount of deposition in the location that had been coated by PMMA. It was determined that the ALD precursors are likely able to diffuse into the PMMA and still deposit at the interface between the Si and PMMA, even if it is only a trace amount. Thus, ALD of TiO_2 is highly selective for Si in comparison to PMMA; however, the effects of the PMMA side walls inhibit deposition so that the dimensions of the TiO_2 feature is smaller than the PMMA pattern. This side wall inhibition significantly affects possible feature sizes using TiO_2 and PMMA patterns. In contrast, HfO_2 is less selective than TiO_2 and demonstrates a mechanism combining selective deposition and lift-off. This lower selectivity limits possible HfO_2 thicknesses before there is blanket coverage, but it also exhibits less side wall inhibition. Significantly smaller feature sizes were obtained with HfO_2 compared to TiO_2 in these ALD conditions. Though the ALD parameters could be optimized further, these results suggest that the deposition mechanism itself, whether it is a truly area selective deposition or a combination of area selectivity and liftoff will always affect possible feature sizes.

9:30 AM EL03.09.04
Fabrication of High-Density, High-Resolution Interconnects via Acoustic Field Assisted Aerosol Jet Printing Roxanne Kate Balanay and Tyler Ray; University of Hawaii, United States

The additive manufacture of production-grade flexible, large-area electronics is of intense interest to rapidly design, prototype, and fabricate electronics without reliance upon traditional electronics fabrication pathways. Such additive processes enable the direct integration of electronics on arbitrary, non-planar surfaces, expanding the potential form factors and application spaces. Of particular interest is Aerosol Jet Printing (AJP) owing to the capacity to fabricate high-resolution printed interconnects with design geometries not possible via other additive manufacturing technologies. AJP is a process by which the controlled deposition of an aerosolized, liquid ink enables the conformal printing of electronic traces. However, several key challenges, such as overspray and process drift, which restrict broad deployment of AJP and limits the feature resolution of printed interconnects. To address these challenges, we report a new type of AJP print process to control and architect aerosolized ink. Termed acoustic focusing aerosol jet printing (AF-AJP), we utilize acoustic forces (AF) to control the width of printed material by focusing the jetted material to a narrower region than what would be possible with a physical orifice alone. As the acoustic focusing effect is dependent on the ink droplet size, the utilization of acoustic focusing provides a means to “refine” the jet (especially if not material-rich) such that the deposited material has a smaller line width and exhibits a reduction in the typically observed particle overspray. We report a typical 30% reduction in trace width, sharp reduction in overspray, and an overall enhancement in print quality via this novel printing technique. We also demonstrate the utilization of AF-AJP to enable the printing of high-resolution traces with electronic materials such as graphene and MXene $Ti_3C_2T_x$, in order to fabricate highly conductive traces with conformal and 3D geometries.

A Novel Approach for High Precision Printing of Micro-Bumps Marc Pascual, Achille Guitton, Amin M'barki and Anthony Fiorini; Hummink, France

High aspect ratio micro-bumps play a critical role in flip chip applications, facilitating enhanced pixel density and reduced pixel-to-pixel coupling noise. The necessity for micro-bumps with a diameter of less than 5 um, featuring these high aspect ratios, underscores the limitation of conventional technologies. This study discussed how HPCAP (High Precision Capillary Printing) Technology, allows the one-step fabrication of such micro-bumps. HPCAP capitalizes on capillary forces and resonance as intrinsic drivers, preventing the requirement for external energy sources. Inspired by Atomic Force Microscopy (AFM), this technique achieves remarkable precision, with up to 5 nm accuracy along the Z-axis and 20 nm along the XY axes. This level of precision ensures impeccable control over the dimensions and shapes of the micro-bumps enabling exceptional versatility in design, dimensions, and choice of materials.

Etching Characteristics of The B and N Co-Doped Amorphous Carbon Films through Nitrogen Concentration Control for Use as Hardmasks
Hongik Kim[1], Ung-Gi Kim[1], Deokgi Hong[1], Young-Chang Joo[1], Seungwu Han[1] and So-Yeon Lee[2]; [1]Seoul National University, Korea (the Republic of); [2]Kumoh National Institute of Technology, Korea (the Republic of)

The challenge to overcome the limits of semiconductor chip shrinkage continues. Shorter-wavelength light sources, such as extreme ultraviolet (EUV), are being utilized to maximize resolution. The use of shorter-wavelength light sources leads to a decrease in the depth of focus (DOF), and consequently, a proportional reduction in the thickness of the photoresist (PR) layer. This limitation in PR layer thickness may lead to a failure in fulfilling its intended role as a mask in the etching process following lithography, risking complete loss or compromise during etching and potentially causing a deterioration in pattern quality. To address the previously mentioned issues, a sacrificial layer called the hard mask is applied between the component to be patterned and the PR. Amorphous carbon is the material that can most effectively meet various characteristics required for use as a sacrificial layer. Various approaches have been attempted to enhance etch selectivity and improve pattern quality in the etching process by altering the properties of this material. While there have been numerous studies analyzing the characteristics by doping different elements into the amorphous carbon layer, the focus has predominantly been on research related to individual elements.
We aimed to investigate how characteristics change from the perspective of etch resistance when boron & nitrogen co-doping is applied, rather than when individual dopants are applied separately. B & N co-doped amorphous carbon (a-BCN) hardmask were obtained by adjusting the nitrogen content in an amorphous carbon film supplied with sufficient boron, using the DC sputter process. The composition of the hardmask film was analyzed through XPS analysis. Subsequently, films deposited under various conditions were evaluated for their relationship with dry etching performance. In particular, we analyzed the relationship between the etching gas and the a-BCN hardmask structure in the ternary system from both physical and chemical reaction perspectives. We figured out that increased nitrogen in the film alters its density and structure, impacting physical etching processes. Additionally, DFT calculations show that higher nitrogen content increases the probability of chemical etching reactions with fluorine. The details of the physical and chemical reaction mechanisms of etching in a-BCN will be discussed in detail. Based on the implementation results of the ternary system in the hardmask, we would like to discuss the changes in etching characteristics from both physical and chemical perspectives.

10:45 AM EL03.10.02
Metal-Organic Framework Crystal Growth in Microgravity Phillip Irace, Ryan D. Reeves and Michael Roberts; International Space Station National Laboratory, United States

Crystals grown in microgravity have been shown to be larger in size, to be more uniform in size and morphology, and to contain fewer structural defects relative to Earth-grown crystals. This is due to the homogenous, diffusion-controlled growth in microgravity that results from the lack of gravity-induced convection and sedimentation. Metal-organic frameworks (MOFs) are a unique class of materials that consist of a central metal ion coordinated to organic ligands that extend to form two- or three-dimensional structures. MOFs have promising applications in electrocatalysts, photovoltaics, thermoelectrics, and electrical energy storage materials due to their tunable chemical, electrical, and mechanical properties. Persistent microgravity provides an ideal environment to study the growth of larger, higher-quality MOF crystals that will lead to more sustainable microelectronics.
The International Space Station (ISS) National Laboratory offers a unique platform in persistent microgravity that enables the elimination of gravity-driven forces to elucidate the fundamental mechanisms of growth, morphology, and defect generation in MOF crystals. An improved understanding of the fundamental mechanisms of MOF crystal formation will lead to the growth of higher-quality MOF crystals both in space and on Earth. Several organic and inorganic crystals have been grown onboard the ISS, including proteins, semiconductors, and graphene aerogels.
In this work, we will introduce the underlying physical phenomena of crystal growth in microgravity. We will present information on current ISS National Lab-sponsored research projects that are growing HKUST-1 3D MOF crystals, and hexaaminotriphenylene (HITP) and hexaaminobenzene (HIB) linker-based 2D MOF crystals. We will also discuss translational lessons learned from microgravity experiments that inform and direct terrestrial research and manufacturing. Finally, we will present opportunities for future microgravity experiments and access to ISS facilities through the ISS National Lab.

11:00 AM EL03.10.03
Highly Conductive 2D Covalent–Organic Framework Films Rui Wang, Hang Lyu and Yoonseob Kim; The Hong Kong University of Science and Technology, Hong Kong

Covalent–organic frameworks (COFs) have been widely used in electronics, catalysis, sensing, adsorption, and water purifications for their high crystallinity, porosity, and tunable functionality. However, the practical applications have been limited due to low intrinsic conductivity. Recent studies show that conjugated 2D COFs have the potential to achieve high conductivity and that the rational design of linkers and metal-containing macrocycles and synthesis optimization is important.[1] Regarding this, our report will demonstrate a bottom-up synthesis of copper-coordinated-fluorinated-phthalocyanine (CuPc) and 2,3,6,7-tetrahydroxy-9,10-anthraquinone-based COF (CuPc-AQ-COF) films, achieving high conductivity levels.[2] These films demonstrate an electrical conductivity of 1.53×10^3 S m^{-1} and a Hall mobility of 6.02×10^2 cm^2 V^{-1} s^{-1} at room temperature, rivaling that of metals. This remarkable performance is attributed to the molecular design that incorporates both 18π electron metal-containing CuPc and a quinone-based linker, and the

significantly improved crystallinity of the films prepared via the vapor-assisted method, which all facilitate charge transport within the COFs. Density functional theory analysis further proves the intralayer donor–acceptor system and further reveals that this system has the smallest band gap between the LUMOs of CuPc center and quinone linkages compared to other published similar COFs structures.[3][4] We also fabricated a field-effect transistor (FET) device with COF films exhibiting bipolar behavior, a low threshold voltage, and a high I_{on}/I_{off}. The results demonstrate the potential of the films in electronic applications. Our findings provide valuable insights into the design and fabrication of high-performance COF films. These stable, porous, and crystalline organic networks with metallic conductivity can realize advanced electronic devices, catalysis, and energy storage systems.

11:15 AM EL03.10.04
Advancements in Stretchable Displays: Exploring Serpentine Electrode Integration for Next-Generation Technologies Seungkyu Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Conventional display research primarily focused on enhancing the performance of components such as pixels, luminance of light-emitting components like LCDs or OLEDs. However, the display market has been expanding towards changes in the substrate, including foldable and rollable displays. The next-generation display research is pivoting towards stretchable displays capable of adapting to various sizes and adhering to the skin (On-skin). Yet, current developments in foldable, rollable, and flexible displays react only to specific directional changes, rendering them susceptible to damage. Future electronic devices are envisioned to adhere to the skin, transition seamlessly to vehicles, and be pocket-friendly like smartphones, simultaneously changing both shape and size.
To adhere to the skin, these displays need high stretchability in all directions while maintaining their structural integrity even when twisted or bent without any defects. Previous research on stretchable displays had weaknesses such as low stretchability (below 10%) or vulnerability to repetitive motions limited to two directions (biaxial direction). Ensuring the device operates normally without faults when the substrate expands is crucial, involving components like the light-emitting diode array, electrodes, TFT, and capacitors.
The research goal is to develop a next-generation preform display platform capable of stretching, bending, twisting, and folding. This platform aims to consider various stresses occurring along all axes and requires both material-based and structural approaches to ensure stability. To create the next-generation preform display, the research is approached from three aspects, as depicted in Figure 4.
The envisioned platform seeks to effectively eliminate diverse stresses occurring in all directions while adhering well to the skin. It aims to possess significantly higher elongation properties than existing displays, ensuring high durability against twisting and folding. This advancement is anticipated to pioneer the future stretchable display market.

11:30 AM EL03.10.05
Enhancing Reliability of Stretchable Electronic Interconnect through Selective Deposition of Crosslinked PDMS Deepesh Patidar and Vijay K. Pal; Indian Institute of Technology Jammu, India

Recent research explores a novel approach to improve the mechanical reliability of stretchable interconnects, crucial components in stretchable electronics. This study introduces an innovative design approach for a stretchable electronics substrate, aiming to achieve equilibrium among factors that could induce stretch-related issues, including plastic strain, out-of-plane deformation, and interfacial delamination.
The reduction in crosslinking at the center layer of the stretchable substrate contributes to an increase in shear strain, leading to interconnect failure through interfacial delamination during stretching. Numerical analysis validates that reducing crosslinking at the center layer of the stretchable substrate contributes to minimizing equivalent plastic strain in the interconnect during stretching. Employing a PDMS 10:1 stretchable substrate to encapsulate the horseshoe interconnect results in a 32% higher plastic stress compared to PDMS 10:30. However, this also leads to an increase in maximum out-of-plane deformation from 58.12 μm to 108.43 μm and in-plane maximum shear strain from 56.4% to 77.7% at interracial delamination locations.
In an effort to mitigate these challenges, we propose an approach involving selective crosslinking deposition on the center layer of the interconnect. This selective deposition is strategically performed at positions corresponding to delamination-prone locations, where high crosslinking PDMS is applied.
In this simulation, three models were considered: A&B (10:1 & 10:1, 10:1 & 20:1, and 10:1 & 30:1). Here, B signifies the deposition of PDMS at the geometric branch, while A represents the center layer other than the geometric branch. The configuration A&B is positioned between layers of 10:1 PDMS, creating a sandwich structure. The numerical models were subjected to up to 40% elongation displacement at one end surface, considering three distinct models as explained earlier. While stretching the substrate in one direction, a lateral contraction continuously occurs due to Poisson's effect, a phenomenon analysed specifically for the 10:1&10:1 stretchable substrate.
Locally, the internal part of the interconnect is under tension, while the outer component is under compression. To further analyze the deformation effects induced by plastic strain on the interconnect, a simulation was conducted. The maximum equivalent plastic strain in the interconnect at the geometric crest concerning the strain. Notably, the maximum equivalent plastic strain for the 10:1&10:1 substrate is approximately 16.2% and 26% smaller than that for the 10:1&20:1, 10:1&30:1 substrate, respectively.
The results revealed interfacial delamination between substrates and the interconnect interface at various locations after a 40% stretch, potentially impacting stretchability. Delamination during stretching is initiated by several factors, with the failure of stretchable substrates due to in-plane shear strain being a crucial factor, as demonstrated in the literature as a significant cause of stretchable interconnect failure through delamination. In-plane shear strain counters are presented for all substrates to correlate failure locations through interfacial delamination using simulation results.
The likelihood of failure through interfacial delamination further increases due to a mismatch between the interconnect and substrate shear strain during stretching. Additionally, the maximum in-plane shear strain values for all three cases are 0.56, 0.58, and 0.65 for 10:1&10:1, 10:1&20:1, and 10:1&30:1, respectively.
By focusing on the delamination location, where in-plane shear strain is a critical factor, the high crosslinking material serves to reinforce the interconnect and substrate interface. This reinforcement helps in maintaining the structural integrity of the stretchable interconnect, ultimately reducing the forces that lead to in-plane shear strain and subsequent delamination.

1:30 PM EL04.01.01
High- Quality Diamond for Scientific Applications: Synthesis, Characterization and Promising Developments John Ciraldo; WD Advanced Materials, United States

Availability and production capabilities in diamond are rapidly expanding. To enable nextgeneration diamond-based solutions, particularly in the quantum and semiconductor realms, WD Advanced Materials (“WDAM”), in cooperation with key industry collaborators, has developed new processes for the synthesis of large-scale single-crystal diamond wafers for electronic applications. Through this talk, led by Chief Technology Officer John Ciraldo, WDAM will share an overview of recent product development breakthroughs supporting these emerging technologies, including R&D results, output from the D2 SCALE under DARPA’s LADDIS initiative, and the latest on a new U.S.-based consortium, created to supply synchrotron-grade diamond to the national market through the DOE ARDAP program. WDAM will share third-party characterization data demonstrating exceptional material quality characteristics coupled with large substrate sizes, including anonymized comparisons to other commercially available products. In furtherance of the team’s form factor expansion efforts, WDAM will also present 13mm+ wafers with full x-ray mapping, highlighting narrow rocking curves of about 30 arcseconds, ultra-high doping concentrations, and evidence of strong electronic transport properties. The discussion will conclude with a summary of new material science process and technology solutions developed at WDAM, including defect mitigation; selective patterning and deposition; heterostacks (e.g. PN/PIN junctions); and continued scale in both material size and quality.

1:45 PM EL04.01.02
Tabletop Deep Ultraviolet Transient Grating Measurements of Diamond and Silicon at Record Sub-300nm Length Scales Brendan McBennett, Emma Nelson, Theodore Culman, Albert Beardo, Henry C. Kapteyn, Margaret Murnane and Joshua Knobloch; University of Colorado and NIST, United States

Transient grating (TG) experiments provide unique insight into microscopic electron and phonon transport dynamics by interfering two laser beams on a sample surface. This results in periodic charge and phonon excitations, and is a non-contact approach – without the need to coat or pattern the sample. Visible TG experiments have observed the onset of non-diffusive heat conduction in semiconductors such as silicon [1] – however, they are limited to opaque materials and length scales set by the visible diffraction limit (>500nm). Recent extreme ultraviolet (EUV) TG implementations can probe transport at much shorter length scales but face practical limitations in manipulating the EUV light. To date, a large free electron laser facility with limited access was required to generate sufficient pump fluence [2]. Here we present a tabletop deep ultraviolet (DUV) TG beamline, which utilizes the 6.3eV / 196nm fourth harmonic of a Ti:Sapphire amplifier to achieve record tabletop excitation periodicities <300nm for the first time. The high DUV photon energy enables the investigation of wide-bandgap materials at high carrier densities, including diamond and boron nitride. Most importantly, the short DUV wavelength accesses transport on length scales that are below the visible diffraction limit, while the <300fs DUV pulse duration is critical for resolving very fast nanoscale electron and phonon dynamics. We first investigate in-plane electron diffusion in diamond, bridging the micron- and nanoscale measurements in Refs. [2] and [3] and show that comparisons between differing pump wavelengths may provide insight into the physical mechanisms modifying the electron diffusion coefficient at high carrier concentrations. We also extend the non-diffusive phonon transport measurements in silicon thin films presented in Ref. [1] to length scales almost an order of magnitude shorter, and compare to the predictions of state-of-the-art hydrodynamic and ballistic phonon transport models. This novel DUV-TG beamline provides a non-contact, tabletop route to rapidly investigate nanoscale carrier dynamics and addresses challenges associated with interfaces, defects and doping in a greatly expanded range of materials.

2:00 PM EL04.01.04
Materials Science and Device Technology Development for Interface-Engineered Super High-K Dielectric Nanolaminate-Based Oxides / Crystalline Diamond for New Generation High Power Electronics Orlando Auciello[1,2]; [1]The University of Texas at Dallas, United States; [2]Original

Biomedical Implants, United States

This abstract focus on describing the fundamental and applied materials science and engineering being performed to develop a new generation of transformational high-power electronics based on the integration of novel multifunctional nanolaminate-oxides thin films, with super high-dielectric constant, and single crystal diamond. Specific R&D to be discussed include:
Materials Science performed to develop transformational TiO_x/Al_2O_3 nanolaminates, exhibiting
giant dielectric constant (up to k=1000), low leakage current (10^{-8} - 10^{-9} A/cm^2, and low losses
(tan d = 0.04), induced by a nanoscale thick Al_2O_3 layer at the top electrode/nanolaminate interface. The information to be presented will include discussion of the physics responsible for the giant dielectric constant, underlined by the Maxwell-Wagner relaxation mechanism, whereby the dielectric constant is controlled by oxygen vacancies at the nanolaminate interfaces.
Materials science and device design performed to integrate the high-K dielectric nanolaminates on single crystal diamond to fabricate the first integrated TiO_x/Al_2O_3 nanolaminates / single crystal diamond MOSFET devices.
Development of the lithography/RIE process to fabricate diamond-based micro / nano-electronic devices with integrated high-K dielectric TiO_x/Al_2O_3 nano-laminates/single crystal H-diamond surface terminated substrate, and measurement of electrical performance of first unoptimized MOSFET devices, which showed very good promising results.
The presentation will include a discussion of materials science issues that need to be addressed to optimize the performance of future TiO_x/Al_2O_3 nano-laminates/single crystal diamond-based micro/ nano-electronic devices, and investigate new HfO_2/TiO_x nanolaminates, involving the key HfO_2 used in gates of current commercial Si-based micro/nano-electronic devices.

2:15 PM EL04.01.05
From Design to Device: Challenges and Opportunities in Computational Discovery of p-Type Transparent Conductors Rachel Woods-Robinson[1,2], Monica Morales-Masis[3], Geoffroy Hautier[4] and Andrea Crovetto[5]; [1]University of Washington, United States; [2]National Renewable Energy Laboratory, United States; [3]University of Twente, Netherlands; [4]Dartmouth College, United States; [5]Technical University of Denmark, Denmark

A high-performance p-type transparent conductor (TC) with a wide band gap does not yet exist, but could lead to advances in a wide range of optoelectronic applications and enable new architectures for next-generation photovoltaic (PV) devices. High-throughput computational material screenings have been a promising approach to filter databases and identify new p-type TC candidates, and some of these predictions have been experimentally validated. However, most of these predicted candidates do not have experimentally-achieved properties on par with n-type TCs used in solar cells, and therefore have not yet been used in commercial devices. Thus, there is still a significant divide between transforming predictions into results that are actually achievable in the lab, and an even greater lag in scaling predicted materials into functional devices.

In this work, we introduce a holistic “device-to-design” materials discovery framework through which to identify and contextualize various disconnects in scaling p-type TC predictions into PV devices, and we apply this framework to highlight some of the most pernicious disconnects. One set of disconnects emerges from assumptions and uncertainties in computational assessment and screening. Other disconnects stem from transforming predicted candidates into thin films in the lab: due to challenges including synthesizability, phase purity, dopability, and unwanted absorption, so far no predicted p-type TC grown in the lab performs on par with n-type TCOs. A third key set of disconnect arises from transforming predictions into scalable optoelectronic devices: challenges emerge such as making sufficient contact to the device, tuning band alignments, and growing interfaces free of defects, and other barriers.

We also discuss specific barriers related to scalability and sustainability. Although the ultimate goal of scaling PV is to mitigate climate change, input and outputs from production and deployment may cause unintentional consequences such damage to ecosystems and human health, and there is an ethical responsibility to minimize harm as we scale new materials such as TCs. Historically, life cycle assessments are conducted after technologies reach commercial scale, which can lead to “technology lock-in” that makes it challenging to replace harmful materials. To avoid "locking-in" technologies with detrimental environmental effects, we encourage materials scientists to integrate life cycle thinking throughout the design process, drawing inspiration from recent methodologies like emerging materials risk analysis and anticipatory life cycle assessment.

Lastly, we propose recommendations for materials designers to address these disconnects while designing commercially-relevant wide band gap materials. We offer guidance on how the research community can overcome such disconnects to bring our predictions into fruition in p-TCs and beyond.

High Etch Selectivity for Dry Etching (Zn,Sn)O Thin Films to SiO_2 for Fabricating The Thin Film Transistor and 3-Dimensional Dynamic Random Access Memory Han Chul Lee[1,2], Jae Won Ham[1], Jinheon Choi[1], Seoyoung Jang[1] and Cheol Seong Hwang[1]; [1]Seoul National University, Korea (the Republic of); [2]SK Hynix, Korea (the Republic of)

Current 2D dynamic random access memory (DRAM) faces the scaling down limitation, so developing 3D DRAM is necessary to improve the integration density without relying solely on lateral device scaling. The semiconductor industry studied polycrystalline silicon as a channel material for 3D DRAM, similar to that used in 3D NAND flash memory. However, adopting polycrystalline silicon poses a critical problem due to its grain boundary effect, leading to degraded cell-to-cell uniformity. Therefore, amorphous oxide semiconductors are suggested as a potential candidate for the 3D DRAM channel materials. Amorphous zinc tin oxide (a-ZTO, Zn:Sn ratio ~ 50:50) can be a suitable channel material for 3D DRAM due to its promising electrical characteristics, such as high electron mobility, low off-current, and wide band gap. Also, it can be readily deposited by the atomic layer deposition (ALD) process, which is inevitable for 3D DRAM integration.
In fabricating 3D DRAM, etching a-ZTO film is required, but it must have a high selectivity to a sublayer, such as a gate insulator (i.e., SiO_2). Also, in 3D DRAM integration, the a-ZTO film is deposited by an ALD along the vertical channel structure, and the a-ZTO film deposited on the top portion of the pattern should be removed using the dry etching process while minimizing the damaging effect on the underlying structures. In the fabrication of a peripheral transistor, a-ZTO film out of the active region should be etched entirely while minimizing damage to the underlying thin gate insulator. The wet etching of ZTO thin films using hydrochloric acid can be used for specific cases. However, its isotropic and selective-grain boundary etching properties can pose several integration issues. Therefore, a stable dry etching process with high etch selectivity is needed. This study reports a stable dry etching process with high etch selectivity of ALD a-ZTO thin films with SiO_2 using the $CH_4/N_2/Ar$ (30/15/31 sccm) plasma. The achieved etch selectivity was as high as 20:1.
This study also verified the possible issues in the electrical characteristics when the above recipe with high selectivity is adapted to fabricate the a-ZTO thin film transistor (a-ZTO-TFT) having TiN source and drain, 100nm-thick thermal SiO_2 gate insulator, and p^{++} Si gate. For the stable operation of the TFT, a-ZTO film other than the channel region must be etched entirely away while minimizing the etching of the underlying SiO_2 layer. It is usual to over-etch the a-ZTO channel layer for this purpose. In this study, the ZTO channel etching was attempted by adopting $BCl_3/N_2/Ar$ (15/5/30 sccm) gases, a previously reported method, and using $CH_4/N_2/Ar$ (30/31/15 sccm) gases, a newly developed method. The over-etch was performed from 20% to 100% at intervals of

20% for each gas condition. Compared to the results of 5 over-etch conditions of applying $BCl_3/N_2/Ar$ gases, less variation of on-current ($1.27x10^{-4}A \rightarrow 4.76x10^{-5}A$ at 20.1V of gate voltage), better average subthreshold swing (0.224V/dec → 0.182V/dec), and less variation of threshold voltage (1.00V → 0.70V) were obtained from the 5 over-etch conditions with the $CH_4/N_2/Ar$ gases. This improvement was attributed to the improved etching selectivity of the latter compared with the former method. The presentation will report more detailed fabrication steps and electrical characteristics of the a-ZTO-TFT for their use in 3D DRAM.

3:15 PM EL04.01.07
Effect of High-*k* Oxide Materials on Amorphous Indium Gallium Zinc Oxide (*α*-IGZO) Channel in Top Gate Field Effect Transistors Reem Alshanbari[1], Oliver Durnan[1], Huaiqian Guo[1], Moshe Eizenberg[2] and Ioannis Kymissis[1]; [1]Columbia University, United States; [2]Technion–Israel Institute of Technology, Israel

The gate dielectric material plays a significant role in high-speed transistor operation and low power consumption in field-effect transistors (FETs). A small conduction band offset energy and a large interface trap density are common problems with high-*k* dielectrics with high permittivity. For that, in this work, the integration of high-*k* dielectrics with PECVD dielectrics has been reported to show improvements in electrical performance. Here, we integrated a high-*k* dielectric with (~10 nm) amorphous indium gallium zinc oxide (*α*-IGZO) FET with different gate dielectrics PECVD (SiO_2 and Si_3N_4). In addition, using a high-*k* dielectric can help overcome the problem of plasma contamination and diffusion, which can impact the device's threshold voltage and power consumption. For that, we use two of the most promising high-*k* dielectrics (HfO_2 and Al_2O_3). Our results showed that *α*-IGZO with optimized HfO_2/SiO_2 dielectrics has a superior electrical performance with high-field effect mobility (50 $cm^2\ V^{-1}s^{-1}$) and an on-current of 10^{-6} A, and the value of the off-current was 10^{-13} A under 0.1 V_{DS} without any dielectric leakage. These results support the idea that increasing the gate capacitance density will improve the electrical performance and material conductivity. Integrating HfO_2 with SiO_2 improves the interface quality between the gate dielectric/channel and reduces the charge trap density and gate leakage. In contrast, there is a degradation in the electrical performance of *α*-IGZO FETs with Al_2O_3/SiO_2, related to the oxygen diffusion where more oxygen atoms diffuse from Al_2O_3 to the *α*-IGZO layer.

SESSION EL04.02: Vertical GaN Electron Devices

GaN Homoepitaxial Growth and Substrate-Dependent Effects for Vertical Power Devices Jennifer Hite[1,2]; [1]U.S. Naval Research Laboratory, United States; [2]University of Florida, United States

Vertical GaN power switch technology is expected to be utilized in next-generation medium to high voltage power converters due to the low ON-resistance and high breakdown voltage enabled by the improved critical electric field and mobility compared to Si and SiC-based devices. As large area substrates have become available by hydride vapor phase epitaxy (HVPE) and ammonothermal growth, the properties of nitrides are no longer dominated by defects introduced by heteroepitaxial growth, allowing recent realization of several fundamental vertical power devices, including diodes with edge termination, trench MOSFETs, and CAVETs. However, additional materials challenges are coming to the forefront that need to be understood and surmounted in order to allow vertical GaN power devices to achieve their full potential, notably the realization of repeatable thick drift layers with low background doping. To enable this, a deeper understanding of substrate preparation and the effects of the substrate and growth initiation on the characteristics of the epitaxial layers is required for MOCVD growth of homoepitaxial films. We investigate these effects on epi morphology, uniformity, and impurity incorporation by growing simultaneously on wafers from different vendors. The goal of this work is to detect and identify defects in GaN substrates with a series of quick, non-destructive, inexpensive techniques with capabilities of mapping whole wafers.
We have characterized multiple substrates from various suppliers and the homoepitaxy grown on those substrates. All the substrates had nominally similar as-received specifications (resistivity, thickness, off-cut angle, bow, surface finish). The substrates were evaluated with a variety of techniques including Raman spectroscopy, photoluminescence, white light interferometry, and Nomarski imaging, enabling to detection of different concentrations of grain boundaries, sample impurities, point defects, v-shaped pits, polishing defects, crystal stress damage, and non-uniform insulating and conducive regions. The substrates can be characterized in two different categories: those with uniform characteristics, including carrier concentration, and those without. Comparing these results to those from homoepitaxial growth on the same wafers, the effects are both subtle and overt. Macroscopic surface morphology, which has shown a direct correlation to leakage current, copies and exaggerates that of the underlying substrate. Photoluminescence of the homoepitaxial surface along with Raman spectroscopy show that non-uniformities in the substrate carrier concentration can continue into the epitaxy. Following optical characterization, vertical Schottky diodes were fabricated to evaluate device performance. While most of the films showed the ability to withstand high electric fields, those with more uniform properties in the substrate also showed more uniform electrical properties. These results show that the bulk substrates enable the path to high voltage vertical devices, but also show the significant influence that substrates can play in device performance.

11:00 AM EL04.02.02
Comparison between Sapphire and GaN Substrates for 1.2kV Rated Vertical GaN Devices Enrico Brusaterra, Eldad Bahat Treidel, Frank Brunner, Alexander Külberg, Mihaela Wolf and Oliver Hilt; Ferdinand-Braun-Institut (FBH), Germany

Vertical GaN based power switching devices, diodes and transistors, are particularly desirable due to their reduced die size in comparison to lateral heterostructures-based devices. This results in a reduction of specific on-state resistance, $R_{DSon}\times A$, by one order of magnitude down to 1.0mW cm^2. Also, vertical device concept allows for aggressive device scaling, in respect to gate periphery length per area, and enables high current densities per unit area. The targeted blocking capability of 1.2kV demands the growth of drift layers thicker than 10µm with low residual background doping. However, the drift region conductivity, in particular for thick n^--GaN drift layers, may be limited by low mobility, low carrier density, back ground compensating doping, high defect density and built-in potential barriers, having a direct impact on the device electrical performance. Previously, we provided an optimization procedure for designing the drift layer properties for a specific voltage rating, and it showed how for 1.2kV and higher it's necessary to increase the drift layer thickness above 5µm. However, growing thick GaN layers is especially challenging for foreign substrates where the lattice mismatch and thermal coefficient differences generate a series of undesirable effects, such as increase of threading dislocations density, increased leakage current, increased stiffness and fragility and increase in wafer bow. While GaN substrates may provide a better solution for the material quality point of view, costs and substrate quality may differ substantially between differently grown wafers. In this presentation we will talk about the issues of growing thick (>5µm) GaN drift layer on Sapphire substrates for vertical high power GaN devices, how to manage the high wafer bow that makes these wafers un-processable on commercial equipment designed for flat Silicon wafers and we will compare the processed devices between sapphire and three differently grown GaN

substrates (Ammonothermal-GaN from vendor 1, “Wafer A”, and HVPE-GaN from vendor 2, “Wafer B”, and vendor 3, “Wafer C”). All processed devices showed >1.2kV breakdown voltage with different ON-state resistivity, Power-Figure-of-Merit and chip cost. *pn* diodes on Ammonothermal-GaN, “Wafer A”, show 1630V breakdown, on “wafer B” and “wafer C” 1485V and 1480V are shown respectively, all three showed avalanche breakdowns. While on sapphire, “Wafer D”, they show 1350V nondestructive breakdown due to high leakage current.
The experiment starts with 4” sapphire substrateand 3× 2” GaN substrates. A total of 14µm thick GaN epitaxial layers are grown on each wafer, epitaxy consists of a 2.2µm un intentionally doped GaN buffer layer, a 2.4µm n^+-GaN:Si ($N_D = 3.0\times10^{18}cm^{-3}$) lower highly conductive layer and a 10µm n-GaN:Si drift layer with a nominal Si concentration of $N_D = 7.5\times10^{15}cm^{-3}$. The effective doping has been measured by CV on diodes and changes based on the substrate material. A 500nm GaN:Mg $1\times10^{19}cm^{-3}$ layer with additional 30nm GaN:Mg $2\times10^{19}cm^{-3}$ contact layer are regrown and in-situ activated in a separate MOVPE reactor. The initial wafer bow after epitaxy grown on sapphire is ~300µm (Radius ~4m) and it would not be processable. Laser patterning is carried out in order to reduce the wafer bow by selectively introducing damage in the substrate close to the bottom interface. The patterning was realized by focusing a laser beam in the sapphire close to its back surface using a laser scriber (WSS4000), which uses a Talisker Ultra Laser from Coherent for internal layer modification. This means that the laser will be focused inside the material and, at this position, the crystal will be modified. The wavelength we use is 532nm. Used repetition rate is 40kHz at a feed speed of 400mm/s and a continuous laser power of 160mW at the point of use. Overall device performances and characteristics will be shown in the presentation, along with benchmarking and comparison of the different substrates.

11:15 AM *EL04.02.03
High-Performance Junction Diodes in GaN using Mg Implantation and Heterogeneous Heterojunctions Spyridon Pavlidis[1], Ramón Collazo[1], Zlatko Sitar[1,2] and Fred A. Kish[1]; [1]North Carolina State University, United States; [2]Adroit Materials, Inc., United States

The enhanced critical electric field of wide bandgap GaN render it an attractive technology for power switching and power amplification devices. Recent improvements in epitaxy and substrate quality have made it possible to focus on the development of advanced devices with complex doping schemes and junctions. This talk will tackle two important cases: (1) vertical GaN Junction Barrier Schottky (JBS) diodes realized with Mg implantation and ultra-high pressure annealing (UHPA), as well as (2) PN junctions using III-V/GaN heterogeneous heterojunctions formed via a novel technique known as Crystal Heterogeneous Integration (CHI). In each case, it will be demonstrated that junctions with near-unity ideality factors can be achieved via careful control of the material interfaces. These results underline the promise of GaN for high performance devices, and pave the way for further innovation in device geometries.

11:45 AM EL04.02.04
pn GaN Regrowth Vertical Diodes Displaying Ten Orders of Magnitude Memory Window Stephen J. Moxim[1], Ory Maimon[2,1], Behrang Hamadani[1], Wei-Chang David Yang[1], Andrew J. Winchester[1], Emily G. Bittle[1], Qiliang Li[2,1], Albert V. Davydov[1], Travis J. Anderson[3], Jennifer Hite[3], Jason P. Campbell[1], Sujitra Pookpanratana[1] and Jason T. Ryan[1]; [1]NIST, United States; [2]George Mason University, United States; [3]U.S. Naval Research Laboratory, United States

The large bandgap of GaN enable advancements in power electronics. pn GaN vertical diodes offer improved efficiency, size, and performance over traditional Si-based power devices making them essential components for next generation power electronic systems. pn GaN diode fabrication typically requires regrowth of the p-GaN layer, which is known to introduce Si impurities at the pn GaN interface.[1-3] While this does impact the performance of power devices,[2, 4, 5] the presence of impurities at the regrowth interface has also been shown to display memristor behavior.[6] Memristor-like behavior in GaN and other nitride device structures has also been reported.[7-9] It is appealing to develop GaN-based memory technologies which could be integrated with GaN high electron mobility transistors. Here, we find that regrown pn vertical diodes display an exceptionally large memory-like hysteresis loop exceeding a previous report.[6]
The pn diodes were fabricated on dot-core GaN substrates. For the regrowth diode, a 5 µm unintentionally-doped drift layer (n between 8E15 and 2E16 cm^{-3}) was first deposited, followed by ex-situ 400 nm p-layer ($N_A \approx 4E17\ cm^{-3}$). For the in-situ grown diode or “control,” a 8 µm drift layer ($n \approx 1.7E16\ cm^{-3}$) was first deposited, and subsequently followed by 400 nm p-layer ($N_A \approx 4\ E17\ cm^{-3}$). Metallization were identical on both sets of devices with Pd/Pt/Au on the p-GaN and Ti/Al/Ni/Au on the GaN substrate.
The regrowth pn diode displayed memory or hysteresis effect at forward bias with 10 orders of magnitude larger on-state current (I_{ON}) than the off-state current (I_{OFF}), while the “control” pn GaN vertical diodes with an *in-situ* grown interface, display no such hysteresis effect. We find that the memory endurance and retention characteristics are robust, with no appreciable degradation in I_{ON}/I_{OFF} ratio after 60k set-reset cycles. To evaluate these devices for potential use as a high temperature memory element, the presence of a reduced switching window was confirmed at temperatures up to 275 °C. To investigate the electronic differences of these two diode structures, electroluminescence (EL) measurements before and after endurance cycling were performed. While the control sample is clearly dominated almost entirely by a single spectral peak at about 3.25 eV (likely a conduction band to Mg acceptor transition), the memory-like devices have three additional strong spectral peaks whose relative contributions evolve with cycling. These three extra peaks are located at 3.1 eV (V_N to Mg acceptor), 2.9 eV (blue luminescence, BL), and 2.3 eV (yellow luminescence, YL). With increasing cycles, the 3.1 eV peak increases in relative contribution while the BL and YL features decrease. We speculate that the BL and YL defects are not critical to the memory effect. TCAD simulations of both the memory and control devices were performed, and the simulated IV characteristics of the control devices agreed with the measured electrical data. The structure of the memory devices for TCAD modelling is currently in development with transmission electron microscopy analysis to identify the regrowth pn GaN interface. We plan to propose a model on the origin of the memristor-like behavior in ex-situ formed pn GaN diodes.

Status of h-BN semi-bulk crystals Jingyu Lin and Hongxing Jiang; Texas Tech University, United States

III-nitride wide bandgap semiconductors have revolutionized the lighting industry and are poised to make a huge impact in power electronics. In the III-nitride family, the crystal growth and use of hexagonal BN (h-BN) as an ultrawide bandgap semiconductor (UWBG) are much less developed. The development of crystal growth technologies for producing semi-bulk crystals in large wafer sizes with high crystalline quality and low defect density is a prerequisite for utilizing h-BN as an UWBG electronic material. In addition to optoelectronic and electronic device applications, h-BN has another unique application for high efficiency solid-state neutron detectors because of an unusually large interaction cross-section between B-10 isotope and thermal neutrons, which however, also require the development of thick semi-bulk crystals.

In this talk, we provide a brief overview and recent progress toward the development of h-BN semi-bulk crystals by hydride vapor phase epitaxy (HVPE) and metal organic chemical vapor deposition (MOCVD). Benchmarking the crystalline and optical qualities of h-BN semi-bulk crystals with respect to the state-of-the-art millimeter-sized bulk crystal flakes grown by the high pressure/high temperature (HP/HT) and the metal flux solution methods together with photoluminescence (PL) emission and photocurrent excitation spectroscopy measurements identified that reducing the density of impurities and defects such as oxygen impurities and boron vacancies remains the most critical task for h-BN semi-bulk crystal growth. The performance of neutron detectors fabricated from semi-bulk h-BN wafers and the attainment of h-BN thermal neutron detectors with a record efficiency of 60% will also be presented. The development of high efficiency h-BN neutron detector technology serves as a stepstone for further advancing the crystal growth technology to produce electronic grade h-BN semi-bulk wafers.

2:00 PM EL04.03.03
Plasma-assisted physical vapor deposition of polycrystalline hexagonal boron nitride films Minsuk Seo[1], Leonardus Bimo Bayu Aji[1], Yan-Kai Tzeng[2], Sang Cheol Kim[2], Tian Li[1], Yilong Zhou[1], Liwen Wan[1], C.E. Kim[1], Tae Wook Heo[1], Bo Wang[1], Luis A. Zepeda-Ruiz[1], Steven Chu[2] and Sergei O. Kucheyev[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Stanford University, United States

Two-dimensional hexagonal boron nitride (2D-hBN), also known as white graphene, is an electrically insulating wide-band-gap material with several emerging applications. However, most of the previous systematic work has focused deposition of cubic BN films, while the synthesis of wafer-scale hBN films with desired properties remains a challenge. Here, we present results of our ongoing systematic study of polycrystalline hBN films with thicknesses in a range of 100-6000 nm deposited by variants of reactive magnetron sputtering with a radiofrequency (RF) driven discharge. We describe how the plasma discharge characteristics and, hence, resultant major film properites can be controlled by the magnetron source design, the confining magnetic field, and process parameters such as the working gas pressure (controlling landing neutral atom ballistics and energetics), subtrate temperature (adatom mobility), and substrate bias (bombarding ion energy). Even without epitaxy, with substrates held close to room temperautre, hBN films are polycrystalline, characterized by a FWHM of the major E_{2g} Raman vibrational mode (1370 cm^{-1}) in the range of 40 – 100 cm^{-1}, depending on deposition conditions. The FWHM reduces to ~30 cm^{-1} when a higher deposition temperature of 600-800 ^{o}C is used. Interestingly, all as-grown films are polycrystalline (turbostratic, with asymmetrically stacked layers) rather than amorphous even for room temperature and high deposition pressure of 50 mTorr characterized by low landing atom energetics. These film growth and characterization experiments are guided by results of in-situ plasma diagnostics, which greatly aids deposition process development.
This work was performed under the auspices of the U.S. DOE by LLNL under Contract DE-AC52-07NA27344.

2:15 PM EL04.03.04
Defect conversion in h-BN using electron beam irradiation for blue emission Yue Xu[1], Edward K. Naland[1], Zackaria Mahfoud[2], Chengyuan Yang[1], Andrew Bettiol[1], Michel Bosman[1,2] and Silvija Gradecak[1]; [1]National University of Singapore, Singapore; [2]Agency for Science, Technology and Research(A*STAR), Singapore

Hexagonal boron nitride (h-BN) is a layered van der Waals material with a bandgap of 6 eV. Thanks to its ultra-wide bandgap, h-BN can host a series of solid-state color centers, covering a range of wavelengths from UV to the visible region. h-BN emitters have attracted particular attention, not only for their high stability and strong luminescence at room temperature, but also due to their anti-bunching behavior, a characteristic of quantum emitters. In this work, we report the controlled generation of 437 nm quantum emitters (referred to as “blue emitters”) in h-BN *via* electron beam irradiation. We demonstrate that irradiation of h-BN using 3–10 keV electron beams in a scanning electron microscope (SEM) produces the blue emitters in a spatially precise manner, as measured using photoluminescence (PL). We establish the correlation between the incident electron dose and PL intensity, indicating that the negative charge trapped in h-BN facilitates the 437 nm emission.
To explore the structural origin of the h-BN blue emitters, we introduce point defects to h-BN using a helium ion microscope (HIM) before electron beam irradiation and show that the blue emitter PL intensity increased in the defect-engineered area. Furthermore, using a scanning transmission electron microscope (STEM) coupled with cathodoluminescence (CL), we observe the real-time activation and saturation of the blue emitter in pristine h-BN. The resulting emission is stable for >1000 s, making it a promising candidate for photonic device integration. We achieved controlled production of electron beam-induced blue emitters in h-BN by tuning the electron dose and native defect density, which advances our understanding of their structural origin as the conversion of native defects in the h-BN lattice. These h-BN blue emitters with enhanced spectral stability can serve as a building block for future photonic devices.

2:30 PM EL04.03.05
Stochastic computing using stochastic memristors from solution-processed hBN Lekai Song, Pengyu Liu, Jingfang Pei, Yang Liu, Songwei Liu, Yingyi Wen and Guohua Hu; Chinese University of Hong Kong, Hong Kong

As the device scaling slows down, it is getting challenging for conventional binary computing competent for the rapidly progressing big data and artificial intelligence technologies. Efficient computing paradigms call for material and device innovations. Stochastic computing with probabilistic bits is an emerging computing solution. Here, we demonstrate stochastic logic gates using stochastic volatile filamentary memristors from solution-processed insulating two-dimensional hexagonal boron nitride (hBN), and perform complex logic functions utilizing the stochastic logic gates for stochastic computing.

We start with hBN ink formulation. Briefly, an ink in isoproposal/2-butanol is prepared by liquid-phase exfoliation of hBN, and is finely tuned in the composition to suit the versatile printing techniques, such as inkjet printing, spin coating, and slot-die. Silver electrodes, patterned by photolithography, are deposited to sandwich the printed hBN to develop Ag/hBN/Ag memristors. Due to the stable insulating property of hBN, the formation and disruption of the silver ion filaments in the hBN switching medium can lead to stochastic yet stable ultrafast switching and memory effect in such a metal/insulator/metal structure. As such, the memristors exhibit stochastic volatile threshold switching with a threshold voltage of ~1 V, an on/off ratio of >10^5, a switching

speed of <300 ns, and an endurance of >10^5 cycles. The memristors can be switched stochastically with a high speed between the ON (1) and OFF (0) states when applied with ultrafast voltage pulses. We show that the proportion of the ON states from a typical memristor device within a sampling period represents a statistical probability when a pulse train is applied. Notably, the pulse voltage can well modulate the probability, and the voltage-probability relation follows a sigmoid function. This enables the memristors to perform logic computations on the probability. To demonstrate this, the memristors are first connected to comparators as stochastic random number generators, and then connected to standard logic gates as stochastic logic gates for complex, stochastic logic operations for stochastic computing. Specifically, we hardware implement stochastic logic functions of AND, OR, XOR, and MUX gates, and construct a convolutional operator to perform edge detection of images.

Stochastic computing with probabilistic bits offers a fundamentally different computing paradigm by physically performing the computation with probabilities, potentially leading to substantial reductions in the area, power, and latency in the computing hardware. Besides, the scalable solution-processed approach allows low-cost, high-speed wafer-scale memristor array fabrication. This holds a promising prospect for the development of stochastic computing particularly at the edges with limited computational resources.

3:15 PM EL04.04.01
Probing Polytype Selection during Metal-Mediated Epitaxy of GaN Quantum Dots and Nanowires Abby Liu[1], Zhucong Xi[1], Meng Li[2,3], Dmitri N. Zakharov[3], Fernando Camino[3], Judith C. Yang[3,2], Liang Qi[1] and Rachel Goldman[1]; [1]University of Michigan, United States; [2]University of Pittsburgh, United States; [3]Brookhaven National Laboratory, United States

Semiconductor polytype heterostructures, which consist of chemically homogeneous structures formed via an abrupt change in crystal structure, offer opportunities for performance exceeding those of composition-based semiconductor heterostructures. Of particular interest are heterostructures formed via an abrupt change in atomic plane stacking sequence, such as the transition from the wurtzite (WZ) polytype to the zincblende (ZB) polytype. At a fixed chemistry WZ/ZB heterojunction, the lattice mismatch and thermal expansion coefficient mismatch are typically < 0.1%, leading to a negligible interfacial defect concentration. Meanwhile, the WZ/ZB band offset and polarization discontinuity are expected to lead to the confinement of a two-dimensional electron gas (2DEG) at the interface, without the need for impurity doping and/or alloying. Such heterostructures would be promising for high power electronics and single photon emitters.

It has been hypothesized that metastable nanowire (NW) polytype selection is governed by surface/interface energies, surface diffusivities, and/or droplet angles that determine ABC vs. AB stacking of atomic planes, resulting in ZB or WZ polytypes. For ZB-polytype-preferring materials, such as III-As and III-P, ZB vs. WZ polytype selection has been described by empirical “contact angle” models, enabling the design and fabrication of NW polytype superlattices. However, for GaN, a WZ-polytype preferring material, the “contact angle” models for NW polytype selection, using literature values for WZ and ZB GaN surface energies, predict ZB polytype formation, across contact angles, even though WZ GaN NWs are most frequently reported in the literature.
We recently discovered a Ga-mediated molecular-beam epitaxy (MBE) process to nucleate ZB and WZ GaN NWs on Si(001) [1]. Key to this process is a Ga pre-deposition step, in which Ga droplet arrays are formed prior to NW growth. For the ZB NW ensembles, reflection-high energy electron diffraction and x-ray diffraction suggest overall ZB-to-WZ transformations at thickness ~20 nm. High-angle annular dark-field STEM reveals WZ NWs with close-packed (0001) planes oriented along the Si [001] surface normal, i.e. [0001]-oriented WZ NWs. On the other hand, ZB NWs with the close-packed (111) planes oriented ~37° from the Si [001] surface normal, i.e. [001]-oriented ZB NWs. Interestingly, the NW axis orientation remains fixed as it transforms to the WZ polytype. We hypothesize that Si incorporation into Ga droplets influences the polytype selecting during NW growth. Preliminary energy dispersive spectroscopy (EDS) data reveals higher Si concentration within ZB NW in comparison to that within WZ GaN NWs. Correspondingly, density functional theory (DFT) calculations show that ~8 at% Si in the Ga sublattice makes ZB GaN thermodynamically more stable than WZ GaN. Thus, Si appears to be a ZB polytype stabilizer for GaN. Direct observations of GaN nucleation in an in-situ environmental TEM (ETEM) will also be presented.

Nitride Nanostructure Nanopatterning with Sequential Infiltration Synthesis for Optoelectronic Advancements Sudarshana Patra; Illinois State University, United States

The research and development of nanomaterials for several applications have made great strides in recent years. With their unique properties on the nanometer scale, nanopatterning of inorganic materials is an emerging field with a wide range of applications such as electronics, optics, photonics, energy, and biomedical engineering. Optoelectronic devices, such as photodetectors, solar cells, and light-emitting diodes (LEDs), are crucial in converting light into electricity and vice versa. Group III nitride (III-N) materials have attracted considerable attention in this field due to their wide energy bandgap and exceptional stability. The nitride family includes significant members such as Gallium Nitride (GaN), Aluminum Nitride (AlN), Boron Nitride (BN), Indium Nitride (InN), as well as compound nitrides like InGaN and AlGaN. Among these materials, AlN and GaN are particularly noteworthy due to their exceptionally wide bandgaps, enabling emissions across the ultraviolet (UV) and visible spectrum. Planar structures of these nitrides have been widely used for blue LED applications; however, nanostructures of these materials have received significant attention recently due to factors such as the prospect of growth on low-cost dissimilar substrates, improved light extraction properties of vertical nanostructures, and better carrier confinement, *etc*. It is challenging to grow nitride materials in general due to their high-temperature requirements and lattice mismatch with conventional substrates, such as silicon (Si). Currently, nitride materials require expensive multistep processes to grow nanostructures, including chemical vapor deposition (CVD) and

sputtering, which are used to make patterns in conjunction with nanolithography. Sequential Infiltration Synthesis (SIS), an inorganic materials infiltration method, has shown potential for nanopatterning inorganic materials used in the microelectronics and optoelectronics industry. In our group, we developed nanopatterns of AlN by SIS technique that can produce scalable, well-ordered, and relatively easy integration of the patterned nanomaterials and investigate their growth mechanism and optical properties. We have used polystyrene-b-polymethylmethacrylate (PS-b-PMMA) self-assembled nanostructures as a guiding pattern and SIS as a deposition method for the AlN nanopattern. We have characterized the patterns by scanning electron microscope, x-ray photoelectron microscope, and Fourier transform infrared (FTIR) spectroscopy. This research of nanopatterning nitride materials with SIS would open new avenues for emerging nitride-based optoelectronic and other devices for large-scale growth, with any substrate, and in a cost-effective way.

III Nitride based Heavy Metal Ion Sensors for Smart Water Quality Monitoring Nipun Sharma, Ankur Gupta and Mahesh Kumar; Indian Institute of Technology, Jodhpur, India

The group III nitride semiconductor devices like AlGaN/GaN high electron mobility transistors (HEMT) have become the most emerging candidates in the last two and half decades. The 2DEG forms at the AlGaN/GaN heterointerface without applying an external electric field, which makes AlGaN/GaN HEMTs normally ON devices. There are surface states on the AlGaN/ GaN High Electron Mobility Transistor due to the availability of dangling bonds at the surface. These surface states have a significant impact on the 2DEG. By using this phenomenon, the AlGaN/GaN HEMT are utilized for the detection of toxic heavy metal ions in water. The quick and easy monitoring of heavy metals in drinking water is utmost important due to their harmful effects on human health.
AlGaN/GaN HEMTs with functionalized gate areas were fabricated for sensitive and selective detection of heavy metal ions such lead, and mercury. In order to study the presence of Pb^{2+} metal ions in water, the fabricated GaN HEMT sensor's gate region was functionalized using graphitic carbon nitride (g-C_3N_4) nanosheets. The limit of detection (LoD) of the g-C_3N_4 functionalized sensor, obtained a sensitivity of about 0.46µA/ppb and 0.32 ppb as lowest limit which is substantially lower than the permissible limit as set by W.H.O. In another work on Pb^{2+} ion detection, the fabrication of AlGaN/GaN HEMT was carried out for the detection of toxic lead ions in the water by functionalization of the Au-gated region by the 2,5-dimercapto-1,3,4-thiadiazole (DMTD). The sensor reaches the lower detection limit of 0.018 ppb. It exhibits a rapid response time of ~ 4 seconds and high sensitivity of 0.607 µA/ppb. Moreover, a study for the selectivity analysis is performed, and it is found that the sensor is highly selective towards Pb^{2+} ions. In another interesting work, we developed a sensor for highly sensitive, selective, and rapid determination of the trace amount of Hg^{2+} ions using molybdenum disulfide (MoS_2) functionalized AlGaN/ GaN HEMT. The sensor showed an excellent sensitivity of 0.64 µA/ppb and an ultra-low-level detection limit of 0.01152 ppb or 11.52 ppt (parts per trillion) with a rapid response time of 1.8 s. Moreover, the sensor exhibits the linear range of detection from 0.1 ppb to 100 ppb and highly selective behavior towards Hg^{2+} ions. To further enhance the sensitivity, we have successfully demonstrated the detection of Hg^{2+} ions using MoS_2 functionalized AlGaN/GaN HEMT under UV illumination which showed an extremely high sensitivity of 548.07uA/ppb with a lower detection limit of 6.15 ppt. In our another work, we observed that the fabricated sensor after functionalization with Ag-MoS_2 ensured faster electron transfer kinetics and showed out remarkable sensitivity of 1.6 mA/ppb and limit of detection (LoD) of upto 20 ppt. Along with the detection on real time water samples from lake water, a proof of concept by enabling it with IoT interface was also demonstrated. Hence, the development and performance of the AlGaN/GaN HEMT based ion sensors suggest that these sensors have a huge potential for other heavy metal ion sensing applications

4:00 PM EL04.04.04
Metallization Scheme for 800 °C Silicon Carbide Microsystems Robert Okojie; NASA Glenn Research Ctr, United States

We have developed and validated a high temperature metallization scheme that can sustain silicon carbide (SiC) microsystem operation at 800 °C in the absence of protective packaging. The metallization system consisted of the ohmic contact, diffusion barrier, and interconnect layers made up of three primary and conventional metallizations of Ti, $TaSi_2$, and Pt. The ohmic contact to the SiC layer is comprised of sequentially deposited Ti (100 nm)/$TaSi_2$ (300 nm) that provides low contact resistance, followed by the diffusion barrier layer of Ti (100 nm/Pt (300 nm) to prevent the native oxygen and excessive upper layer platinum migrations to the underlying SiC layer. The interconnecting layer is comprised of Ti (20 nm)/$TaSi_2$ (20 nm/Pt (300 nm)/Ti (20 nm)/$TaSi_2$ (20 nm), which also functions as a diffusion barrier against oxygen from the atmosphere. The bond pad contact layer is Ti (100 nm)/Pt (300 nm)/Au (500 nm). The metallization was implemented on the n-type epilayer of batch fabricated 4H-SiC pressure sensors to demonstrate functionality in a real device. The metallization system on the sensor was analyzed with Auger Electron Spectroscopy (AES), Focus Ion Beam (FIB) Field Emission Scanning Electron Microscopy (FE-SEM), and X-ray Photoelectron Spectroscopy (XPS) at various sections and stages during different steps of the fabrication. Further analyses were performed after fabrication at high temperature up to 800 °C in air. Electrical measurement was also performed on the bare die under a worst-case condition of no package protection of the sensor at high temperature in air.
The FIB-FESEM cross section after soaking the bare die at 800 °C in air revealed non-smooth interfaces between the layers of the oxide and metallization. The metallization on the oxide layers followed the undulating surfaces of the oxide layers, resulting in likely local discontinuities. However, these presumed discontinuities did not affect the electrical conduction path from the ohmic contact, through the interconnect, and to the bond pad. The observed rough surfaces of the oxide were believed to have occurred during the series of reactive ion etching steps of the oxide via for the ohmic contact, the interconnect, and the bond pad. Overall, the elemental analyses showed a well-preserved metallization, with only native oxygen observed in expected places. Electrically, the SiC sensors that were packaged and tested confirmed the effectiveness of the metallization scheme to support reliable operation at 800 °C. Further improvement to realize a smooth surface morphology was subsequently implemented. The complete details of this work will be presented at the meeting.

4:15 PM EL04.04.05
Dopant-selective photoelectrochemical etching of 4H-SiC for wafer-scalable SiCOI integrated photonics Jason Lipton, John vajo, Adam Sorensen, Brett Yurash, Biqin Huang, Sam Whiteley, Xiwei Bai, Tong Wang, Sam Rubin, Adrian Portales, Shanying Cui and Jason Graetz; HRL Laboratories, United States

Usable quantum networks with long distance baselines requires quantum repeaters with integrated quantum memories. 4H-SiC hosts a variety of optically addressable defects, can yield low-loss photonics while being compatible with CMOS fabrication processes, and has a highly mature wafer-scale supply chain. However >3”, total thickness variation (TTV) of SiC thin film during the SiC-on-insulator (SiCOI) fabrication impedes scalable fabrication of integrated photonic devices with acceptable propagation loss and efficient coupling of optical elements. While the high chemical stability of SiC makes traditional wet processes ineffective, we have demonstrated dopant-selective photoelectrochemical (PEC) etching of SiC epitaxial layers using n-type SiC as a sacrificial layer with a p-type etch stop. We apply the concept of selective PEC to a realistic SiC-on-insulator (SiCOI) stack for highly effective TTV reduction. We show that by using selective PEC etching to etch a sacrificial n-type layer and stop selectively on an intrinsic photonic layer, we are able to reduce the TTV of the SiC by over an order of magnitude. We show that the reduced TTV results in a dramatically improved yield and propagation loss of waveguides compared to the standard polishing process. The results presented here represent a step forward in realization of scalable 4H-SiC integrated photonic devices toward long-distance quantum networking.

4:30 PM EL04.04.06
Dielectric and Phase Engineering of Van der Waals Sb2O3 Films via PLD Jing Yu[1], Ruey Jinq Ong[1], Atta Ur Rehman[1], Chris Tang[1], Wei Han[2] and Francis Chi-Chung Ling[1]; [1]The University of Hong Kong, Hong Kong; [2]Hubei University, China

Van der Waals dielectrics are broadly utilized to retain the intrinsic properties of two-dimensional (2D) electronic devices. As a 2D inorganic molecular crystal, Sb2O3 have attracted many research interests as a promising high k gate dielectric with low-cost and CMOS compatibility. However, fabricating 2D Sb2O3 film with controllable dielectric constant and crystal phase is challenging. Here, we designed an oxygen-assisted PLD method for the phase-selective growth of α- and β- Sb2O3 thin films with super-high κ (>100) and good homogeneity by PLD. This is realized by tuning the oxygen gas pressure in the growth products to obtain two phases Sb2O3. This phase-controlled bottom-up synthesis offers a simple and efficient way for manipulating the relevant device structures and provides a general approach for producing other multi-phase materials with unique properties and allows us to characterize their intrinsic optical and electrical properties. Using dielectric and electrical measurements, we show that α phases exhibit good dielectric performance. Our Sb2O3 dielectric film not only show higher κ than other conventional dielectrics in terms of compatibility to CMOS processes, but also keeps their comparative advantages in the fabrication of high-performance electronic devices over conventional dielectrics. Our approach of fabricating Sb2O3 dielectrics using PLD may open promising opportunities to promote such unprecedented 2D devices to industry applications.

SESSION EL04.05: UWBG Nitrides
Session Chairs: Elaheh Ahmadi and Sriram Krishnamoorthy

Room 345, Level 3, Summit

8:45 AM *EL04.05.01
Addressing Challenges in AlGaN-Channel High Electron Mobility Transistors Brianna A. Klein[1], A. A. Allerman[1], Andrew Armstrong[1], Mary Rosprim[1], Yinxuan Zhu[2], Chandan Joishi[2], Chris Chae[2], Jinwoo Hwang[2] and Siddharth Rajan[2]; [1]Sandia National Laboratories, United States; [2]The Ohio State University, United States

Next-generation semiconductor switches and integrated circuits require higher power density, greater customizability, and improved radiation hardness than what is commercially available today. Nitride-based Ultrawide-Bandgap (UWBG) semiconductors, namely AlGaN (aluminum gallium nitride) are well-suited to meet these performance demands. Higher bandgaps result in exponentially higher critical electric fields, thus enabling power electronics with larger breakdown voltage and output power than devices made from conventional semiconductors (e.g., Si, GaN). In elevated temperatures, large bandgaps reduce noise and leakage from intrinsic carrier effects and thermionic emission. However, AlGaN faces challenges in realizing low-resistance Ohmic contacts and reduced mobility due to alloy scattering.
This talk will discuss efforts at Sandia to address these challenges, as well as highlight key device results.
Significant improvements of Ohmic contacts on aluminum rich HEMTs (channel compositions of $Al_{0.7}Ga_{0.3}N$) have resulted in reduced specific contact resistance values, with latest developments reaching the 10^{-6} Ωcm^2 range. The power transistor developments have targeted increases in current and standoff voltage, while processes to realize p-AlGaN based enhancement mode (normally off) gates have been developed.

First Principles Modeling of High Field Transport in Ultra-Wide Bandgap Materials Jonah Shoemaker, Reza Vatan, Tathagata Biswas, Arunima K. Singh, Marco Saraniti and Stephen M. Goodnick; Arizona State University, United States

Ultra-wide band gap (UWBG) materials offer the potential for greatly improved power electronic device performance due to their predicted higher breakdown fields limited by avalanche breakdown, as well as their favorable transport characteristics such as high mobility and drift velocity, which reduce on-resistance and allow for high frequency operation in power conversion applications. Experimental data on the high field transport properties of UWBG materials such as the impact ionization coefficients are relatively limited, with considerable variability. Hence, to understand the limits of performance of these materials, we report on first principles theoretical calculations of the high field transport properties of UWBG materials using a combination of ab initio calculations of the electronic and phononic structure coupled with particle based full-band Cellular Monte Carlo (CMC) high field transport simulation.

The electronic structure is computed using the GW method based on the BerkeleyGW code, which accurately predicts the bandgaps and excited states of UWBG materials. The phonon dispersion is calculated from DFPT (density functional perturbation theory) using Quantum Espresso. The full wave-vector dependent deformation potentials are computed using the GW eigenvectors as input to the EPW (electron-phonon using Wannier) code, to calculate the electron-phonon scattering rate from first principles. The calculated electronic structure, phonon dispersion, and anisotropic electron-phonon deformation potentials are then input to the CMC code. The CMC code has been developed in-house for a number of years, and simulates the dynamics of an ensemble of charge carriers using scattering rates tabulated in a large look-up table, which allows computationally efficient simulation of non-equilibrium carrier dynamics across the entire Brillouin zone. Besides electron-phonon and defect scattering, we calculate the band-to-band impact ionization scattering rate directly from the GW electronic structure, using a screened Coulomb interaction based on the full band frequency-dependent Lindhard dielectric function. Based on these scattering mechanisms as input, transport quantities such as the velocity-field characteristics and impact ionization coefficients as a function of field are calculated from full band Cellular Monte Carlo (CMC) simulation.

We have applied this framework initially to diamond in comparison to available high field transport data. One important observation is that while the critical field depends strongly on the material bandgap, the relative magnitude of the deformation potential plays an important role as well. Lower values of the deformation potential lead to more energetic electron and hole populations which favor impact ionization, hence reducing the breakdown field. We compare different approximations of the deformation potential in relation to the simulated impact ionization coefficients and their impact on breakdown. The impact of other scattering processes due to defects such as ionized impurities on the high field properties are also under investigation. We also are currently investigating other UWBG materials, specifically BN and AlN, and will report on their high field properties as well.

9:45 AM EL04.05.03
Rapid Prediction of Phonon Density of States by Graph Neural Network and High-Throughput Screening of Candidate Substrates for Wide Bandgap Electronic Cooling Ming Hu; University of South Carolina, United States

Machine learning has demonstrated superior performance in predicting vast materials properties. However, predicting a continuous material property such as phonon density of states (DOS) is more challenging for machine learning due to the inherent issues of data smoothing and sensitivity to peak positions. In this work, phonon DOS of ~5,000 inorganic cubic structures with 63 unique elements from the Open Quantum Materials Database are calculated by high precision density functional theory (DFT). With these training data, we build an equivariant graph neural network (GNN) for total phonon DOS of crystalline materials that utilizes site positions with their atomic masses as input features. The computational cost of training the GNN model is several orders of magnitude cheaper than full DFT calculations. More interestingly, the trained GNN model can predict partial DOS of the constituent atomic species even if such data were not included in the training, which demonstrates GNN's capability in predicting the species contributions (node-level) of partial DOS from the total DOS predictions without additional computational cost. We then deploy the trained GNN model to predict phonon DOS of >40,000 non-zero bandgap materials to search for thermally conductive substrates for cooling a few representative high electron mobility transistors (HEMT) in terms of high interfacial thermal conductance (ITC). Our results show that high vibrational similarity or phonon DOS overlap is not the only requirement to obtain high ITC. Instead, the average group velocity of heat source and heat sink for the acoustic branches in the phonon DOS overlap region is equally important in determining ITC. Moreover, we highlight that the lattice thermal conductivity of substrates does not always play a significant positive role in determining ITC when cooling HEMT devices. However, higher lattice thermal conductivity substrates indeed cause higher magnitudes of heat flux transporting at the interface. This work demonstrates the power of GNN models and paves the way for high-throughput screening of novel crystalline materials with desirable high ITC for phonon-mediated thermal management of wide bandgap electronics.

Addressing the challenges of n-type doping in AlN films grown on N-polar AlN substrate Irfan Khan[1] and Elaheh Ahmadi[2]; [1]University of Michigan--Ann Arbor, United States; [2]University of California, Los Angeles, United States

Ultra-wide bandgap AlN has gained significant attention for high power and extreme environment applications due to its high breakdown field, high thermal conductivity and high temperature stability. However, achieving a controllable and uniform n-type doping as well as ohmic contacts with low resistance remain significant challenges for AlN based electronic and optoelectronic devices. Our work is focused on addressing these challenges on Nitrogen-polar (N-polar) AlN.
In this talk, I will present our recent results on Si-doped AlN films and polarization doping in graded N-polar AlN->AlGaN films.

11:00 AM EL04.05.05
Adsorption controlled homoepitaxial growth of *c*-plane sapphire by thermal laser epitaxy Felix V. Hensling[1], Lena N. Majer[1], Sander Smink[1], Jochen Mannhart[1] and Wolfgang Braun[1,2]; [1]Max Planck Institute, Germany; [2]epiray GmbH, Germany

Its low cost, superior properties over silicon, high quality wafer availability, and the possible integration with silicon have established sapphire as widely used substrate material.[1] The ultra-wide bandgap and attractive dielectric constant of sapphire equally promise to reach regimes of semiconductor electronics and photonics thought to be impossible.[2] A cornerstone for further advancing the use of sapphire is the to growth of high quality homoepitaxial sapphire films. However, epitaxial films of c-plane oriented sapphire, one of the most common cuts of sapphire, have so far been out of reach due to the preferred formation of the Al_2O_3 γ-phase.[3] Epitaxial films grown on other cuts of sapphire usually suffer from a bandgap reduction.[2,4] In the presentation, I will demonstrate that the extensive parameter space available in TLE solves those problems.[5] The CO_2-laser driven substrate heating system allows to heat sapphire substrates to their melting point. The high accessible and precisely controllable temperatures enable a smooth sapphire substrate preparation – the first step for successful homoepitaxy.[6] I further present how the crystal quality and surface smoothness of homoepitaxial sapphire increase with increasing substrate temperature in case the growth is performed in the adsorption-controlled mode. Even at high temperatures growth rates > 1 υm/h are realized. At a growth temperature of 1600 °C, the films were found to be practically undistinguishable from the underlying substrate regarding their crystallinity and optical properties, even exceeding the substrate's purity.

Metastable Shallow Donors and Origin of n-type Doping in AlN and AlGaN Yujie Liu, Sieun Chae and Emmanouil Kioupakis; University of Michigan, United States

The n-type doping of AlN and Al-rich AlGaN alloys through the incorporation of group-IV donors is constrained by the formation of compensating DX centers. Within the DX configuration, the bond connecting the donor atom to its adjacent N atom is disrupted, consequently causing the N atom to undergo a buckling distortion in the reverse direction. This results in the creation of a deep defect level within the band gap that is capable of trapping two electrons. Nevertheless, recent experimental works [1-4] have observed shallow donor formation and high conductivity and in Si- or Ge-implanted AlN. However, the nature of these shallow donors and the mechanism of doping remain unclear. Here, we apply predictive atomistic calculations to understand the formation of shallow donors and compensating defects in n-type AlN. We first identify that the high conductivity of Si- and Ge-implanted AlN arises from Al interstitials introduced by the ion damage. At the same time, the substitutional implanted Si and Ge ions form complexes with Al vacancies, which maintain the group-IV donors in the shallow configuration and prevent compensation. The presence of these complexes has been identified experimentally through their characteristic peaks in photoluminescence. Moreover, although the DX-center geometry is the most stable configuration of Si and Ge dopants for Fermi levels close to the conduction band, Fermi levels near the middle of the gap cause donors to adopt the shallow-donor geometry, in which Al atoms are substituted by the dopants without bond severance or strong bond distortions. This indicates that Fermi-level engineering during the material growth or

processing can stabilize donors in the shallow geometry and prevent the formation of DX centers. Furthermore, once equilibrium is re-established in n-type AlN and the Fermi level shifts closer to the conduction band, the disruption of the Si-N bond is inhibited by an energy barrier of ~1 eV, preventing the conversion of the metastable shallow Si donors into DX centers over a sufficiently long time. Our results explain the mechanisms for the efficient n-type doping of AlN and Al-rich AlGaN, and identify Fermi-level engineering strategies to further increase the doping efficiency and improve the conductivity.

11:30 AM EL04.05.07
Comparative Study of Low-Frequency Noise in Diodes Made of Ultra-Wide Band Semiconductors Subhajit Ghosh[1], Dinusha Herath Mudiyanselage[2], Fariborz Kargar[1], Yuji Zhao[3], Houqiang Fu[2], Stephen M. Goodnick[2], Robert J. Nemanich[2] and Alexander A. Balandin[1]; [1]University of California, Los Angeles, United States; [2]Arizona State University, United States; [3]Rice University, United States

In recent years, ultra-wide bandgap (UWBG) semiconductors have attracted increasing attention owing to the ever-increasing industry demand for high-power density electronics. Materials such as diamond, AlGaN, BN, and β-Ga_2O_3 emerged as viable alternatives to the well-established wide-bandgap technologies such as GaN and SiC. Low-frequency electronic noise produced by a device is an important metric. From one side, the level of low-frequency noise should be reduced for device applications in communications or sensors. On the other side, low-frequency noise can provide valuable information about the material quality and device reliability. The low-frequency noise includes the 1/f, flicker noise, and generation-recombination (G-R) noise with a Lorentzian-type spectrum (f is the frequency). Both 1/f and G-R noise are associated with material defects acting as trapping centers for the charge carriers. The latter can be used to understand the charge carrier dynamics and defects in materials. To some degree, the noise level can be used as a metric to assess the maturity of the material and device technology. We have conducted detailed noise studies in GaN vertical PIN diodes [1], high-current diamond diodes [2], β-$(Al_xGa_{1-x})_2O_3$ Schottky barrier diodes [3], and NiO_x/ β-Ga_2O_3 *p-n* heterojunction diodes [4]. At the presentation, we will compare the overall noise level in different UWBG technologies and comment on the effects of the material quality and device design. We will also describe the most interesting features observed in the noise spectra for some of the devices. Specifically, it was found that the noise of the diamond diodes is dominated by the 1/f and G-R noise. The G-R bulges are characteristic of diamond diodes with lower turn-on voltages. The characteristic trap time constants, extracted from the noise data, show a uniquely strong dependence on current. Interestingly, the performance of the diamond diodes improves with the increasing temperature. The noise spectral density of the β-$(Al_xGa_{1-x})_2O_3$ diodes, at room temperature, reveals 1/f dependence, with superimposed Lorentzian bulges at the intermediate current regimes. At the intermediate current level, the Lorentzian component belongs to the random telegraph signal (RTS) noise. The RTS noise was attributed to the defects near the Schottky barrier affecting the local electric field and the potential barrier, which correspondingly impacts the electric current.

11:45 AM EL04.05.08
Novel deposition of amorphous aluminum oxide thin film using a direct liquid injection chemical vapor deposition (DLI-CVD) system Jiseon Kim[1,2], Wei-Fan Hsu[2], Simon Mellaerts[2], Claudio Bellani[2], Alberto Binetti[2], Koen Schouteden[2], Jean-pierre Locquet[2], Jin Won Seo[2] and Caroline Sunyong S. Lee[1]; [1]Hanyang University, Korea (the Republic of); [2]KU Leuven, Belgium

Aluminum oxide (Al_2O_3) stands out as a representative ceramic material thanks to its wide applicability, e.g., in electronic and optical devices, sensors, wear-resistant coatings, and catalyst support. Especially, amorphous aluminum oxide films hold great promise due to their flexibility, uniformity, and high dielectric properties compared to crystalline counterparts. Various deposition methods, such as sputtering, chemical vapor deposition (CVD), and sol-gel method have been used so far.
This study introduces a noble direct liquid injection CVD (DLI-CVD) technique to fabricate amorphous Al_2O_3 thin films. DLI-CVD, unlike conventional CVD process, offers various advantages: It can avoid the unnecessary decomposition of precursors prior to deposition, by making us of a vaporization chamber (Vapbox). The liquid precursor is injected into the Vapbox and transported to the deposition chamber through the nitrogen carrier gas. Simultaneously, oxygen gas is injected into the chamber for enabling the oxide film deposition. The precursor mixture is directly injected as vapor into the deposition chamber. The decomposition occurs on the surface of the substrate, where the deposition reaction is initiated. As the precursor molecules are decomposed directly on the surface, unwanted by-products can be prevented. Furthermore, strong chemical bonds between precursor molecules and organic solvent break in advance, while minimizing the required heat energy.
In this study, Al_2O_3 thin films were deposited by varying parameters such as the substrate temperature, the deposition time, and the ratio between nitrogen and oxygen gas flow. Aluminum acetylacetonate ($Al(acac)_3$) was selected as the aluminum precursor due to its stability, non-toxicity, and non-flammability, compared to alternatives like trimethylaluminum and aluminum chloride. X-ray reflectivity (XRR) analysis confirmed that the film thickness scaled with the substrate temperature and deposition time. Atomic force microscopy (AFM), x-ray photoelectron spectroscopy (XPS) and Fourier transform infrared spectroscopy (FT-IR) analysis elucidated the roughness, uniformity, and composition of Al_2O_3 films. Cross-sectional transmission electron microscopy (TEM) provided insights into the film morphology and growth mechanism. This work demonstrates the applicability of the novel DLI-CVD technique and enhances our understanding of this innovative thin film process.

1:30 PM ^EL04.06.01
Multidimensional Power Devices in WBG and UWBG Semiconductors Yuhao Zhang; Virginia Tech, United States

Power electronics technologies provide electrical energy conversion using semiconductor devices and passive components. The global power device market reaches US$40 billion and is rapidly expanding, driven by applications like electric vehicles, data centers, consumer electronics, electric grids, and renewable energy processing.

Power device advances are driven by materials and device architectures. In addition to using wide-bandgap (WBG) or ultrawide-bandgap (UWBG) materials, multidimensional architectures – such as superjunction, multi-channel, and multi-gate – can also improve device performance, regardless of the underlying material technology. These structures enable electrostatics engineering in additional dimensions and bring the benefits of geometrical scaling into power devices.

This talk presents our efforts in developing multidimensional power devices in WBG material GaN and UWBG material Ga_2O_3, the performance of which have exceeded the 1-D power device limit of the respective material. Particular focus will be placed on GaN power FinFETs, GaN multi-channel lateral devices, as well as the vertical GaN and Ga_2O_3 superjunction devices. These devices hold great potential for advancing the speed, efficiency, and form factor of power electronics systems, and some of them are currently being commercialized. The theoretical limits, figure of merits, and scaling laws of these multidimensional power devices will also be discussed for WBG and UWBG materials. Finally, these devices provide an exciting platform to study the fundamental material properties and carrier transports in homogenous or heterogenous, charge-balanced junctions under sub-micron second fast switching conditions.

2:00 PM EL04.06.02
Design Optimization of Ultra-Wide Bandgap Power Diodes: A Co-Design Approach to Understanding the Impact of UWBG Semiconductor Materials Properties on Power Device Performance Jonah Shoemaker[1,2], Robert J. Kaplar[2], Stephen M. Goodnick[1], Reza Vatan[1], Jack Flicker[2], Andrew Binder[2] and Srabanti Chowdhury[3]; [1]Arizona State University, United States; [2]Sandia National Laboratories, United States; [3]Stanford University, United States

Ultra-Wide Bandgap (UWBG) semiconductors constitute the fourth generation of semiconductor science and technology, and as such are at the forefront of semiconductor research today. This class of materials is roughly defined as those semiconductors having a bandgap greater than that of GaN ([endif]--> eV). The unipolar figure of merit (UFOM) of [endif]--> is a useful metric for comparing between semiconductor materials for power device application, but tThe incorporation of UWBG devices into systems is not determined on a UFOM b UFOM basis. It i, but is instead driven by the system-level benefits derived by incorporation of a device at given operational parameters (e.g. switching frequency, hold-off voltage, current-carrying ability). The various UWBG materials are at different levels stages of development for devices such as PIiN vs Schottky diodes, so a direct comparison with state-of-the-art wide bandgap materials based on device I-V curves is misleading.
In order to determine the system-level operational regimes for which various combinations of UWBG materials and diode architecture are preferred over more developed WBG devices, we have developed the optimization tool first reported in [1]. This optimizer takes various system operational parameters as input (reverse operating bias, forward current density, system frequency, etc.) and optimizes the width of the device drift region and the doping level to minimize system power dissipation. Effects particular to UWBG materials, such as incomplete ionization due to deep dopant energy depth, space-charge limited current, and doping- and device thickness-dependent breakdown fields, have been incorporated into the optimizer to more accurately model the performance of UWBG materials.
For a given device type and material, a mobility model is used to determine carrier mobilities at a given temperature, doping level, and electric field. For some materials, this mobility model is computed from various scattering contributions, while for the rest of the materials empirical models available in the literature are used instead. The operational parameters of the diode in the system are also defined. These are the reverse operating bias, forward current density, switching frequency, duty cycle, and device operational temperature. The critical fields are tabulated for various values of doping concentration and device thickness using the method described in section IIB. The optimization program then minimizes power dissipation in the system by altering device drift region thickness and doping concentration subject to the constraints described in [1]. By iterating across all available system operating parameters, it is possible to develop a map in system operating space and determine which devices/materials produce the lowest power loss for any given system operational point based on materials properties.
The resulting preferred device color-maps show a strong dependence on many of the material parameters used as input, including impact ionization coefficients, dopant activation energies, and carrier mobilities. We compare preferred device color-maps across a range of temperatures and forward current densities to show the effects of UWBG-specific effects incomplete ionization and space-charge limited conduction. Then we vary the material parameter inputs to show the sensitivity of the final color-maps on each material input. While these color-maps are always being updated with newly published results on UWBG materials, these sensitivity analyses can nonetheless give researchers a more educated insight on which materials show the greatest promise in any given region of operating space.

2:15 PM EL04.06.03
Lateral p-GaN/AlGaN/GaN Hybrid Anode Diodes (HADs) with Hydrogen Plasma Guard Line Termination Dawei Wang, Dinusha Herath Mudiyanselage, Ziyi He, Bingcheng Da and Houqiang Fu; Arizona State University, United States

Wide bandgap material GaN is promising in high-efficiency power conversion systems. To realize GaN power integrated circuits (ICs), peripheral logic circuits based on GaN are necessary, such as controllers, drivers, and protection circuits. Using the p-GaN/AlGaN/GaN high electron mobility transistors (HEMTs) platform, all these components can be integrated on a single chip, dramatically reducing parasitic effects, such as gate ringing and false turn-on of power transistors. Recently, Lateral AlGaN/GaN hybrid anode diodes (HADs) have been demonstrated on the commercial p-GaN/AlGaN/GaN platform, attracting significant attention due to the advantages of low on-resistance and low reverse leakage. It has a hybrid Schottky/ohmic anode composed of electrically connected ohmic contact and Schottky gate. The anode voltage can directly cut off the 2DEG channel at reverse bias, thus improving the reverse performance. Etching-free low-damage hydrogen plasma-treated HADs have also been demonstrated for lower turn-on voltage and lower on-resistance. However, the electric field crowding effect at the edge of the anode still exists in the previous reports.

In this work, we perform the design and fabrication of p-GaN/AlGaN/GaN Hybrid Anode Diodes (HADs) with Hydrogen Plasma Guard Line Termination for better electric field management. The high electric field at reverse bias would extend to the whole anode-to-cathode area. The device epilayers were grown by metal-organic chemical vapor deposition (MOCVD) on a sapphire substrate, consisting of a thick GaN buffer layer, a 300 nm UID-GaN layer, a 1 nm AlN space layer, a 20 nm Al0.2Ga0.8N layer and a 90 nm p-GaN layer with an acceptor Mg concentration of 3×10^{19} cm^{-3}. The substrate was annealed at 800 °C for 30 minutes to break the Mg-H bond and activate the p-GaN layer. The metal stack Ti/Al/Ni/Au was deposited as cathode, followed by post-annealing at 850 °C for 30s. The p-GaN layer under the cathode was etched before metal deposition for better ohmic contact. Then, several hydrogen plasma-treated pattered arrays termination, i.e., guard lines termination, were fabricated to eliminate high electric field crowding at the edge of the anode. The photoresist-based patterns were developed as the mask on the p-GaN layer. The pattern of the guard lines is different from the traditional guard ring termination for vertical GaN devices. The guard line was formed by a series of discontinuous trapezoid-like shapes for partially depleting the 2DEG channel so that the p-GaN would not cut off the 2DEG current along the whole device. The trapezoid shapes were designed for optimized electric field management. In addition, stripe edge termination structures were also introduced at the edge of the anode. Hydrogen plasma treatment was applied to the surface for 5 minutes. The photoresist was then removed using Micro Remover PG at 120 °C. The post-annealing at 400 °C was applied for hydrogen diffusion. Finally, the gate metal Ni was deposited via magnitude sputtering, followed by Au deposition using e-beam deposition. The electrical testing indicated that hydrogen plasma treatment could fully passivate the p-GaN current. The forward current and on-resistance are comparable with the previous reports. The breakdown voltage increased in the devices that have the hydrogen plasma guard line termination structure, and the on-resistance only has a slight increase. The device breakdown voltage was several-kV-class with an anode-to-cathode length (L_{AC}) from 25 to 75 um. The device is still under optimization for higher breakdown voltage. These results can provide critical references for the future development of high breakdown voltage lateral p-GaN/AlGaN/GaN devices.

3:30 PM *EL04.07.01
The Application of The Photonic Atom Probe to The Study of Wide Bandgap Semiconductors Lorenzo Rigutti[1], Abraham Diaz Damian[1], Jonathan Houard[1], Enrico Di Russo[2], Georges Beainy[1], Pradip Dalapati[1], Angela Vella[1], François Vurpillot[1], Jean-Michel Chauveau[3], Maxime Hugues[4], Grzegorz Muziol[5] and Henryk Turski[5]; [1]University of Rouen Normandie, France; [2]University Of Padova, Italy; [3]University of Versailles St Quentin, France; [4]CRHEA, France; [5]Unipress, Poland

The Photonic Atom Probe (PAP) allows for the measurement of Photoluminescence (PL) of a sample tip while it is being analyzed by Laser-Assisted Atom Probe. The femtosecond Laser pulse required for the La-APT measurement also serves to excite the free charge carriers, whose recombination provide the PL signal. As a consequence, it becomes possible to correlate the optical signature of the different parts of a complex structure with the 3D distribution of the contained chemical species [1].
We present an application of the PAP on III-nitride p-i-n junctions, namely a thick (> 1µm thickness) multi-layer structure containing InGaN quantum wells and a buried tunnel junction [2]. Plasma-assisted molecular beam epitaxy-grown structures, which were used in the study, are characterized by diverse doping concentrations in both p- and n-type regions. The PL spectra can be correlated with the 3D chemical information from APT [3]. The PL signals exhibit indeed a donor-acceptor pair (DAP) emission, whose spectral features can be related to the 3D distribution of the Mg dopants and of the InGaN heterostructures. These results open interesting perspectives for studies of light-emitting defects at the nanoscale.
Besides the interest of this instrument as a microscope [3], the particular conditions in which the optical signatures of localized light emitters are collected open intriguing possibilities for the study of field ion emission under high field and under laser illumination [4]. As an example, the PL spectral shift allows measuring the stress induced by the application of a strong electric field at the tip apex and its propagation through the tip. This has been evidenced both through the study of the stress-induced splitting of the zero-phonon line of the NV^0 center in diamond [5] and of the quantum well (QW) emission in a ZnO/(Mg,Zn)O system [6], allowing measuring stresss levels ranging from 9 GPa to ~1 GPa.

4:00 PM EL04.07.02
Unraveling the Atomic Mechanism of the Disorder- Order Phase transition from γ-Ga2O3 to β-Ga_2O_3 by in situ Transmission Electron Microscopy Martin Albrecht[1], Charlotte Wouters[1], Musbah Nofal[1], Piero Mazzolini[2], Jijun Zhang[1], Thilo Remmele[1], Albert Kwasniewski[1] and Oliver Bierwagen[2]; [1]Leibniz Institut fuer Kristallzuechtung, Germany; [2]Paul-Drude-Instit für Festkörperelektronik, Germany

Monoclinic Ga_2O_3 (β-Ga_2O_3) is a semiconductor with a bandgap of 4.7 eV and an estimated breakdown field strength of 8 $MVcm^{-1}$. It has attracted considerable interest as a promising material for electronic applications such as solar blind UV photodetectors, and high power devices. In addition to the thermodynamically stable monoclinic β-phase, Ga_2O_3 can be stabilized under ambient conditions in a number of metastable structures (α-Ga2O3 , γ-Ga2O3, κ-Ga2O3 and δ-Ga2O3) in which Ga cations exist in both tetrahedral (GaO4) and octahedral (GaO6) coordination. The polymorphic transition between β-Ga_2O_3 and γ-Ga_2O_3 has recently attracted particular attention and has become the focus of intense research efforts. These research activities were triggered by the experimental observation that after implantation of Si or Ge, used to selectively n-dope β-Ga_2O_3, a phase transition from β-Ga_2O_3 to γ-Ga_2O_3 was observed. [1,2,3] Recovery of β-Ga_2O_3 was observed after annealing. [1,2] It was also observed that β-Ga_2O_3 is extremely radiation tolerant. Since none of the other crystalline phases were observed to form, the question of a hidden structural relationship between γ-Ga_2O_3 and β-Ga_2O_3 was raised. In this paper we study the reverse direction, i.e. the disorder-order phase transition from amorphous Ga_2O_3 to γ-Ga_2O_3 and then to β-Ga_2O_3 by *in situ* transmission electron microscopy. The *in situ* studies are complemented by *ex situ* annealing experiments, the results of which are analyzed by X-ray diffraction and high resolution (scanning) transmission electron microscopy. Amorphous Ga_2O_3 deposited at 100°C by molecular beam epitaxy crystallizes

at 470°C in the γ phase , which undergoes a phase transition to the β phase above 500°C. Between 500° and 900°C we find a mixture of γ-Ga_2O_3 and the β-Ga_2O_3 coexisting. Above 950°C we find only β-Ga_2O_3. Taking into account the crystallographic symmetry relations, we construct a common lattice of both structures containing a common fcc-type sublattice occupied by oxygen atoms, the cation sites of β-Ga_2O_3 common to both phases, and partially occupied cation sites in the γ-phase corresponding to interstitial sites in the β-phase. We assign the atomic displacements within this lattice that transform γ-Ga_2O_3 (the defective spinel structure with partially occupied cation sites) into perfectly ordered β-Ga_2O_3. By its nature, this is a reconstructive disorder-order phase transition in which atoms exchange positions to the nearest neighbor sites. Few of the exchange processes we derive from crystallographic symmetry relations match those derived by Huang et al. [2,3] from analysis of atomically resolved scanning transmission electron microscopy (STEM) images of implanted β-Ga_2O_3. Our results explain, why disordering of the lattice, e.g. by implantation, causes the formation of γ-Ga_2O_3 and not any of the other phases. This would require a martensitic transition, i.e. shearing of the oxygen sublattice and not simply displacement of cations. It also explains, why annealing causes the reverse phase transition and results in a perfect β-Ga_2O_3 lattice as described by Huang et al.. [2]

4:15 PM *EL04.07.03
Probing The Atomic-Scale Chemistry and Doping Defect Interactions in UWBG Semiconductors Baishakhi Mazumder; University at Buffalo, The State University of New York, United States

Ultra-wide bandgap (UWBG) semiconductors are revolutionizing high-power electronics, promising unprecedented control over conductivity and transport properties. To unleash their full potential, we must navigate the intricate interplay between material chemistry, electrical properties, and defects. Direct experimental insights into the structural and chemical components that govern electrical transport are essential, forging a connection between theory and practical application. Among UWBG semiconductors, Ga_2O_3 and its alloys shine as promising candidates for high-power electronics. Yet, their success hinges on the microstructures and nanoscale chemistry of active layers. Achieving tailored electrical properties and defect mitigation necessitates an intricate understanding of the interplay between structure and chemistry. Atom Probe Tomography (APT) is an advanced instrument that offers three-dimensional chemical imaging of individual atoms. When combined with machine learning, APT generates comprehensive datasets that shed light on material systems, offering insights into dopant solubility, dopant diffusion, impurities, vacancies, and defect complexes. These insights deepen our understanding of their impact on electrical transport, surpassing the limitations of conventional techniques.
In this work, we undertake an atomic-scale investigation of doped Ga_2O_3 and its associated alloys. This presentation underscores the critical significance of APT in elucidating the intricate structural and chemical characteristics of Ga_2O_3-based UWBG semiconductors, thereby advancing their design and development for power electronics applications. Our inquiry delves into the intricacies of doping, exerting influence on both the alpha and beta phases, while also addressing the challenges presented by defects. The knowledge gained from this analysis has the potential to reshape the synthesis of UWBG semiconductor materials, offering a new dawn for high-power electronics technology. Join us on this quest as we delve into the heart of UWBG semiconductors, where science meets innovation.

SESSION EL04.08: Poster Session
Session Chairs: Robert Kaplar and Sriram Krishnamoorthy
Wednesday Afternoon, April 24, 2024

5:00 PM EL04.08.01
Band Gap Behavior and Order/Disorder in $Sn_{1-x}Ge_xO_2$ Alloys for Deep UV Transparent Conducting Oxides Sabrine Hachmioune[1,2], Alexander Squires[3], Michael B. Sullivan[2] and David O. Scanlon[3]; [1]UCL, United Kingdom; [2]Agency for Science, Technology and Research, Singapore; [3]University of Birmingham, United Kingdom

Transparent conducting oxides (TCOs) with deep ultraviolet (DUV) transparency have a wide range of applications, including optoelectronics, sensors, and optical coatings. However, achieving high optical transmittance in the DUV range (< 300 nm) remains challenging due to the empirical trade-off in conductivity with increasing band gap, and conventional TCOs having optical band gaps too small for DUV transparency. To address this, recent studies have shown that the addition of germanium (Ge) to rutile-SnO_2 can increase the band gap from 3.79 eV to 4.09 eV (at x = 0.7), making it a promising candidate for DUV-TCO applications.[1]

In this work, we employ a comprehensive modelling approach combining hybrid-Density Functional Theory (DFT) calculations, Cluster Expansion and Monte Carlo simulations to investigate the band gap behaviour of Sn_{1-x} Ge_xO_2 alloys ($0 \geq x \geq 1$). Our methodology allows us to determine the ground state atomic structure and calculate the band structure for each composition. Additionally, we analyse the extent and impact of cation disorder in the alloyed systems.

Understanding the order/disorder behaviour in these alloyed systems is crucial as it directly influences the band gaps, electronic properties, and optical characteristics of the material. Furthermore, we explore the effect of dopants on disorder, building upon previous research that suggests the incorporation of Ta^{5+} impurities can enhance conductivity.[1]

By elucidating the order/disorder relationships, their impact on the properties of Sn_{1-x} Ge_xO_2 alloys and the interaction of bulk disorder with impurity doping, this study provides valuable insights for the design and optimization of DUV-TCO materials.

5:00 PM EL04.08.02
Self-Aligned Fabrication of Sub-50 nm Top Gate Coplanar ITO/IGZO Thin-Film Transistors without Nanoscale Patterning Jiyoung Bang, Yeonghun Lee, Yeonsu Lee, Minjin Kwon, Hyoungbeen Ju, Hyeonjeong Sun, Sangduk Kim, Seungmin Choi, Youngsoo Noh, Hyowon Kim, Eunsuk Choi and Seung-Beck Lee; Hanyang University, Korea (the Republic of)

Amorphous oxide semiconductor (AOS) thin-film transistors (TFTs) are attracting interest due to their wide bandgap, low leakage, and capacity for low-temperature processing and have been effectively commercialized particularly in display backplane applications. One significant approach to improving the TFT's performance involves reducing the channel length to sub-micron levels. However, to fabricate nanoscale TFTs for large-scale display applications, traditional nanoscale pattern definition methods may not be applied and require the development of methods that would produce nanoscale patterns without nanolithography. We introduce a high-throughput nanoscale patterning method for fabricating top gate coplanar oxide semiconductor TFTs. Our method involves the angled thermal evaporation of an aluminum etch mask layer, taking advantage of shadowing effects induced by SiO_2 stepped spacers. First, the active channel layer, an ITO/IGZO bilayer, was sputter deposited. Then a 50 nm Mo contact metal layer was sputter deposited. Normally at this stage, a nanogap in the Mo would be introduced by nanolithography followed by reactive ion etching (RIE). However, our method defines a nanogap in the etch mask by Al angled deposition. A layer of SiO_2 is deposited on the Mo layer and an optical lithography step is used to mark the position of the SiO_2 step that will be formed by RIE down to the Mo surface. When Al is thermally evaporated at an angle on the SiO_2 step, the shadowing effect will introduce a nanogap between the Al on top of the SiO_2 step and on top of the Mo layer. Using the discontinuous Al layer as the hard mask, sub 100 nm gap in the Mo layer can be inserted by RIE, thereby forming a nanogap between the source/drain contacts. After the Al layer is removed chemically, the Al_2O_3 gate insulator and Mo top gate layers were self-aligned to the nanogap position by ALD and sputtering, respectively. By controlling the Al deposition angle and the SiO_2 step height, the nanogap width was controlled between 40 nm ~ 100 nm. Utilizing this technique, we successfully fabricated a top gate coplanar ITO/IGZO TFT with a gate length of 50 nm. Measurements showed that at a drain-source voltage of 40 mV, the device exhibited an on current of 1.3×10^{-6} A/μm at a gate voltage of 20 V. And the off-current levels were below 10^{-14} A/cm^2 with a threshold voltage of -2.1 V, and a sub-threshold swing of 301 mV. The results demonstrate that this technique has the potential for broad application in large-scale nanoscale metal oxide TFT fabrication.

5:00 PM EL04.08.04

Investigating The Oxygen Defects of Nano-Heterojunction for Toxic Gas by Using Synchrotron and Raman Spectroscopy Lin Yuru[1], Chun-Yen Lai[2], Cheng-En Lee[3], Wen-Wei Wu[2] and Ping-Hung Yeh[3]; [1]Tamkang University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan; [3]Department of Physics, Tamkang University, Taiwan

In this study, a multifunctional wearable sensor with high-precision of toxic gas, nitric oxide, and multiple wavelength light detection abilities was fabricated by defect-rich nano-heterojunction SnO_2-TiO_2 nanofibers. Choosing nitric oxide as the measured gas is motivated by its potential for assessing airway inflammation by measuring its concentration in exhaled breath. While Fractional Exhaled Nitric Oxide (FENO) exists for this purpose, challenging measurement techniques and methods have hindered its clinical applicability. According to the research, the nano-heterojunction device produced in this experiment exhibits a sensitivity to low concentrations of nitric oxide that is up to seven times higher. Therefore, the ultimate goal of this experiment is to utilize the prepared nano-heterojunction device for asthma sensing.
The properties of dynamic internal charge transport and recombination process can be precisely controlled through the sol-gel drop casting method, which forms numerous oxygen defect structures at the nano-heterojunction gate between SnO_2 nanofibers and TiO_2 nanoparticles, allowing the tuning of the band gap within the range of 3.6 to 3.27 eV. The reason of band gap reducing might be a significant number of oxygen defect structures are formed at the nano-heterojunction gate, acting as generation-recombination centers to precisely trap or release free carriers. This process converts various photon energies (ranging from 365 to 520 nm) into different photocurrent levels.
To investigate the relationship between the adsorption and desorption of oxygen defect structures, the in-situ Raman spectroscopy and electrical measurement systems can be used for toxic gases detection. Furthermore, the conductivity and sensitivity of the wearable sensor for monitoring toxic gas can be enhanced through the defect-rich toxic gas molecular adhesion layer on the surface of nanofibers. The electronic structure and functionality of each oxygen defect structures, including out-of-plane oxygen defects, bridge oxygen defects, and in-plane oxygen defects, were studied using synchrotron analysis to investigate the electron transfer between the oxygen defect energy state and the conduction bands. Based on the results, the in-plane oxygen defects will be decreased, if the nano-heterojunction increases. The electrical results indicate that defects-rich SnO_2-TiO_2 nano-heterojunction nanofiber devices could be highly sensitive to toxic gases and serve as light sensing devices in our daily lives. Moreover, they are expected to be used in asthma detection in the future.

5:00 PM EL04.08.05

Addressing the orientation of defect-related crystal domains by Atom Probe Tomography in III-N heterostructures Lorenzo Rigutti[1], Jesus Cañas[2], Névine Rochat[3], Adeline Grenier[3], Audrey Jannaud[3], ZIneb Saghi[3], Jean-Luc Rouvière[2], Edith Bellet-Amalric[2], Catherine Bougerol[4] and Eva Monroy[2]; [1]University of Rouen Normandie, France; [2]CEA IRIG, France; [3]CEA LETI, France; [4]CNRS Institut Néel, France

Atom Probe Tomography (APT) may be applied as a tool for the assessment of the crystallographic orientation of microstructural features. In the present study, such features are related to defects formed during the growth of AlGaN/AlN quantum dot superlattices. These defects are the origin of the low-energy component of a bimodal luminescence emission in the 230-300 nm spectral range [1]. The defects are cone-shaped, starting at the AlN buffer/superlattice interface and propagating vertically, associated to a dislocation that produces strong shear strain and favors the formation of 30° faceted pits. They also may be responsible for local formation of misoriented domains. We show that the effective surface field intensity maps obtained through the statistics of the charge states *n* of the field-emitted Al^{+n} ions can be used as a means to locate the direction of the [0001] crystal pole with respect to the needle axis. This provides a way to track changes of crystal orientations by several degrees and to correlate them with the morphological and chemical features of the sample. The results indicate that such misorientations can occur, but not systematically.

5:00 PM EL04.08.06

Plasma Assisted Remediation of SiC Surfaces Michael A. Mathews[1,2], Andrew R. Graves[1,3], David R. Boris[2], Scott G. Walton[2] and Charter D. Stinespring[1]; [1]West Virginia University, United States; [2]U.S. Naval Research Laboratory, United States; [3]The Pennsylvania State University, United States

Due to advances in chemical mechanical polishing (CMP), SiC surface quality has improved remarkably over the years. Despite this progress, there is extensive literature reporting the limitations of the CMP process. Wafers purported to have CMP surfaces can range from high-quality, optically perfect surfaces, exhibiting well-defined step and terrace structure to low-quality surfaces with highly scratched regions. Thus, methods are required to remediate these surfaces if they are to be used effectively as substrates for device fabrication. The novel surface remediation approach explored in this presentation utilizes a three-step scalable method referred to here as plasma assisted remediation. In this process, a CF_4-based inductively coupled plasma with reactive ion etch was used to remove material to a depth which was unaffected by surface and sub-surface polishing damage. This produced a planarized but carbon-rich fluorinated surface. This surface was exposed to a rapid thermal oxidation in air to oxidize and volatilize the excess carbon and fluorinated species. The resulting surface oxide was stripped using a dilute hydrofluoric acid in water solution. This process reproducibly yielded planarized, stoichiometric surfaces with low levels of carbon and oxygen contamination for both 4H- and 6H-SiC(0001) surfaces. This presentation describes x-ray photoelectron spectroscopy and atomic force microscopy studies used to characterize each step of the process and provide an understanding of the process mechanism. In addition, experimental studies under ion-rich and radical-dominant plasma conditions are reported which provide greater insight into the underlying chemistry and physics of the process.

Precision Gas Sensing: Tuning The Defect Energy Level of SnO_2 Nanofiber Devices by Surface Defect Engineering Cheng-En Lee[1], Lin Yuru[1], Chun-Yen Lai[2], Wen-Wei Wu[2] and Ping-Hung Yeh[1]; [1]Tamkang University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

In the last decade, surface defect engineering in metal oxide semiconductor materials is gaining more attention since it provides controllability and opens up possibilities for commercial use in various fields like gas sensors, photocatalysis, nanoparticle filters and so much more.
In this work, the enhancement of gas detection ability of SnO_2 nanofiber devices (NFDs) can be achieved by using electrospinning and surface defect engineering. Increasing surface area can provide more reaction centers for gas molecules, so as to boost the detection ability of SnO_2 NFDs by colloidal film deposition. With colloidal film deposition, the sensitivity of NO gas (less than 50 ppb) detection can be increased more than three times. Furthermore, specific gas molecules can be detected by tuning the surface defect energy through nano-heterojunction integration. This is due to the variation in absorption energy among different gases. To investigate the density of states and to control the energy levels of defects, the X-ray absorption near edge structure (XANES) spectrum and Raman spectrum were used to measure SnO_2 NFDs. Based on the XANES results, the out of plane and in plane oxygen defects can be varied significantly by surface engineering.
In summary, through surface defect engineering techniques, we have acquired the capability to fully control the characterization and distribution of surface defects in SnO_2 NFDs. Combining with the nanoscale advantage, we can realize low-concentration gas sensing with high precision.

Field-Effect Mobility Enhancement of a-InGaZnO Thin Film Transistors through Metal Capping Layer Oxidation Induced Carrier Boosting Hyeonjeong Sun, Jiyoung Bang, Hyoungbeen Ju, Seungmin Choi, Youngsoo Noh, Hyowon Kim and Seung-Beck Lee; Hanyang University, Korea (the Republic of)

Amorphous oxide semiconductor (AOS), such as amorphous In-Ga-Zn-O (a-IGZO), has gained attention as channel materials for thin-film transistors (TFTs) based on attractive benefits, including low-temperature thin-film processing, low leakage current characteristics, and excellent optical properties due to its wide band gap. However, with relatively low carrier mobility in the range of 10-40 cm2/Vs, improving the mobility becomes one of the most important research concerns of AOS TFTs.
Various methods to enhance the mobility of AOS have been suggested thus far, including changes in the composition of metal cation and proportion ratio of IGZO to form strong s-orbital overlap to enhance percolation conduction. Recently, there has been active research focused on enhancing the conduction of the channel by adopting a capping layer on AOS TFT channel surfaces. Performance-enhancing strategies were reported using oxidation of Ca/Al capping layers and low-temperature crystallization of various AOS using Mo, Ti and Al. Several papers have reported on using Ti and Ta capping layers for AOS TFTs to enhance the crystallinity of the channel through low-temperature thermal annealing.
Our focus was on increasing the oxygen vacancies within the IGZO channel, thereby improving its conductivity and therefore its field-effect mobility μFE. The XPS results confirmed that Ta capping with PDA at 200 °C increased the oxygen vacancy of the IGZO film from 21% to 31% by breaking M-O bonds in IGZO and allowing oxygen diffusion to the Ta layer, which in turn acts as a carrier source.
Based on the observed carrier boosting effects, the characteristics of Ta capped a-IGZO TFTs were investigated with increasing Ta coverage area. We observed that with 90% channel coverage (Ta capping) demonstrated a remarkable 875% enhancement in μFE, increasing from 16 cm^2/Vs to 140 cm^2/Vs, while maintaining near-zero threshold voltage and low off-state leakage current. One problem with increasing the carrier concentration throughout the length is a severe negative shift in the threshold voltage Vth. The extremely high carrier concentration raises the Fermi level near the contact high enough to make the TFT operate in the depletion mode, or not turn off with nominal negative gate voltages. However, if a part of the back channel is left uncapped, the uncapped IGZO region would create a homojunction and act as a potential barrier, effectively maintaining the off-state current, while the capped IGZO region acts as a carrier-boosted region, facilitating higher channel conduction. We formed this IGZO homojunction and allowed the TFT to operate in the enhancement mode with a positive Vth and prevented an increase in the off-state current. As the carrier-boosted region becomes wider, the total carrier concentration increases, leading to an increase in on-current and μFE. The results reported in this paper provide a simple method to achieve high-performance metal oxide semiconductor devices, which are expected to be applicable to various next-generation device applications.

GaN Nanowire Wrap-Gate Transistor: Barrier Height, Ideality Factor and Inhomogeneities at The AlGaN/GaN Interface Yeojin Choi, Reddy S. Mallem, Yuna Lee and Sungjin An; Kumoh National Institute of Technology, Korea (the Republic of)

For the creation of next-generation nanoscale devices, it is crucial to comprehend the barrier height, ideality factor, and function of inhomogeneities at the metal/semiconductor interfaces in nanowires. Here, we study the GaN nanowire wrap-gate transistors (WGTs) drain current (Ids)–gate voltage (Vgs) characteristics over a range of gate potentials over the broad temperature range of 130–310 K. When the temperature is lowered, an unusual decrease in the experimental barrier height and an increase in the ideality factor are observed. Notably, assuming a double Gaussian distribution of barrier heights at 310–190 K (distribution 1) and 190–130 K (distribution 2), the variations in barrier height and ideality factor are attributed to the spatial barrier inhomogeneities at the AlGaN/GaN interface in the GaN nanowire WGTs. The standard deviation for distribution 2 is lower than that of distribution 1, which suggests that distribution 2 reflects more homogeneity at the AlGaN/GaN interface in the transistor's source/drain regions than distribution 1.

Li-Doped NiO/Un-Doped NiO/β-Ga_2O_3-Based p-i-n Diode for Power Device Application Jiyoung Min[1], Madani Labed[1], Hyungseok Kim[2], Kyungwho Choi[3], Teakjib Choi[1] and You Seung Rim[1]; [1]Sejong University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Recently, beta gallium oxide (β-Ga_2O_3, 4.7–4.9eV), which has a wide band gap than SiC and GaN, has been attracting attentions in the field of power electronic applications [1]. The Baliga's figure of merit(B-FOM) of Ga_2O_3 is about 3000, which is 4 times that of GaN and 10 times that of SiC, and is expected to achieving high breakdown voltage at low on-resistance in the power device [2]. However, despite these high numbers, the actual reported performance of the power unit is much lower than expected. This is because it is difficult to implement p-type Ga_2O_3, which can be used as PN junction termination to improve breakdown voltage value [3]. For further improvement of devices which require lower on-resistance(R_{on}) and higher breakdown voltage, it is important to form a junction termination structure such as a guard ring and a merged structure using a p-type material even to reduce the maximum electric field of a wide bandgap materials. However, the development of p-type β-Ga_2O_3 remains insufficient, only the theoretical studies and few experimental results reported. Because a very low mobility of self-trap holes and a deep acceptor level are expected, p-type β-Ga_2O_3 may intrinsically not be practical for power device applications. As a strategy to compensate for this is to construct p–n heterojunctions by integrating n-type Ga_2O_3 with other p-type semiconductors if the interface quality is controlled in an appropriate manner [4].
In this study, a diode to form a p-n heterojunction with optimized β-Ga_2O_3 was fabricated using NiO, a material with p-type conductivity [5]. Among p-type oxide families, the wide-bandgap NiO material has promising potentials in the applications of various optoelectronic and power devices due to its high visible spectral transparency and p-type conductivity stemming from nickel vacancies or monovalent impurities [6].
It was confirmed that the p-type NiO was inserted between the β-Ga_2O_3 and the Ni Schottky junction to ensure the p-n characteristics and thus the

depletion layer expanded. In addition, the conductivity control of nickel oxide was attempted by lithium doping and oxygen concentration regulation. As a result, lithium-doped nickel oxide exhibited improved ohmic contact properties with Ni due to the thin film's low specific resistance characteristics compared to undoped nickel oxide, which induced the diode's low on-resistance. Therefore, using these current characteristics, NiO was stacked in two layers to design a heterojunction diode with a Li-NiO/NiO/β-Ga_2O_3 structure and a device that achieves a high breakdown voltage of -1678 V while maintaining a low on-resistance of 7.1 mΩcm^2

Cone-shaped defects on AlGaN quantum dots for electron-beam pumped UV-emitters Jesus Cañas[1], Névine Rochat[2], Adeline Grenier[2], Audrey Jannaud[2], ZIneb Saghi[2], Jean-Luc Rouvière[1], Edith Bellet-Amalric[1], Anjali Harikumar[1], Catherine Bougerol[3], Lorenzo Rigutti[4] and Eva Monroy[1]; [1]CEA IRIG, France; [2]CEA LETI, France; [3]CNRS Institut Néel, France; [4]University of Rouen Normandie, France

One alternative to the challenges posed by AlGaN LEDs is the use of electron-beam pumped lamps based on AlGaN quantum dot (QD) superlattices (SLs). This approach offers the advantage of circumventing the challenging p-type doping and contacts of AlGaN, while providing a large active region. Previous reports from our group demonstrated UVC-emitting AlGaN QD-SLs grown by plasma-assisted molecular beam epitaxy with internal quantum efficiency in the range of 50% [1]. However, the samples still exhibit spatial inhomogeneities and relatively wide (between ~10 and ~20 nm) emission lines, sometimes with multi-peak structure. In this contribution, we delve into the origin of bimodal emission in AlGaN/AlN QD superlattices in the 230-300 nm spectral range. The secondary emission at longer wavelengths is linked to the presence of cone-shaped defects originating at the AlN buffer/superlattice interface and propagating vertically. These defects are associated with a dislocation that produces strong shear strain, which favors the formation of 30° faceted pits. The cone-like structures present Ga enrichment at the boundary facets and larger QDs within the defect. The bimodality is attributed to the differing QD size/composition within the defects and at the defect boundaries, which is confirmed by the correlation of microscopy results and Schrödinger-Poisson calculations [2].

The self-compensation process and its dependence on Ga and In donor doping in ZnO nanocrystal films Georgiy Polupan, Brahim Ei Filali and Tetyana v. Torchynska; Instituto Politecnico Nacional, Mexico

Zinc oxide has important optical, electrical, and microstructural characteristics, important for optoelectronic applications as transparent conduction oxide (TCO) in solar cells, gas sensors, flat screens and touch panel displays, light emitting diodes, or in thermal mirrors. The conductivity of pure ZnO films is not high enough to be used as TCO windows. The important donors for ZnO film technology are the Al, Ga, In elements. However, in doped ZnO films the electron density is limited by the self-compensating effect, connected with the generation of acceptor defects to counteract of high donor doping. The nature of acceptor defects and the factors that favor the initiation of the self-compensating process remain to be studied.
The reason for the self – compensating effect can be related to the significant level of elastic stresses in doped ZnO films with high donor concentrations. It is assumed that using co-doping by Ga and In atoms with lower (Ga) and higher (In) ionic radii compared to Zn ions is expected to reduce stresses in the films and allow changing the onset of the self-compensating effect at higher donor contents. In the work presented, the variation of the optical, structural and electrical parameters of ZnO nanocrystal (NC) films doped with Ga and In atoms has been investigated. ZnO films were grown by ultrasonic spray pyrolysis with a permanent In contents of 1.0 at% or 2.0 at% and Ga contents varied in the range of 0.5 to 3.5 at %. ZnO films have been studied using scanning electron microscopy (SEM), energy dispersive X ray spectroscopy (EDS), X ray diffraction (XRD), photoluminescence (PL) and X-ray photo electronic spectroscopy (XPS).
Non-monotonic changes in the morphology of the films were revealed that correlate with non-monotonic changes of the ZnO film parameters with the variation of Ga contents. It was shown that high donor doping is accompanied by the appearance of a new near band edge (NBE) emission band, related to carrier recombination in donor-acceptor pairs (DAPs), which is a “fingerprint” of a start of the self-compensating process. The compressive stresses arising due to single In doping prevent effective oxidation in the film crystallization. The elastic stresses were calculated in ZnO films with the wurtzite crystal lattice and preferential (002) orientation. Changes in the crystal lattice parameters are detected and the stress values in the films are estimated. Doping with Ga up to 1.5 -2.0 at% makes it possible to compensate the compressive stresses in the films related to In atom doping that is favored to the ZnO oxidation and dissolution of the donors at thermal annealing. The minimum electrical resistivity in ZnO:In:Ga films about $6.0x10^{-4}$ Ω cm is detected. The nature of defects generated in the self-compensating process is discussed.

Steady-state and transient electron transport in the two-dimensional electron gas associated with boron nitride-based heterojunctions Alireza Azimi[1], Mohammadreza Azimi[1], Michael S. Shur[2], Walid A. Hadi[3] and Stephen K. O'Leary[1]; [1]University of British Columbia, Canada; [2]Rensselaer Polytechnic Institute, United States; [3]Florida State University Panama City, United States

Cubic boron nitride is the latest III-V nitride-based semiconductor to draw the attention of the electronic materials community. Noting that state-of-the-art electron devices are often achieved through the use of heterojunctions, we explore possible boron nitride-based heterojunction configurations. Noticing that in the locality of a heterojunction a two-dimensional electron gas typically forms, we examine how the presence of such a gas influences the performance of boron nitride heterojunction-based devices. An electron gas can both enhance the low field mobility and influence the electron drift velocity for higher applied electric field strengths. Using a self-consistent Schrödinger-Poisson equation solver, we determine the distribution of electrons within such a two-dimensional electron gas. A comparison will then be made with results acquired using the analytical approach of Ambacher *et al.* [1]; while Ambacher *et al.* [1] applied their analysis to the case of gallium nitride-based heterojunctions, the same concepts apply here. The impact of this two-dimensional electron gas on the steady-state and transient electron transport that occurs within this material will then be critically examined. The device implications will be explored.

The impact of threading dislocation lines on cubic boron nitride's low-field electron mobility John Chilleri[1], Alireza Azimi[2], Mohammadreza Azimi[2], Michael S. Shur[3] and Stephen K. O'Leary[2]; [1]New Mexico Institute of Mining and Technology, United States; [2]University of British Columbia, Canada; [3]Rensselaer Polytechnic Institute, United States

Threading dislocation lines are present within boron nitride's cubic phase. Within the framework of a relaxation-time approximation based low-field electron drift mobility formalism, we incorporate the treatment of threading dislocation line related scattering into this analytical framework. How the presence of threading dislocation lines influences the low-field electron transport of this material will be examined. Threading dislocation lines are found to make a significant contribution to cubic boron nitride's low-field electron transport response. The device implications of these results are then examined. A new approach to characterizing the importance of the various scattering processes is introduced as a corollary to this analysis.

5:00 PM EL04.08.15
Microwave-plasma-assisted chemical vapor deposition of BN as gate dielectric for AlGaN/GaN metal-insulator-semiconductor high electron mobility transistors Ziyi He[1], Dawei Wang[1], Dinusha Herath Mudiyanselage[1], Bingcheng Da[1], Yuji Zhao[2] and Houqiang Fu[1]; [1]Arizona State University, United States; [2]Rice University, United States

AlGaN/GaN high electron mobility transistors (HEMTs) are considered as next-generation devices for high power and high frequency applications due to the existence of a high mobility polarization-induced two-dimensional electron gas (2DEG) at the AlGaN/GaN interface. Nevertheless, the performance of conventional Schottky-gate HEMTs has been limited by the high leakage current. As a result, metal–insulator–semiconductor high electron mobility transistors (MISHEMTs) with gate dielectrics serve an effective solution to suppress the leakage current of conventional Schottky-gate HEMTs with the improvement of device performance. Boron nitride (BN), with an ultra-wide bandgap of ~5.2 eV, dielectric constant of 3.8, high breakdown electric fields of 12 MV/cm, high chemical stability, and excellent thermal conductivity, is promising for high-power and high-temperature electronics.
The AlGaN/GaN HEMT structure was grown by metalorganic chemical deposition (MOCVD) on Si substrates. The Al, Ga, and N sources are trimethylaluminum (TMAl), trimethylgallium (TMGa), and ammonia (NH_3), respectively. SiH_4 was used as an n-type dopant and H_2 was the carrier gas. The structure consists of a 2.5 nm GaN cap layer, followed by a 20 nm $Al_{0.25}Ga_{0.75}N$ barrier layer, a 1 nm AlN interlayer, a 200 nm n-GaN layer, and a 2.7 µm unintentionally doped GaN buffer layer. A ~7 nm BN thin film layer was deposited as a gate dielectric on AlGaN/GaN HEMTs. The boron nitride film deposition was performed by microwave-plasma-assisted chemical vapor deposition using ammonia borane as the precursor. The growth temperature was 400 °C and the pressure was around 1 Torr. The MISHEMT devices are with gate width (W_G) = 100 µm, gate length (L_G) = 5 µm, gate-to-source distance (L_{GS}) = 4 µm, and gate-to-drain distance (L_{GD}) = 4 µm. The conventional Schottky-barrier-gate HEMTs were also fabricated with the same dimensions for reference. The XPS and UPS confirmed the existence of the BN film and the band alignment of BN/GaN. The transfer characteristics of BN MISHEMTs and HEMT when V_{DS} = 1 V. The MISHEMTs showed a threshold voltage of -5.9 V with a slight reduction of the maximum transconductance (g_{mmax} = 42 mS/mm) as compared with those for the HEMT (V_T = -3.2 V and g_{mmax} = 58 mS/mm, which are attributed to the insertion of BN thin film and the interface charge introduced. The MISHEMT devices exhibit a subthreshold swing of 363.8 mV/dec and a much higher I_{on}/I_{off} ratio (on the order of 10^8) than the HEMT. The effective interface state density Dit can be estimated by the subthreshold swing equation to be over 1×10^{13} $cm^{-2}\times eV^{-1}$. The gate leakage–gate voltage (I_G–V_G) curve for the HEMT and BN MISHEMT were measured as shown, while the drain voltage and source voltage are set as 0 V. A very low gate leakage current of ~10^{-7} mA/mm at reverse bias was observed for MISHEMT, which is 3 orders of magnitude lower than the HEMT. The temperature dispersion from 25 °C to 205 °C of the leakage current is also analyzed. These results can serve as important references for future studies on BN-based gate dielectrics for GaN power devices.

5:00 PM EL04.08.16
Development of Ga_2O_3-based bipolar heterostructures for application of high-power electrical devices Kwangeun Kim; Korea Aerospace University, Korea (the Republic of)

Objective
The objective of this work is to develop Ga_2O_3-based bipolar heterostructures for application of high-power electrical devices. The npn Si/Si/Ga_2O_3 heterostructure was constructed through the membrane transfer method, in which the p- and n-Si membranes were sequentially transferred on the n-Ga_2O_3 substrate to form the Ga_2O_3-collector bipolar junction transistors with high-power density.
Results and discussion
β-Ga_2O_3 is a representative wide bandgap material for high-power electrical applications with the large bandgap energy and high breakdown field. The npn Si/Si/β-Ga_2O_3 heterostructures were achieved by the junction-bonding method and the electrical characteristics of back-to-back diodes were demonstrated for the development of bipolar transistors. The junction-bonded n-Si/p-Si and p-Si/n-Ga_2O_3 diodes exhibited the rectifying properties with the ideality factors under 1.4. The Ga_2O_3-collector bipolar transistors were manufactured with different thickness of p-Si base layers to improve the bipolar operation properties with high power density, gain, and cut-off frequency. The results on the formation of npn high-power heterostructures with wide bandgap materials can be applicable to the development of high-power heterojunction bipolar transistors and insulated-gate bipolar transistors.
Experimental
Sn-doped Ga_2O_3 single crystal substrate with a doping concentration of 1.7 x 10^{18} cm^{-3} was grown by metal-organic vapor phase epitaxy. The surface roughness of as-grown β-Ga_2O_3 was around 1 nm. The single crystal Si membranes were obtained from the top layers of highly-doped silicon-on-insulator wafers. The removal of sacrificial layer was carried out by dipping the wafers into HF solution, then the undercut Si membranes were picked up using elastomeric stamp and laminated onto the Ga_2O_3 substrate, leading to the formation of npn bipolar structures. The device fabrication was performed through semiconductor cleanroom process and the electrical characteristics were measured using semiconductor parameter analyzer.

5:00 PM EL04.08.17
On the Possibility of p-Type Doping in $BaSnO_3$ Joe Willis[1], Kieran B. Spooner[2] and David O. Scanlon[2]; [1]University College London, United Kingdom; [2]University of Birmingham, United Kingdom

The discovery of a p-type transparent conductor would revolutionise optoelectronic devices by enabling fully transparent p-n junctions. Of particular interest are fully transparent homojunctions, which would greatly simplify the manufacturing process and potentially aid device performance. Recent work[1] has produced transparent p-n junctions from $BaSnO_3$, but the p-type behaviour of the compound has thus far been overlooked in the literature.

Here we seek to understand the defect and transport behaviour of p-type $BaSnO_3$ using hybrid density functional theory (DFT).[2] Group 1 metals Li, Na and K and group 13 metals Al, Ga and In are assessed as extrinsic p-type dopants on the Ba and Sn sites, respectively. We find that K and In are the most promising dopants, reaching concentrations of up to $4.7\text{x}10^{16}$ cm^{-3} and $1.6\text{x}10^{19}$ cm^{-3} respectively. Both, however, are compensated by low energy O vacancies, limiting the hole carrier concentrations to $5.2\text{x}10^{14}$ cm^{-3} and $9.8\text{x}10^{15}$ cm^{-3} respectively. Such high defect concentrations also severely limit the

electronic transport, with room temperature mobilities of 5.96 $cm^2 V^{-1} s^{-1}$ and 1.27 $cm^2 V^{-1} s^{-1}$ respectively. While this does not reach the levels seen in n-type transparent conductors, it does guide the way towards the higher doping concentrations than have so far been achieved experimentally.

5:00 PM EL04.08.18
Fabrication of broadband UV MSM photodetector using reactive sputtered nickel oxide film Swati Suman[1], Anupama Behera[1], Ashok Allamula[2], Satyesh Kumar Yadav[2] and Parasuraman Swaminathan[1,3]; [1]Indian Institute of Technology Madras, India; [2]Indian Institute of Technology, India; [3]Indian Institute of Technology Bombay, India

Efficient ultraviolet (UV) photodetectors are of significant interest due to their wide area of applications, such as bio-sensing, communications, and military applications[1-3]. In this work, a metal oxide semiconductor sandwiched between metal electrodes (MSM structure) was developed as a broadband UV photodetector. The MSM photodetectors has garnered lot of interest because of its simple fabrication design, large active area, low dark current facilitating fast response. The metal oxide used was *p*-type nickel oxide (NiO) deposited by DC magnetron sputtering technique on top of indium tin oxide (ITO). Reactive sputtering from a pure nickel target was used to deposit NiO and the effect of oxygen concentration on the morphological and optoelectronic properties of the NiO was investigated.
ITO is capable of providing good electrical conductivity and charge transporting behaviour which supports low leakage current[4]. It is a n-type degenerate semiconductor which is widely used for transparent conducting films. Among different metal oxides, NiO is a promising *p*-type semiconductor with wide band gap value (3.2 to 3.8 eV, depending on stoichiometry)[5]. In this study, we explore the fabrication and characterization of a UV photodetector using ITO and NiO heterojunction. The device performance will be optimized by varying oxygen concentration during deposition of NiO. The variation of oxygen will be done by keeping argon concentration constant. The DC magnetron sputtered NiO thin film, acts as the photosensitive layer. Silver electrodes were used as contacts for the two layers. Material characterization has been done using different techniques like XRD, SEM, UV-vis spectroscopy, Raman spectroscopy and photoluminescence spectroscopy while electrical characterization has been performed using I-V source meter and four probe. The fabricated device demonstrates good change in light to dark current at low applied biased voltage.
In conclusion, the development of UV photodetectors using DC magnetron sputtered p-type NiO thin films represents an encouraging route in the realm of optoelectronics. The tunablility of NiO film properties at the interface with the ITO substrate provide further leverage for advancements in photon sensing.

High breakdown voltage, low specific on-resistance GaN on GaN PiN diodes with low contact resistance on p-type GaN for high power applications Donghan Kim[1,2], Hyung-seok Lee[2], Hongsik Park[1], Sung-Beum Bae[2], Dong-young Kim[2] and Zin-Sig Kim[2]; [1]Kyungpook National University, Korea (the Republic of); [2]Electronics and Telecommunications Research Institute, Korea (the Republic of)

In the last few years, wide band gap(WBG) semiconductors such as SiC,Ga_2O_3 and GaN have received considerable attention for the next-generation power electronics and RF devices. Especially GaN is promising material candidates for high power and high current applications due to its superior material properties like wide bandgap(~3.4 ev), high critical electric field(~3.5 MV/cm), high electron saturation velocities and low switching losses.
For power applications, GaN-based transistors such as GaN-on-Si HEMTs have been widely used commercially since 2009. However, for mid- and high-range power applications(>~1.2 kV), it is difficult to handle power electronics with GaN-on-Si HEMTs. To handle high voltage for efficient high power applications, the chip size of GaN HEMT increases significantly, resulting in difficulty of current extraction and poor reliability. Moreover, the difficulty of growing thicker high quality GaN or AlGaN layers on a Si substrate leads to a vertical buffer breakdown which also limits the operating voltage of HEMTs below a few kV. Therefore, in this point of view, GaN-based vertical power device such as PiN diode, vertical MOSFET, CAVET attracted increasing attention due to its high breakdown voltage(>~1.2 kV) by increasing drift region thickness, while remaining the device footprint. Additionally, uniform electric field and current distribution give a superior thermal performance and increasing reliability compared to lateral GaN HEMTs. For these GaN-based vertical power devices, which include highly doped p-type GaN, the formation of ohmic contact on p-type GaN with low specific contact resistance(ρ_c) is essential in order to minimize the device specific on-resistance($R_{on,sp}$) and power losses. However, formation of ohmic contact with low specific contact resistance on p-type GaN is still challenging due to p-type GaN's wide bandgap(~6.6 ev) which leads to a high schottky barrier height at the interface of metal/p-type GaN interface. Moreover, because of the high ionization energy of the dopants(150 ~ 200 meV in the case of Mg in GaN), the activation ratio for acceptors in p-type GaN is typically below to 5%, resulting in low net hole concentrations and hole mobility.
Here, we report the formation of ohmic contact on p-type GaN with low specific contact resistance using a tri-layer Pd/Ni/Au thin films. Our work shows that specific contact resistance can be significantly reduced using Pd/Ni/Au tri-layer with suitable rapid thermal process. The role of process parameters such as temperature, time and annealing ambient were carefully studied to obtain ohmic contact on p-type GaN. We demonstrates low-specific contact resistance of Pd/Ni/Au on p-type GaN can be reached to the lowest value of 1 x 10^{-5} Ω×cm^2 by annealed at 600 °C in air condition(N_2 + O_2) for 5 min. The mechanisms of ohmic contact formation on p-type GaN were analyzed by microstructural analysis with X-ray photoelectron spectroscopy(XPS), transmission electron microscopy(TEM), and secondary ion mass spectrometry(SIMS). Additionally, We fabricated GaN-on-GaN PiN diode with Pd-based tri-layer thin films(Pd/Ni/Au) for anode in diode. This GaN-on-GaN PiN diode with Pd-based ohmic contacts on p-type GaN diode shows 30 times higher forward current compared with Ni/Au based ohmic contacts while achieving low specific on-resistance with high breakdown voltage. Therefore, low specific on-resistance($R_{on,sp}$) of 0.5 mΩ×cm^2 and breakdown voltage of 1.9 kV, corresponding to Baliga's figure of merit(BFOM) of 7.22 GW/cm^2, are demonstrated experimentally. Our research indicates that the formation of ohmic contact with low contact resistance on p-type GaN in vertical GaN power diode leads to high value of Baliga's figure of merit device which is suitable for next-generation high power applications

Optimization of growth rate and morphology of a SiC wafter by physical vapor transport method in the aids of finite element numerical simulation TsungYu Huang and Xiao Kai Lin; ming chi university of technology, Taiwan

The rapid advancement of compound semiconductors in recent years has generated considerable interest in silicon carbide, and it has steadily gained attention in the market due to its wide bandgap, high power capabilities, exceptional thermal conductivity, and a remarkable electron saturation velocity. The growing adoption of silicon carbide as the primary material for field-effect transistors by major companies has further bolstered its popularity. In terms

of silicon carbide wafer fabrication, the predominant method utilized is the physical vapor transport (PVT) process.
In the PVT process, high-purity silicon carbide powder is placed in a graphite crucible within a crystal growth furnace. The furnace employs induction coils to heat the silicon carbide powder, raising its temperature to over 2000 °C for sublimation. A single crystal seed is strategically positioned above the powder to ensure the growth of single-crystal silicon carbide. However, the PVT method faces limitations, notably the inability to monitor internal conditions during the crystal growth process. This is due to the requirement of maintaining high temperatures and a vacuum environment. As the demand for larger wafer sizes continues to rise, the internal thermal distribution within the crystal growth furnace becomes uneven. This non-uniformity results in variations in wafer curvature between the center and edges, making subsequent processing challenging.
To address these issues, our objective is to employ the finite element method to construct a comprehensive model of the crystal growth furnace. This model includes various components such as a water-cooled copper heating coil, a stainless-steel furnace cover, an argon gas atmosphere zone, a graphite lining, a graphite crucible, quartz supports, and the crystal seed. In our simulation, we couple multiple physical processes, including electromagnetic induction, heat conduction, convection, fluid distribution, mass transfer, crystal growth thermodynamics, dislocation density growth, and feedback systems to replicate the intricate crystal growth process. Our goal is to optimize the internal thermal distribution within the furnace by exploring alterations to the crucible structure and the morphology of the source materials. The primary aim is to achieve radial uniformity in the thermal field, which will result in even heating of the center and edges of wafers, effectively reducing curvature discrepancies. Furthermore, we seek to attain larger axial temperature gradients to enhance the crystal growth rate significantly.

Synthesis and Characterization of Single Photon Emitters from Chemically Exfoliated Hexagonal Boron Nitride Nanosheets Edgar Dimitrov, George Bepete, Gothamie Ratnayake, Sahin Ozdemir and Mauricio Terrones; The Pennsylvania State University, United States

Single-photon emitters are an essential component in the emerging applications of quantum communication, quantum computing, and integrated quantum photonics. Hexagonal boron nitride (hBN) is of particular interest as a material with a wide bandgap, which allows it to host a wide range of visible to UV emitters and retain stability at room temperature. These emitters arise from spatially isolated defects which introduce mid-gap states which can be excited to act as emitting color centers. In this work, we investigate the properties of single photon emitters in hBN nanosheets, which have been generated by using commercially available hBN powders and intercalating them with molten potassium. Following alkali metal intercalation, hBN was chemically exfoliated in solution and then drop casted onto any substrate. This process introduces a variety of defects embedded in the hBN, in particular, an excess of nitrogen vacancies which has been shown by X-ray photoelectron spectroscopy (XPS). We have found that this system can host bright single photon emitters which are active at room temperature and are stable for months in atmosphere without bleaching or blinking. Through a Hanbury-Brown Twiss Interferometer we have characterized multiple emitters in the range of 570-650 nm with values $g2(0)<0.15$ without background subtraction, indicating high quality emitters. These findings help to provide insights into the importance of defects in hBN that are responsible for single photon emission, thus opening the possibility for tailoring these defects through chemical functionalization.

SESSION EL04.09: Gallium Oxide I
Session Chairs: Sriram Krishnamoorthy and Joel Varley
Thursday Morning, April 25, 2024
Room 345, Level 3, Summit

8:15 AM EL04.09.01
Investigation of Temperature-dependent Hysteresis and Interface Trap Density in E-Beam Evaporated NiO_x/β-Ga_2O_3 p-n Diodes Bingcheng Da, Dinusha Herath Mudiyanselage, Dawei Wang, Ziyi He and Houqiang Fu; Arizona State University, United States

β-Ga_2O_3, an ultra-wide bandgap (UWBG) material with a bandgap of 4.9 eV and a high breakdown field of ~8 MV/cm, holds promise for power, optical, and RF electronics. However, due to the absence of p-type Ga_2O_3, most demonstrated devices have been unipolar. This limitation is attributed to the lack of shallow acceptors and the presence of holes trapped in localized polarons. To address this, p-NiO_x has been utilized to create p-n heterojunctions with β-Ga_2O_3, resulting in devices such as p-n diodes and junction barrier Schottky (JBS) diodes. While these devices exhibit desirable properties, they also exhibit charge trapping, hysteresis in forward and reverse bias, and induced interface states at the heterojunction. This study aims to comprehensively investigate the temperature-dependent hysteresis and interface trap density in NiO_x/β-Ga_2O_3 p-n diodes on (-201) Ga_2O_3 crystal orientations.
The edge-defined film-fed grown β-Ga_2O_3 substrates were sourced from Novel Crystal Technology, Inc. (Japan) and had a n-type doping concentration of $[Sn] = 5\times10^{18}$ cm^{-3}, with uniform thickness and polished front sides. Prior to device fabrication, substrate cleaning involved sequential treatments with acetone, isopropyl alcohol (IPA), and deionized (DI) water. Subsequently, electron beam (E-beam) evaporation was used to deposit Ti/Au (20/130 nm) back contacts, followed by rapid thermal annealing at 500 °C in an N_2 environment. Photolithography was employed to define circular areas of 300 µm in diameter for NiO_x and anode material deposition (Ni/Au, 20/130 nm). Layers of NiO_x (200 nm) were deposited using e-beam evaporation, and a liftoff process was executed to isolate individual devices. Post-fabrication, devices underwent annealing at 350 °C in an N_2 atmosphere for 1 minute to improve performance by reducing the number of interface states at the NiO_x/β-Ga_2O_3 heterojunction.
Preliminary findings indicate hysteresis during forward and reverse bias, but none in C-V measurements. With increasing temperature, forward bias hysteresis decreases, while reverse bias hysteresis remains constant. The experiment covers a voltage range of +3 V to −10 V. Concurrently, capacitance-frequency measurements were conducted to evaluate trap density, which varied between 5×10^{11} and 2×10^{11} $eV^{-1}cm^{-2}$ as the temperature ranged from room temperature to 395 K. These results suggest that temperature-dependent interface trap states contribute to the observed hysteresis in the devices. Future investigations will extend to NiO_x/β-Ga_2O_3 devices on (010) crystal orientation. Previous studies have indicated distinct electronic properties between (-201) and (010) devices due to crystal anisotropy. This study will provide valuable insights into transport properties of NiO_x/β-Ga_2O_3 p-n diodes and pave the path for device optimization by reducing interface trap states.

8:30 AM *EL04.09.02
What Is In Store for Gallium Oxide Power Devices in the Next Decade? Man Hoi Wong; Hong Kong University of Science and Technology, Hong Kong

Ultrawide-bandgap semiconductors have attracted increasing interests to expand the application space for next-generation power electronics. These research efforts have been driven in large part by a need for new medium/high-voltage power devices that meet stringent requirements for system size and cost in emerging areas such as electrified transportation, motor-drive systems, and renewable energy integration with the grid. Materials with shallow hydrogenic dopants show the best projected performance for power switching. Realizing high material purity with low background compensation will enable low doping concentrations to fully exploit the intrinsic material properties. Due to the availability of shallow donors and low background impurity

compensation enabling rapid device prototyping, beta-phase gallium oxide (β-Ga_2O_3) has emerged as a relevant contender for power devices and has repeatedly pushed the boundaries of high-field performance. In addition, β-Ga_2O_3 is the only (ultra)wide-bandgap material that has a melt-grown native substrate, indicating a path to a commercially viable and cost-competitive technology.

As one of the most widely studied ultrawide-bandgap semiconductors today, β-Ga_2O_3 has attracted international attention across disciplines. Thanks to the success of high-purity homoepitaxial growths on bulk substrates, a broad portfolio of β-Ga_2O_3 devices has demonstrated favorable attributes to be the next frontier technology in power conversion, integrated high-voltage RF, and high-temperature electronics. Various strategies of field management, including edge termination techniques and multi-dimensional device architectures, have been devised to effectively harness the high critical electric field afforded by β-Ga_2O_3. Heterojunctions with β-$(Al_xGa_{1-x})_2O_3$ and *p*-type oxides (notably NiO) have created an abundance of new design possibilities. Additionally, reports of high-performance packaging, device robustness, and converter applications all consolidate the promise of β-Ga_2O_3 for power electronics. While β-Ga_2O_3 devices are noted for their high-temperature resilience, heat dissipation to limit the junction temperature and improve the component reliability will be critical for maximizing their performance and long-term reliability.

After the first report of a single-crystal β-Ga_2O_3 power device by Higashiwaki and co-workers in 2012, β-Ga_2O_3 has showcased technical and programmatic momentum not seen in decades since the rise of SiC and GaN research. Following a survey of the landmarks in β-Ga_2O_3 research including device engineering, process innovations, and theoretical understandings of relevant physics, I will reflect on the demonstrated benefits as well as unrealized potentials of the emerging β-Ga_2O_3 technology, then conclude with my projections of the future directions and opportunities for β-Ga_2O_3 in the coming decade.

9:00 AM EL04.09.03
MBE Growth and Properties of Monoclinic $(Al_xGa_{1-x-y}In_y)_2O_3$ Alloys Stephen T. Schaefer, Kingsley Egbo, Glenn Teeter, Syed Hasan, Andriy Zakutayev and Marshall B. Tellekamp; National Renewable Energy Laboratory, United States

Gallium oxide (Ga_2O_3) is an emerging ultra-wide bandgap semiconductor material that has attracted attention for its potential to outperform existing SiC and GaN based devices operating at high breakdown voltages and high temperature. The thermodynamically stable phase at room temperature and pressure is the monoclinic β-phase with symmetry *C2/m*. β-Ga_2O_3 has a direct bandgap energy of 4.76 eV and critical field as high as 8 MV/cm. Isovalent alloying of In and Al in β-Ga_2O_3 provides the ability to engineer bandgap energy and strain of the material, however the monoclinic structure is not the ground state for Al_2O_3 or In_2O_3. First-principles calculations indicate a range of bandgap energies from 7.2-7.5 eV for monoclinic θ-Al_2O_3 to 2.7 eV for monoclinic In_2O_3. The corresponding lattice mismatch to β-Ga_2O_3 ranges from about 4% for θ-Al_2O_3 to 10% for monoclinic In_2O_3. In principle the quaternary $(Al_xGa_{1-x-y}In_y)_2O_3$ can span this bandgap energy and strain range, providing device designers with additional degrees of freedom to tune band offsets and electronic properties.

However, efforts to synthesize isovalent alloys are complicated by their tendency to phase separate. Strain balanced alloys of $(Al_xGa_{1-x})_2O_3$ and $(In_xGa_{1-x})_2O_3$ may be able to overcome the tendency for phase separation and stabilize the monoclinic crystal, however literature reports of the quaternary $(Al_xGa_{1-x-y}In_y)_2O_3$ are limited to <1% unintentional indium incorporation in In-catalyzed $(Al_xGa_{1-x})_2O_3$.[1] The primary limitation to quaternary formation is the limited incorporation of indium at elevated growth temperatures. This limited incorporation is due to both the volatility of indium oxide and Al and Ga cation exchange reactions which replace indium in In_2O_3.[2]

We report on the first successful synthesis of phase pure monoclinic $(Al_xGa_{1-x-y}In_y)_2O_3$ by molecular beam epitaxy. Plasma-assisted molecular beam epitaxy (MBE) is used to grow $(Al_xGa_{1-x-y}In_y)_2O_3$ on (010) oriented Fe doped β-Ga_2O_3 substrates at 750 °C and Ga and In beam equivalent pressures (BEP) of 5×10^{-8} and 2×10^{-7} torr, respectively. The Al BEP varies from 1×10^{-9} to 1.5×10^{-8} torr. X-ray diffraction measurements of the (020) plane indicate a strained film consistent with the structural incorporation of both Al and In, and this incorporation is chemically corroborated by x-ray fluorescence (XRF) and X-ray photoemission spectroscopy (XPS). Wide-angle ω-2θ survey scans confirm the absence of additional XRD peaks, indicating the films are monoclinic with no phase separation. Spectroscopic ellipsometry measurements show a monotonic shift in the extinction coefficient edge from approximately 4.7 to 5.2 eV with increasing Al BEP. Additional structural, chemical, optical, and electrical characterization measurements including Rutherford back-scattering spectrometry, scanning tunneling microscopy will be presented, concluding with an outlook on the applicability of these quaternary films to gallium oxide device design.

9:15 AM *EL04.09.04
Dielectric Integration and interface defect engineering for β-Ga_2O_3 MOS devices Ahmad E. Islam[1], Ashok Dheenan[2], Weisong Wang[3], Kevin Leedy[1], Kyle Liddy[1], Daniel Dryden[1], Guru Subramanyam[4], Aaron Arehart[2], Siddharth Rajan[2], Kelson Chabak[1] and Andrew Green[1]; [1]Air Force Research Laboratory, United States; [2]The Ohio State University, United States; [3]Wright State University, United States; [4]University of Dayton, United States

Dielectric integration is always challenging for any semiconductor material when used in a metal-oxide-semiconductor (MOS) configuration. SiO_2 offers the best oxide interface on Si, mainly because the SiO_2/Si interface was carefully engineered by the pioneering works of Atalla et al. Interfacial defect engineering is currently being investigated for wide-bandgap semiconductor such as SiC. Such defect engineering solutions are, however, missing for other oxide/semiconductor interfaces involving wide or ultra-wide bandgap semiconducting materials.

The newest semiconductor β-Ga_2O_3 can be grown from melt, has a high critical electric field, a low switching loss that can be obtained at a high breakdown voltage, and an efficient high frequency performance. β-Ga_2O_3 has therefore already demonstrated promises for power switching applications with drive current > 100A and high temperature electronics with operating temperature T >500 ºC. The dielectric/semiconductor interface of β-Ga_2O_3 however has large interface defect density (N_{IT}) mainly due to the deposition of dielectrics after many process steps in a device fabrication process. A dielectric-early process flow is preferred for reducing N_{IT}; to enable this process, dielectrics will have to withstand all the remaining semiconductor process steps, some of which (such as dopant activation anneal) involves >900 ºC process temperature. Such high T processes induce poly-crystallization (resulting in electrical and mass transport through the grain boundaries) in most dielectrics formed using atomic layer deposition (ALD) – a deposition process that is routinely used for all semiconductor device processes.
Till 2020, most of the MOS devices made on β-Ga_2O_3 substrates exhibited $N_{IT} > 10^{12}$ cm^{-2} and, therefore, devices exhibited large hysteresis and frequency dispersion during the capacitance-voltage (C-V) and current-voltage (I-V) characteristics. Using conventional crystalline semiconductor wisdom, crystallization of dielectrics via high T annealing were considered for defect reduction (and hence hysteresis and dispersion reduction); this however had limited success as the resultant poly-crystalline suffered from grain boundary conduction and materials diffusion. Therefore, dielectrics with low N_{IT} and

good thermal stability still remained elusive for establishing electronic-grade semiconductor process flow for β-Ga_2O_3 devices.
In this work, we will highlight the general challenge for integrating dielectrics on β-Ga_2O_3, address the associated requirements for obtaining high-quality dielectric with low N_{IT}, and in particular discuss the integration of Al_2O_3 and SiO_2 dielectrics on (010) β-Ga_2O_3 substrates. We will discuss the role of surface roughness, surface cleanliness (using piranha treatment), surface defective layer removal (using buffered HF), and post-deposition annealing on interface defect density. We will also compare the thermal stability and interface quality of SiO_2 and Al_2O_3 dielectrics formed on β-Ga_2O_3. We will explain how interfacial crystallization of monolayer Al_2O_3 (during a low temp ALD deposition at 250 ^oC) enabled formation of high-quality interfaces at the Al_2O_3/β-Ga_2O_3 interface – therefore, showed the lowest interface defect density. This is mainly because the crystal structures of γ-Al_2O_3 and β-Ga_2O_3 resembles each other and hence promotes the formation of monolayer γ-Al_2O_3 at the Al_2O_3/β-Ga_2O_3 interface even at 250 ^oC deposition temperature.
All these considerations have enabled us to envision pathways towards electronic-grade integration of dielectrics on β-Ga_2O_3 substrates needed to attain high breakdown voltage in power electronics applications and also to attain low frequency dispersion and high operating frequency in radio frequency applications.

10:15 AM +EL04.09.05
Defects and doping in (Al,Ga)N and β-$(Al,Ga)_2O_3$ alloys Filip Tuomisto; University of Helsinki, Finland

Si is the n-type dopant of choice for GaN and β-Ga_2O_3. However, in (Al,Ga)N and β-$(Al,Ga)_2O_3$ alloys, when the Al content is increased, the the n-type conductivity produced by the added Si impurities is efficiently compensated. The critical Al fractions are about 70% for the (Al,Ga)N alloys and as low as 30% for the β-$(Al,Ga)_2O_3$ alloys. AlN and Al_2O_3 are well known to be poorly n-type dopable even with Si, but the detailed compensation mechanisms in the alloys are not necessarily the same as in the compounds.

Positron annihilation spectroscopy is a useful method for studying neutral and negatively charged vacancy-type defects, as well as negatively charged defects with no open volume such as acceptor impurities [1]. I will discuss the most recent results obtained in Si-doped (Al,Ga)N and β-$(Al,Ga)_2O_3$ alloys in the light of the compensation phenomena caused by cation vacancies, carbon impurities and Si DX center formation. The local environment of the Si dopants appears to have a strong impact on the doping efficiency.

First-principles calculations on point defects and doping in $(Al,Ga)_2O_3$ ultrawide-band gap semiconductors Joel B. Varley; Lawrence Livermore National Laboratory, United States

Semiconductor devices utilizing ever-wider band gap materials have the promise of more compact and efficient energy conversion that can help accelerate the transformation to an energy infrastructure based primarily on renewable resources. Gallium oxide and related alloys are rapidly developing as promising material platforms for next-generation power electronics owing to their large, tunable band gaps, controllable electrical conductivity, and commercially-available single-crystal substrates that can be grown via a number of industrially-scalable processes. Analogous to the AlGaN system, the incorporation of Al into Ga_2O_3 to form $(Al_xGa_{1-x})_2O_3$ (AGO) alloys can lead to a significant increase of the band gap, but spanning a much larger rage of ~4.8 eV-8.6 eV. AGO also exhibits the possibility of different crystal structures and lattice constants, leading to a number of possible epitaxial relationships beyond the wurtzite AlGaN system. Despite this promise, a number of questions remain as to the effectiveness of donor doping and how to overcome the possibility of compensation in the limit high Al-contents, similar to that in AlGaN. Here we assess *n*-type doping of Ga_2O_3 and consider the prospects of doping in the larger-gap Al-containing alloys using first-principles modelling approaches based on hybrid functional calculations. We consider a number of conventional dopants such as Si, Ge and Sn, as well as lesser-explored transition-metal donor dopants that have been identified as effective alternatives. We additionally consider the role of native cation vacancies, which are known to be potentially problematic sources of compensation. Our results identify composition regimes in AGO alloys that may be most effectively targeted for increased band gaps and effective donor doping, with composition regimes specific to particular dopant species. These results provide guidance for doping in Ga_2O_3 and related alloys incorporated into heterostructure devices.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and supported by the LLNL Laboratory Directed Research and Development funding under project number 22-SI-003 and the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. DOE, Office of Energy Efficiency and Renewable Energy, Advanced Materials and Manufacturing Office.

11:15 AM EL04.09.07
Quantitative Modelling of Defect Concentrations in β-Ga_2O_3 for Equilibrium, Full Quenching, and Generalized Quenching Scenarios Khandakar Aaditta Arnab[1], Isaac Maxfield[1], Chennyung Lee[2], Elif Ertekin[2], Joel B. Varley[3], Ymir K. Frodason[4] and Michael Scarpulla[1]; [1]University of Utah, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Lawrence Livermore National Laboratory, United States; [4]Centre for materials Science and Nanotechnology Physics, Norway

β-gallium oxide (β-Ga_2O_3) is of intense current interest because of its ultra-wide bandgap, high critical field, and availability of melt-grown substrates. Point defects and complexes determine the properties of bulk crystals as well as epitaxial layers, thus, predictive models of defect concentrations under various impurity and processing scenarios are of very high value. First-principle calculations of defect energetics have provided critical insights into the defect system in β-Ga_2O_3, but translating computed enthalpies into defect concentrations corresponding to real-world crystal growth requires additional steps. Material processing in terms of growth or annealing typically controls the sample's thermochemical trajectory in terms of temperatures and partial pressures, while computational papers frequently present results holding chemical potentials constant.
Here we report quantitative modelling of equilibrium defect concentrations in Ga_2O_3, considering especially the temperature dependence of the bandgap and temperature-dependent chemical potentials from the Ga-O binary system's known thermochemistry. Additionally, we compute results for realistic sample types such as Fe- or Sn-doped wafers accounting for the fixed concentrations of these impurities as opposed to their fixed chemical potentials. Results are presented for various background n-type doping and for equilibrium and quenching, corresponding respectively to 0 or infinite cooling rates. We find significant departures from prior simpler predictions, especially in the case of the bandgap temperature dependence which tends to suppress V_{Ga}. We compare our predicted results to experimental cases such as annealing in O_2 or Ga_2O vapors.
Finally, to give semi-quantitative insight into defect concentrations expected in finite-sized samples subjected to finite cooling rates without full-fledged defect reaction-diffusion simulations, we introduce the concept of generalized quenching as a 3rd type of computation. At the heart of generalized quenching is the insight that, because of their different diffusion constants, different types of defects located at different distances from free surfaces will be "frozen-in" at different temperatures. By combining the correct series of equilibrium and quenching calculations, it is possible to predict defect concentrations present in real-world samples e.g. as a function of radius within a boule or for thin films of different thicknesses. We compare these results to the known phenomena from bulk crystal growth, indicating differences in carrier density between the center and periphery of CZ-grown boules.

11:30 AM *EL04.09.08
Lateral and Vertical β-Ga_2O_3 Transistors for Next-Generation Power Applications Kornelius Tetzner, Zbigniew Galazka, Andreas Popp, Joachim Würfl and Oliver Hilt; Ferdinand-Braun-Institut, Germany

The semiconductor β-Ga_2O_3, distinguished by its ultra-wide bandgap of approximately 4.8 eV, has gained substantial attention in recent years within the context of advancing the next generation of power electronic devices. The assessed high breakdown strength of 8 MV/cm and the resultant elevated Baliga's figure of merit exceeding 3,000 signify the potential for developing significantly more compact and, consequently, efficient power converters employing this material when compared to well-established SiC and GaN technologies. Notably, lateral β-Ga_2O_3 metal-oxide-semiconductor field-effect transistor (MOSFET) devices have exhibited remarkable performances. These transistors currently manifest an average breakdown strength of up to 5.5 MV/cm and showcase record-breaking breakdown voltages reaching 10 kV. Furthermore, the power figure of merit demonstrates a continual ascent, nearly surpassing a value of 1 GW/cm^2, attributed to ongoing enhancements in material quality and device optimizations.
This presentation aims to provide an overview on the current status of the process development for lateral and vertical β-Ga_2O_3 power transistor devices for high-voltage switching applications, with a specific focus on outcomes achieved at FBH and IKZ. For both scenarios, diverse approaches to bulk crystal growth, epitaxial layer structures, and device designs, tailored to attain the targeted performance parameters, will be deliberated, particularly in terms of breakdown voltage and channel current density. In this regard, we demonstrate the fabrication of lateral (100) β-Ga_2O_3 MOSFET devices with breakdown voltages up to 1.8 kV featuring a power figure of merit up to 155 MW/cm^2. Large periphery devices with a total gate width of 10 mm verify fast switching at 400 V with a turn-on switching speed up to 78 V/ns. In addition, the incorporation of p-type SnO highlights the considerable potential for realizing high-performance heterojunction SnO/Ga_2O_3 field-effect transistors.
Furthermore, we present vertical (100) β-Ga_2O_3 FinFET devices exhibiting enhancement-mode characteristics and a breakdown strength of 2.7 MV/cm. A comprehensive device simulation encompassing the entire FinFET structure using Silvaco Atlas identifies electric field peaks outside the active area within the SiN_x passivation layers and Al_2O_3 gate oxide, potentially serving as primary contributors to breakdown phenomena. As a culmination of these advancements, specific challenges, both in material and device domains, are identified, necessitating prospective resolutions to overcome prevailing breakdown limitations.

SESSION EL04.10: Gallium Oxide II
Session Chairs: Ahmad Islam and Sriram Krishnamoorthy
Thursday Afternoon, April 25, 2024
Room 345, Level 3, Summit

1:30 PM *EL04.10.01
Photoluminescence Mapping of Defects in β-Ga_2O_3 Matthew D. McCluskey[1,2], Jesse Huso[2], Cassandra Remple[1], John McCloy[1], Steve Rebollo[3], Sriram Krishnamoorthy[3] and James Speck[3]; [1]Washington State University, United States; [2]Klar Scientific, United States; [3]University of California, Santa Barbara, United States

Monoclinic gallium oxide (β-Ga_2O_3) is an ultrawide bandgap semiconductor with potential applications in power electronics. Photoluminescence (PL) spectroscopy is an important method to characterize dopants and defects in this material. Common features in the PL spectrum include the intrinsic UV band, blue and green bands that involve donor-acceptor pairs, and red emission due to Cr^{3+} impurities. PL mapping with excitation wavelengths ranging from 266 to 532 nm reveals the spatial distribution of these features with micron resolution. In Czochralski-grown β-Ga_2O_3, the Cr^{3+} emission intensity shows striations that are attributed due to inhomogeneities during growth. In addition to defects in the bulk, PL microscopy has revealed several specific defects on the surface. Some of these localized centers are very bright UV emitters. Homoepitaxial layers show defects that are observed via the shifts in the PL band, likely due to the strain field around a dislocation core. Damage due to high-intensity laser pulses results in significant changes in the intensity and energy of the UV band. *In situ* PL spectroscopy performed with a pulsed 266 nm laser shows characteristic emission peaks attributed to Ga atoms ablated from the surface.

2:00 PM EL04.10.02
Microscopic-scale Defect Identification in β-Ga_2O_3 Epitaxy Min-Yeong Kim[1,2,3], Andrew J. Winchester[1], Ory Maimon[2,1], Sang-Mo Koo[3], Qiliang Li[2,1] and Sujitra Pookpanratana[1]; [1]NIST, United States; [2]George Mason University, United States; [3]Kwangwoon University, Korea (the Republic of)

β-gallium oxide (β-Ga_2O_3) is a promising ultrawide bandgap semiconductor for next generation high power electronics that can surpass the performance of silicon, silicon carbide, and gallium nitride. In addition, the facile growth of crystalline β-Ga_2O_3 has significantly contributed to the rapid development of β-Ga_2O_3 power devices. However, device performance issues remain, where crystalline and thin-film defects contribute to this limiting factor. Crystalline defects in technologically mature materials have been identified and classified,[1, 2] since it is economically beneficial to isolate failure mechanisms at the source rather than relying on backend testing after device fabrication. The various defects could be categorized into killer or non-killer defects, where killer defects can hinder the operation of high-performance devices by trapping charge carriers or causing increased leakage current. The defects in Ga_2O_3 are largely unclassified, therefore identifying defects that cause electrical device degradation must be solved for widespread adoption of β-Ga_2O_3.
In this work, photoemission electron microscopy (PEEM) is used to visualize micrometer-scale defects and determine their electronic impact. PEEM is based on the photoelectric effect and is a non-destructive analysis method where light is used to excite and eject electrons from the sample surface and these electrons are analyzed. We investigated the defects on commercially-available epitaxially-grown β-Ga_2O_3 on (010) β-Ga_2O_3 substrates. The epitaxy was formed by hydride vapor phase epitaxy (HVPE) with a target doping of 1 10^{18} cm^{-3} on the (010) semi-insulating β-Ga_2O_3 wafer. We identified two types of elongated structures on the β-Ga_2O_3 epi-layer that appear in multiple locations on the sample surface and are oriented in a parallel direction. One of these features resembles the "carrot" defect observed in SiC epitaxy.[3] The carrot defect appears topographically as a bump with a density of 5 x 10^4 cm^{-2}, and shows a difference in the electronic properties (either in work function and/or gap states) compared to the non-defect surroundings. The second defect, or line defect, appears as depression with a higher density of 2 x 10^5 cm^{-2} and shows no change in electronic properties compared to non-defect surroundings. The local electrical influence of these defects are investigated with tunneling atomic force microscopy (TUNA), and both defects display reduced current compared to the non-defect surroundings. Ongoing work to identify the structural origin these defects through transmission electron microscopy will be presented. Together, we will present a discussion on the nature of these distinct features and their implication on device performance.

Heterogeneous Integration with Wide and Ultrawide Bandgap Semiconductors Mark Goorsky[1], Michael Liao[1,2], Kenny Huynh[1] and Kaicheng Pan[1]; [1]University of California, Los Angeles, United States; [2]U.S. Naval Research Laboratory, United States

Combining optimal properties of different semiconductors is an especially important consideration for wide bandgap materials due to limitations in thermal conductivities, dopant activation, and compatible crystal structures. Through focus on wafer bonding techniques, we present several cases of materials combinations to achieve an improved / novel performance. First, substrate engineering describes the formation of a template layer of a wide bandgap semiconductor on a substrate with favorable lattice parameter, thermal conductivity, and / or thermal expansion coefficient. Examples include b-Ga_2O_3 and GaN template layers and demonstrate the use of bonding and exfoliation techniques to achieve the desired structures. Second, the role of different bonding practices – and the formation of novel bonding pairs – including bonding with single crystal diamond demonstrates that benefits of certain techniques compared to others. Next, interfaces can be formed without the use of foreign bonding layers. Bonding of AlN with GaN, for example, highlights the importance of substrate perfection, chemical-mechanical polishing, and surface chemistry for achieving direct bonded interfaces free of other species. Finally, the use of designed interface layers can lead to interfaces with improved thermal transport across an interface. Examples of phonon bridging layers will be described. These examples illustrate pathways to achieve the potential of ultrawide bandgap semiconductors.

Direct growth of wafer-scale self-separated GaN on reusable two-dimensional material substrate Chang Hsun Huang[1], Chia-Yi Wu[2] and Yi-Chia Chou[1]; [1]National Taiwan University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

Gallium nitride (GaN) is extensively employed in light-emitting diodes, lasers, and high-power electronic devices due to its wide direct band gap and chemical stability.[1] Given the difficulty of obtaining high-quality GaN substrates, most current GaN-based devices are heteroepitaxially grown on foreign substrates, such as sapphire, Si, and silicon carbide.[2] However, the conventional growth of GaN films on these substrates generates a high defect density and considerable biaxial strain, attributed to the large lattice and thermal mismatch between the GaN films and their substrates. Thus, the lack of GaN native substrates is the main obstacle for the extending development of GaN-based devices. Although several conventional methods exist for obtaining free-standing GaN, such as laser lift-off, void-assisted separation, and chemical etching of the intermediate layer between GaN and the original substrate, the process of removing the substrate from a thick GaN film is complicated, expensive, and time-consuming. Furthermore, the original substrate can be damaged or contaminated during this process.[3]
Recently, the van der Waals epitaxial growth of III-V films on two-dimensional (2D) materials has been proposed to effectively mitigate the lattice mismatch effect caused by the weak bonds between III-V films and 2D materials.[4] Fluorphlogopite mica is a thermally stable material with a flexible atomic flat surface and low commercial cost, making it an ideal 2D material substrate. However, the dangling bond-free surface of 2D materials suppresses the nucleation of the III-V film, limiting the growth of large-area single crystals. Although some studies have proposed graphene as an intermediate layer in bridging techniques for growing and lifting off III-V films,[5] the integration of GaN growth with mica for self-separation is a relatively unexplored area. In this research, we successfully grew a 2-inch thick GaN film with high uniformity on a fluorphlogopite mica substrate via hydride vapor phase epitaxy. The 2-inch thick GaN film easily self-separated from the mica substrate during rapid cooling. After the film growth process, the residual GaN on the mica substrate was effectively eliminated through deionized water, owing to the hydrophilic characteristic of mica and the weak bonding between GaN and mica. Moreover, we demonstrated the capability of reusing the mica substrates by repeatedly growing self-separated GaN films on the same substrate. Additionally, to verify that the thick GaN film was of device quality, we demonstrated a fully functional ultraviolet light-emitting diode with a wavelength of 378 nm. In summary, our proposed approach may facilitate the epitaxy of large-area single-crystalline GaN on 2D materials, offering a new substrate option in the self-separation technology of III-V materials.

Fabrication of Vertical AlGaN-based UV-B Semiconductor Lasers Motoaki Iwaya[1], Sho Iwayama[1], Tetsuya Takeuchi[1], Satoshi Kamiyama[1] and Hideto Miyake[2]; [1]Meijo University, Japan; [2]Mie University, Japan

In recent years, the performance of AlGaN-based ultraviolet semiconductor light-emitting devices has been rapidly improving; in LEDs, high-performance devices with external quantum efficiencies approaching 10% are being realized in the wide wavelength range from UV-A to UV-C. On the other hand, similarly in semiconductor lasers, device operation at room temperature has been realized in the wide wavelength range from UV-A to UV-C. The most important challenge for achieving even higher performance in the future is to increase optical output power. To increase the optical output of light-emitting devices, it is necessary to improve the external quantum efficiency of the device itself and to increase the operating current. To increase the operating current, it is essential to increase the device size, which requires the realization of vertical devices in which the current flows perpendicularly to the p-n junction. However, most of the current AlGaN-based ultraviolet light-emitting devices use insulating sapphire or AlN as a substrate to obtain high-quality crystals, resulting in lateral devices in which the current flows horizontally in the n-type layer. Especially in semiconductor lasers, there are no reported

cases of vertical devices in UV-B and UV-C. In this report, we present the results of successful room-temperature operation of vertical AlGaN-based UV-B laser diodes by using a laser lift-off method and a substrate exfoliation technique with heated and pressurized water. We also would like to discuss the device characteristics and other related topics.

4:00 PM EL04.11.02
Origin of strong Auger-Meitner recombination in AlGaN deep-ultraviolet emitters Nick Pant[1,2], Kyle Bushick[1], Woncheol Lee[1], Chris G. Van de Walle[3] and Emmanouil Kioupakis[1]; [1]University of Michigan, United States; [2]The University of Texas at Austin, United States; [3]University of California, Santa Barbara, United States

The quantum efficiency of AlGaN-based deep-ultraviolet (DUV) light-emitting diodes lags severely behind its visible-light counterparts. Continued advancements in the synthesis and doping of AlGaN alloys are expected to reduce extrinsic losses, however the intrinsic energy-loss mechanisms in AlGaN are less well understood. Auger-Meitner recombination (AMR) is a non-radiative process involving the scattering of three carriers via the Coulomb interaction that causes the quantum efficiency of light emitters to decrease (droop) at high operating powers. The importance of this non-radiative-loss mechanism in AlGaN remains unclear, because its ultra-wide band gap makes it exceedingly difficult to simultaneously satisfy energy and crystal-momentum conservation for the direct AMR process. In this work, we develop and apply first-principles calculations based on density-functional theory to obtain mechanistic insights into the radiative and AMR processes in bulk AlGaN alloys and AlGaN quantum wells. We find that the additional momentum provided by electron-phonon coupling and alloy disorder lead to indirect AMR coefficients C in AlGaN that are as large as in InGaN ($C \sim 10^{-31}$ cm^6/s), which is known to suffer from severe efficiency droop. Moreover, we find that quantum confinement introduces a new scattering channel that significantly exacerbates AMR in AlGaN quantum wells, leading to an enhancement of the C/B ratio (where the B coefficient quantifies the radiative recombination) by an order of magnitude relative to the bulk. We propose experimentally feasible approaches for removing disorder and minimizing quantum confinement to mitigate efficiency droop in AlGaN DUV emitters.

Surface-Emitting Lasers in The Ultraviolet Spectrum Åsa Haglund[1], Estrella Torres[1], Lars Persson[1], Giulia Cardinali[2], Sarina Graupeter[2], Dogukan Apaydin[1], Hjalmar Andersson[1], Lukas Uhlig[3], Filip Hjort[1], Nelson Rebelo[1], Massimo Grigoletto[2], Michael Bergmann[1], Johannes Enslin[2], Nando Prokop[2], Martin Guttmann[2], Luca Sulmoni[2], Neysha Lobo Ploch[4], Munise Cobert[2], Tim Kolbe[4], Ryan Page[1], Andreas Liudi Mulyo[1], Ulrich Theodor Schwarz[3], Philippe Tassin[1], Joachim Ciers[1], Tim Wernicke[2] and Michael Kneissl[2,4]; [1]Chalmers University of Technology, Sweden; [2]Technische Universität Berlin, Germany; [3]Chemnitz University of Technology, Germany; [4]Ferdinand-Braun-Institut, Germany

The recent demonstrations of edge-emitting lasers in the UVB (280 – 320 nm) operating under pulsed conditions, and in the UVC (< 280 nm) operating continuous-wave bode very well for the development of more complex laser structures in the ultraviolet (UV), such as vertical-cavity surface-emitting lasers (VCSELs) and photonic crystal surface emitting lasers (PCSELs). Recently, optically pumped versions of both of these surface-emitting lasers, emitting in the UVB and UVC, have been realized; there are, however, significant challenges precluding electrical injection. Here, we will summarize the state of the art for these UV surface-emitting lasers and outline the remaining challenges for realizing electrically injected devices.

For VCSELs, we will go in depth into our concept for achieving high reflectivity mirrors with accurate cavity lengths based on substrate removal by selective electrochemical etching. In addition to paving the way to demonstrations of both UVB and UVC VCSELs, this technology has yielded a large reduction in the lasing threshold by allowing us access to both sides of the cavity for post-growth detuning setting. It has also facilitated lasers with an inherently temperature-stable lasing wavelength by enabling the integration of materials with negative thermo-optic coefficients. Moving towards electrically driven UV VCSELs, one major challenge is applying the electrochemical etch technique to heavily doped device structures, since the doping-selective etch process can unintentionally damage doped device layers. Here, we will discuss several important steps towards overcoming this challenge, specifically, the successful substrate removal for thin-film UVB light-emitting diodes (LEDs) and resonant cavity LEDs employing tunnel junctions, without any parasitic etching of device layers. With these results in hand, the only remaining building block to electrically driven UV VCSELs is the development of an aperture scheme for horizontal current confinement.

For PCSELs, we will show single-mode devices that lase in the UVB and in the UVC under optical pumping, despite the challenging surface morphology and the inherently low refractive index of AlGaN. A narrow beam divergence below 1° has been achieved by tailoring PCSEL parameters, such as the hole filling factor. The development of electrically injected PCSELs will benefit from the great progress that has been made for electrically injected edge-emitting lasers, since their epitaxial structures are similar. However, since PCSELs have an electrical injection path that is in the same direction as the outcoupled light they face similar challenges as VCSELs, such as achieving good lateral current spreading without the use of metals that can block the vertical emission.

The question now is, will we first see electrically driven UV PCSELs or VCSELs?

4:45 PM EL04.11.04
Fabrication of Broadband UV MSM Photodetector Using Reactive Sputtered Nickel Oxide Film Swati Suman; Indian Institute of Technology Madras, India

Efficient ultraviolet (UV) photodetectors are of significant interest due to their wide area of applications, such as bio-sensing, communications, and military applications1-3 . In this work, a metal oxide semiconductor sandwiched between metal electrodes (MSM structure) was developed as a broadband UV photodetector. The MSM photodetectors has garnered lot of interest because of its simple fabrication design, large active area, low dark current facilitating fast response. The metal oxide used was p-type nickel oxide (NiO) deposited by DC magnetron sputtering technique on top of indium tin oxide (ITO). Reactive sputtering from a pure nickel target was used to deposit NiO and the effect of oxygen concentration on the morphological and optoelectronic properties of the NiO was investigated. ITO is capable of providing good electrical conductivity and charge transporting behaviour which supports low leakage current4 . It is a n-type degenerate semiconductor which is widely used for transparent conducting films. Among different metal oxides, NiO is a promising p-type semiconductor with wide band gap value (3.2 to 3.8 eV, depending on stoichiometry) 5 . In this study, we explore the fabrication and characterization of a UV photodetector using ITO and NiO heterojunction. The device performance will be optimized by varying oxygen concentration during deposition of NiO. The variation of oxygen will be done by keeping argon concentration constant. The DC magnetron sputtered NiO thin film, acts as the photosensitive layer. Silver electrodes were used as contacts for the two layers. Material characterization has been done using different techniques like XRD, SEM, UV-vis spectroscopy, Raman spectroscopy and photoluminescence spectroscopy while electrical characterization has been performed using I-V source meter and four probe. The fabricated device demonstrates good change in light to dark current at low applied biased voltage. In conclusion, the development of UV photodetectors using DC magnetron sputtered p-type NiO thin films represents an encouraging route in the realm of optoelectronics. The tunablility of NiO film properties at the interface with the ITO substrate provide further leverage for advancements in photon sensing.

Diamond: A versatile ultra-wide bandgap electronic material for many applications Subhajit Chatterjee, Bellarmine Francis, Ramasubramanian Kannan, Nikhil C and M S Ramachandra Rao; IIT Madras, India

Diamond, an exceptional ultra-wide bandgap material, has drawn a lot of attention due to its potential in quantum devices, power electronics, high-frequency devices, mechanical applications, and thermal management. Diamond's bandgap energy of 5.5 eV allows for the creation of powerful power devices like field-effect transistors and high-voltage diodes. Diamond lattice is amenable to doping and boron doped diamond makes it a potential granular superconductor for quantum devices. Nitrogen doped diamond offers potential applications in quantum computing and magnetometry. Diamond's exceptional thermal conductivity is crucial in heat dissipation and lessens the need for complex and large cooling systems – using diamond coatings. Diamond's ultra-wide bandgap helps RF devices to operate more efficiently and for longer periods of time by reducing power losses, improving breakdown voltages, and heat dissipation.
To fully realize the promise of diamond in power electronics and high-frequency applications, our group is focussed on material engineering and device design. This entails the creation of cutting-edge growing processes and doping innovations to customize the attributes of diamonds to specific needs. In conclusion, the domains of power electronics and high-frequency devices are about to undergo a revolution, thanks to diamond. With far-reaching developments for multiple industries, the utility of diamond heralds new advance and sustainable technologies. Work carried out on various aspects of diamond, in our centres, will be presented.

9:45 AM EL04.12.03
Approaches for phosphorus incorporation on (100) oriented diamond surfaces Franz A. Koeck and Robert J. Nemanich; Arizona State University, United States

Diamond based electronics, in particular for high power, high frequency and harsh ambients are evolving more rapidly in part due to the availability of high-quality substrates with increasing size. A more economical device fabrication can be achieved for larger wafers and with a (100) oriented surface. However, prominent device demonstrations for p-i-n diodes and bi-polar junction transistors utilized (111) substrates as sufficiently high phosphorus incorporation for the n-type layer is more readily achieved. We present an approach for phosphorus doping of (100) oriented surfaces that utilizes in-situ monitoring of the gas chemistry via residual gas analysis (RGA) during a pulsed deposition technique. An ASTeX style, plasma enhanced chemical vapor deposition (PECVD) system was equipped with an RGA system to monitor and control in real-time the gas chemistry during growth. Results established that the concentration of PH radicals during plasma growth was related to the incorporated phosphorus concentration. Doped diamond growth was performed on CVD type IIa (100) diamond substrates with a surface finish of 5nm Ra. Process gases included hydrogen, methane and a 200ppm trimethylphosphine (TMP) in hydrogen gas mixture. The pulsed deposition technique included growth steps separated by cooling steps where the growth process was interrupted. With optimized conditions a phosphorus concentration approaching $10^{19}cm^{-3}$ was measured by secondary ion mass spectroscopy (SIMS) with an abrupt doping gradient. The doping results will be described in terms of the surface chemistry and the pulsed growth technique. Improvements in phosphorus doping will be discussed in terms of miscut, growth mode (step-bunching), surface finish and surface pre-treatment processes.
This research was support by the NSF through grant DMR-2003567 and the U.S. Department of Energy, Office of Science, Basic Energy Sciences through ULTRA, an Energy Frontier Research Center under Award #DE-SC0021230.

Electronic and Optical Properties of Antiferromagnetic MnF_2 Andre Schleife[1], Kisung Kang[2] and Yi-Ting Lee[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Fritz Haber Institute, Germany

In recent decades, MnF_2 has received considerable interest due to its simple antiferromagnetic structure and its promising applications in spintronic devices. While the magnetic properties of MnF2 have been extensively characterized experimentally, theoretical approaches have failed to accurately predict its electronic structure. This is evident in the discrepancy between the values predicted by electronic-structure theory, which is less than 7.3 eV, and the measured values of more than 9.9 eV based on reflectance and absorption spectra. Furthermore, no prior computational studies have predicted its optical properties to enlighten this question. We employed DFT with the HSE06 hybrid exchange-correlation functional and applied many-body perturbation theory via GW calculations to compute the electronic structure. Subsequently, we approximated this data using a PBE+*U* approach and a band-dependent scissor shift to achieve a converged **k**-point sampling for Bethe-Salpeter calculations of the excitonic optical spectrum. Surprisingly, we find excellent agreement with peak positions and amplitudes of the experimental spectrum across a wide range of photon energies up to 17 eV only after assuming an additional scissor shift of 2.4 eV. To explain additional shift, we analyze the effect of the lattice parameter, the magnetic structure, and different *GW* methods.

10:45 AM EL04.13.02
Static and time-dependent optical properties of CuI Andre Schleife and Brian Robinson; University of Illinois at Urbana-Champaign, United States

We aim to use first-principles electronic-structure theory to explain the static and time-dependent optical properties of the wide-band gap semiconductor CuI, which is a promising candidate for a transparent conducting material. In particular, we aim to clarify the importance of the spin-orbit interaction for the appearance of an above-gap spectral feature that is reported in multiple experiments. Measurements of the linear optical properties that have been reported in the literature agree in attributing that peak in the spectrum to a spin-orbit split-off valence-band state. However, the significant oscillator strength of the peak might raise doubts about its origin due to the spin-orbit interaction. We use a combination of density-functional and many-body perturbation theory to simulate the electronic structure and optical properties including excitonic effects. Our simulations do not reproduce the experimentally reported peak structure and we show that the optical dipole transitions from the corresponding spin-orbit split-off electronic state do not show a polarization dependence. We interpret this as an indication that more direct experimental evidence is needed to support the spin-orbit origin of any feature in this spectral range. We also solve the Boltzmann transport equation to account for electron-phonon scattering as a relaxation mechanism in pump-probe experiments and implement the resulting time-dependent occupation numbers as constraint in simulations of the spectrum. Our predicted pump-probe spectra for this material show that increasing the intensity of the excitation only significantly changes the magnitude of the spectrum values, while increasing the excitation energy leads to changes in the presence of peaks, peak location, and peak width.

11:00 AM EL04.13.03
Computational Prediction of an n-type Transparent Conducting Oxide F-doped Sb_2O_5 Ke Li[1,1], Joe Willis[1,1], Seán R. Kavanagh[2,1] and David O. Scanlon[3]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]University of Birmingham, United Kingdom

Transparent conducting oxides possess a unique combination of optical transparency and electrical conductivity, making them indispensable in optoelectronic applications. [1] However, the heavy dependence on a small number of established transparent conducting oxides (In_2O_3, SnO_2, ZnO and Ga_2O_3) places limitations on the number and types of devices they can support. Additionally, the high cost due to the scarcity of rare elements raises concerns about their long-term sustainability and large-scale production. [2] Discovering more wide band gap oxides that can be doped to display metallic-like conductivity is therefore necessary.

In this work, we use the PBE0 hybrid functional to investigate the defect chemistry of the binary Sb(V) system, Sb_2O_5. [3] We observe a large optical band gap over 3.6 eV, enabling transparency. The calculated Sb_2O_5 electronic structure shows a dispersive conduction band minimum with low electron effective masses, revealing its n-type properties. Our defect analysis reveals that Sb_2O_5 does not display metallic-like conductivity when nominally undoped, however, F-doped Sb_2O_5 displays degenerate n-type transparent conducting behaviour. Our band alignment calculations demonstrate that Sb_2O_5 has a larger electron affinity than the established transparent conductors, which can facilitate electron extraction for organic solar cells applications. The findings of this under-explored Sb(V) binary system prove the feasibility and potential for Sb(V)-based materials to be promising transparent conducting oxides.

Thermal Conversion of Ultrathin Nickel Hydroxide for Wide Bandgap 2D Nickel Oxides Lu Ping, Nickolas Russo and Xi Ling; Boston University, United States

Wide bandgap (WBG) semiconductors in two-dimensional (2D) form have demonstrated great potential in 2D electronics, optoelectronics, and power industries.[1–3] However, as an essential group of WBG semiconductors, 2D transition metal oxides (TMOs) remain largely understudied in terms of physical properties and applications in 2D electronic devices due to the lack of sufficiently large 2D crystals. Various 2D TMOs nanosheets have been produced,[4–6] but the nanometer scale crystals are not desirable enough for 2D electronics study, which usually require larger lateral domains (>10 μm) for device design.[7,8] And some common TMOs (e.g., Ni_xO_y) still lack of systematical study and knowledge to be designable for application studies. Therefore, we are inspired and driven to expand the 2D TMOs family from developing a universal synthesis pathway with desirably large lateral domains that will serve 2D electronics study well. Here, we present the WBG 2D nickel oxide (NiO) thermally converted from 2D nickel hydroxide ($Ni(OH)_2$) with largest ever reported lateral domain size (>20 μm). A facile and scalable synthesis approach is employed firstly to produce 2D $Ni(OH)_2$ flakes, which are subsequently transformed into NiO through a simple and controlled thermal conversion process. The morphology and structure variation is investigated and the chemical reaction during the thermal conversion under different temperature zones are established. Optical bandgap of the thermally converted 2D NiO (E_g > 3.7 eV) is higher than that of 2D α-$Ni(OH)_2$ (E_g > 2.5 eV), showing even better potential to serve as gate dielectric layers. The oxidation process is further studied by X-ray absorption spectroscopy (XAS) and X-ray emission spectroscopy (XES), to provide more insights and understandings on the electronic structure and bandgap of 2D NiO. We believe our investigation on 2D NiO will project and inspire more profound studies on other 2D WBG semiconductors.

11:30 AM EL04.13.05
Control of ZnO defects for quantum information applications Shirin Riahi[1], Abbas Nakhlband[1], David Lister[1], Manu Hegde[1], Xingyi Wang[2], Kai-Mei Fu[2] and Simon P. Watkins[1]; [1]Simon Fraser University, Canada; [2]University of Washington, United States

ZnO is a promising candidate for the manipulation of quantum information (QI) in a direct bandgap semiconductor. Among compound semiconductors, ZnO has very low spin orbit coupling which results in much longer spin-lattice relaxation times than GaAs, InP etc.[1] In nanostructured form, ZnO has

low surface recombination rates compared with GaAs and other compound semiconductors, meaning that it is a very strong emitter of light even for sub-optical nanowire dimensions. Donor bound exciton (D^0X) defects such as simple substitutional group III elements are promising candidates for QI applications and can be coupled to their donor final state spins by very sharp line excitonic transitions. In addition, the exciton Bohr radius of ZnO is considerably smaller than GaAs, and InP making it less likely for donors within a NW to experience quantum confinement effects or surface fields. D^0X centers in nanowires grown by metalorganic vapor phase epitaxy (MOVPE) achieve optical linewidths comparable to the best quality bulk material. Recently coherent optical trapping of excitons was observed in In-donors in Zn) NWs grown by MOVPE. [2]
In this work, we discuss methods of achieving very low densities of such defects in ZnO in bulk and NW form. First, we show how the concentration of Ga donors can be controlled down to the 10^{15} cm^{-3} range by MOVPE using triethylgallium as a dopant. We use a simple model of exciton pair interactions to estimate these numbers. A second example is the so-called I_{10} defect which is known from radioisotope studies to contain Sn on Zn site.[3] We consider 2 types of samples: (1) bulk Sn-doped ZnO grown by CVD and (2) ZnO bulk substrates implanted with Sn ions. From an application point of view, Sn implantation is a preferred method for generating these defects. We show that I_{10} emission can be reversibly generated and destroyed by heat treatments. After annealing in a nitrogen environment at 900ºC, the intensity of I_{10} in the CVD samples can be reduced by several orders of magnitude. After such a heat treatment, by annealing under Li, the I_{10}emission can be completely restored. This strongly suggests that I_{10} is a complex consisting of a Sn double donor complexed with a Li acceptor. Density functional calculations are consistent with this model. This defect provides a promising avenue of study for addressing single donor spins for QI since the concentration can be carefully controlled by means of low temperature diffusion or annealing under inert gas. A set of Li-related lines D^0X lines is also observed in addition to I_{10}.
A final issue related to the use of NWs for QI involves a broad emission band, SX, commonly seen in high purity samples in the 3.364 eV energy range. This band is attributed to excitons bound to surface states, and results in a strong background as sample purity increases and NW radius decreases. This may impact the ability to detect and control small numbers of donor spins for QI applications. We present the results of photoluminescence excitation (PLE) measurements indicating that the SX band is associated with localized surface states, with varying binding energies, rather some kind of band bending mechanism as previously proposed. The effect of surface treatments on this emission band are also discussed in this paper.

SESSION EL04.14: Emerging WBG and UWBG Materials II
Session Chairs: Robert Kaplar and Sriram Krishnamoorthy
Friday Afternoon, April 26, 2024
Room 345, Level 3, Summit

1:45 PM EL04.14.01
Transparent Conductive Titanium and Fluorine Co-doped Zinc Oxide Films Deposited via Aerosol Assisted Chemical Vapour Deposition Iqra Ramzan; University College London, United Kingdom

Aerosol-assisted chemical vapor deposition (AACVD) was applied to deposit highly transparent and conductive titanium or fluorine-doped and titanium-fluorine co-doped thin films on a glass substrate at 450ºC. All films were characterized by X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD), UV-Vis spectroscopy, scanning electron spectroscopy (SEM), and four-point probe. The films were 350-400 nm thick, crystalline, and highly transparent (80-87%). The co-doped film consists of 0.70 at.% titanium and 1 at.% fluorine, displaying a charger carrier mobility and charge carrier concentration of 8.4 $cm^2 V^{-1} s^{-1}$, 3.97 x 10^{20} cm^{-3}, respectively. A band gap of 3.6 eV was observed for the co-doped film. Compared to the undoped and singly doped films, the co-doped film displayed a notably higher structure morphology suitable for transparent conducting oxide applications. The highly transparent and conductive titanium-fluorine co-doped films have been deposited for the first time.

2:00 PM EL04.14.02
Two excitation pathways of Pr^{3+}ion emission in HfO_2:Si:Pr films depending on crystalline phase transformations in annealing Tetyana v. Torchynska[1], Manuel Garcia Andrade[1], Georgiy Polupan[1], Larysa Khomenkova[2,3] and Fabris Gourbilleau6[4]; [1]Instituto Politecnico Nacional, Mexico; [2]V. Lashkaryov Institute of Semiconductor Physics at NASU, Ukraine; [3]National University "Kyiv-Mohyla Academy, Ukraine; [4]CIMAP, UMR CNRS/CEA/ENSICAEN/UNICAEN, France

HfO_2 based materials offer high refractive index and high transparency in UV-NIR spectral ranges that are promising for photonic applications. For this purpose, the stabilization of HfO_2 structure is required to minimize the optical losses in the HfO_2 based optical materials. It is known that stabilization of tetragonal/cubic structure can be achieved via HfO_2 doping with trivalent atoms, such as rare-earth (RE) elements. In this case, electrical neutrality is achieved via formation of oxygen vacancies, i.e. one vacancy for two dopant atoms. At the same time, the interaction between different ions, the RE ion excitation mechanism and their redistribution upon high temperature annealing were not well addressed.
In this report the impact of annealing on the emission and transformation of the crystalline phases in Si rich HfO_2:Pr films was investigated by analyzing the morphology, chemical composition, structure, and light emitting characteristics. The films were grown on Si substrates by radio frequency magnetron sputtering in argon plasma and annealed at T_A=1000 or 1100ºC for t_A=15-60 min in inert atmosphere. The transformation of film properties was studied by means of SEM, EDS, XRD, XPS, and photoluminescence (PL) techniques.
Heat treatment at 1000ºC for 30 min stimulates phase transformation together with the appearance of a tetragonal HfO_2 phase and Si quantum dot (QDs). For HfO_2 films doped with Pr ions, the stabilization of the tetragonal HfO_2 phase in annealed films was observed contrary to the monoclinic structure of pure HfO_2 films. The main reason responsible for this structural phenomenon is the formation of oxygen vacancies (V_O). The formation of Si QDs and oxygen vacancies is accompanied by the appearance of emission of rare earth (RE) ions Pr^{3+} related to the transitions in the 4f energy levels. The shape of RE-related PL spectra followed the structural transformation. Narrow RE-related PL peaks were detected in the samples annealed for 30-60 min that confirms the location of RE ions in the tetragonal phase with a high crystal field.
Annealing for 60 min stimulates the complete oxidation of the Si QDs with the formation of the tetragonal SiO_2 phase along with partial destruction of a tetragonal HfO_2 phase. This last process is accompanied by the significant increase of the intensity of Pr^{3+} ion emission. Two forms of luminescence excitation in 4f energy levels of Pr^{3+} ions are discussed, related to energy transfer to Pr^{3+} ions, first from Si QDs and then from host V_O defects in HfO_2. These changes in the excitation pathways of Pr^{3+} ion emissions are stimulated by the transformations of the crystalline phases in the thermal treatment together with the generation of host HfO_2 defects. Hafnia-based materials doped with RE elements are interesting for telecommunication technology and

applications in waveguides and optoelectronic devices.

2:15 PM EL04.14.03
UV-Selective Transparent PV Devices with Wide Bandgap $ZnO_{1-x}S_x$ Mixed Crystal Absorbers Deposited by Atomic Layer Deposition for Seamless PV Building Integration Gustavo A Alvarez[1], Alex J. Lopez-Garcia[1], Victoria Rotaru[1], Maxim Guc[1], Jose M. Asensi López[2], Victor Izquierdo-Roca[1] and Alejandro Perez-Rodriguez[1,2]; [1]Institut de Recerca en Energia de Catalunya, Spain; [2]Universitat de Barcelona, Spain

One of the great limitations of integrating PV technologies on window or ceramic façades is the high light absorption of existing technologies that give these devices an opaque appearance, and other issues as weight. Therefore, when applied on glass, ceramic, or polymeric substrates they completely modify their aesthetic properties, making them practically inapplicable to the vast majority of urban buildings where aesthetic value is of fundamental importance.[1] This is a challenge since one of the most important aspects of non-intrusive integration of PV technologies is achieving a good balance between the efficiency of the cell and the degree of transparency. In this aspect, results have shown that wide-bandgap (WBG) materials based on oxides such as ZnO or $ZnO_{1-X}S_X$, present reasonably good photovoltaic properties while maintaining a high degree of transparency.[2–4] Particularly, $ZnO_{1-X}S_X$ has been proposed as an ideal UV absorber thanks to a composition-tuneable bandgap that can shift from 3.2 eV down to 2.7 eV at intermediate relative sulfur content, matching the UV spectral onset for the AM1.5G spectrum.[5,6]
In this work, transparent PV cells based on $ZnO_{1-X}S_X$ with a relative sulfur content of x=0.7 and the architecture SLG/FTO/MoO_3(HTL)/$ZnO_{0.3}S_{0.7}$/ZnO/AZO(ETL)/AZO have been fabricated and characterized. Preliminary results present the first evidence of PV effect using a fully ALD-deposited $ZnO_{1-X}S_X$ absorber and other WBG oxide materials as carrier selective contacts. These results show a notable V_{oc} of 401 mV but a low J_{sc} , limiting the PV effect. The Average Photopic Transmittance (APT) of the device has a value of 73%, showing indeed excellent transparency and color-neutrality thanks to the use of materials with bandgaps higher than 3eV. Optical, structural and electrical characterization of the absorber and devices will be presented (Spectrophotometry, Photothermal Deflection Spectroscopy, SEM, Raman, J-V characteristics under illumination). Ongoing work based on optoelectronic characterization will determine the UV detection capabilities of this structure measuring intensity dependent J-V characteristics under UV light under no bias as well as at the maximum-power-point, which are the prominent values at which a PV device will ideally operate. By such the TPV device based on this WBG material can be multifunctional and serve as a UV detector under PV operation. Also, to increase J_{sc} and thus PCE different compositions and selective contacts are being actively studied.
This research is relevant for the advancement of thin film technologies and in particular Transparent PV technologies. The proposed architecture has the potential to revolutionize photovoltaic technology by enabling on-site generation while minimizing visual impact. It is noteworthy that $ZnO_{1-X}S_X$ is a material composed of earth-abundant raw elements, compatible with scalable fabrication processes and can be synthesized at relatively low temperatures, which potentially allows minimizing the carbon footprint, the economic costs and energy expenditure associated with the manufacture of devices.
This work has received funding from MCIN/AEI/10.13039/501100011033 under grant numbers PID2022-138434OB-C51 and TED2021-129758B-C32 and by the NextGeratiouEU/PRTR.

3:00 PM EL04.15.01
Boron Nitride Nanotube, Its Chemistry and Application in Sensors and Transistors Jingwen Guan[1], Shiva Ashoori[2], Huimin Ding[1], Ping Lu[1], Eyal Roseshter[3], Liliana Gaburici[1], Ravi Prakash[2], Stephen Mihailov[1] and Christopher T. Kingston[1]; [1]Security & Disruptive Technologies Research Centre, National Research Council Canada, Canada; [2]Department of Electronics Engineering, Carleton University, Canada; [3]Department of Physics, Carleton University, Canada

Boron nitride nanotube (BNNT) is another emerging mankind one dimensional nanomaterial discovered at the same time frame around the years of 1990 as its counterpart carbon nanotube (CNT), but it has been much delayed in its synthesis for a large scale, its chemistry and application due to its differences in production and material characteristics from CNT. BNNT possesses a compelling set of intrinsic properties similar to CNT, such as one-dimensional tubular structures, light weight, high mechanical strength, and high thermal conductivity. But unlike CNT, BNNT is an electrical insulator with a wide bandgap about 5.5 eV, and has a hetero-atomic network of B and N in turn instead of homo-atomic of C network structure, therefore, BNNT has additional characteristics such as transparency in visible light, high thermal stability and high oxidation resistance over 900 ^oC in air. These properties make them high potential in many applications such as high-temperature and extreme environments, transparent armor materials, and radiation shielding protections. Especially, the polarity of B-N bonds in the BNNT network offers unique surface chemistry that can be taken in full advantages for sensing applications, for instance, due to interfacial compatibility and reactivity to its environment. We will present the use of HABS-BNNT materials produced at the National Research Council Canada (NRC) through thermal induction plasma process and the development of the surface chemistry by in-situ B-N bond cleavage with liquid bromine treatment in aqueous solution, leading to OH and amino (NH_2) dual surface functionalities at the same steps. Such functionalized BNNTs are highly soluble in aqueous and polar organic solvents by themselves without adding any surface agent. Our report will include up to today's results that such functionalized BNNTs as a sensing material for the active coating layers on optical fiber devices as well as a dielectric material for the applications in capacitors and in organic thin film transistors (OTFTs) for improving their performance and shelf life. An indicative outlook will be briefly discussed in the further development of BNNT-integrated transistors.

Study on Dynamic Wetting Characteristics of Al/3C-SiC System under Micro-Streching Yi Lv[1,2]; [1]Hubei University of Arts and Science, China; [2]Hubei Longzhong Laboratory, China

Aluminum-based silicon carbide (AlSiC) is an aluminum-based silicon carbide particle reinforced composite material, which fully combines the different advantages of silicon carbide ceramics and metal aluminum, with high thermal conductivity, thermal expansion coefficient matched with the chip, low density, light weight, and high hardness and high bending strength and other advantages, is widely used in aviation, aerospace, high-speed iron and microwave and other important fields. It is the preferred material to solve the packaging thermal management problems of microelectronics, power devices and optoelectronic devices. However, in the process of preparing AlSiC composites, the wettability between silicon carbide reinforced particles and aluminum solution is often poor, and it is difficult to achieve uniform distribution of SiC particles.
Many studies showed that the wettability between the ceramic reinforcement phase and the matrix was mainly affected by three factors: temperature, Si atom concentration and SiC surface structure. However, these results were mostly obtained by experimental methods, and some experimental conditions such as droplet shape, ambient temperature and pressure were difficult to accurately control, which made these results not reproducible to a certain extent. In addition, these factors have not been used to explain the dynamic mechanism of Al droplet wetting SiC surface from the microscopic perspective. Therefore, in this study, a molecular dynamics model was established, the dynamic stretching of the 3C-SiC substrate was introduced to simulate the microvibration state of the substrate surface. First, a 3C-SiC substrate with all Si atoms and C atoms on the upper surface was established, and then some atoms were removed from the surface of Si-terminated substrate to form rectangular and wedge grooves, and then some C atoms were added to the grooves. As a result, six Al/SiC systems were constructed, including a Si-terminated system (Si), C-terminated system (C), rectangular groove system (RG), rectangular groove system embedded with atoms (RGEA), wedge groove system (WG), and wedge groove system embedded with atoms (WGEA). The size of the substrate was $87.59 \times 87.59 \times 6.57$ nm^3, and the Al droplet size was 10.95 nm^3. In this study, Newtonian mechanics principle was applied to solve the motion of Al atomic and molecular system on SiC surface at 1100 K. The hybrid potential functions, including Tersoff, EAM and 12-6 LJ, were used to calculate the interaction between Al, Si and C atoms respectively. The time step was 1 fs, and the system simulation times were 10^5. In order to simulate the microvibration state and prevent atoms from squeezing or displacing each other during substrate stretching, the SiC substrate was stretched along the x-axis at a deformation rate of 10^{-3} per 100 steps, resulting in a substrate deformed only 1 nm along the x-axis in a calculated period of 10^5 fs. Then, the wettability of Al droplet on the surface of 3C-SiC was studied, including the variation trend of the wetting angle, self-diffusion coefficient and interaction energy with the simulation process.
The wetting angles of the six systems after stretching were greatly reduced, and the wettability of the substrate was improved, especially in the C-terminated system and the RGEA system. Although the interaction energy decreased and the self-diffusion coefficient increased in the WGEA system after stretching, the wetting angle of the substrate did not decrease much as expected, and even some of the wetting angles were greater than 90°, and the wettability of the substrate had not been significantly improved. This study has important application value for the preparation of a more uniform and reliable AlSiC substrate by pressure-free osmosis method.

3:30 PM EL04.15.03
Understanding the Role of Defects at Diamond/c-BN Interface: A First-Principles Study Shikha Saini[1], Kevin J. Tibbetts[2], Mark Polking[2] and Bilge Yildiz[1]; [1]Massachusetts Institute of Technology, United States; [2]Lincoln Laboratory, Massachusetts Institute of Technology, United States

In the realms of high-power and radio frequency electronics, diamond and cubic boron nitride (c-BN) stand out for their wide bandgaps, high thermal conductivities, high breakdown fields, and high mobilities. We have recently developed a protocol for preparing high-quality heteroepitaxial c-BN films on diamond substrates for next-generation power and RF field effect transistors (FETs). However, the development of practical electronic devices based on these heterojunctions remains challenging due to a limited understanding of the electronic structure and intrinsic interfacial defects at the diamond/c-BN interface and their impacts on dopant activation and free carrier density. Here, we present results of a first-principles study of diamond/c-BN epitaxial heterostructures. We first explore the electronic structures of different interface types, including both B and N-terminated (100) and (111) interfaces as well as the non-polar (110) interface. We analyze the band alignments for these low-index interfaces and calculate formation energies of potential substitutional, vacancy, and interstitial defects at these interfaces. Further, we analyze the stabilities of potential complexes of both multiple intrinsic defects and intrinsic defects combined with extrinsic dopants, such as Si, Mg, S, and Be, to assess the feasibility of achieving high carrier densities of both p- and n-type at the diamond/c-BN interface. We finally combine these results to determine ideal interface types, dopants, and growth conditions conducive to the formation of high-density two-dimensional electron and hole gases useful for RF FET devices. For instance, we show that B_C and C_N defects at the (110) interface induce p-type doping and lead to the formation of a two-dimensional hole gas (2DHG) in the diamond substrate. The intrinsic electron-deficient nature of these defects and the type-II band alignment are key factors in forming a 2DHG at the interface. However, we have observed that these B_C and C_N defects can be compensated by external dopants such as O and F, which are commonly introduced unintentionally in c-BN epitaxial growth processes. This leads to more stable configurations under B-rich conditions, viz. B_CO_C, B_CO_N, C_NF_N, and C_NO_N. Moreover, our calculated results for the diamond/cBN(100) interface show that interface states cross the Fermi level for both C–B and C–N interfacial bonds, indicating strong p-type (type-II band alignment) and n-type (type-I band alignment) doping, respectively. Therefore, high carrier densities on the diamond surface can be achieved through proper interface engineering with c-BN. Our comprehensive analysis reveals new insights into the structure and properties of diamond/c-BN heterointerfaces and provides a detailed roadmap for engineering next-generation power and RF FETs based on diamond/c-BN heterojunctions.

3:45 PM EL04.15.04
Revolutionizing Wafer Reusability: Innovative Porosification Techniques for Multiple Layer Transfers in Indium Phosphide Erfan T. Osman, Jürgen Carstensen, Catarina Schmidt and Rainer Adelung; Christian-Albrechts-Universität zu Kiel, Germany

In pursuit of sustainable and cost-effective semiconductor manufacturing, we present ground-breaking porosification techniques tailored for multiple layer transfers in Indium Phosphide (InP) wafers, with the ultimate goal of achieving complete wafer reusability.
Indium phosphide (InP) layers have wide range applications in various optoelectronic devices, such as solar cells, light-emitting diodes (LEDs), and high-speed transistors. In most of these applications, only a layer thickness in the order of 10 µm is typically needed. The main materials and device processing standard in industry for such layers are epitaxial growth techniques (MBE, MOCVD, etc), ion cut (Smart Cut ®) and chemical mechanical polishing (CMP) after a wafer bonding process. Smart Cut ® and CMP both require complex and expensive preparation steps to achieve surfaces suitable for bonding. Epitaxy (heteroepitaxy) on the other hand has a difficulty in producing layers with high crystalline quality especially when there is a high lattice mismatch.
An attractive material processing alternative to these techniques is the use of electrochemical methods to grow pores with tuneable properties (pore morphologies, depths, and diameters) into the InP wafer. Such pore tunability means that at a certain desired pore depth, pore diameters can be enlarged to create a continuous cavity that can then be detached as one intact layer from the parent wafer. The parent wafer can then be recycled completely in subsequent runs. This technique provides a fast, inexpensive and simple way to transfer porous InP layers particularly in optoelectronic applications where porosity in the InP layer is an added benefit. Additionally, hetero-integration with such layers is similar to the unetched InP wafers since the entire wafer surface can be transferred.
With the aid of a special etching profile invented by us, different types of pores can be grown into InP wafers, characterised as crysto-, curro- or mixed-pores using advanced characterisation techniques. It is crucial to have precise control of these pore growth kinetics in order to achieve a high device yield

and to ensure reproducibility. This presents a challenge since electrochemical systems are complex systems containing many variables such as global and local doping differences, temperature fluctuations, heat generation and release, concentration fluctuations, surface conditions, back side contacts, etc. In these cases, quantitative approaches to estimate pore growth dynamics in semiconductor materials can be the key to producing well defined porous layers. This quantitative description of the growth kinetics is presented. The power of such a quantitative approach is that AI-driven models can be trained on this data that can then forecast pore growth dynamics in semiconductor materials, facilitating the tunability of porosity for specific applications and enhancing the reproducibility of porous layers.

4:00 PM EL04.15.05
Vertical β-$(Al_xGa_{1-x})_2O_3$ Schottky Barrier Diodes with a BN Interlayer Bingcheng Da[1], Dinusha Herath Mudiyanselage[1], Dawei Wang[1], Abhijit Biswas[2], Pulickel Ajayan[2], Yuji Zhao[2] and Houqiang Fu[1]; [1]Arizona State University, United States; [2]Rice University, United States

Ultrawide bandgap (UWBG) semiconductors have attracted significant attention due to their potential applications in power electronics, optoelectronics, and RF electronics. Among these materials, β-Ga2O3 stands out as a promising candidate for UWBG semiconductors owing to its notable properties such as a high breakdown field of 8 MV/cm and a wide bandgap ranging from 4.6 to 4.9 eV. Additionally, it exhibits a high Baliga's figure of merit (BFOM) in comparison to GaN and SiC. Moreover, the availability of large native substrates makes β-Ga_2O_3 highly promising for cost-effective high-voltage power electronics. By alloying β-Ga_2O_3 with Al_2O_3, $(Al_xGa_{1-x})_2O_3$ is produced with a tunable bandgap (e.g., 4.8-6.2 eV for x = 0 to 0.71). This alloy is expected to possess a higher BFOM than β-Ga_2O_3, making it more suitable for power electronic applications. Recent research has shown optoelectronic and power devices utilizing β-$(Al_xGa_{1-x})_2O_3$, yet most of these power devices operate laterally, which often underperforms compared to their theoretical limits. In contrast, vertical architectures dominate in commercial Si and SiC power devices, particularly in high-voltage and high-power applications. Vertical architectures offer advantages such as increased current and voltage handling capability, superior avalanche capability, absence of surface-related issues, enhanced heat dissipation, and reduced chip area.

Various methods have been proposed to enhance the reverse leakage current performance of Schottky barrier diodes (SBDs), including field plates, guard rings, and junction termination extensions. Additionally, metal–insulator–semiconductor (MIS) diodes have emerged as an appealing alternative to improve reverse performance. Introducing an ultrathin dielectric layer can effectively suppress reverse leakage current and mitigate electrical field effects at Schottky contact edges. Boron nitride (BN) is a promising candidate for MIS diodes due to its UWBG of 6 eV, high breakdown electric field of 12 MV/cm, high stability, and flat surface.

This study successfully demonstrated β-$(Al_xGa_{1-x})_2O_3$ metal–insulator–semiconductor (MIS) vertical diodes with a ~10 nm BN interlayer. β-$(Al_xGa_{1-x})_2O_3$ epilayer with an Al composition of 21% and a nominal Si doping of 2×10^{17} cm^{-3}, grown by molecular beam epitaxy. BN interlayer was directly deposited on the β-$(Al_xGa_{1-x})_2O_3$ epilayer using pulsed laser deposition. Pt/Ti/Au was utilized on the BN layer as the top Schottky contact, while Ti/Au served as the bottom Ohmic contact. Forward and reverse I-V measurements were conducted, revealing excellent rectification with a high on/off ratio of $\sim 10^9$. Remarkably, the insertion of the thin BN layer led to a nearly two-order decrease in reverse leakage current compared to traditional vertical β-$(Al_xGa_{1-x})_2O_3$ SBDs, with the turn-on voltage increasing from 1.5 to 2 V. This approach presents a promising solution to address reverse leakage current issues in β-$(Al_xGa_{1-x})_2O_3$-based vertical devices, paving the way for next-generation high-power electronics.

4:15 PM EL04.15.06
Developing High-Voltage AlN Schottky Barrier Diodes on AlN Substrates for Power Electronic Device Applications Dinusha Herath Mudiyanselage, Dawei Wang, Bingcheng Da, Ziyi He and Houqiang Fu; Arizona State University, United States

Aluminum Nitride (AlN) is an ultrawide bandgap (UWBG) semiconductor material with a bandgap of 6.1 eV and a high critical field of 12-15 MV/cm, gaining increasing attention as a material suitable for power electronic devices. AlN, in terms of Baliga's Figure of Merit (BFOM), shows the potential to surpass other wide bandgap semiconductors like GaN, SiC, and Ga_2O_3. Despite the potential, devices based on AlN are still in the early phases of development. They encounter several challenges, including the need for high-quality epitaxial growth, establishing proper Ohmic and Schottky contacts, managing high costs, and dealing with a scarcity of conductive substrates. Recently, we have demonstrated 3 kV AlN Schottky Barrier Diodes (SBDs) with the assistance of AlN bulk substrates. Nevertheless, persistent challenges arise from the resistive nature and defects in the material, resulting in a limited understanding of the current transport mechanisms in both forward and reverse bias conditions. Additionally, under high reverse bias, the devices demonstrate elevated leakage currents, necessitating reduction for practical applications in power electronics.
In this research, AlN epilayers were grown using metal-organic chemical vapor deposition (MOCVD) with trimethylaluminum (TMAl) and ammonia (NH_3) as the Al and N sources, and SiH_4 as the *n*-type dopant Si precursor. The device structure comprised of a 1-µm-thick resistive UID AlN underlayer, a 200 nm Si-doped *n*-AlN layer, and a 2 nm UID GaN capping layer to prevent the oxidation of underlying AlN epilayers. Subsequently, lateral SBDs were fabricated through conventional photolithography, with varying distances between the anode and cathode (d = 5, 10, 25, and 50 µm). The device configuration included Ti/Al/Ni/Au as Ohmic contacts, and Pt/Au for the Schottky contact, with the Ohmic contacts annealed at 950 °C for 30 s in an N_2 atmosphere. Previous observations revealed that for, d > 50 µm, the devices did not exhibit breakdown up to 3 kV, necessitating control for managing the devices' breakdown and critical electrical field. Testing was conducted using a Keithly 4200 Semiconductor parameter analyzer equipped with a controllable thermal chuck, and high voltage measurements were performed using a Keysight B1505A Power device analyzer. The devices exhibited rectification ratios ranging from 10^6 to 10^7 as the distance changed from 50 to 5 µm. Temperature-dependent measurements indicated an increasing on/off ratio from 10^7 to 10^9 as the temperature varies from 293 to 623 K. Similarly, reverse leakage current testing at -40 V showed an increase from 10^{-12} to 10^{-10} A. Breakdown testing indicated breakdown voltages of 0.62, 1.2, 2.6, and < 3 kV for devices with d = 5, 10, 25, and 50 µm, respectively. These breakdown voltages correspond to an average electric field range of 1.1-1.2 MV/cm. While these electric fields are not high compared to other wideband gap semiconductor technologies, they represent a high value compared to the reported AlN devices without any edge termination or passivation. To enhance device breakdown, SiO_2 passivation will be implemented and tested. Additionally, field-plated structures will be explored to mitigate electric field crowding, particularly at the anode edge, and sustain high breakdown voltages. The potential for further performance enhancement through surface passivation by BN will also be investigated. This research serves as a valuable reference for the development of multi-class AlN high-voltage and high-power devices.

8:00 AM *EL04.16.01
Status and Progress of Vertical GaN-on-Silicon Devices Youssef Hamdaoui, Idriss Abid, Katir Ziouche and Farid Medjdoub; IEMN-CNRS, France

Lateral GaN-on-silicon power transistors are now qualified up to 650 V voltage operation. On the other hand, the development of cost-effective GaN-based vertical devices grown on large diameter silicon substrate combines the advantages of potentially higher voltage operation with avalanche mechanism, high current, high threshold voltage together with a smaller footprint, unreachable with lateral transistors. In addition, vertical architectures rely on current conduction through a drift layer with a uniformly distributed electric field that should prevent the issue of surface charge trapping effects. Nevertheless, this technology is still at an early stage and both material and device fabrication need to be optimized. In this talk, I will discuss the status and rapid progress of fully vertical GaN-on-Silicon devices. In particular, material and processing optimization results in state-of-the-art combination of breakdown voltage (BV) and on-state resistance (Ron) with the first demonstration of avalanche capability.

8:30 AM *EL04.16.02
Recent advances in GaN microwave HEMTs: buffer-free stack and thermal management strategies Digbijoy N. Nath; Indian Institute of Science, India

AlGaN/GaN microwave HEMTs are a mature technology and fast penetrating the market for 5G/wireless communication and military/strategic applications. However, challenges still remain in terms of improving the management of heat which is generated in such devices. Diamond heat sink has been extensively studied for this although commercial RF HEMTs still use Cu-heat sink. In this talk, we shall show our recent results on developing a cooling manifold using microfluidic channels whereby laser is used to etch the channels. The superiority of this approach against usual DRIE-etch based approach will be discussed along with experimental results. Our ongoing work on multi-finger X-band HEMTs with such liquid-cooling approach will be presented.
In the next part, we shall discuss our recent results on buffer-free GaN HEMTs with respect to C- and X-band performance, The study on passivation, gate dielectric and development of multi-finger HEMTs on such platforms will be presented along with load pull data.

9:00 AM EL04.16.03
Surface morphology and electrical resistivity in Ga-doped ZnO thin films: a grayscale fractal study Chenlei Jing; Ankang University, China

The Ga-doped ZnO (GZO) thin films with different sputtering pressures were prepared on glass substrates by RF-magnetron sputtering at room temperature. The surface morphologies and resistivity were examined by atomic force microscopy (AFM) and a Van der Pauw Method. The fractal geometry of films was further analyzed by the grayscale fractal study. The root-mean-square (RMS) roughness shows a decreasing trend with sputtering pressure while the fractal dimension and resistivity do not change synchronously as the pressure changes. The results show that resistivity is closely affected by the morphology like cluster height, cluster size, and the distance between adjacent clusters, and the cluster change could be obtained by the fractal spectra given by the grayscale study. What's more, resistivity is significantly related to cluster height.

9:05 AM EL04.16.04
Ballistic Quantum Transport in Terahertz Indium Gallium Nitride C-Plane and A-plane High Electron Mobility Transistors Choudhury J. Praharaj[1,2]; [1]Silicon Institute of Technology, India; [2]Band Photonics Materials, United States

This paper presents numerical calculations of ballistic quantum transport in c-plane and a-plane indium gallium nitride high electron mobility transistors (HEMTs). We calculate quantum mechanical transit times across the channel region of the HEMT and take into account spontaneous and piezoelectric polarization in these materials. Unity gain frequencies of 2.8 terahertz are achievable using nanoscale device dimensions. Ballistic gate lengths of 10.8nm-15nm are obtained from quantum transport calculations. A-plane transistors are able to achieve normally-off HEMT operation due to elimination of spontaneous and piezoelectric polarization effects. A-plane transistors also offer higher immunity to gate-drain leakage and to stress-related barrier reliability issues. We explicitly take into account the effect of longitudinal optical (LO) phonon scattering rates on the ballistic device dimensions. Our calculations show that plasmon collective oscillations do not substantially affect the device dimensions in terahertz and near-terahertz regimes for typical device parameters in this material system. We also explicitly study the effect of indium percentage in the indium gallium nitride channel on device characteristics like unity gain frequencies and current densities.

Measuring the Static and Dynamic Disorder in β-Ga_2O_3 Using Optical Transmission Ariful Islam, Nathan Rock and Michael Scarpulla; The University of Utah, United States

Gallium oxide (Ga_2O_3) has an extremely wide bandgap, predicted high breakdown field, and can be produced from melt crystal growth techniques making it attractive for next-generation high-power electronics. It is well-known that the optical transitions in monoclinic β-Ga_2O_3 are anisotropic; the threshold energies for carrier generation using linearly polarized light depend on crystallographic direction. Using transmission optical spectroscopy, which probes subtly differently than e.g., ellipsometry, we have investigated the optical transitions of Fe doped [100] β-Ga_2O_3 as function of elevated temperature, and have documented the dramatic bandgap narrowing with temperature, which was recently explained using density functional theory [1]. In addition, we have done the optical transmission of Sn doped [010], [001], [-201] at room temperature and liquid nitrogen temperature.
We elucidate the differences between ellipsometric and transmission measurements and demonstrate that transmission measurements in the literature have determined erroneous values for the bandgap because of very strong Urbach tails. We report on the anisotropy and doping dependencies of the disorder-induced tails in the optical absorption coefficient for β-Ga_2O_3 and separate the tails into static and dynamic disorder induced by phonons. Given the low symmetry of β-Ga_2O_3 and its strong electron-phonon coupling, we observed that the Urbach energy increases at elevated temperature due to the contribution of static and dynamic disorder and exhibit significant anisotropy. However, at liquid nitrogen temperature (77K), the Urbach energy for Fe-doped crystals decreases as the dynamic disorder is suppressed but increases at elevated temperatures. We also show that in the case of room temperature and liquid nitrogen temperature for Sn doped crystal. We analyze the dynamic and static components within the model of Cody et al., [2] and find that the static disorder is actually dominant. We discuss the possible microscopic origins in terms of point and extended defects; interestingly at low absorption coefficients even imperfect surface polishing may contribute. We combine the temperature dependences of the Urbach tails from our measurements with those of the optical transitions from ellipsometry [3], [4] to extract the mean square displacement-deformation potential product for Ga2O3 along different crystal directions. These parameters play roles in optical transitions and carrier scattering and are thus critical to measure. We elucidate open questions and opportunities especially for further theory and calculation to predict the implications on multiple properties of wider interest than the Urbach tails per-se.

9:35 AM EL04.16.06
Improving Optoelectrical Properties of Ga_2O_3 Photodetector by Reduced Graphene Oxide (rGO) Decoration for Deep UV Photodetection Malti

Kumari[1], Basanta Roul[1,2], S.B. Krupanidhi[1] and Karuna K. Nanda[1,3]; [1]Indian Institute of Science, India; [2]Central Research Laboratory, Bharat Electronics, India; [3]Institute of Physics, India

Deep ultraviolet (200-280 nm) photodetectors have received much attention in the fields of biology, industry, military, etc. The promising optical and electrical properties of wide bandgap, n-type gallium oxide (Ga_2O_3) make it quite suitable for deep UV photodetection. Our work shows that decorating reduced graphene oxide (rGO) can further enhance the photoresponse of the Ga_2O_3 photodetector (PD). rGO - a 2D material has received a lot of interest recently because of its distinctive qualities. In this work, we fabricated rGO/Ga_2O_3 heterostructure for deep UV photodetection where Ga_2O_3 thin film was deposited on c-plane sapphire substrate using Pulsed laser deposition, and rGO was synthesised by modified hummers method followed by thermal reduction, which was then drop casted on Ga_2O_3 film. The photoresponse of the rGO/Ga_2O_3 PD illuminated under 250 nm light was found to be substantially higher than the Ga_2O_3 PD, indicating an improvement of photoelectric properties for the UV photodetector based on Ga_2O_3 thin film. The dark current was found to be lower for rGO/Ga_2O_3 PD, and the illumination-to-dark current ratio ($I_{illumination}/I_{dark}$) was increased to 78.31 from 7.30 for Ga_2O_3 PD at a voltage of 5 bias and power density of 12.83 mW/cm^2. Thus, it can be concluded from the results that rGO/Ga_2O_3 PDs have great promise for photodetection applications.

9:50 AM EL04.16.07
The disorder and strain transformation of β-Ga_2O_3:Si,N after implantation to heated substrate Iraida N. Demchenko[1], Yevgen Syryanyy[1,2], Asiyeh Shokri[1], Yevgen Melikhov[3] and Maryna Chernyshova[1]; [1]Institute of Plasma Physics and Laser Microfusion, Poland; [2]Warsaw University of Technology, Faculty of Electronics and Information Technology, Poland; [3]Institute of Fundamental Technological Research Polish Academy of Sciences, Poland

Ga_2O_3 can become a powerful substitute for GaN in the power electronics industry in devices, such as MOSFETs and others [1-2]. Together with ion implantation, which is a versatile fabrication technique widely adopted in the mass production of commercial semiconductors, the fabrication of all-ion-implanted vertical gallium oxide transistor could greatly enhance the prospects for Ga_2O_3-based power electronics. For the realization of such systems, ion implantation can be used for channel/contact region doping and device isolation if necessary [3]. The important limitation of implantation is the buildup of lattice disorder due to the ballistic character of this process. Consequently, there is strong motivation to study the defects formation and their transformations. The ion implantation effects in compound crystals, e.g. GaN and ZnO, have been extensively studied in the last decade [4]. In the case of Ga_2O_3 however, the mechanism of defect buildup is completely unknown. The main problem comes from the fact that the accumulation of defects and their transformations in ion implanted compound crystals is a complicated multistep process resulting in the formation of a mixture of different types of defects. It is important to identify the location of implanted ions in the bulk and thin film crystal lattice, their surroundings, interaction with the host matrix and with structural and native point defects. In addition, an important consideration for the viability of ion implantation in Ga_2O_3 is the rate of diffusion of the different impurities.
In this work, we study the effect of inserting Si/N atoms into β-Ga_2O_3 utilizing ion implantation to a heated substrate. This process of material formation offers an interesting and complex field of study, with plenty of intrinsic defects, as well as their formation into defect complexes with the implanted ion. Such complexity requires the use of a variety of complementary analytical methods in order to perform a quantitative analysis. Here, we report the results of many analytical techniques, such as Rutherford Backscattering Spectrometry, Particle Induce X-ray Emission, High-resolution X-Ray Diffraction, Raman spectroscopy, Transmission Electron Microscopy, as well as synchrotron radiation-based technique as X-Ray Absorption Near Edge Structure supported by Density Functional Theory. All of this allows us to create a novel approach to study Ga_2O_3 implanted by Si/N ions.

Controlling The Alloy Fluctuations in AlGaN Materials Grown by Plasma-Assisted Molecular Beam Epitaxy: Effect on Ultraviolet Light Emitting Diodes Pushan Guha Roy[1], Sayantani Sen[1,2] and Anirban Bhattacharyya[1]; [1]University of Calcutta, India; [2]Sister Nivedita University, India

Molecular beam epitaxy (MBE) has been extensively used for the growth of III-Nitride materials and devices as this technique has the scope of accessing a much wider range of operating parameter-space than competing technologies. These can be exploited to address the problems in the UV-LEDs, such as low internal quantum efficiency, poor p-type doping etc. This work focuses on the effect of group III/V flux ratio variation on the AlGaN alloy properties, and consequently on the characteristics of UV emitters. Furthermore, in-situ monitoring of this parameter which is essential for accurate and reproducible growth process has been addressed.

AlGaN alloys were grown using a VEECO GEN930 plasma-assisted molecular beam epitaxy (PA-MBE) system. The growth was monitored in real-time based on the temporal evolution of RHEED patterns and a custom designed image capture and analysis system. An algorithm was developed for the direct monitoring of excess metallic film on the growth surface using the RHEED pattern, which was found to be the critical parameter. A series of otherwise identical samples were grown under various group III/V flux ratios ranging from excess group III to near-stoichiometric, and UV-LEDs were fabricated.

For series A devices (covering the high group III flux range), a single electroluminescence peak was observed, which was red-shifted from 323 nm under III/V>1 conditions to 348 nm under III/V>>1 growth, while the intensity of the peak increased by nearly 30 times. Furthermore, the droop, that is the reduction of peak intensity with increased injection currents reduced significantly for the samples grown under III/V>>1 conditions.

These results can be attributed to the presence of in-plane compositional inhomogeneities in the active region material. For growth under excess group III conditions, a thin metallic film of Ga always remains on top of the growth surface. The Al atoms are incorporated in this film, and subsequent reaction with plasma nitrogen results in the formation of AlGaN. As the metallic film consists of an inhomogeneous mixture of Al and Ga, the resulting AlGaN film possesses nano-scale fluctuations in the composition. Under conditions of III/V>>1, deep level fluctuations are formed within the AlGaN alloy, that give rise to single red-shifted peaks. These fluctuations are spatially dense, inhibiting the carriers from travelling to non-radiative recombination sites and thus reducing the probability of current droop in the devices.

For series B devices (covering the near-stoichiometric growth regime), however, clear dual-wavelength behavior was observed with two peaks at around 330 nm (P1) and 345 nm (P2). Interestingly, switching between these two peaks was observed when the duty cycle of the excitation was varied from 10% to dc values, without any change in the other excitation parameters. In this series, other devices grown under slightly different deposition conditions indicated a switching between 310 nm and 350 nm.

Under conditions of near-stoichiometry, there is nearly no metallic film on the growth surface. As liquid Ga also acts as a surfactant, the absence of it leads to limited surface adatom mobility, specifically of Al compared to Ga, which eventually result in short range fluctuations in the AlGaN films. These give rise to two peaks of distinctly different wavelengths in the devices of series B. The wavelength-switching phenomenon is due to the difference in thermal dissociation of excitons in fluctuations of different energy depths which was confirmed by carrying out temperature dependent electroluminescence measurements.

We conclude that the emission parameters are influenced by change in growth conditions, specifically the group III/V flux ratio, generating not only single-peak LEDs that displayed significantly reduced droop but also switchable dual wavelength LEDs.

10:20 AM EL04.16.09
Effect of Copper Doping on Zinc Oxide and the Potential for Nanowire Devices Sazzad Hussain and Larry R. Carley; Carnegie Mellon University, United States

While silicon continues to dominate the semiconductor landscape, other materials have shown significant promise in conventional field-effect transistor (FET) devices as well as in optoelectronics and flexible electronics regime, zinc oxide (ZnO) being one of them. The doping of ZnO to generate carriers and consequently, designing devices of interest are active areas of research with several materials touted as possible dopants. In particular, much effort has gone into finding a reliable acceptor doping scheme as it has proven to be complicated to develop p-doped ZnO preventing the widespread use of it in certain applications. The goal of this study is to find the effects of copper (Cu) substitutional doping on ZnO using quantum mechanical computational models namely density functional theory (DFT) in conjunction with semi-empirical tight-binding extended Hückel method and non-equilibrium Green's function (NEGF). DFT is used for material property determination whereas the semi-empirical model is used for device simulations which provides some key advantages over DFT in the context of this study including a reasonable simulation time for a system with a large number of atoms as is the case with most electronic devices.

Analyses of how selectively supplanting zinc (Zn) with copper (Cu) impacts the electronic properties of the resultant structure and if the alterations can be leveraged to construct nanowire FET devices are performed. The density of states and carrier concentration calculations reveal that Cu doping of ZnO leads to p-type characteristics in the semiconductor. A massive increase in hole concentration to the order of 10^{18} cm^{-3} takes place after the addition of copper. The resultant structure is then used to build junctionless nanowire metal-oxide-semiconductor field-effect transistors (MOSFETs). The choice of the junctionless variant of the MOSFET is driven by its robust performance in the short-channel domain and fabrication simplicity. The nanoscale device exhibits excellent figures of merit including an on-current (I_{on}) of more than 500 μA/μm and an on-current to off-current ratio (I_{on}/I_{off}) of greater than 5×10^6 for certain configurations. In addition, several parameters like source/drain underlap length and work function of the gate material among others are varied, and guidelines are presented on optimization concerning I_{on}/I_{off}, I_{on}, and subthreshold swing (SS). The effects of different dielectric materials on the device performance are also studied. It is found that the use of high-κ dielectrics like hafnium oxide (HfO_2) can significantly improve the performance of the device. Furthermore, the merits and challenges of the modeling approach are discussed.

10:35 AM EL04.16.10
Comparative Studies on the Structural, Electrical and Optical Properties of Single-Doped (Al) and Co-Doped (Al/B, Al/In, Al/Gd) ZnO Films deposited by Sol-Gel Angel R. Torres Duarte, Humberto Arizpe-Chavez, Temistocles Mendivil-Reynoso and Roberto Mora-Monroy; Universidad de Sonora, Mexico

We investigated the effects of various doping concentrations on the structural, electrical, and optical properties of ZnO films single-doped with Aluminium and co-doped with Al/In, Al/B, and Al/Gd. The purpose of this study is to explore the role of Aluminium as a dopant in the lattice of ZnO. The films were deposited on glass substracts by dip coating in sol-gel solutions. The doping concentration levels were 4, 8, and 12 %. Zinc acetate dihydrated with a constant molar concentration of 0.5 M was used as a precursor. Absolute Ethanol and Diethanolamine were used as solvent and stabilizing agents respectively co-doping was prepared in an equimolar manner. The films annealed at 500 °C, were characterized by X-ray diffraction (XRD), UV-Vis-NIR spectroscopy, Atomic Force Microscopy (AFM), Scanning Electron Microscopy (SEM), and X-ray photoelectron spectroscopy (XPS). Resistivity was measured with the four-point probe method. The results revealed the formation of a nanostructured hexagonal (wurtzite) ZnO structure with no preferred orientation. The crystallite sizes decrease with the increase of dopant levels, in a general trend. Small variations in the calculated lattice parameters were attributed to the differences in the ionic radii of Zn^{2+} and the dopants. Resistivity results were related with oxygen vacancies and intersitial oxygen defects present in the high-doped samples. A red shift of the band gaps was discussed in terms of the doping levels and the Bursten-Moss effect. Also, the role of traps in the evolution of the optical band gap, was determined by the curves of Ln(Absorbance) and Ln(Absorption coefficient) as a function of the photon energy.

10:40 AM *EL04.16.11
Impact of Interface Chemistry and Crystalline Defects on The Reliability of 4H-SiC MOSFETs Patrick Fiorenza; CNR-IMM, Italy

The growing silicon carbide (4H-SiC) device demand in applications with high reliability constrains (i.e. automotive etc) imposes the scientific community to acquire a deeper comprehension of the physical phenomena affecting the device integrity under prolonged stress, with a particular focus on the impact of the crystalline defects in the semiconductor epitaxial layer. However, threshold voltage (V_{th}) instability phenomena and poor field effect channel mobility (μ_{FE}) are still observed in 4H-SiC MOSFETs, and can be only partially mitigated by post-oxidation (POA) or post-oxide deposition annealing (PDA) processes.
In this context, in this invited talk, some reliability concerns affecting the performances of 4H-SiC MOSFETs are discussed. In particular, the following aspects will be addressed: the SiO_2/SiC interface chemistry and the impact of the device fabrication processes on the MOSFET threshold voltage (V_{th}) stability, and the impact of the semiconductor crystalline defect on the device lifetime.
4H-SiC MOSFETs were characterized by means of current voltage (I_D-V_G) transfer characteristics and capacitance–voltage (C-V) measurements. Furthermore, on selected failed devices, Scanning Transmission Electron Microscopy (STEM) analyses combined to electron energy loss spectroscopy (EELS), and electrical Scanning Probe Microscopy (SPM) analyses have been used to elucidate the physical mechanisms affecting their reliability.
An important aspect is related the breakdown of 4H-SiC MOSFETs correlated to the presence of different crystalline defects in the 4H-SiC epitaxial layer. Of particular interest are the wafer level characterization of both the failed devices at t=0s, and of the devices showing an anomalous Fowler-Nordheim (FN) gate bias conduction. In fact, it is possible to correlate devices failing under high temperature gate bias (HTGB) stress with the presence of an anomalous FN behavior and the presence of a surface bump on the semiconductor. Moreover, the role of the threading dislocation (TD) in high temperature reverse bias (HTRB) failures was demonstrated employing high-resolution SPM techniques. These nanoscale methods elucidated the physical mechanism of the dielectric breakdown, revealing an increase of the minority carrier concentration close the insulator/semiconductor interface.Furthermore, a method to monitor the V_{th} variation from single point drain current (I_D) measurement using a single gate bias (V_{read}) value is presented. This method allowed to probe the interface states close to the 4H-SiC conduction and valence band edges and the amount of trapped charge at the interface close to 4H-SiC band

edges (N_{it}) an inside the near interface oxide region (NIOTs).
These finding demonstrated that the threshold voltage instability of 4H-SiC MOSFETs, associated to different trapping mechanisms, is directly related to the SiO_2/SiC interface chemistry and can be mitigated by an accurate control of the nitridation conditions of deposited oxides.

First Principale Calculation of Resistive Switching in ZnO Satyasiban Dash and Prahallad Padhan; Indian Institute of Technology, Madras, India

The resistance of the metal oxides under external bias has been observed to show brain-like synapses. Switching of resistance forms the base criterion for realizing stable neuromorphic electronic devices. Resistive switching involves the alternative change of resistance with the applied external bias. With a suitable metal-metal oxide-metal configuration, it is possible to create Resistive-Random Access Memories (ReRAMs). Unlike conventional RAMs, the RERAMs are characterized by faster switching time, low power consumption and enhanced stability. Under the condition of ON state, i.e., low resistance state, a conductive filament formed in the oxide layer due to segregation of oxygen vacancy or metal ions. In the case of the OFF state, this filament gets ruptured, leading to a high resistive state. Several metal oxides, like TiO2, HfO2, SrTiO3, ZnO, etc., have shown this behaviour. The physical nature, electrical properties, and morphology of conductive filament formation have been studied through various in-situ and ex-situ techniques like transport measurement, transmission electron microscopy, x-ray photoelectron spectroscopy, and atomic force microscopy. However, the nature of electron distribution and subsequent contribution from other orbital remains tricky. In this regard, we have explored the resistive switching phenomena of ZnO on the basis of charge injection and charge removal using density functional theory. In the case of ZnO, the oxygen vacancy migration and subsequent charge transfer occur through the conductive filament. Oxygen vacancies can exist in three different states , , and with two, one and zero electron, respectively. The band structure clearly shows that these oxygen vacancies act as a deep donor. The appeared near the VBM and was found to be stable at higher energy than and . When an electron from is removed, it forms state, a metastable paramagnetic and unstable state, but upon removing the other electron, the state is very stable. The formation energy of both and is less comparable to state thus, oxygen vacancy acts as a negative U-centre point defect. For the state, the four Zn nearest neighbours are displaced inward by 12 % of the equilibrium Zn–O bond length, whereas for the and states, the displacements are outward by 2 % and 23 %, respectively. In order to mimic the conductive filament, vacancies are created along [010] direction, and rupture is replicated by replacing a vacancy with oxygen. Electron localisation and band decomposed charge density calculations have confirmed the observation of conductive filament. A better understanding of the nature of resistive switching will help in the development of ReRAMs and neuromorphic electronic devices.

Will 2D Materials Play a Role in The Semiconductor Industry? Eric Pop; Stanford University, United States

This talk will present my (biased) perspective on whether two-dimensional (2D) materials could play a role in the semiconductor industry. It is important to recognize that 2D materials are good for applications where their ultrathin nature gives them distinct advantages, such as flexible electronics [1] or light-weight solar cells [2]. They may not be good where conventional materials work sufficiently well, like transistors thicker than a few nanometers. I will focus on 2D materials for 3D heterogeneous integration of electronics, which has major advantages for energy-efficient computing [3]. Here, 2D materials could be monolayer transistors with ultralow leakage [4] (due to larger band gaps than silicon), used to access high-density memory [5]. Recent results from our group [6,7] and others [8] have shown monolayer transistors with good performance, which cannot be achieved with sub-nanometer thin conventional semiconductors, and the 2D performance could be further boosted by strain [9]. I will also describe some unconventional applications, using 2D materials as thermal insulators [10], heat spreaders [11], and thermal transistors [12]. These could enable control of heat in "thermal circuits" analogous with electrical circuits. Combined, these studies reveal fundamental limits and some key applications of 2D materials, which take advantage of their unique properties. **Refs: [1]** A. Daus et al., Nat. 11:15 AM EL05.01.02
Advancements in 2D Semiconductor CMOS: Length Scaling, Gate Dielectric, Doping Engineering and Machine Learning Co-Optimization Hao-Yu Lan[1], Yi Wan[2], Chih-Pin Lin[1,3], Chin-Cheng Chiang[1], Tuo-Hung Hou[3], Lain-Jong Li[2], Joerg Appenzeller[1] and Zhihong Chen[1]; [1]Birck Nanotechnology Center, Purdue University, United States; [2]The University of Hong Kong, Hong Kong; [3]National Yang Ming Chiao Tung University, Taiwan

This research presents recent advancements in 2D Transition Metal Dichalcogenides (TMD) Ribbon Field-Effect Transistors (RibbonFETs) as potential successors to Silicon RibbonFETs. These advancements include the scalable fabrication of ultra-narrow TMD nanoribbons, as narrow as 30 nm, leading to an impressive on-current I_{ON} of approximately 700 µA/µm at V_{DS}= 1 V. The improved electrostatics and heat distribution contribute to a significant 40% enhancement in both on-state and off-state performance. In terms of dielectric interface engineering for monolayer MoS_2 (1L-MoS_2) FETs, the integration of a high-κ TaO_x interfacial layer reduces active interface trap states and acts as an effective doping layer. This results in a superior I_{ON} of 861 µA/µm at V_{DS}= 1.5 V and reduced contact resistance (R_C) of 230 Ω µm. Dual-gate (DG) FETs achieve subthreshold swing (*SS*) values of approximately 70 mV/dec. Despite its small bandgap, hexagonal boron nitride (hBN) serves as a passivation and crystalline interfacial layer, improving device reliability and achieving an ideal *SS* of 62 mV/dec. The study also addresses reliability concerns of 1L-MoS_2 FETs on thin high-κ HfO_2, indicating that optimized ALD processes can ensure notable stability. Furthermore, the study introduces a novel nitric oxide (NO) doping approach for monolayer tungsten diselenide (1L-WSe_2) transistors, addressing issues with high-resistive metal contact and threshold voltage. This molecular doping technique enables unipolar p-type transport and reduces Schottky barrier, resulting in a record-low R_C of 875 Ω µm, the highest transconductance (g_m) of 400 µS/µm, and the lowest *SS* of 90 mV/dec. Additionally, a hybrid p-doping strategy combining tungsten oxide (WO_x) charge transfer with NO molecular doping achieves record-high I_{ON} and g_m while maintaining intrinsic channel properties. To improve the performance of 2D transistors, we propose a design and process co-optimization framework using Machine Learning (ML), similar to conventional Design of Experiments (DOE) for process optimization. Overall, these findings highlight significant progress in 2D semiconductor CMOS transistors, with a focus on length scaling, gate dielectrics, innovative p-doping techniques, and Machine Learning Co-Optimization.

Monolayer WSe_2 Nanoribbon Transistors with WO_x Passivated Edges Sihan Chen, Yue Zhang, William P. King, Arend M. van der Zande and Rashid Bashir; University of Illinois at Urbana-Champaign, United States

Two-dimensional (2D) semiconductors like transition metal dichalcogenides (TMDs) such as MoS_2 and WSe_2, have demonstrated record-high electron and hole mobility values with sub-nm body thicknesses,[1,2] showing great promise to sustain the transistor scaling trend beyond silicon complementary metal–oxide–semiconductor (CMOS) technologies. Since front-end silicon transistors are moving to a gate-all-around nanoribbon architecture, TMDs will adopt a similar stacked nanoribbon geometry to be competitive.[3] However, as the channel width approaches sub-100 nm, the effects of edge states of the nanoribbon channel become pronounced, limiting the carrier mobility of TMD nanoribbons.[4] The edge states must be passivated to fabricate high-performance, ultra-scaled TMD transistors.[5]

This work demonstrates a facile edge passivation method that significantly reduces edge disorders and enhances the electrical performance of p-type monolayer WSe_2 nanoribbon field-effect transistors (FETs). We achieved this by fabricating monolayer WSe_2 nanoribbon transistors with WO_x passivated edges. The process involved using nanolithography to deposit polymer masks on prefabricated microribbon transistors, followed by a controlled remote O_2 plasma treatment. To avoid device-to-device variation, we sequentially fabricated and measured two types of nanoribbons on the same devices – passivated-edge nanoribbons and open-edge nanoribbons, with a width ranging from 50 nm to 70 nm. Open-edge nanoribbons are the nanoribbons with dangling bonds at the edges, whereas passivated-edge nanoribbons are the nanoribbons with edge atoms covalently bonded to WO_x. Compared to the open-edge nanoribbon FETs, the passivated-edge nanoribbon FETs increased the maximum current by 7–120 times, improved field-effect mobility by 6–24 times and decreased subthreshold swing by an average of 38±9 %. Hole doping induced by edge-bound WO_x was ~1×10^{12} cm^{-2}.The enhanced electrical performance in passivated-edge nanoribbon FETs primarily results from reduced disorders by eliminating dangling bonds, rather than the doping effect from WO_x at the edges. Here we report, for the first time, a working p-type transistor from TMD monolayers with a channel width smaller than 100 nm. Owing to its simplicity and robustness, this edge passivation method holds the potential to become a turnkey manufacturing solution for large-scale integration of high-performance, ultra-scaled WSe_2 p-FETs into commercial silicon foundries.

11:45 AM EL05.01.04
Enhancing Carrier Mobility with Process Induced Strain in Monolayer MoS_2 Transistors Kevin Zhao, Yue Zhang and Arend M. van der Zande; University of Illinois at Urbana-Champaign, United States

Two-dimensional materials are a promising candidate for future non-silicon electronics based in the "More Moore" development path, owing to their ability to circumvent many fundamental challenges hindering the continued scaling of current silicon-based technologies. Using atomically-thin channels strongly suppresses undesirable short channel effects such as drain-induced barrier-lowering and body punchthrough. However, there are important knowledge gaps in how thin film deposition materials and processes impact 2D materials properties, leading to enormous variability in reported device performance metrics. Understanding these interactions has practical implications on improving not just the reliabililty but also enhancing the performance of 2D transistors. Analogously, one of the many commercially implemented performance enhancement techniques in CMOS is the deposition of high stress capping layers, which increase the carrier mobilities of NMOS and PMOS transistors. The key question is how thin film deposition will impact doping and strain in 2D materials, and how to unravel their relative effects. Here, we systematically quantify the effects of thin film processed induced strain on the carrier mobility of monolayer MoS_2 transistors. To achieve this, we encapsulate the monolayer MoS_2 transistors under a HfO_2 barrier layer via atomic layer deposition before using E-beam evaporation to sequentially deposit MgO films on the same set of devices, while measuring the Raman spectra and transport between each deposition. The evaporated MgO film has a built-in internal compressive stress, which applies a tensile strain to the underlying transistor channel. This approach both maximizes data consistency by removing sample-to-sample variation.

We use vector decomposition on the Raman peak shifts in the channel to unravel the relative strain and doping induced by the film deposition. We found a systematic shift in the strain as a function of MgO thickness reaching a value of 0.45% at 150 nm. The initial deposition of MgO created a doping shift of $3\times10^{12}/cm^2$. The addition of the HfO_2 barrier suppressed further doping fluctuations to under $1\times10^{12}/cm^2$. Raman mapping confirmed the uniformity of channel strain for up to 150 nm of MgO, at which point we observe slip induced nonuniformities in the strain distribution. We measured the transfer and output characteristics of the MoS_2 transistor as a function of film thickness. Under 0.45% tensile strain, the MoS_2 transistors exhibit a electron mobility enhancement of 40%, a saturation current enhancement of 45%, and a -15 V shift in the threshold voltage. This yields the rate of mobility enhancement of n-type MoS_2 to be 90% per percent of biaxial strain.

We are now extending this experiment to p-type transition metal dichalcogenide transistors as well as compressive strains, to fully realize strain-enhanced two-dimensional CMOS logic. We are applying the Transfer Length Method to systematically isolate the relative impact of contact resistances versus channel conductivity on transistor performance. These results form a critical foundation for the design and characterization of commercialized high-speed two-dimensional integrated electronics, using existing thin-film deposition technologies in industry.

Heterogeneous and Monolithic 3D Integration of 2D Materials-Based Devices for Future Computing Jinfeng Leong, Baoshan Tang, Maheswari Sivan, Jianan Li, Evgeny Zamburg and Aaron Thean; National University of Singapore, Singapore

The inherent limitation of silicon-based complementary metal oxide semiconductors (CMOS) has placed constraints on the continuous performance enhancement of integrated circuits through dimension scaling. Monolithic three-dimensional (M3D) integration, which involves the stacking of devices on top of conventional silicon chips, offers promising avenues for enhancing system performance [1]. Integration of silicon-based CMOS transistors above the metal interconnect layers for massive M3D circuits compromises the devices and interconnect wires due to the high process thermal budget, necessitating exploration for low-thermal budget solutions beyond silicon. This presentation outlines our recent research efforts to explore high throughput, solution-processable 2DM compatible with semiconductor CMOS chip process technology capable of low-thermal budget heterogeneous integration. Specifically, we showed that analog memories formed from a composite stack of liquid-exfoliated MoS2 flakes can attain superior resistive memory switching performance relative to both single-layer 2DM-based and oxide-based devices [3]. These solution-processed MoS2 analog memories can be formed under low-thermal budgets and have been demonstrated on a wafer-level for the realization of M3D in-memory computing. Moreover, these MoS2 nalog memories can also be heterogeneously integrated with photonic neural networks to address the challenges of implementing non-linear activation functions in photonic neurons [4]. To tackle the limitations of materials and device engineering, we will also discuss system architecture-device-materials co-design strategies [4,5] to enhance overall on-chip computational functionality.

Semiconductor Industry Progress on 2D TMD Transistors and Challenges Ahead Kevin P. OBrien; Intel - Components Research, United States

The key question is, can any material replace Silicon transistors and why would you. Both the academic and industrial communities have proposed two-dimensional (2D) transition metal dichalcogenide (TMD) semiconductors as a future option to beat silicon transistors at sub-10nm physical gate lengths. In this talk, we highlight what TMD transistors need to meet in terms of performance and architecture. In addition, we share the recent progress in the fabrication of complementary metal-oxide-semiconductor (CMOS) devices based on stacked 2D TMD nanoribbons. We will specifically highlight issues

that need to be resolved by the 2D community in five crucial research areas: contacts, channel growth, gate oxide, variability, and doping. While 2D TMD transistors have great potential, more research is needed to understand the physical interactions of 2D materials at the atomic scale.

Short Top-Gate Length in 2D p-FETs achieved via Van der Waals Integration Min Sup Choi[1], Tien Dat Ngo[2], Tuyen Huynh[2] and Won Jong Yoo[2]; [1]Chungnam National University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

The lack of high-performance p-type field effect transistors (p-FETs) is impeding the potential of 2D materials in upcoming CMOS technology. One potential solution to this challenge is the use of a top-gate (TG) structure with a p-doped spacer area.[1-3] However, designing and processing the device to create gate stacks presents significant obstacles in realizing ideal p-FETs and PMOS inverters. In this research, we propose a novel method for achieving high-performance lateral $p^+ – p – p^+$ junction WSe_2 FETs with controlled TG length. Our approach involves the integration of self-aligned TG stacks through van der Waals (vdW) integration, followed by oxygen plasma doping in the contact spacer regions. Unlike traditional techniques, we demonstrate effective electrostatic control of 2D p-FETs by implementing the TG stacks. The use of self-aligned TG as a doping mask yields a high on-off current ratio of $>10^7$, a small subthreshold swing (SS) of 98 mV dec^{-1}, and a nearly zero threshold voltage (V_{th}) in WSe_2 p-FETs. Scaling down the TG length to 300 nm results in a high on-state current of approximately 100 µA $µm^{-1}$, preserving on/off ratio of 10^4. Additionally, we validate the effectiveness of our method by demonstrating a PMOS inverter with a remarkably low power consumption of ~4.5 nW.

3:15 PM EL05.03.01
Atomic Force Microscopy for Routine, Fast and Reliable Defect Quantification in 2D Materials Kaikui Xu[1], Madisen Holbrook[2], Yucheng Yang[1], Luke N. Holtzman[2], Kristyna Yang[1], Abhay Pasupathy[2], Katayun Barmak[2], James Hone[2] and Matthew R. Rosenberger[1]; [1]University of Notre Dame, United States; [2]Columbia University, United States

Routine defect characterization is a critical capability for understanding defect-property correlations and optimizing growth of two-dimensional (2D) materials. High throughput optical methods for defect characterization, such as Raman spectroscopy, are useful for graphene, but are insufficiently sensitive to defects in some other 2D materials, such as transition metal dichalcogenides (TMDs), particularly for defect densities of about 10^{12} cm^{-2} or less. Typical methods for directly detecting defects at the atomic scale, such as scanning transmission electron microscopy (STEM) and scanning tunneling microscopy (STM), are effective, but they are slow and often require arduous sample preparation. There is a need for 2D material defect characterization techniques that are routine, fast, and reliable. Here, we demonstrate two atomic force microscopy (AFM)-based techniques for locating and quantifying atomic-scale defects in 2D materials. First, we show that conductive AFM can locate and differentiate the same defects as STM by comparing conductive AFM and STM on the same region of a TMD crystal[1]. Our work establishes conductive AFM as a higher-throughput alternative to STM for defect quantification. Second, we show that lateral force microscopy (LFM) can locate atomic-scale defects through a direct comparison of LFM with conductive AFM on a TMD crystal[2]. Importantly, we show that LFM can also identify atomic-scale defects in insulators, such as hexagonal boron nitride, because LFM is a purely mechanical technique. The AFM-based methods presented here enable routine defect characterization, which will facilitate rapid investigations of defect-property relationships and speed up the development of new growth processes.

3:30 PM EL05.03.02
Overcoming Negative nFET V_{TH} in Ultra-Thin ITO-IGZO Hetero-Oxide Channel FET by Defect-Compensation to Achieve Record Mobility Sonu Devi, Chen Chun-Kuei, Manohar Lal, Evgeny Zamburg and Aaron Thean; National University of Singapore, Singapore

In this work, we have successfully demonstrated, low-thermal budget amorphous oxide-based field effect transistor (FETs) with a record ON-current ($I_{D, Max}$) of 790 µA/µm at V_{DS}=1V. This device shows an enhancement-mode operation (V_{TH}>0), sub-threshold slope (S.S.) <90 mV/dec., and DIBL ~20mV/V at an ultra-scaled channel length (L_{CH}) of 50 nm. The FETs have been fabricated at low-temperature (<350°C) combining sputter deposition (channel layer) and atomic layer deposition (gate insulator HfO_2), making this fabrication approach compatible with low-thermal budget Cu interconnects for back-end-of-line (BEOL). In pure ITO channel, ON-current increases with channel thickness but the V_{TH} become progressively negative and the SS is degraded. However, in hetero-junction channel, the performance of our FET is comparable to emerging two-dimensional materials and superior to that of existing metal oxides. The high performance is enabled by interfacial channel defect self-compensation in an optimized InSnOx-InGaZnOx (ITO-IGZO) hetero-junction channel. Moreover, this approach overcame the fundamental issue of negative V_{TH} seen in n-type oxide FETs due to donor-type channel oxygen vacancy (Vo) and the limited tunability of gate metal work function. Through our ITO-IGZO channel and defect self-compensation approach, our transistor effective mobility (μ_{eff}) is boosted to 110 cm^2/Vs which is independent of the channel thickness (T_{CH}) when the T_{CH} is scaled down to 4 nm. This unique T_{CH}-independent mobility behaviour is not observed for IGZO or ITO mono-channel FETs. With such enhancement, our ITO-IGZO FETs exhibit the best-in-class mobility among oxide-based FETs, and are competitive to unstrained Silicon thin film and SOI FETs, while being compatible with sub-400 °C BEOL processes.

3:45 PM EL05.03.03
Er_2O_3 Top Gate MoS_2 FET with EOT Lower than 1 nm Shuhong Li, Tomonori Nishimura, Kaito Kanahashi and Kosuke Nagashio; University of Tokyo, Japan

Two-dimensional (2D) molybdenum disulfide (MoS_2) has emerged as a promising channel material for the next generation of electronics, offering a solution to the scaling limitations of silicon due to its atomic thinness and the maintained mobility the layered structure brings. To achieve effective gate control of MoS_2-based field-effect transistors (FETs) while meeting scaling requirements, the integration of high dielectric (high-k) oxides onto the MoS_2 surface is essential. However, the absence of dangling bonds at the MoS_2 surface significantly hinders conventional atomic layer deposition (ALD) method for high-k oxides, which relies on an active surface as a nucleation site. Alternative techniques, like van der Waals integration, are considered as ideal for minimizing interface traps between the insulator and the MoS_2 channel. Nonetheless, both the choice of materials and the integration mechanisms are requiring further investigation from the viewpoint of real application. The judicious selection of materials and suitable integration methods is, therefore, of paramount importance for the prospective application of MoS_2 FETs in the future.
While the thermal evaporation method is widely employed for thin film fabrication, the thermal evaporation of high-k materials faces a significant challenge due to their exceptionally high melting points, often exceeding 2000°C. This makes it nearly impossible to attain the desired partial pressure for deposition. Instead, the evaporation of a metal, followed by subsequent oxidation to form high-k oxides, offers a potential solution. Herein, erbium (Er), with its oxidation product Er_2O_3, was selected as the high-k material based on a well-designed differential partial pressure system, allowing for the separated evaporation and oxidation by meticulously controlling the vapor pressure of the Er source and the partial pressure of the oxygen supply. As the result, extremely low deposition rate of approximately 0.16 Å/s was achieved. This low deposition rate is expected to have minimal impact on the intrinsic properties of the MoS_2 surface. Furthermore, the thickness of the deposited Er_2O_3 can be precisely controlled by adjusting the deposition time, offering the possibility of reducing the equivalent oxide thickness (EOT).
In this study, a dual-gated MoS_2 FET with a 3.5 nm Er_2O_3 stack was fabricated using the differential partial pressure deposition system. The top gate capacitance was evaluated through I-V characteristics, utilizing a sweep of both top gate voltage and back gate voltage. The results revealed negligible threshold shifts and on/off switching within a 1 V range, confirming a high top-gate capacitance with k = ~13, resulting in an EOT of 0.94 nm. Low-temperature photoluminescence (LT-PL) and Raman characterizations indicated a lack of defect-bound exciton response, as well as no significant Raman peak shift or broadening, suggesting that the high-k deposition is non-destructive.
Moreover, the stability of Er_2O_3 and the electrical reliability of the Er_2O_3/MoS_2 gate stack were investigated over an extended period, up to 100 days. Although the reduction of the dielectric constant was observed for the Er_2O_3/MoS_2 stack, the Er_2O_3/SiO_2 stack exhibited no reduction in dielectric constant over the same duration, suggesting that stability concerns were attributed to the MoS_2 surface rather than the high-k Er_2O_3. On the contrary, the interface properties, as exemplified by the subthreshold swings (S.S.), were improved over time, which may be attributed to the relaxation of strain introduced during the high-k deposition process. These findings regarding the degradation of bulk property (k) and the enhancement of S.S. over time highlight that improving the initial interface quality between high-k materials and 2D materials will lead to enhanced bulk properties.

4:00 PM EL05.03.04
A High-κ Wide-Gap Layered Dielectric for Two-Dimensional Van der Waals Heterostructures Aljoscha Söll[1], Edoardo Lopriore[2,2], Asmund Ottesen[2,2], Jan Luxa[1], Gabriele Pasquale[2,2], Jiri Sturala[1], František Hájek[3], Vítězslav Jarý[3], David Sedmidubský[1], Kseniia Mosina[1], Andras Kis[2,2] and Zdenek Sofer[1]; [1]University of Chemistry and Technology, Prague, Czechia; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]Institute of Physics of the Czech Academy of Sciences, v.v.i., Czechia

Van der Waals heterostructures of two-dimensional materials have opened up new frontiers in condensed matter physics, unlocking unexplored possibilities in electronic and photonic device applications. However, the investigation of wide-gap high-κ layered dielectrics for devices based on van der Waals structures has been relatively limited. In this work, we demonstrate an easily reproducible synthesis method for the rare earth oxyhalide LaOBr, and we exfoliate it as a 2D layered material with a measured static out-of-plane dielectric constant of 9 and a wide bandgap of 5.3 eV. Furthermore, our research demonstrates that LaOBr can be used as a high-κ dielectric in van der Waals field-effect transistors with high performance and low interface defect concentrations. Additionally, it proves to be an attractive choice for electrical gating in excitonic devices based on 2D materials. Our work demonstrates the versatile realization and functionality of 2D systems with wide-gap and high-κ van der Waals dielectric environments.

4:15 PM EL05.03.05
Effects of High-k Dielectric Encapsulation and Carrier Density on Raman Scattering in Synthetic Monolayer WS_2 Jerry A. Yang, Lauren Hoang, Tara Pena, Zhepeng Zhang, Andrew J. Mannix and Eric Pop; Stanford University, United States

Two-dimensional (2D) semiconductors have gained significant interest due to their atomically thin structure, theoretically pristine van der Waals interfaces, good carrier mobility, and potential utility for future opto-electronics. Among 2D semiconductors, tungsten disulfide, WS_2 is particularly interesting, as it can exhibit electronic ambipolarity at monolayer and bilayer thicknesses [1].

Raman spectroscopy is a fast, non-destructive characterization technique that enables rapid, large-area analysis of 2D semiconductors. Previous work has utilized Raman spectroscopy to quantify the strain and carrier density in monolayer MoS_2 [2], as well as evaluate the damage induced in MoS_2 from metal deposition [3]. However, these characterization techniques have not been experimentally examined in WS_2, which features different Raman signatures from MoS_2.

Here, we investigate the effects of dielectric environment and carrier density on the Raman spectrum of WS_2. We start with three samples of monolayer WS_2 grown by chemical vapor deposition, one on SiO_2/Si and the others on sapphire. We then transfer the two sapphire samples onto 125-µm thick polyethylene naphthalate (PEN) containing a patterned high-k/metal-gate stack as described in [4]. We encapsulate the as-grown SiO_2/Si sample and one PEN sample with a 1.5 nm Al seed layer + 10 nm Al_2O_3 [4], then the final PEN sample with 1 nm Si seed layer + 10 nm Al_2O_3 [5].

We find that, of the primary peaks in the WS_2 Raman spectrum, the 2LA(M) peak at ~350 cm^{-1} is the most sensitive to encapsulation. The as-grown, unencapsulated WS_2 on SiO_2 sample exhibited a 2LA(M) peak position ~3.2 ± 0.3 cm^{-1} higher than the transferred, unencapsulated WS_2 on Al_2O_3 back-gate sample. After encapsulation with the Al+Al_2O_3 layer, the 2LA(M) peak in the SiO_2 sample redshifts by an additional ~1.0 ± 0.4 cm^{-1} while that of the Al_2O_3 sample redshifts by ~4.5 ± 0.5 cm^{-1}. We also find a 2× stronger red-shift for the 2LA(M) peak in the Si seed sample (~8.1 ± 0.8 cm^{-1}) than in the Al seed encapsulation sample. This indicates that the 2LA(M) peak may be useful as an optical marker for interfacial quality. In comparison, the first-order E' and A' peaks shift by less than 1.5 ± 0.5 cm^{-1} across all samples.

We also perform *in situ* Raman measurements as a function of carrier density in the same back-gated WS_2 structure. We find that the 2LA(M) peak red-shifts by 0.44 ± 0.06 cm^{-1}/V and the A' peak red-shifts by 0.24 ± 0.03 cm^{-1}/V, while the E' peak does not shift substantially. With a ~350 nF/cm^2 Al_2O_3 gate oxide capacitance, these shift rates correlate to ~0.19 ± 0.01 cm^{-1} per 10^{12} cm^{-2} carriers for the 2LA(M) peak and ~0.1 ± 0.05 cm^{-1} per 10^{12} cm^{-2} carriers for the A' peak. This study is the first measurement of the carrier density-dependent Raman spectra of WS_2 without ionic liquid gating, which

provides a better benchmark relative to the intrinsic carrier density of WS_2 compared with previous work [6].

Our results advance Raman spectroscopy for 2D materials in two ways: first, they extend previous studies on spectroscopic carrier density measurements to near-intrinsic carrier densities, and second, they showcase the utility of Raman spectroscopy for characterizing interactions between 2D materials and high-k dielectrics for industry-relevant integration. This work was supported in part by a NSF Graduate Fellowship (J.A.Y.), by the Stanford SystemX Alliance, and by the SRC-SUPREME Center.

Enhancing Single Photon Emission (SPE) Purity via Design of Van der Waals Heterostructures Hsun Jen J. Chuang[1], Christopher E. Stevens[2], Matthew R. Rosenberger[3], Sungjoon Lee[4,1], Kathleen M. McCreary[1], Joshua R. Hendrickson[2] and Berend Jonker[1]; [1]Naval Research Laboratory, United States; [2]AFRL, United States; [3]University of Notre Dame, United States; [4]ASEE, United States

Single photon emitters (SPEs), or quantum emitters, are key components in a wide range of nascent quantum-based technologies. A solid-state host offers many advantages for realization of a functional system, but creation and placement of SPEs are difficult to control. We describe here a novel paradigm for encoding strain into 2D materials to create and deterministically place SPEs in arbitrary locations with nanometer-scale precision [1]. We demonstrate the direct writing of SPEs in monolayer WSe_2 using an atomic force microscope nano-indentation process. This quantum calligraphy allows deterministic placement and real time design of arbitrary patterns of SPEs for facile coupling with photonic waveguides, cavities and plasmonic structures. Because monolayer WSe_2 is a direct gap semiconductor, SPE emission at a given wavelength is often intermixed with classical light resulting from conventional excitonic recombination, reducing the purity of the quantum emission as quantified by the second order autocorrelation function $g^{(2)}(t=0)$. We show that this undesirable classical emission, arising primarily from defect bound excitonic processes, can be significantly suppressed by electrostatic gating [2] or incorporating the WSe_2 layer in a simple van der Waals heterostructure [3]. Suppression of this classical emission allows a more accurate assessment of the quantum emission character, and results in values of $g^{(2)}$ as low as 0.07 at low temperature. In addition, the SPE intensity at a given wavelength can be strongly modulated by changing the polarity of the gate bias, a feature of technological importance for practical applications. Initial results for SPEs in hBN will also be summarized, time permitting.

Room-Temperature Direct Growth of Transition Metal Dichalcogenide Films via Remote Plasma-Assisted Chemical Vapor Deposition Jina Lee[1], Seok Joon Yun[2] and ki kang Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]University of Ulsan, Korea (the Republic of)

Transition metal dichalcogenides (TMDs) have gained significant attention in recent years for their unique electronic and optical properties, making them promising candidates for various applications in electronic and optoelectronic devices. This study presents a novel approach for the room-temperature growth of TMDs materials utilizing a plasma-assisted chemical vapor deposition (plasma-assisted CVD) method. The conventional methods for TMDs synthesis often require high temperatures, limiting their compatibility with certain substrates and device integration processes. The proposed plasma-assisted CVD method aims to overcome these challenges by enabling the growth of high-quality TMDs films at room temperature.
The plasma-assisted approach leverages the advantages of reactive species generated in the plasma, promoting enhanced precursor reactivity and efficient material deposition at lower temperatures. The study investigates the influence of key process parameters, such as precursor gas composition, plasma power, and substrate conditions, on the growth kinetics, crystal quality, and morphology of the TMDs films. Characterization techniques, including scanning electron microscopy (SEM), transmission electron microscopy (TEM) and Raman spectroscopy, are employed to analyze the structural and morphological properties of the synthesized TMDs materials.
The findings highlight the feasibility and efficacy of the room-temperature growth of TMDs using the proposed plasma-assisted CVD method, paving the way for the development of flexible and scalable fabrication processes for TMDs-based devices. The ability to grow TMDs films at lower temperatures expands their compatibility with a broader range of substrates, offering new opportunities for integration into advanced electronic and optoelectronic applications. This research contributes to the ongoing efforts to advance the synthesis techniques of TMDs materials and unlock their full potential for next-generation electronic technologies.

Au Nanoparticle Floating-Gate Memristor Array for Low-Power Neuromorphic System Hongwoon Yun and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)

The von Neumann architecture, which physically separates the CPU and memory devices, has been dominant for a long time. However, it has limitation in computational speed due to bottlenecks and waste a large amount of energy. To address the energy and speed issue, we made a neuromorphic system based on au nanoparticle floating gate memristor (AuNp-FGM).

Our memristor, utilizing graphene as floating gate, MoS_2 as channel, have been recognized for its excellent performance [1,2]. Also, it has been recognized as one of the most promising candidates for neuromorphic system [3]. In this study, by forming au nanoparticles between floating gate and tunneling oxide, a two-terminal memristor which operates in the ±3V region is fabricated. Additionally, we made a neuromorphic array, calculated the energy used for learning simulation.
Using the change of the Fermi energy level (E_f) of graphene, (AuNp-FGM) exhibits memory characteristic. The device exhibits high on/off ratio over than 10^6, retention more than 9 hours and robust endurance more than 80,000 times. AuNp-FGM also showed low cycle to cycle variability of C_v = 3.6% (n = 90, C_v = , = standard deviation, = mean value). Furthermore, it showed excellent linearity, indicating applicability to neuromorphic systems. For 100 level potentiation (+4V, 0.5s), non-linearity factor ranges from 0.1 to 0.6. For 100 level depression (-3V, 0.2s), it ranges from 2.3 to 4.6 (n = 15). A similar trend was shown even when the number of input pulses was changed (50, 100, 200, 300, 400 inputs).
Based on AuNp-FGM, we fabricated a neuromorphic array consisting of 2 neurons and 32 synapses. Three types of data (horizontal, vertical, diagonal) were used in 40 learning simulation. The total energy consumed was 70uJ, which confirmed to be a 97% energy reduction compared to the previous experiment [3].

5:00 PM EL05.04.04
Multi-Neuron Connection Using Multi-Terminal Floating-Gate Memristor for Unsupervised Learning Mihyang Park and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)

Heterosynaptic plasticity in synapses has been successfully demonstrated by multi-terminal memristor and memtransistor (MT-MEMs)[1,2]. However, these MT-MEMs lack the capability to mimic the membrane potential of neurons in multiple neuronal connections. In this study, we demonstrate a multi-terminal floating-gate memristor (MT-FGMEM) to emulate multi-neuron connections. The variable Fermi level (E_F) in graphene allows the charging and discharging of MT-FGMEM using multiple horizontally spaced electrodes. The MT-FGMEM exhibits a high on/off ratio over 10^5 with a retention time of 1000 seconds, approximately 10,000 times higher than other MT-MEMs. The linear relationship between current (I_D) and floating gate potential (V_{FG}) in the triode region of the MT-FGMEM allows for accurate spike integration at the neuron membrane. The MT-FGMEM fully mimics the temporal and spatial summation of multi-neuron connections, based on the leaky-integrate-and-fire (LIF) functionality. Our artificial neuron consumes significantly less energy, approximately 100,000 times lower (150 pJ), compared to conventional neurons based on silicon integrated circuits (11.7 μJ). By integrating neurons and synapses using MT-FGMEMs, we successfully emulate spiking neurosynaptic training and classification of directional lines in the visual area one (V1), based on the LIF functionality of neurons and the spike-timing-dependent plasticity (STDP) of synapses. We achieved a learning accuracy of 83.08% on the unlabeled MNIST handwritten dataset in unsupervised learning based on our artificial neurons and synapses.

5:00 PM EL05.04.05
Self-Powered Asymmetric-Geometry 2D Diodes for Sensing Volatile Organic Compounds Mirette Fawzy, Amirhossein Hasani, Thushani De Silva, Michael M. adachi and Karen L. Kavanagh; Simon Fraser University, Canada

Volatile Organic Compounds (VOCs) when present in human bodily fluids such as breath, sweat, urine, tears, saliva, and blood, may be regarded as potential indicators for various health conditions and diseases. Thus, the ability to monitor and detect these VOCs can be used as a screening tool to detect diseases in the early stage when treatment options are more effective. In this work, we report the development of photovoltaic, self-powered VOC sensors based on asymmetric-geometry 2D transition-metal, dichalcogenide (TMD) diodes.

Our sensors employ mechanically-exfoliated, multilayer, TMD flakes (In_2Se_3, MoS_2, $MoSe_2$, and WSe_2) as the sensing channel. We exploit the geometric asymmetry of the exfoliated crystals, forming two TMD-metal contacts, of different cross-sectional lengths and areas, but with the same contact metal. This induces a diode, current-voltage characteristic with a large rectification ratio (10^5) presumably due to the 2D nature of the built-in electric field. We have used a similar diode structure for sensing biomolecules (eg. cytokines)[1].

In this work, the sensor diode is either externally biased or self-powered via a photovoltaic response, such that under UV illumination. For example, a MoS_2 device demonstrated an open-circuit voltage (V_{oc}) of 450 mV and a short-circuit current density (J_{sc}) of -1.58 mA/cm^2. Operating under zero applied bias, the same sensor exposed to various VOCs (acetone, ethanol, 2-propanol, butanone, hexane, and water), demonstrated sensitivities comparable to other self-powered VOC sensors (20 - 200 ppm)[2]. The mechanism is via adsorbate charge effects on the magnitude of the surface depletion and diode rectification. A current signal compared to background (responsivity) of > 60 with a response time (typically 10 sec) were measured. These self-powered portable sensors based on a simple 2D diode fabrication, is a promising candidate for a highly sensitive, and low-power, gas monitoring system.

5:00 PM EL05.04.06
Synthesis of Te and Sb Doped Black Phosphorus Single Crystals, Oxidation-Resistance and Room-Temperature Gas Sensing Applications Chih-Ying Huang, Yi-Rong Wang, Ying-Hao Bai, Yi-Syuan Chen, Sin-Pei Wang, Yong-Wei Bai, Yi-Chen Chen, Yu-Jie Shih, Wen-Chieh Hsieh, Yi-Wen Lin, Chia-Yin Cheng, Shang-Jung Wu, Hung-Shuo Chang and Chun-Hua Chen; National Yang Ming Chiao Tung University, Taiwan

Black phosphorus (BP) is another highly potential semiconducting two-dimensional (2D) material after graphene and transition metal dichalcogenides (TMDCs). Its optoelectronic properties depend on the number of layers and the in-plane directions of the BP 2D structure. The optoelectronic properties range from monolayer Phosphorene to bulk BP can just link those of graphene and TMDCs, enabling 2D materials to cover a wide range of optoelectronic properties. Besides, coupled with its unique armchair wrinkled crystal structure, BP has irreplaceable advantages and can be widely used in sensing, optics, electronics, thermoelectrics, and other fields. However, since each phosphorus atom in the BP structure has a lone electron pair, it is easy to spontaneously degrade in the atmospheric environment, which significantly limits its practical application in various fields. So far, many studies have shown that the environmental stability of BP or the performance of BP components can be effectively improved by surface coating, nanostructure modification, or element doping. However, different protection strategies are often accompanied by changes in the essential characteristics of BP, and the causal relationship is still, up to now, not fully clear yet.
In this study, BP crystals were prepared by chemical vapor transport (CVT), and tellurium and antimony were respectively doped in the synthesis process to potentially change the energy band structure of BP and improve its environmental stability. The obtained BP crystals were further exfoliated by

ultrasonic liquid phase exfoliation (LPE). A series of BP nanosheets, tellurium-doped BP nanosheets, and antimony-doped BP nanosheets were prepared in the organic solvent N-methylpyrrolidone (NMP) with a 900-watt ultrasonic wave. Then, BP nanosheets with a specific size distribution are screened by centrifugal rotation speed. Then, various techniques were applied to analyze the degradation degree of these three types of BP nanosheets exposed to a specific atmospheric environment (relative humidity: 75%~90%, temperature: 23~30°C). Finally, these three types of BP nanosheets were respectively placed on the interdigitated substrate for gas sensing. It was found that the highest conversion rate of pure BP, tellurium-doped BP, and antimony-doped BP crystals can reach ~98%. According to x-ray diffraction (XRD), x-ray photoelectron spectroscopy (XPS), Raman spectroscopy, optical microscopy (OM), atomic force probe microscopy (AFM), and transmission electron microscopy (TEM) analysis, it was confirmed that the doping of tellurium or antimony is an effective strategy to improve the environmental stability of BP nanosheets. Finally, the gas sensing results show that among eleven kinds of gases (CH_4, C_2H_6, C_3H_8, NO_2, NO, NH_3, C_2H_5OH, CO, acetone, HCOH, H_2), all the prepared BP nanosheets, tellurium or antimony doped BP nanosheets exhibited highly selective responses to NO_2 and NO at room temperature. In addition, doping of tellurium and antimony could also reduce the response/recovery time to NO_2 and NO.

Novel Technique to Fabricate Thick CNT based Buckypaper for EMI Shielding Applications Syed M. Sajl; Khalifa University, United Arab Emirates

Carbon nanotube thin films are very important for many applications such as radar absorbing materials (RAM), electromagnetic interference shielding (EMI), supercapacitors and lithium-ion battery (LIB). The thickness of individual buckypaper sheet, produced by the film casting technique, often falls within the range of 40-100 µm. This work presents the efforts made in producing exceptionally thick buckypapers by enhancing the film casting technique, with the aim of achieving a thickness exceeding 400 µm. The mechanical and electrical properties of the thick buckypaper is studied. The measurement of EMI Shielding Efficiency (EMI SE) was conducted to determine the corresponding parameters of electromagnetic wave absorption. The thick buckypaper fabricated using the modified SETC process demonstrates considerable potential, displaying improved or equivalent properties. The buckypaper with a thickness of 400 µm had commendable mechanical properties, namely a tensile strength of 70.10 N. Additionally, it demonstrated significant electromagnetic interference (EMI) shielding properties, with an EMI shielding effectiveness (SE) of 86.70 dB.

5:00 PM EL05.04.08
Structural and Physical Properties of Two Distinct Two-Dimensional Lead Halides with Intercalated Cu(II): A Comparative Study Kanika Parashar[1], Zheng Zhang[2], Volodymyr Buturlim[3], Krzysztof Gofryk[3] and Bayram Saparov[1]; [1]University of Oklahoma, United States; [2]Tulane University, United States; [3]Idaho National Laboratory, United States

Transition metal cations intercalated between the two-dimensional (2D) layers of metal halides is a new and distinct category of the metal halides family. In this work we focus the synthesis and property characterizations of two layered hybrid lead halides: **(1)** a new compound $[Cu(O_2C\text{-}CH_2\text{-}NH_2)_2]Pb_2Br_4$ and **(2)** the reported $[Cu(O_2C\text{-}(CH_2)_3\text{-}NH_3)_2]PbBr_4$. These compounds have a 2D layered structure with the intercalated Cu^{2+} metals between the layers, achieved by combining metal halides with zwitterionic amino acids. The incorporation of metal organic cluster consisting of zwitterions and transition metal cation as an interlayer result in improvement of electronic charge transport properties between the layers. Physical properties like magnetization measurements and thermal conductivity have also been studied for both compounds. To gain more insights into their structural and chemical diversity, we explored the solution chemistry for the synthesis of the titled compounds. The fingerprints of formed metal-halide complexes in solution were confirmed by UV−Vis spectroscopy and small-angle X-ray scattering (SAXS) experimental techniques combined with density functional theory (DFT) calculations. Moreover compound (1) showed anisotropic charge transport properties with a good and different semiconductor resistivity measured along the a-axis and along the bc plane, respectively. The fabricated prototype detector showed response to soft low-energy X-rays at 8 keV with a detector sensitivity of 1462.7 $uCGy^{-1}cm^{-2}$, indicating its potential application for ionizing radiation detection.

Van der Waals Interface Engineering for Enhancemen of Semiconductor Device Performance Su-yeon Cho, Do Hyeon Lee and Jun Hong Park; Gyeongsang National University, Korea (the Republic of)

Since the performance of semiconductor devices is highly dependent on charge injection between the metal electrode and the semiconductor channel, it is important to reduce defect density through interfacial engineering at the metal-semiconductor interface. Typically, as metal is directly deposited on the semiconductor surface to form the contact electrode, metal atoms can diffuse into the semiconductor lattice and degrade the charge injection performance. In this study, we propose a method to insert a WSe_2 layer to reduce the defect density at the metal/semiconductor interface. The WSe_2 layer inserted at the metal/semiconductor interface acts as a diffusion barrier to prevent the diffusion of metal atoms into the semiconductor lattice, thereby suppressing structural defects. The metal/WSe_2/Si diode is fabricated by transferring a WSe_2 layer thermally grown on a SiO_2 substrate to a p-type Si substrate by a wet transfer method and then depositing metal electrodes (Ni, Ag, Ti, Cr/Au) onto the WSe_2/Si substrate using an E-Beam evaporator. The C-V (Capacitance-Voltage) characteristics of the diodes confirm that the insertion of the WSe_2 layer induces a low interfacial defect density (D_{it}). Furthermore, the I-V (Current-Voltage) characterization of the diodes shows that the WSe_2 layer not only provides a diffusion barrier but also reduces the leakage current and improves the stability, thereby improving the overall diode performance. In conclusion, the interfacial control method with WSe_2 layer insertion proposed in this work provides a strategy to overcome the challenges of 2D material-based Si semiconductor technology aimed at improving performance and reliability.

5:00 PM EL05.04.10
Monolayer MoS_2 with Controllable and Localized Micro-Scale Domains of Strain enabled by Spatially Varying Nanotopography Boran Kumral, Peter Serles, Akshat Rastogi, Pedro G. Demingos, Akhil Nair, Nima Barri, Cristina Amon, Chandra Veer Singh and Tobin Filleter; University of Toronto, Canada

The remarkable strain limit of two-dimensional (2D) materials as a result of strong in-plane covalent or ionic bonding provides a straightforward means to tune electronic states by modulating the interatomic distances through mechanical strain[1,2]. The high strain sensitivity along with low bending modulus of 2D materials make them promising candidates for eagerly sought-after gradient bandgap materials in which the bandgap spatially varies within the same material [3–5]. These materials would enable absorption and conversion of a broad light spectrum for use in photovoltaics, photocatalysis, and photodetectors[6–8]. Meanwhile, two-photon lithography (2PL) is newly capable of lateral resolutions below 200 nm to rapidly fabricate complex three-dimensional structures[9,10]. Here, we use 2PL fabricated non-Euclidian nanotopography comprised of periodic undulations with spatially varying height as a patterned substrate for monolayer molybdenum disulfide (MoS_2). The monolayer conformed to the nanotopography locally strains the monolayer with both spatial and magnitudinal control. The conformity of the monolayer is characterized using scanning electron microscopy and atomic force microscopy, and the localized domains of strain in the conformed monolayer are characterized using Raman and photoluminescence spectroscopy. This study serves as a starting point for deterministic straining of 2D materials and development of 2D materials-based broad-spectrum sensing.

Semiempirical Pseudopotential Method for Low-Dimensional Materials Raj K. Paudel[1,2], Chung Yuan Ren[3] and Yia-Chung Chang[1,2]; [1]Academia Sinica, Taiwan; [2]National Cheng-Kung Unversity, Taiwan; [3]National Kaohsiung Normal University, Taiwan

In recent years, there has been a significant focus on developing precise and efficient approaches to expedite Density Functional Theory (DFT) calculations for large unit cells. Among these techniques, the Semiempirical Pseudopotential Method (SEPM) [1] has emerged as a valuable tool for accurately determining band structures, especially in the realm of low-dimensional materials. SEPM operates by utilizing atomic pseudopotentials, which are derived from DFT calculations. Significantly, SEPM calculations offer a unique advantage compared to DFT as they eliminate the requirement for iterative self-consistent solutions in solving the Schrödinger equation, leading to a substantial reduction in computational complexity.
The incorporation of both non-local and local Semiempirical Pseudopotentials in our current approach yields band structures and wavefunctions with enhanced precision compared to traditional empirical methods [2]. When applied to graphene, our model's computed band structure closely aligns with that obtained via DFT calculations [3]. Impressively, our method demands only a fraction of the time required in comparison to the CG iterative solver with self-consistent charge density from DFT. Additionally, we utilized the SEPM technique for armchair graphene nanoribbons (aGNR), achieving results that closely align with those obtained through DFT, but with significantly reduced computational time. Furthermore, we extended the application of our SEPM approach to monolayer TMDCs, adjusting the parameters to align with pertinent values obtained from DFT computations. This enables us to faithfully replicate the band structure, opening avenues for investigating the optoelectronic properties of TMDCs and exploring their potential applications in nanodevices consisting of TMDC nanostructures or related moir[endif]--> structures.

5:00 PM EL05.04.12
Berry Curvature Dipole Induced Giant Mid-Infrared Second-Harmonic Generation in 2D Weyl Semiconductor Qundong Fu[1], Xin Cong[2], Xiaodong Xu[3], Song Zhu[1] and Zheng Liu[1]; [1]Nanyang Technological University, Singapore; [2]University of South Florida, United States; [3]Harbin Institute of Technology, China

Due to its inversion-broken triple helix structure and the nature of Weyl semiconductor, two-dimensional Tellurene (2D Te) is promising to possess a strong nonlinear optical response in the infrared region, which is rarely reported in 2D materials. We demonstrated a giant nonlinear infrared response induced by large Berry curvature dipole (BCD) in the Weyl semiconductor 2D Te. Ultrahigh SHG response was acquired from 2D Te with a large second-order nonlinear optical susceptibility ($\chi^{(2)}$), which is up to 23.3 times higher than that of monolayer MoS_2 in the range of 700-1500 nm. Notably, distinct from other 2D nonlinear semiconductors, $\chi^{(2)}$ of 2D Te increases extraordinarily with increasing wavelength and reaches up to 5.58 nm/V at ~2300 nm, which is the best infrared performance. Large $\chi^{(2)}$ of 2D Te also enables the high-intensity sum-frequency generation with an ultralow continuous-wave (CW) pump power. Theoretical calculations reveal that the exceptional performance is attributed to the presence of large BCD located at the Weyl points of 2D Te. These results unravel a new linkage between Weyl semiconductor and strong optical nonlinear responses, rendering 2D Te a competitive candidate for highly efficient nonlinear 2D semiconductors in the infrared region.

5:00 PM EL05.04.13
Growth and Characterization of 2D-MoS_2 for NO_2 Gas Application Using Chemical Vapor Deposition Method Ashok Kumar and Mahesh Kumar; Indian Institute of Technology Jodhpur, India

Gas sensors that have a low power consumption and can be easily connected into a large-scale sensor network are a necessity for the Internet of Things for environmental monitoring. The high operating temperature of semiconductor gas sensors limits their applications considering their numerous advantages which include excellent sensitivity and cost-effective. In recent years, the research curiosity in two-dimensional (2D) materials, especially molybdenum disulfde (MoS_2) have showed much more intensive attention in gas sensor due to tunable band gap, abundant edge sites and high ratio of surface to volume. Herein, the synthesis of MoS_2 nanoflower was conducted within a tube furnace using a novel three-step chemical vapour deposition (CVD) technique. This process involved the sequential deposition and sulfuration of MoO_3. The MoS_2 nanoflower were confirmed by scanning electron microscopy, Raman spectroscopy, and X-ray diffraction. The resistive gas sensors based on as-prepared bilayer MoS_2 nanoflower showed a p-type character and achieved a superior response of 16% to 100 ppm NO_2 gas, excellent reproducibility, fast response, and complete recovery at room temperature. This sensing property of the resistive gas sensor based on as-prepared MoS_2 films by the three-step CVD method represents an advance in the development of large-scale MoS_2 synthesis and gas sensor fabrication.

Design of Electronic Structure and Transport in S-Doped Few-Layer Graphene Armin Sahinovic[1,1], Paolo Fortugno[1,1], Nicholas Wilson[2,2], Hartmut Wiggers[1,1] and Rossitza Pentcheva[1,1]; [1]Universität Duisburg-Essen, Germany; [2]University of Waterloo, Canada

Compared to a single sheet of graphene, few-layer graphene (FLG) shows additional degrees of freedom dependent on the number of layers and interlayer interactions, leading to a unique combination of surface and bulk-like states [1]. While the properties N- and S-doped monolayer graphene have been addressed previously [2,3], the interplay between defects, doping and the layered structure of FLG are largely unknown.

Based on density functional theory calculations we explore the effect of sulfur doping and vacancies on FLG. The formation energies and electronic structure of different defect types are assessed as a function of concentration and distribution. Direct incorporation of S into the lattice is associated with a high formation energy, which can be reduced by the creation of additional vacancies to bond the sulfur dopands. The most energetically favorable defect configuration is a hypervalent S bonding state in the single vacancy system. While this defect opens a small gap of 0.151 eV in the monolayer system, the multilayer system maintains a Dirac point with linear dispersion. Intriguingly, doped monolayer double vacancies promote weak ferromagnetism not present in the multilayer counterpart. We find a strong layer dependence of the doping allowing for a design of the electronic structure. The surface layers are most prone to doping, giving rise to complex buckling, resulting in a modified band structure and a band gap opening at certain doping concentrations not found for doping in the inner layers. Moreover, doping just below the surface layer allows to preserve the linear dispersion of the Dirac cone in the surface layer.

Initial experimental work on the synthesis of S-doped few-layer graphene (FLG) in a microwave plasma reactor confirms the incorporation of sulfur into the graphene structure and shows that electronic conductivity can be increased by up to 50% compared to undoped FLG. This is consistent with the transport properties, obtained via the BoltZtrap2 code [4], revealing that S doping systematically enhances the conductivity in single-layer and few-layer graphene. Charge-transfer from the doped to the surrounding pristine layers leads to indirect doping, additionally enhancing the transport in FLG compared to the monolayer case. In contrast, when FLG is doped in the surface layers the charge transfer is impeded by the buckling and local charge accommodation, thus a smaller increase of conductivity is found. In this work we show that tailoring the incorporation of S into FLG enables one to modify selectively the electronic structure in view of energy conversion and storage applications e.g. as a battery material, or in catalysis (oxygen reduction).

5:00 PM EL05.04.15
Direct Growth on Dielectric Substrates: Area-Selective Growth of Mono- and Bi-Layer Transition Metal Dichalcogenides WS_2 Lin-Yun Huang[1], Shih-Chu Lin[1], Ming-Chun Hsu[2], Ching-Hao Hsu[2], Yu-Tung Lin[2], Po-Sen Mao[1], Chih-I Wu[2], Wen-Hao Chang[1], Lain-Jong Li[3] and Kung-Hwa Wei[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]National Taiwan University, Taiwan; [3]The University of Hong Kong, Hong Kong

Two-dimensional Transition metal dichalcogenides (TMDs) show great potential to surpass the latest technology node of electronic device scaling and are therefore a focus of research. Bilayer (BL) TMDs have attracted increasing attention in recent years due to their potential to outperform monolayer (ML) TMDs, which are hampered by limited carrier mobility and high contact resistance. Uniform BL TMDs have been demonstrated through the use of excess precursor, additional promoter or substrate pre-treatment methods. These methods, however, introduce random distribution or require additional transfer processes, making them impractical for large scale manufacturing. Here, we present an approach[1] that can grow area-selected uniform monolayer or bilayer WS_2 directly on dielectric substrates. This approach involves first controlling the oxidation degree of the pre-deposited tungsten metal pad, and then converting the tungsten oxide to mono- or bi-layer WS_2, respectively, thereby tuning the number of layers. Simultaneously, WS_2 would grow only around the tungsten metal pad, suggesting area selectivity. The direct-growth method provides cleaner WS_2 interfaces and thus results in improved quality and performances. The optical microscopy and Atomic Force Microscopy images show the capability of controlling the number of WS_2 layers. Furthermore, the Raman and photoluminescence spectra present the uniformity and high optical quality of the fabricated WS_2 bilayer. The Transmission Electron Microscopy (TEM) and Scanning TEM images further displays the AA stacking order of the as-grown bilayer WSe_2, which is desired to result in higher mobility. These ML and BL WS_2 were utilized in field-effect transistors, demonstrating the validity of this approach as a foundation for further device applications.

Synthesis of Stabilized Black Phosphorus for Gas Sensing Application Shang-Jung Wu, Chun-Hua Chen, Cheng-Ju Yang, Yi-Wen Lin, Chia-Yin Cheng, Hung-Shuo Chang, Wen-Chieh Hsieh, Yen-Ling Wang and Karan Giri; National Chiao Tung University, Taiwan

Black phosphorus (BP) is a two-dimensional material with a unique armchair-folded structure that imparts distinct electrical and optical properties in different directions, making it highly sought after in recent years. Additionally, its layered structure provides superior electron mobility, and BP exhibits tunable band structures, allowing it to excel in various applications, essentially bridging the gap between graphene and transition metal dichalcogenides (TMDCs). However, there are still significant challenges to realizing widespread applications of BP. Each phosphorus atom in the BP structure possesses lone electron pairs, making it highly susceptible to spontaneous degradation in ambient conditions, severely limiting its practical utility in various fields. Furthermore, the techniques for preparing and modifying BP are continuously evolving, making it crucial to address these issues effectively.

Keywords: black phosphorus, two-dimensional material, CVT, doping, gas sensor.

Direct Growth of Graphene on Dielectric Materials by Low Temperature Plasma-Enhanced CVD Umut Kaya, Hehe Zhang, Leon Lörcher, Carmen Nordhoff, Wolfgang Mertin and Gerd Bacher; University of Duisburg-Essen, Germany

Graphene offers outstanding electronic and optical properties, such as high electrical conductivity and high transparency in the UV-VIS spectral range. The most developed method for growing high quality graphene is chemical vapor deposition (CVD) on copper (Cu) substrates, where Cu has a catalytic effect on the growth. Practical applications, however, require a subsequent transfer of the graphene onto target substrates like, e.g., dielectric materials. This transfer process induces defects and contaminations, which in turn leads to reduced performance of the intended applications [1]. Thus, a direct growth on dielectric substrates, such as sapphire and (Al,Ga)N is preferable, enabling, e.g., the use of graphene as a transparent electrode for (Al,Ga)N-LEDs [2], 2D-photodetectors [3] or biosensors [4] without any complex transfer process.

We developed a low temperature plasma-enhanced CVD (PECVD) process for depositing graphene on dielectric substrates in a transfer-free approach. The PECVD process was conducted in an industrially relevant 4-inch system with methane (CH_4) as the precursor. For growing graphene on (Al,Ga)N, the conventionally used hydrogen (H_2) carrier gas was replaced by nitrogen (N_2) for preventing surface decomposition of the (Al,Ga)N [2]. Under optimized conditions, i.e., a gas mixture of CH_4/N_2, a plasma power of 40 W, a growth time of 60 min and a growth temperature of 670 °C, graphene layers with Raman intensity ratios $I_D/I_G \approx 1.6$ and $I_{2D}/I_G \approx 1.4$, respectively, have been realized. The sheet resistance could be reduced to < 5 kΩ/sq and the transmittance of the optimized graphene film was ≥ 90% in the UV-VIS spectral range. For graphene growth on sapphire with different crystal orientations (c-plane, ca-plane, a-plane and r-plane), no distinct dependence of the graphene quality on the crystal orientation is found, in contrast to findings for thermal CVD as reported in literature [5]. Under optimized conditions, the I_D/I_G ratio was as low as 0.7 and a sheet resistance down to 1.65 kΩ/sq could be achieved. Apparently, the PECVD process seems to provide a flexible approach for depositing graphene on dielectric substrates, where the balance between sheet resistance and optical transmittance can be willingly adjusted by the growth parameters.

Tunable Semiconductivity in Nitrogen-Doped Graphene Nanosheets for High Surface-Area Optoelectronics Daniel Ranke, Yingqiao Wang and Tzahi Cohen-Karni; Carnegie Mellon University, United States

Semiconducting graphene has been identified for high potential electronic and optical applications since its discovery. Previously, substitutional atomic doping of graphene, particularly nitrogen, has shown to induce semiconducting behavior. However, variability in final dopant defect states, particularly from bottom-up synthesis, results in limited control over band structure and has thus formed a firm ceiling on the application of such structures. Here we report a plasma-enhanced chemical vapor deposition approach for the synthesis of switchable p and n-type nitrogen doped vertically oriented graphene nanosheets and applications towards enhanced carrier extraction in optoelectronics. Tuning between in-situ and ex-situ nitrogen doping has shown fine control over pyridinic/graphitic nitrogen dopant ratio, in turn shifting band structures towards more electron or hole-dominated carrier transport. In conjunction with the vertical orientation and density of nanosheets, these nanostructures allowed for the development of optically active p-i-n and n-i-p heterostructures with charge storage capacity and active surface area many times greater than what is possible with traditional planar architectures. With such structures, we show a route towards developing stable, high-surface area, efficient carrier extractors for optoelectronics. Technologies that are critically limited by active surface area, such as photovoltaic electrochemical cells and optical bioelectronic stimulators, show enhanced potential for co-application with these semiconducting graphene nanostructures and pave a clear road forward toward future hybrid-nanomaterial development.

Molecular Dynamics Simulation of ZrS_2 Oxidation Liqiu Yang, Rajiv Kalia, Aiichiro Nakano and Priya Vashishta; University of Southern California, United States

Among transition metal dichalcogenides (TMDCs) family, ZrS_2 is an important semiconductor and shows superior chemical catalytic properties and electrical properties especially with its 1T phase. ZrS_2 has been reported to be easily oxidized under native environment. Here, we perform large-scale reactive molecular dynamics simulations with optimized reactive force field to study the ZrS_2 oxidation. We present the initial oxidation events locally taking place on the ZrS_2 surface, which results in surface defects that promote further oxidation. The final product of the thermal oxidation is also investigated. This work provides an atomic-level understanding for describing and controlling the oxidation of ZrS_2 as well as for synthesis of oxide and oxysulfide products.

Non Epitaxial Growth of Single-Crystalline TMDs on Amorphous below 400 C Jeehwan Kim; Massachusetts Institute of Technology, United States

The integration of electronics in three dimensions has gained significance in modern electronics due to limitations in scaling nanoscale devices. Vertical chip stacking reduces RC delays, leading to lower power consumption and more efficient data exchange in system-on-chip designs. Despite huge technical challenges, through-silicon-via (TSV) has been an only viable solution. A more concise and effective approach for connecting electronic devices is wafer-free monolithic 3D (M3D) integration. However, the scarcity of methods for locating single-crystalline thin film device layers at low temperatures has limited experimental demonstrations of M3D with single-crystalline devices. We now present our pioneering demonstration of single-crystal growth of TMD channel materials at 350°C on an amorphous layer-coated silicon wafer. This breakthrough allows seamless integration of single-crystalline n-type MOS devices on top of amorphous insulation layers of underlying single-crystalline p-type MOS chips. Our work establishes a foundation for advancing Moore's law. Furthermore, successfully growing single-crystalline devices on finished circuitry holds the promise of true wafer-free vertical monolithic

integration of electronics and photonics in the future.

8:30 AM EL05.05.02
Ferecrystals: Non-Epitaxial Multilayer Growth of 2D Materials by Atomic Layer Deposition Jun Yang[1], Dongho Shin[1], Sebastian Lehmann[1], Tobias Ritschel[2], Jochen Geck[2] and Kornelius Nielsch[1,3,4]; [1]IFW Dresden, Germany; [2]Institute of Solid State Physics, TUD, Germany; [3]Institute of Applied Physics, TUD, Germany; [4]Institute of Materials Science, TUD, Germany

Atomic layer deposition is a very versatile technology for the deposition of thin films with precise thickness control on large areas, non-planar surfaces and 3D objects. The chemical reaction is surface limited, well defined and works in most cases at low temperatures (RT to 150 °C). For a number of classical van der Waals 2D materials, there have been reports on ALD of transition metal dichalcogenide (TMDC) of MoS_2, SnS_2, WS_2 and WSe_2, which also included the electronic characterization as a field effect transistor (FET).

In this work, we have fabricated by atomic layer deposition (ALD) multilayers of layered materials based on topological insulators and van der Waals materials, called *ferecrystals.* These ferecrystals can be tailored to exhibit unusual properties such as high electrical conductivity or low thermal conductivity or magnetic properties. A detailed ferecrystal study was performed on ferecrytals of Sb_2Te_3 and SbO_x, which has been grown at the same temperature as single layers of Sb_2Te_3. Without post-annealing, the electrical and thermoelectric characterisation of the highly ordered samples have been performed with the ZT-chip setup. In general, the carrier mobility is very high >150 Vs^2/cm^2 and is even improved when the thickness of the Sb_2Te_3 layers is reduced and the number of SbO_x layers (typically 2 nm thickness) is increased. Detailed XRD investigations have been performed and an enhanced crystalline order is observed in the ferecrystal system compared to individual layers of Sb_2Te_3. We have grown ferecrystals based on Sb_2Te_3 and Sb_2Se_3 with tetrahedral and orthorhombic crystal structure, respectively. The p-type hole carrier concentration of Sb_2Te_3 films can be enhanced through the sublayer doping of Sb_2Se_3. The highest carrier concentration achieved was 2.5×10^{19} cm^{-2} when the thickness ratio of Sb_2Te_3 to Sb_2Se_3 was (4 nm:2 nm). Further reduction of the Sb_2Te_3 thickness resulted in a high Seebeck coefficient of 172 μV/K at room temperature.

8:45 AM EL05.05.03
Plasma-Based Integrated System for Synthesis, Etching and Machine Learning of 2D TMDc Hyeong-U Kim[1], Muyoung Kim[1], Seongho Kim[2], Minji Kang[1] and Min Sup Choi[2]; [1]Korea Institute of Machinery and Materials (KIMM), Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of)

The research presented in this work represents a culmination of over a decade of dedicated efforts toward the development and implementation of a plasma-based integrated system for the synthesis, etching, and machine learning of two-dimensional (2D) transition metal dichalcogenides (TMDc). Our journey began in 2013 with a groundbreaking achievement: the successful synthesis of semiconducting MoS_2 at 300 °C using an inductively coupled plasma (ICP)-plasma enhanced chemical vapor deposition (PECVD) technique (PLASMART, Republic of Korea) on a 4-inch substrate. This milestone was the first step towards realizing the immense potential of 2D TMDc materials in various applications.
Building on this initial success, we continued to advance our capabilities. In 2015, we lowered the synthesis temperature to 150 °C, enabling direct deposition on polyimide substrates. This development not only expanded the range of possible applications but also demonstrated our commitment to environmentally sustainable processes. In 2020, we achieved another significant milestone by successfully synthesizing 2D WS_2, a member of the same TMDc group, in the metallic 1T phase using PECVD.
The year 2021 marked a breakthrough as we overcame previous limitations in heterostructure fabrication by creating a MoS_2-WS_2 heterostructure using H_2S + Ar plasma on a 4-inch hetero-metallic (Mo-W) layer. This achievement unlocked the potential for novel electronic and optoelectronic devices based on these heterostructures. Various forms of TMDc, all consisting of 4-5 layers, were systematically obtained, laying the foundation for further exploration.
By 2023, we had established precise etching conditions at the atomic layer level using ICP-reactive ion etching (RIE) with a carefully designed three-gas mixture ($Ar+O_2+CF_4$) and optimized RIE utilization. This enabled us to tailor the properties of 2D TMDc materials with unprecedented precision. Furthermore, we employed density functional theory (DFT) calculations and optical emission spectroscopy (OES) diagnostic results to gain deeper insights into the plasma reaction mechanisms, shedding light on the underlying physical processes.
In a remarkable culmination of our efforts, we harnessed the power of machine learning (ML) to predict process outcomes in 2023, revolutionizing the way we approach material synthesis and etching. This achievement represents a significant leap forward in terms of efficiency and precision, with implications spanning various industries and research domains.
In summary, our research journey has led to the development of a comprehensive and versatile plasma-based integrated system for 2D TMDc materials. Over the course of a decade, we have pushed the boundaries of what is possible in material synthesis, etching, and process optimization, ultimately contributing to the advancement of science and technology.

9:00 AM EL05.05.04
Atomic Layer Deposition of WS_2 on Low-k Dielectric Substrates for Back-End-Of-Line Integration Muhammed Juvaid Mangattuchali[1], Hao Tan[1], Hippolyte P. Astier[1], Chandan Das[2], John L. Sudijono[2] and Silvija Gradecak[1]; [1]NUS Singapore, Singapore; [2]Applied Materials, Inc., Singapore

The progressive miniaturization of silicon integrated circuits necessitates the exploration of alternative materials for both the front-end-of-line (FEOL, transistors) and back-end-of-line (BEOL, interconnects) circuitry. Currently, the efficacy of traditional liners and barriers (e.g., Ta/TaN) requires an approximate thickness of 30-40 Å. In forthcoming sub-5 nm nodes, these components will occupy a significant portion of the interconnect cross-section, leading to a substantial increase in the resistivity of Cu interconnects. Conversely, the reduction in thickness of liner and barrier layers would result in a decrease in Cu blocking efficiency. Two-dimensional (2D) transition metal dichalcogenides (TMDs) were recently demonstrated as promising candidates for bifunctional ultra-thin liner and diffusion barrier materials in the sub-nanometer-scales. However, the majority of 2D TMDs are synthesized *via* chemical vapor deposition processes at elevated temperatures (>800°C). This makes it difficult to use them in BEOL integration, where the temperature limit is 450°C. While plasma-assisted growth offers the potential to mitigate the high-temperature requirement, it also implies poor conformality in deposition, and the emergence of plasma-induced defects in the TMDs as limitations.
Here, we present a thermal atomic layer deposition (ALD) approach that does not require plasma assistance to grow crystalline WS_2 at temperatures below 400°C, on dielectric materials, including low- k and SiO_2 substrates. This growth approach does not alter the stoichiometry of the low- k material and retains its k value, making it a suitable method for BEOL integration. The process results in layer-controlled, conformal (>95%) wafer-scale growth of WS_2 on 200 mm dielectric substrates. Furthermore, the single-layer WS_2 helps reduce Cu resistivity >70% compared to the reference low- k and SiO_2/Si substrates. Thermal and electrical stress tests on the monolayer WS_2 film reveal a high blocking efficiency against both types of stress. This low- k -compatible ALD-grown monolayer WS_2 not only addresses the downscaling challenge but also serves as an efficient bifunctional (liner and barrier) layer grown using a directly industry-compatible process.

9:15 AM EL05.05.05
Fabricating Freestanding Ultrathin Materials by Atomic Layer Deposition Karen Ehrhardt, Jessica M. Coleman and Scott C. Warren; University of North Carolina at Chapel Hill, United States

Ultrathin materials have risen to an increasingly important role in recent years, both due to the nano-scaling of existing technologies and the advancement of new applications that utilize the distinct properties of ultrathin structures compared to bulk materials. Because these properties strongly depend on thickness and uniformity, vapor-based synthesis is popular. In particular, atomic layer deposition (ALD) is a popular strategy to fabricate precisely controlled ultrathin materials because of self-limiting growth and high conformality. However, to fully realize the potential of ultrathin materials from ALD, there exists a need for freestanding structures, which would allow the exploration of applications such as membranes or photolithographic pellicles. Despite the prominence of ALD, no general method of fabricating freestanding ultrathin materials with cm-scale dimension currently exists. This gap exists due to the nature of ALD, in which precursor molecules chemisorb strongly to and are difficult to remove from the substrate surface. To address the challenge of prepared freestanding ALD materials, we report a strategy of growing materials on a tailored single-crystal NaCl surface. Although NaCl is typically a poor substrate for ALD, the insertion of hydroxyl functional groups across the surface results in a heterogeneous surface that forms both bonding and nonbonding interactions with ALD materials. Once deposited, the material is easily removed under mild conditions and transferred to an arbitrary substrate. This approach yields ALD materials that have cm-scale sizes and are low in defects in cracks and pinholes. The strategy provides access to a diverse range of freestanding ultrathin compositions, creating opportunities to investigate structure-property relationships that are distinct from those in bulk material counterparts.

9:30 AM EL05.05.06
Lithographically Defined Synthesis of Transition Metal Dichalcogenides Aidar Kemelbay, Ricardo Ruiz, Archana Raja, Adam Schwartzberg, Shaul Aloni and Tevye Kuykendall; Lawrence Berkeley National Lab, United States

Transition metal dichalcogenides (TMDs) possess unique and highly tunable optoelectronic properties, but their large-scale fabrication and integration is still challenging. To address this problem, we developed a "lateral conversion" technique, which enables the synthesis of TMDs with predefined thickness and shape at specific locations on a wafer. The lateral conversion of metals, metal oxides, and nitrides into metal dichalcogenides resulted in few-layer TMDs covered with a capping layer. This layer protects the delicate TMD interfaces during subsequent fabrication steps from contamination, as well as improves their air stability. We demonstrated that lateral conversion can be used to synthesize various sulfides, selenides and tellurides, as well as alloys, lateral and vertical heterostructures. The patterned TMDs can be easily transferred from growth to device substrates or directly integrated into silicon-based CMOS platforms.

9:45 AM EL05.05.07
Substrate Van der Waals Force Effect on The Stability of Violet Phosphorous Sarabpreet Singh[1], Mahdi Ghafariasl[1], Hsin-Yu Ko[2], Sampath Gamage[1], Robert DiStasio Jr[2], Michael Snure[3] and Yohannes Abate[1]; [1]University of Georgia, United States; [2]Cornell University, United States; [3]Air Force Research Laboratory, United States

The weak van der Waals (vdWs) forces between monolayers has been a unique distinguishing feature of exfoliable materials since the first isolation of graphene. However, the vdWs interaction of exfoliable materials with the substrate and how this interface force influences the interaction of vdWs materials with the surroundings have yet to be well understood. Here, we experimentally and theoretically unravel the role of vdWs forces between the recently rediscovered wide band gap p-type vdW semiconductor violet phosphorus (VP), with various substrates (including, SiO_2, mica, Si, Au) and quantify how VP stability in air and its interaction with its surroundings is influenced by the interface force. Using a combination of infrared nanoimaging and theoretical modelling we find three main factors that influence how VP interacts with its surroundings: the vdWs force at the interface, the hydrophobicity of the substrate, and substrate surface roughness. We found that VP can maintain its stability for a prolonged period if it is exfoliated on SiO_2 substrate, followed by mica and Au substrates, and is least stable when placed on a Si substrate. Our results could guide in the selection of substrates when vdW materials are prepared and more generally highlight the key role of interface force effects that could significantly alter physical properties of vdWs materials. Our findings can assist in the choice of substrates to exfoliate vdWs materials and emphasize the crucial impact that interface forces can have on altering the physical properties of exfoliable materials.

Wafer-Scale Epitaxy of 2D Transition Metal Dichalcogenides on Sapphire – An Enabling Technology for Large Area Devices Joan M. Redwing; The Pennsylvania State University, United States

Monolayer and few-layer semiconducting transition metal dichalcogenides (TMDs), exemplified by materials like MoS_2 and WSe_2 have garnered increasing interest for next generation gate-all-around nanosheet devices and heterogeneous integration with silicon CMOS technology. The interest in TMDs arises from their ultra-thin body nature, however, realization of high-performance devices requires advances in TMD synthesis to provide wafer-scale films that can be readily integrated into devices via either direct growth or layer transfer methods. Our work has focused on the development of metalorganic chemical vapor deposition (MOCVD) as a manufacturing-compatible approach for wafer-scale semiconducting TMDs. The TMDs are grown epitaxially on c-plane sapphire by MOCVD at elevated temperatures (>800 °C) to obtain high crystal quality. Pre-annealing the sapphire surface in H_2S or H_2Se modifies the nucleation behavior of the TMDs on sapphire which is attributed to passivation of dangling bonds on the sapphire surface. Passivation of step terraces can drive nucleation to occur preferentially at step edges on sapphire leading to unidirectional domains and a significant reduction in mirror twin defects. In situ spectroscopic ellipsometry is demonstrated to be an effective real time monitor of TMD growth even at the sub-monolayer level which can be exploited to track surface coverage as a function of time under varying growth conditions. The ability to precisely control and modulate precursor flux during growth is used to synthesize in-plane heterostructures that enable localized exciton confinement and emission. Applications for wafer-scale TMD monolayers in nanoelectronics, sensing and photonics will be discussed.

11:00 AM EL05.05.09
Selective Area Epitaxy Growth of 2D Materials by Molecular Beam Epitaxy Yongchen Liu[1], Mingyu Yu[1] and Stephanie Law[2]; [1]University of Delaware, United States; [2]The Pennsylvania State University, United States

Two-dimensional (2D) materials have exploded in popularity due to their wide range of properties and the fact that they can be stacked into devices. The vast majority of devices made from 2D materials use exfoliated flakes, which works well for creating prototypes and to understand basic physics, but exfoliation is difficult to scale up. For traditional materials, devices are fabricated using wafer-scale films and subtractive manufacturing processes. Unfortunately, wafer-scale films of 2D materials grown by physical vapor deposition or chemical vapor deposition techniques often have a high density of

grain boundaries and twin defects, which lead to unwanted conducting channels in electronic devices, non-radiative recombination pathways in optical devices, and decoherence in quantum devices. In addition, etching often damages the edges of the 2D material, further degrading device performance. One way to solve this problem is to take a new approach to the wafer-scale manufacturing of 2D material devices. Instead of growing a wafer-scale film and using subtractive techniques to fabricate devices, we use selective area epitaxy (SAE), an additive technique, to build devices from the bottom up.
In SAE, a mask is patterned on the substrate before growth with precisely placed holes through to the substrate. The growth conditions are selected such that the film only nucleates and grows within the openings in the mask, thus defining the location, size, and shape of the film. By choosing the growth conditions correctly, we can ensure that only a single grain of 2D material grows in each opening, eliminating issues with grain boundaries and film coalescence. Multiple materials can be stacked together using SAE to create functional device stacks. If contacts to the stack are needed, they can be made as edge contacts before epitaxy and/or as top contacts post-growth. Using SAE, we can synthesize quantum-confined 2D materials without the need for etching, thus preserving the intrinsic properties of the material. Overall, SAE has the potential to transform growth of 2D materials for devices by enabling the synthesis of 2D materials free of grain boundaries with precise locations and sizes.
In this talk, I will discuss our recent results on SAE of 2D materials using molecular beam epitaxy (MBE). MBE is an ultra-high vacuum physical vapor deposition technique, in which high-purity elemental source materials are thermally evaporated. The atoms impinge upon the substrate and react to form the film. In the past decade, MBE has been used to grow a wide range of 2D materials and heterostructures and due to its high purity, is a good choice for SAE. To begin, we explored SAE of the topological insulator Bi2Se3 on GaAs substrates using Al2O3 masks deposited by electron beam evaporation and atomic layer deposition. We find that we can obtain SAE in a narrow but reproducible growth window. We also find differences in SAE growth windows for electron beam deposited Al2O3 compared to atomic layer deposited Al2O3, likely due to the difference in smoothness and the number and density of dangling bonds. I will further show results for SAE of Ga2Se2 on GaAs and for Bi2Se3 on Si. Overall, SAE is a promising technique for the growth of high-quality 2D material devices.

11:15 AM EL05.05.10
Scalable Synthesis of Molecular-Intercalated Bulk Monolayer MoS_2 with Tailored Electron Doping Boxuan Zhou, Jingyuan Zhou and Xiangfeng Duan; University of California Los Angeles, United States

Molybdenum disulfide (MoS_2) is an extensively studied two-dimensional layered semiconductor with interesting electronic and optical properties. Monolayer MoS_2 features strong light-matter interactions due to its direct bandgap, whereas multilayer MoS_2 is an indirect bandgap semiconductor and optically inactive. The molecular intercalation of MoS_2 with organic cations offers a strategy to decouple the interlayer interaction, producing a bulk monolayer material, but is usually accompanied by a heavy electron doping effect that can diminish the intrinsic semiconductor properties or induce a phase transition. Herein, we report a chemical-dedoping strategy to tailor electron density in molecular-intercalated MoS_2, therefore retaining monolayer properties. By introducing a poly(vinylpyrrolidone)-bromine complex during the electrochemical intercalation process, we show bulk monolayer MoS_2 thin film can be produced with decoupled interlayer interaction and reduced electron concentration. The resulting thin films display strong excitonic emission, 20- and > 400 times stronger than the exfoliated monolayer and multilayer material respectively, as well as high valley polarization and enhanced photo-electric response. Our study opens a scalable path to large-area bulk monolayer MoS_2 thin films with monolayer-like optical properties and greatly increased optical cross-section, presenting an attractive material platform for both fundamental photophysics studies and scalable optoelectronic applications.

11:30 AM EL05.05.11
Wafer Scale Lateral Heterojunctions of MoS_2 and WS_2 for Photocurrent Applications Sivasakthya Mohan[1], Yuqian Gu[1,2], Martha Serna[1], Jia Yu[1], Shanmukh Kutagulla[1], Keji Lai[1], Kenneth Liechti[1] and Deji Akinwande[1]; [1]The University of Texas at Austin, United States; [2]Intel Corporation, United States

Despite the widespread research in studying the synthesis and properties of two-dimensional (2D) materials for electronic devices, there are still some intrinsic challenges such as zero bandgap (for e.g., graphene), low carrier mobilities (e.g., Transition Metal Dichalcogenides or TMDs) which prevent their successful transition to real-world applications. 2D heterostructures present new prospects for advanced materials design for specific optoelectronic and transport applications. By combining the unique properties of different 2D materials, heterostructures can be tailored suitably to possess distinct functionalities. While the fabrication of vertical heterostructures is more common through exfoliation and transfer methods, contaminations and stacking orientations between the layers often restrict their device performance[1]. To this end, efforts have been made in the synthesis of lateral heterostructures where the different domains are covalently bonded and can enhance device performance.
In this work, we synthesized wafer-scale lateral heterostructures of MoS_2 and WS_2 on sapphire, through e-beam lithographic patterning followed by one-step, low-temperature sulfurization[2] of the thin metal films of molybdenum and tungsten. The quality and number of layers of the sulfurized heterostructures have been evaluated using optical microscopy, large-area Raman maps, and cross-section TEM. The seamless transition between the 2D TMDs at the interface has been further evaluated using high-resolution characterization techniques such as XPS, ToFSIMS, and atomic force microscopy. A scanning microwave impedance microscope (MIM) was employed to obtain the spatial conductivity resolution of the heterojunctions. Enhanced photocurrent measurements obtained on the fabricated devices pointed to potential applications in photo-sensing devices.

Resolution Limits and Their Effect on Structure and Morphology of Lithographically Defined TMD Synthesized by Lateral Conversion Shaul Aloni, Marco D'Allesandro, Ricardo Ruiz, Aidar Kamelbay and Tevye Kuykendall; Lawrence Berkeley National Laboratory, United States

Recently, we developed a wafer-scalable method to synthesize lithographically patterned transition metal dichalcogenides (TMDs), using a process that we call “lateral conversion.” Briefly, this method relies on the diffusion of chalcogen precursors to convert metal-oxide thin-films via interlayer diffusion, which proceeds from the exposed film edges at lithographically defined locations. In this work, we explore the resolution limits of our method and its effect on its structure and properties. The synthesis approach initially relied on photolithography to fabricate structures with micron-scale resolution. In this work, we show that this method is suitable to achieve lithographically defined sub-20nm features achievable using a block copolymer lithography. We were able to develop simple transfer techniques to lift the patterned structure and transfer it to a substrate of choice such as a silicon wafer or electron transparent substrate for TEM analysis. This allowed us to study the effect of synthetic parameters on the morphology and structure of the TMD and improve the quality of the TMD films.

Integration 3D Micro and Nano Structures with 2D Materials via Self-Assembly Approach Zihao Lin[1], Shehua C. Thor[1], Chunhui Dai[1], Sodam Choi[2], Chiwon Ahn[2] and Jeong-Hyun Cho[1]; [1]University of Minnesota, Twin Cities, United States; [2]KAIST, Korea (the Republic of)

Two-dimensional (2D) materials have been widely researched for the past decades. Despite this, there is recently a large interest in bringing 2D materials to 3D micro/nano architectures as the later one offers many new functionalities in space dimension compared with the 2D plane, such as robotics, electronic skins, molecular sieves, and sensors. In this work, 2D materials are integrated on 3D micro and nano structures via self-assembly technique. This approach can be witnessed with several advantages. First, it is well compatible with traditional two-dimensional (2D) lithographic processes. Second, complex 3D structures which are usually challenging to achieve by traditional top-down techniques can be easily fabricated by this bottom-up method. Third, it is a manual-free and wire-free process. Moreover, it can be well applicable by patterning different kinds of materials on it with different dimensions and subsequently self-assembled together with stimulus-based active layers to realize 3D architectures, which offers great flexibility and strong functionality. Here, two fabrication processes that meet the previously mentioned benefits are introduced. They facilitate the incorporation of 2D materials, including Graphene, Graphene Oxide, and MXenes, onto a wide range of 3D micro and nanostructures. First, electron beam induced in-situ monitored self-assembly technique. 2D materials together with other active nano layers can be firstly patterned on the planar surface and then subsequently curved up to 3D nano structures stimulated by focused electron beam induced stress deformation. This technique offers nanometer resolution control of the 3D object, and the desired 3D shape can be meticulously crafted. Second, 3D self-assembly process uses stress gradient in negative photoresist (SU-8). The stress gradient in the SU-8 enables the formation of 3D graphene-based polyhedral structures. The graphene and SU-8 layers are patterned, then transitioned into 3D structures when the stress gradient, instigated by an UV-energy source, is alleviated. Simulation is performed to demonstrate the strong 3D volumetric light confinement in 3D graphene nano structures and high optical chirality in 3D graphene microstructures. The developed fabrication technique can further be used to construct 2D materials-based fluidic channels, actuators, micro/nano machines and 3D passive elements.

Charge Trap Engineering and Synaptic Behavior of Transition Metal Dichalcogenides Transistor, via Molecular Dynamics MiJi Kwon, Yeonjin Je, Chang hwan Oh and Jun Hong Park; School of Materials Science & Engineering, Gyeongsang National University, Korea (the Republic of)

The electrical performance of semiconductor devices has a significant dependence on the surface states of the semiconductors because the channel between source and drain regions for charge carrier transports is mostly formed near the surface with applying gate bias. Therefore, it is critical to engineering the surface chemistry of the semiconductor material. Coupling an intrinsically atomically thin body with a finite bandgap, layered transition metal dichalcogenides (TMDCs) have been employed as semiconducting channel platforms with a large ON/OFF ratio and near theoretical subthreshold swing. Here, reconfigurable synapse behaviors of TMDC via molecular adsorption of chemically and the receptive layer are demonstrated with three terminal TMDc synapse devices.
Molecular adsorption on the $MoSe_2$ surface is induced with dipping in $(NH_4)_2S$(aq) diluted in H2O with 25%, while the solution temperature is held at 50 degrees celsius. H_2S or HS molecules can be adsorbed on the $MoSe_2$ surface during this chemical treatment and act as trapping centers for transported carriers. The adsorbed molecules can be desorbed from $MoSe_2$ surfaces with wash with isopropanol.
To mimic the biological synapse, the electrical synapse response of $MoSe_2$ transistors is modulated by a pulse generator wherein excitatory modes; thereby synapse plasticity is controlled by spike-like gate bias as a presynaptic input. After applying pulse gate bias with 50 ms pulse duration, for bare $MoSe_2$ devices, there is no synapse response, including changes in conductance, consistent with the absence of the plasticity. However, after chemical treatment, molecular adsorption increases conductance upon pre-synapse inputs consistent with a significant increase from 5.9 S to 68.6 S (a postsynaptic conductance), consistent with the manifest of plasticity. The observed plasticity can disappear with the desorption of molecules from the surface of synapse devices.
To emulate the visual sensory behavior of humans, the artificial synaptic plasticity of synaptic devices has been explored by applying light pulse. As light stimulation with pulse modulation, the channel's conductance near-linearly increases as the number of light pulses increases, consistent with optical potentiation. Afterward, electric depression of molecularly functionalized synapse can be observed with the linear decrease of conductance. In addition, although it is crucial to fabricate the receptive layer in which a particular molecule reacts selectively, TMDC materials are absence of dangling bonds and surface state, resulting in degradation of selectivity. Therefore the TiOPc monolayers on the TMDC surface is deposit as the artificial receptive layer to induce the selective electric signal upon molecular absorption.
Consequently, since the present report demonstrates the reconfigurable plasticity of TMDCs synapse devices with the optically sensory response, it can be a milestone to develop a brain-inspired computing system that integrates sensory function upon chemical and optical stimulation

2:15 PM EL05.06.03
Exciton and Trion Emission in Wafer-Scale MoS_2 Layers – The Role of Bilayer Islands Henrik Myja, Tilmar Kümmell and Gerd Bacher; University Duisburg-Essen, Germany

2D materials, especially the group of semiconducting transition metal dichalcogenides (TMDCs), have emerged as highly promising for electronic and optoelectronic devices over the past decades [1][2]. For industrially relevant applications, wafer-scale growth of high quality TMDCs is essential. Until today, the control of defects, crystallinity and grain size in wafer-scale synthesis via metal organic chemical vapor deposition (MOCVD) is still challenging. E.g., in molybdenum disulfide (MoS_2) or related sulfur based TMDCs, sulfur vacancies are known to lead to a background n-doping, thus affecting device performance significantly. While there are various approaches for post-growth treatments of defective TMDCs (e.g. super-acid treatment or partial oxidization), little is known about controlling sulfur vacancies and thus background doping in the growth process.
In this contribution we use confocal photoluminescence (PL) measurements with < 500 nm spatial resolution to monitor the local charge carrier distribution in MOCVD grown MoS_2 via the ratio of neutral exciton and trion emission. A 2" c-plane sapphire substrate with 1° off-axis cut is used as the growth substrate in MOCVD. The wafer-scale growth results in MoS_2 monolayers with crystal grain sizes above 50 µm as extracted from grain boundary visualization in transmission electron microscopy (TEM), and a ~15 % coverage with bilayer domains of ~500 nm in size. Despite the large grain sizes, the average PL quantum yield of the MoS_2 monolayer sample is only about 10^{-3} %. This is attributed to the high point defect density of $(4.1\pm1.6)*10^{13}$ cm^{-2} as determined by atomically resolved scanning tunneling microscopy (STM) [3] and the impact of interfacial defects and substrate-induced doping, respectively [4]. Surprisingly, our spatially resolved PL mappings indicate an unusual behavior for monolayer and bilayer regions on the sample. The PL obtained from monolayers is dominated by trion emission, indicating a strong influence of n-type background doping. In contrast, the PL on bilayer domains mainly shows neutral exciton emission, combined with reduced line width and a significantly enhanced intensity. This on one hand confirms literature reports on preferred nonradiative recombination via trions [5], and on the other hand hints to a suppression of background doping and thus defect

formation in bilayer areas. The latter might be highly relevant for achieving less defective TMDCs via MOCVD growth. Low temperature micro-PL mapping is used to investigate the defect structure of the samples in more detail and to verify this interpretation.

Programmable Graphene e-Nose Sensor Arrays for Fast, Sensitive and Label-Free Identification of Chemical Vapors Haolin Li, Anjali D. Sivakumar, Chandrakalavathi Thota, Ruchi Sharma, Xiaheng Huang, Xudong Fan and Zhaohui Zhong; University of Michigan–Ann Arbor, United States

Conventional electrical chemical vapor sensors are mostly based on charge transfer mechanisms and have struggled with the trade-off between sensitivity and response time. To address this challenge, our groups previously demonstrated a new type of fast, sensitive, and broad-spectrum electronic vapor sensor by exploiting the fringing field capacitance effect in graphene transistors. The typically trivial fringing field capacitance change due to analyte absorption is greatly amplified by both the graphene transistor and a micro-flow channel covering the surface of graphene. In this work, we demonstrate programmable graphene e-nose sensor arrays toward true label-free sensing and identification of chemical vapors. Individual graphene sensors within the 1D sensor array (up to 1 x 9) are optimized to offer sensitive (down to picogram) and fast (sub-second) detection toward a variety of analytes. More importantly, its responsivity toward different analytes can be programmed by electrostatic gating on the graphene transistor. By combining with advanced data analysis tools, the graphene e-nose array has the potential to offer label-free chemical vapor sensing without the need to individually functionalize each sensor as in traditional e-nose devices. We will also discuss the integration of the graphene e-nose sensor array with a micro-gas chromatography chip and a smartphone-sized custom PCB board for electronic control and readout and Bluetooth data communication. The graphene e-nose sensor arrays offer a sensing platform for real-time rapid on-site monitoring of complex gas mixtures including polar, nonpolar, organic, and inorganic molecules. Furthermore, the result should pave the way for fast, sensitive, and true label-free chemical vapor sensing and identification using nanoelectronic sensors.

Single Crystalline and Polycrystalline 2D-Layered BiOI for Ionising Radiation Detection Kavya Reddy Dudipala and Robert L. Hoye; University of Oxford, United Kingdom

Emergence of graphene and transition metal dichalcogenides (TMDs) has escalated interest in novel 2D materials and van der Waals (vdW) solids for their applications across various scientific and engineering disciplines owing to their exceptional electrical, optical, thermal, and physical properties. In the field of medical imaging, radiological diagnostic tests like mammography/CT scan, require detection of low doses of ionizing radiation such as X-rays and γ-rays to limit radiation damage imposed on patients. Low dose radiation detection requires absorber materials with high linear attenuation co-efficient, high resistivity and large drift mobility-lifetime products.[1] In this work, we explore 2D-layered BiOI for radiation detection, where we firstly study its photophysical properties like photoexcited charge-carrier lattice coupling dynamics and its implications for efficient detector performance. Then we demonstrate X-ray detectors based on BiOI single crystals with high sensitivities reaching 1.1 x 10^3 $\mu CGy_{air}^{-1}cm^{-2}$ and lowest dose rate directly measured upto 22 $nGy_{air}s^{-1}$.[2] We develop scalable polycrystalline synthesis and device fabrication routes that are better suited for commercialization, through uniaxial pressing of BiOI powders/single crystals into wafers of desired thickness and through chemical vapor deposition of BiOI thick films. The results presented here highlight the potential of novel high-Z 2D materials for radiation detection applications.

4:00 PM EL05.07.05
Highly Integrated Graphene-Based Chemical Sensing Platform for Structural Monitoring Applications Christian E. Lopez Angeles and Tomas Palacios; Massachusetts Institute of Technology, United States

Two-dimensional materials, such as graphene, hold promise for sensing applications. Graphene's remarkable surface-to-volume ratio, when employed as a transducer, enables the sensor channel to be readily modulated in response to chemical changes in proximity to its surface, effectively converting chemical signals into the electrical domain. However, their utilization has been constrained due to variations in device-to-device performance arising from synthesis and fabrication processes.
To address this challenge, we employ Graphene Field Effect Transistors (GFETs) in developing a robust and multiplexed chemical sensing array comprising tens of sensing units. This array is coupled with custom-designed high-speed readout electronics for structural monitoring applications.
For example, in harsh environmental conditions, structures constructed from reinforced concrete may experience degradation due to corrosion, a chemical process initiated by carbonation and significant fluctuations in temperature and humidity. Under normal conditions, concrete maintains a pH level within the alkaline range of 13 to 14. However, when subjected to carbonation, its pH decreases to values between 8 and 9.
Our platform excels in real-time pH monitoring. By conducting I-V sweep measurements in the sensor channel, we have established a correlation between [H+] concentration and the gate-source voltage (Vgs) at graphene's Dirac point with an accuracy of roughly 98%. This system and correlation allows for the prompt detection of any deviations induced by corrosion within a concrete environment.

5:00 PM EL05.08.01
Synthesis of 2D $PtSe_2$ Nanolayers on Glass Substrates and Their Integration in Device Applications Vera G. Marinova[1], Nikolay Minev[1] and Dimitre Dimitrov[1,2]; [1]IOMT-BAS, Bulgaria; [2]ISSP-BAS, Bulgaria

We report the synthesis details of 2D PtSe2 layers on soda lime (glass) substrates by selenization of pre-deposited Pt films using thermally assisted conversion (TAC) method at 430°C and atmospheric pressure. PtSe2 layers with different thicknesses were prepared by varying the Pt deposition time (Pt 3s, Pt 8s and Pt 10s), afterwards estimated by ellipsometric measurements to correspond to 7nm, 9 nm and 12nm, respectively. The X-Ray diffraction patterns showed the diffraction peaks characteristic with improving crystallinity when increasing the Pt deposition time. The Raman spectra revealed typical PtSe2 modes, while a decrease of Se/Pt ratio and a transition from *p*-doped to *n*-doped PtSe2 for longer Pt deposition times was found by X-ray photoelectron spectroscopy analysis. Formation of reactive oxygen species (ROS), mainly hydroxyl radicals (OH) on the PtSe2 surface under light irradiation was demonstrated by EPR analysis.
PtSe2 coatings demonstrate antibacterial activity against *Escherichia coli* in dark and under light irradiation owing to their 2D layered morphology, crystalline structure and optical properties. The antibacterial activity was tested applying ISO standard procedure: (i) in dark, the antibacterial activity increased with the increase of Pt deposition time and the viability of the bacteria was reduced to 30% (Pt 3s) and 15% (Pt 10s) after treatment for 6 h. The effect was attributed to the increasing film thickness, roughness and surface coverage which facilitate the mechanical destruction of the bacteria cell; (ii) under light irradiation, the activity of PtSe2 (Pt 3s) was similar to that in dark showing low sensitivity to light. On the contrary, the PtSe2 (Pt 8s) and (Pt 10s) appeared very effective under light, with the bacteria viability after 6 h being only 7.3% and 1.2%, respectively. The observed photo-induced antibacterial activity is related to the synergy of several parameters, i.e. high crystallinity, semiconductor behavior and chemical composition.
In addition, integration of PtSe2 as transparent, conductive layers in Polymer Dispersed Liquid Crystal (PDLC) structures operating as near infrared light shutters is demonstrated. The proposed simple and inexpensive synthesis approach opens new directions towards PtSe2 potential technological applications, including ITO-free optoelectronics.

Telecom Quantum Emitters in Van der Waals Materials Huan Zhao[1,2] and Han Htoon[2]; [1]Los Alamos National Laboratory, United States; [2]Oak Ridge National Laboratory, United States

In the poster, I present the site-controlled creation of near-infrared (NIR) NIR single-photon emitters in 2D transition metal dichalcogenide (TMDC) monolayers, multilayers, and heterobilayers. The emission of non-classical light is induced through the deterministic implantation of localized strain using a scalable, nanopillar-based, strain engineering technique. The excitons trapped by the strain-induced potential wells produce bright, narrow-bandwidth photoluminescence (PL) with emission wavelength ranging from 900 nm to 1.6 µm. Our Hanbury Brown and Twiss (HBT) experiment yielded near-complete photon antibunching, unambiguously proving the quantum nature of the emitters. The high-purity single-photon emission can be maintained at liquid nitrogen temperature without a significant decrease in the emission intensity. No photon bleaching, blinking, or spectrum diffusion was observed in the time domain, suggesting the quantum emitters are photon stable. These newly discovered 2D quantum emitters extend the emission range of 2D SPEs to the NIR regime and offer new opportunities for the development of next-generation fiber-based quantum communication and quantum information applications.

Heterojunctions of 2D Materials for Molecular Electronics Bhartendu Papnai[1,2] and Mario Hofmann[3]; [1]Academia Sinica, Taiwan; [2]National Tsing Hua University, Taiwan; [3]National Taiwan University, Taiwan

Molecular electronics offer an appealing alternative for future electronic devices, providing advanced functionalities that surpass the current scaling limits of silicon-based electronics. Our work demonstrates that two-dimensional (2D) materials such as graphene that come into contact with the molecular layer contribute to the formation of highly efficient devices. The fabrication of the molecular layer with Langmuir-Blodgett film was utilized to show the tunneling effect of the molecular transistor. The sharp decrease in current with increasing voltage shows a negative differential resistance effect with a high on-off ratio.

Furthermore, our research extends to the examination of thermal and thermoelectric properties within molecular junctions by incorporating molecular monolayers into a thin film configuration. Specifically, our objective is to enhance the performance of thermoelectric devices by integrating graphene-Langmuir Blodgett (LB) films.Our research also delves into Langmuir Blodgett films featuring 2D material heterojunctions, especially in the context of adaptability to diverse light sources, which is a critical aspect of our research.

5:00 PM EL05.08.06
Hydrogenated Borophene-Graphene Broadband Photodetectors for Ultrahigh Photoresponsivity Digvijay S. Tomar and Surojit Chattopadhyay; National Yang Ming Chiao Tung University, Taiwan

2D nanomaterials like graphene, hexagonal boron nitride (h-BN), black phosphorous (BP), and transition metal dichalcogenides (TMDs) have gained significant attention in the past two decades due to their distinct thermal, electrical, optical, and magnetic properties compared to their bulk counterparts[1]. In contrast, borophene, a unique 2D nanomaterial composed entirely of boron atoms, stands out for its advantages in optoelectronic device applications. These include high electrical conductivity, optical transparency in the visible spectrum, strong light-matter interaction, notable mechanical properties (high tensile strength and flexibility), the potential for superconductivity, and good chemical stability, making it suitable for harsh environments[2]. Here, we synthesized hydrogenated borophene through the thermal decomposition of $NaBH_4$ in the presence of H_2. Subsequently, we fabricated a 2-terminal coplanar Borophene/Graphene/SiO_2/Si broadband (405-1064 nm) photodetector (PD) with high photoresponsivity (R). The Borophene/Graphene/SiO_2/Si PD exhibits an outstanding R~ 3.65 x 10^3 A/W under 405 nm laser illumination (@1V bias, 0.05 mW/cm^2). This performance surpasses previously reported values for Borophene-based PDs, which ranged from 0.48 to 9.13 A/W [3-5]. Our PD shows short response, and recovery times of 82, and 83 ms under 633 nm laser illumination compared to previous reports in the range of 110 to 660 ms [3-5]. Our results may stir interest in Borophene for nanophotonics, and optoelectronics devices.

Enhancing Gas Sensing Performance with 2D Material-Integrated Sub-Wavelength Grating Micro-Ring Resonator: Improved Sensitivity and Selective Detection Boxin Zhang, Yadvendra Singh and Harish Subbaraman; Oregon State University, United States

Silicon photonics devices are widely utilized in optical gas sensing owing to their compact size and compatibility with CMOS technology. However, their limited sensitivity hampers their versatility. In this study, we introduce a highly sensitive gas sensor incorporating a 2D material gas-absorbing layer and a sub-wavelength grating (SWG) micro-ring resonator. Leveraging the large surface-volume ratio of the 2D material layer, it efficiently absorbs gas molecules and induces substantial refractive index changes during sensing. Finite-Difference Time-Domain (FDTD) simulation results will be showcased which demonstrate enhancement in both bulk sensitivity and surface sensitivity upon incorporating the 2D material layer. Moreover, the SWG design enables a larger evanescent field-analyte interaction region, resulting in an elevated quality factor for the proposed sensor. Furthermore, by coating the micro-ring resonators with different 2D materials, we envision highly selective sensor architectures.

Large-Scale Growth of Non-Centrosymmetric $MoSe_2$ by Chemical Vapor Deposition and Their Enhanced Nonlinear Optical Response Joohyeon Ahn[1], Seongju Ha[2], Jungseok Choi[1], Dong-Il Yeom[1,1] and Youngdong Yoo[1]; [1]Ajou University, Korea (the Republic of); [2]Korea Research Institute of Standards and Science (KRISS), Korea (the Republic of)

Transition metal dichalcogenides (TMDCs) have various novel electronic and optical properties depending on their structure. Monolayer TMDCs have been used for advanced 2D electronics and 2D optoelectronics due to their exceptional physical and chemical properties. Spiral TMDCs grown through the formation of screw dislocations have been extensively utilized for nonlinear optics due to their non-centrosymmetric structure. However, large-scale growth of TMDCs remains challenging. Here, we report the large-scale growth of monolayer $MoSe_2$ and spiral $MoSe_2$ using a flux-controlled chemical vapor deposition method. With a low flux, monolayer $MoSe_2$ is synthesized, whereas thick spiral $MoSe_2$ is obtained with a high flux. With a medium flux condition, both monolayer and spiral $MoSe_2$ are synthesized. We utilized various analysis techniques such as optical microscopy (OM), atomic force microscopy (AFM), and Raman and photoluminescence (PL) spectroscopy for characterization of synthesized non-centrosymmetric $MoSe_2$. Additionally, nonlinear optical (NLO) signal measurements of monolayer $MoSe_2$ and spiral $MoSe_2$ show the enhancement of NLO signals originating from both non-centrosymmetric structure and the excitonic resonance effects. Monolayer $MoSe_2$ and spiral $MoSe_2$ synthesized using this method are expected to be used as advanced optical materials for electronics, optoelectronics, and nonlinear optics.

5:00 PM EL05.08.09
Controllable Growth of Large Area P-Type MoS2 with Transition Metal Doping using Confined Space CVD Muhammad Suleman, Minwook Kim and Seo Yongho; Sejong University, Korea (the Republic of)

2D molybdenum Disulfide has been used extensively as a semiconductor in recent years. Typically, MoS2 demonstrates an N-Type Behavior as there are sulfur vacancies that are present in the material. However, the large-scale synthesis of P-Type MoS2 and other 2D materials can still be challenging. Various methods can be used for doping the pristine MoS2 to provide P-Type behavior and one of these methods is substitutional doping. Group VB Transition metals like Niobium (Nb), Vanadium (V) and Tantalum (Ta) can be used to achieve substitutional doping into the MoS2 crystal lattice. In this work we have achieved P-Type behavior in CVD grown MoS2 through a similar method. Moreover, the existence of doping atoms was confirmed by using XPS (X-ray photoelectron spectroscopy), EDX (Energy dispersive X-ray) and TEM (Transmission Electron Microscopy). The fabricated back gate FETs also confirm the behavior as a P-Type material. This proposed method for the synthesis of P-Type MoS2 can have a lot of potential applications ranging from photodiodes, photodetectors, optoelectronics, field effect transistors, synaptic transistors, advanced materials heterostructures and energy harvesting.

5:00 PM EL05.08.10
Integrated TEM Membrane Platforms for Lateral Conversion TMD Synthesis Tevye Kuykendall, Aidar Kemelbay, Misael Campos, Alexander Herman and Shaul Aloni; Lawrence Berkeley National Lab, United States

Two dimensional transition metal dichalcogenides (TMDs) are a promising family of materials for a wide range of applications. However, their integration into traditional fabrication pipelines remains challenging. Our research has been working to develop a lithographically patterned, wafer-scalable fabrication process that we call “lateral conversion synthesis.” We have demonstrated this on a host of TMDs, including W, Mo, Pt, sulfides, selenides, and tellurides,

alloys and heterostructures. We will present an overview of these results, as well as a process to directly synthesize TMDs on electron transparent membranes for performing transmission electron microscopy. We demonstrate that by using these membranes, we can resolve and optimize the crystalline microstructure, domains and lattice structures of the TMDs grown through lateral conversion.

5:00 PM EL05.08.11
Chemical Vapor Transport Growth of Selenene and its Heterostructures with TMDs Renjith N, Bhargav Rajbongshi and Manikoth Shaijumon; IISER Thiruvanathapuram, India

2-dimensional (2D) materials have attracted a lot of scientific attention recently beyond graphene, due to their distinct physicochemical features. Elemental 2D crystals have emerged as promising materials for advanced electronics and optoelectronics applications.[1] In particular, group-VI elemental 2D semiconductors, including selenene and tellurene, have attracted significant attention for their simple composition and excellent properties, such as higher carrier mobility, better environmental stability, and high photoconductivity, which triggered intense activities on their fundamental and application-oriented research.[2] 2D heterostructures based on various 2D layered materials with distinct properties have been demonstrated to exhibit novel physicochemical properties for their potential application in electronics, optoelectronics, and catalysis, owing to their tunable band alignment and sharp interfaces.[3] Forming new structures by stacking transition metal dichalcogenide (TMD) layers has been explored by several groups; however, the mechanical transfer method is time-consuming and suffers from having reasonable control on the layer stacking. Single-step and two-step chemical vapor deposition (CVD) growth of lateral and vertical TMD heterostructures have been considered to be a promising approach to realize the potential applications of these heterostructures.[4]. Achieving controllable growth of high-quality, ultra-thin flakes of elemental 2D materials remains a challenge. Herein, we demonstrate a seed-assisted chemical vapor transport (CVT) growth of ultra-thin triangular flakes of highly crystalline trigonal selenium (t-Se) oriented in (0001) direction, with lateral size >30 μm.[5,6] To study their promising photo-electrocatalytic properties and further realize the device applications, we employed a single-step CVT approach to grow selenene/WSe_2 heterostructures. Vertical heterostructures of bi-layer selenene and monolayer WSe_2 domains obtained via the CVT method are characterized by optical microscopy, transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), and Raman spectroscopy. The Se/WSe_2 heterostructure exhibit improvements in the HER activity as evidenced by the overpotential which is dramatically decreased from 163 mV to 121 mV for a current density of 10 mA cm^{-2} and the Tafel slope also reduces from 109 mV dec^{-1} to 75 mV dec^{-1} upon shining the light. The method could be extended to synthesize different 2D elemental and TMD heterostructures.

5:00 PM EL05.08.12
Direct-Growth-Enabled Monolithic Integration of Monolayer MoS_2 Vertical Field-Effect Transistors Huimin Lee[1], Seonguk Yang[1], Kihan Kim[2], Saeyoung Oh[1], Huyoung Jeong[1], Byungchul Jang[2] and Joonki Suh[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of)

The ultimate hyper-scaling regime for two-dimensional (2D) semiconductors requires device innovations beyond conventional planar structures, and so it is in the urgent need for developing a tailored integration solution. Recently, 2D-layered semiconductors have shown great potential as channel materials for various electronic devices due to their atomically thin structure, dangling-bond-free characteristic, and well-controlled electrostatics that can overcome intrinsic limitations as seen in sub-5-nm-body-scaling-node of silicon (Si). Nevertheless, the relevant 2D semiconductor integration has been often limited to low-fidelity transfer approaches, obviously not friendly for non-planar device structures. Here, we demonstrate vertical MoS_2 transistor and non-volatile memory with sequential growth level integrated 2D semiconductors in a 3D architecture enabling simple processes at scalable array scale with precisely fined vertical channel thicknesses down to ~ 6.5 Åm for high density. Such monolayer MoS_2-based vertical field-effect transistor (FET) shows excellent switching and leakage current characteristics with an on/off ratio of ~ 10^8 and a SS_{min} of ~ 77 mV dec^{-1}. Technology computer-aided design (TCAD) simulations were successfully performed to verify that the vertical MoS_2 channels aligned along the vertical sidewalls showing the capabilities of modulating the vertical transport properties via additional side control gates. Furthermore, high crystalline 2D MoS_2 was applied as a channel material for a vertical charge trap flash (CTF) memory showing excellent on/off ratio as well as reliable retention characteristics and endurance performance. This work promotes the monolithic production of vertical 2D MoS_2, which can break through the lateral integration limits, and presents a new platform as a next-generation V-NAND channel material with atomically thin conformality and high crystallinity that can be scaled up to ~ 10 μm, corresponding to V-NAND 300-layers scale.

Complementary 2D Tunnel FETs with Extremely Asymmetric Dual-Barrier Heterostructures Hanbin Cho, Seonguk Yang, Donggyu Park and Joonki Suh; UNIST, Korea (the Republic of)

Conventional metal oxide semiconductor field-effect transistor (MOSFET) technology currently suffers from the scaling of supply voltage owing to the required power per computed bit of information tightly bound to the subthreshold swing (SS) of 60 mV/dec at room temperature. Tunneling field-effect transistor (TFET) is a promising building block for low-power and steep-slope switching applications in that the lower limit of MOSFET SS, inherently caused by thermionic emission, can be overcome by utilizing band-to-band tunneling. In this presentation, we propose the TFETs using band-offset engineering via 2D van der Waals (vdW) hetero- and multi-junctions. Indeed, 2D materials are ideally suited since they are free from non-ideal tunneling tendencies originating from lattice mismatch as seen in bulk hetero-junctions and their atom-thick body is under the complete electrostatic control. In the fabricated 2D heterostructured TFETs, $SnSe_2$ and SnSe not only function as the electron and hole reservoirs but provide a highly asymmetric band offset alignment to the intrinsic channel where MoS_2 and WSe_2 are employed for nTFET and pTFET, respectively. The van der Waals coupled TFETs show the promising device characteristics of low-power switching operations in terms of SS and off-current compared to MOSFETs using the same kinds of channels. In addition, complementary 2D TFETs, implemented in both n-type and p-type, expand the breadth of logic configurations. We expect to be able to leverage this naturally biased 2D material platform to implement effective low-power circuits.

Synthesis and Atomic-Scale Investigation of Phosphorus-Doped Graphene on Copper Oscar Chavez, Jerome Brown, Owen Hudak and Li Gao; California State University, Northridge, United States

Phosphorus doped graphene has potential applications in supercapacitors, lithium ion batteries, fuel cells, and sensors. A phosphorus-containing sole precursor has been used for the synthesis of phosphorus-doped graphene on the Cu(111) surface. The surface morphology, electronic structure of phosphorus dopants, and doping-induced variation of local work function of graphene have been studied on the atomic scale by using scanning tunneling microscopy, dI/dV spectroscopy and dZ/dV spectroscopy. Bias-dependent atomic-resolution STM images of the predominant type of phosphorus dopants have been obtained. dI/dV spectra show the effect of phosphorus doping on the electronic structure of the graphene surface. dZ/dV spectra show that the local work function decreases at the phosphorus dopant site, leading to a downward energy shift of field emission resonances. X-ray photoelectron spectroscopy measurements are also performed to characterize the overall phosphorus doping properties on the sample surface. This work provides atomic-scale experimental insights into the phosphorus dopants in graphene for the first time.

5:00 PM EL05.08.15
Synthesis, Structure and Magnetic Properties of a New Spin-1 Honeycomb Lattice $KNiAsO_4$ with a Zig-Zag Magnetic Structure Duminda Sanjeewa; University of Missouri–Columbia, United States

Identifying and characterizing new honeycomb magnetic systems are the key ingredients to explore new candidate materials for the Kitaev model as the model realizes the exact quantum spin liquids ground state. Recently the Kitaev model with higher spins ($S = 1$) systems have been proposed as candidate materials to host the quantum spin liquid state. Honeycomb compound, KNiAsO4, is one such magnetic system and here, we present a comprehensive series of magnetic and neutron scattering measurements and evaluate the potential for Kitaev physics via the experimental determination of the spin-Hamiltonian. Bulk magnetic measurements of KNiAsO4 reveal an antiferromagnetic transition at ~ 19 K which is generally robust to applied magnetic fields. Neutron diffraction measurements show magnetic order with a k = (3/2 , 0, 0) ordering vector which results in the well-known “zigzag” magnetic structure thought to be adjacent to the spin-liquid ground state. Inelastic neutron scattering experiments show a well defined gapped spin-wave spectrum with no evidence of the continuum expected for fractionalized excitations. Modeling of the spin waves shows that the extended Kitaev spin-Hamiltonians is generally necessary to model the spectra and reproduce the observed magnetic order. Overall, our results demonstrate that the KNiAsO4 is a promising candidate to study Kitaev physics associate with spin-1 honeycomb system.

5:00 PM EL05.08.17
Photoelectric Properties of Funnel Devices Based on Asymmetrically Strained Two-Dimensional Materials Kyung-Hwa Yoo; Yonsei University, Korea (the Republic of)

Strain applied to transition metal dichalcogenides (TMDs) decreases their energy bandgap. When local strains are present, a band structure resembling a funnel is created, guiding excitons toward the most strained region. In this study, we present a device with a funnel-like structure based on WS_2 and MoS_2, achieved through asymmetric strains. These strains were induced by transferring TMD flakes onto a fork-shaped SU-8 microstructure. The Raman and photoluminescence spectra peaks were observed to shift based on the morphology of the SU-8 microstructure, confirming the application of asymmetric strains on the TMDs. To examine the potential conversion of funneled excitons into electrical currents, we fabricated various devices by depositing electrodes, both symmetric and asymmetric, onto the strained TMDs. Scanning photocurrent mapping (SPCM) images exhibited a fork-shaped pattern, suggesting the likely conversion of funneled excitons into electrical currents. Specifically, funnel devices with asymmetric Au and Al electrodes demonstrated an enhancement of short-circuit current (I_{SC}) in WS_2 due to the applied strains. On the other hand, I_{SC} in MoS_2 was suppressed as the increasing strain lowered the Schottky barrier, unlike WS_2 where the Schottky barrier was not affected by the strain. These findings underscore the potential of utilizing asymmetrically strained TMDs for implementing funnel devices, and emphasize the TMD-specific impact of strains on the Schottky barrier.

5:00 PM EL05.08.18
Lithography-Free Patterned Growth of Few-Layer MoS_2 Assisted by Electron Irradiation Haobo Li, Edward K. Naland and Silvija Gradecak; National University of Singapore, Singapore

Two-dimensional (2D) transition metal dichalcogenides (TMDs) have emerged as promising candidates for applications such as gas sensors, photodetectors, and channel materials in field-effect transistors, thanks to their tunable band structures, reduced leakage current, and high carrier mobility. The patterning of 2D-TMDs is critical in device fabrication, traditionally requiring a complex lithography process. We demonstrate an approach to depositing MoS_2 flakes on SiO_2/Si substrates with a predefined pattern shape, utilizing localized electron irradiation on the surface of SiO_2/Si wafers. Within the regions exposed to low-dose electron irradiation, we successfully achieve area-selective growth of MoS_2 during chemical vapor deposition (CVD) process with selectivity of >0.7. In contrast, negative selectivity with suppressed growth is achieved in heavily irradiated areas of the substrate.

We have investigated the modification of surface potential on SiO_2/Si substrates due to localized electron irradiation using Kelvin probe force microscopy (KPFM) and demonstrated that selective growth takes advantage of the local surface potential difference. The variation of the surface potential is predictable by an analytical model. Raman spectroscopy analysis reveals the adsorption of carbon species due to irradiation, acting as a blocking layer that inhibits MoS_2 growth and contributes to the observed negative selectivity. We will discuss the role of CVD parameters (e.g., precursor flux), surface potential, adsorption of carbon species, and surface topography change observed by atomic force microscopy (AFM) in achieving the desired selectivity in CVD growth of MoS_2. Our findings pave the way for a controllable lithography-free patterned synthesis of 2D-TMD materials, eliminating the need for complex lithography processes and minimizing contamination. This study presents a promising approach to achieving a bottom-up fabrication process for the next-generation TMD-based device fabrication and its further scaling.

5:00 PM EL05.08.19
Formation of Silicon/Graphene Heterostructures through Co-Gas-Phase Synthesis Muhammad Ali[1,2], Hartmut Wiggers[1] and Michael Pope[2]; [1]University of Duisburg-Essen, Germany; [2]University of Waterloo, Canada

The introduction of 2D materials as an active or enabling component is of significant interest in the field of electrochemical energy storage because it provides properties such as mechanical stability, large surface area and at the same time low material requirements. Furthermore, graphene-like 2D structures show strong electrical conductivity and electrochemical stability. While each individual 2D material has unique advantages, the deliberate assembly of heterostructures made up of different flakes in configurations such as 2D/2D or particle-flake (0D/2D) emerges as an important advancement. Such finely built heterostructures not only improve functioning but also have potential to push the performance of energy storage devices to levels that were not previously possible. A simple, competitive and scalable strategy to produce heterostructures by combining 0D nanoparticles and 2D graphene in the gas phase is reported in this research work. Gas-phase synthesis of graphene is known for more than a decade which is now further developed to give production rates of few hundred mg/h of few-layer graphene (FLG). By combining two independent gas phase reactors, this few-layer graphene is controllably mixed with other functional materials in the gas phase to obtain heterostructures without the use of structure directing agents. The reactor system was involving a microwave plasma and a hot wall reactor. Silicon nanoparticles were synthesized in the hot wall reactor, meanwhile graphene was produced in the MW plasma reactor. Both reactors were connected in such a way that the nanoparticles and graphene get in contact with each other directly in the gas phase after their inception. In this way the self-assembled heterostructures of graphene and nanoparticles are produced with the production rate reaching almost 800 mg/h. The materials were characterized with TEM, Raman spectroscopy, XPS and XRD to investigate the morphology, composition and structure. TEM images indicate silicon is present as almost spherical nanoparticles that form small aggregates. These particles are interconnected by graphene. EDX mapping shows silicon nanoparticles having graphene surrounding them. It is present between the aggregates of nanoparticles as well as connecting them to each other. Raman as well as XRD spectra confirmed the presence of silicon and graphene in heterostructures with extraordinary purity. The presence of silicon in crystalline as well as amorphous form was also confirmed from Raman spectra. It will be shown that the successful formation of 0D/2D silicon/graphene heterostructures used as anode material for lithium-ion batteries has illustrated some significant improvements. Compared to pure silicon, their combination results in excellent long-term stability of the anode while also increasing its Coulombic efficiency. Thus, the formation of these heterostructures in the gas phase offers the possibility to exploit the potential of silicon to significantly increase the anode storage capacity.

5:00 PM EL05.08.20
Wafer-Scale Synthesis of MoS_2 Atomic Layers with Different Mo Precursor Solutions and Application to Thin-Film Transistors Woon-Seop Choi; Hoseo University, Korea (the Republic of)

Recently, transition-metal dichalcogenides (TMDs) have attracted much attention as new materials for electronics devices, electrocatalysts, photocatalysts, sensors, batteries, and bio-applications. Most TMDs are two-dimensional (2D) materials with a single layer. Bonds between each layer are made up of Van der Waals bonds, while intra-layer atoms bind together as covalent bonds.
Chemical vapor deposition (CVD) with sulfur gas is the most popular method for synthesizing large- scale 2D materials with high quality. Various MoS_2 can be obtained from this method using various precursors with different properties, process temperatures, and substrate materials. Solution process methods show advantages for preparing films with large size, high throughput, low cost, thickness control, and an environmentally friendly process. Even though there is sulfur in the precursors of the solution-process synthesis methods, supplementing the sulfur that is lost in the high-temperature CVD process is unavoidable.
In this study, two precursors of ammonium tetrathiomolybdate and ammonium molybdate were used in different solvent formulations to make MoS_2 crystalline by using simple thermal annealing and bottom-up thermolysis methods. These methods were relatively easy to handle, safe, and environmentally friendly processes. Importantly, these MoS_2 atomic layers were completed without additional sulfurization using CVD, but just with a single step of annealing because of sulfur-rich formulations.
The 2D atomic layers were controlled to 2 to 7 layers with precursor concentrations with both formulations, which were confirmed by STEM-FIB. Thin-film transistors (TFTs) were prepared from the solution-processed MoS_2 on Al_2O_3 and SiO_2 dielectric with thermal evaporated Al source and drain electrodes. The results show improved mobilities of 9 to 48 $cm^2 V^{-1}s^{-1}$ and reasonable on-off ratios of around 1.0×10^5 with solid output saturations. These new methodologies can be applied to multifarious devices and have the potential for scalability in 2D MoS_2 materials.

5:00 PM EL05.08.21
Efficient Room Temperature Gas Detection Using a with Au-MoS_2 Hybrid Gas Sensor Saurabh Rawat, shivani Dangwal, Charu Dwivedi and Himani Sharma; Doon Unniversity, India

The pressing need for effective gas sensing devices is evident, given the critical role they play in environmental monitoring, industrial safety, and health diagnostics. Addressing this demand, we synthesized triangular domains of molybdenum disulfide (MoS_2) using the Chemical Vapor Deposition (CVD) method. To elevate their gas sensing potential, these MoS_2 domains were decorated with gold (Au) nanoparticles via thermal evaporation. Additionally, for sensing applications, an electrode pattern was meticulously fabricated over the MoS_2 triangular domains using thermal evaporation. The thorough characterization involved techniques like Scanning Electron Microscopy (SEM), X-ray Photoelectron Spectroscopy (XPS), Ultraviolet Photoelectron Spectroscopy (UPS), and Kelvin Probe Force Microscopy (KPFM) to determine their surface potential and electronic properties. A significant finding was that the enhanced gas sensing response observed in the Au-decorated MoS_2, which was 4.5 times greater than its undecorated counterpart, was attributed to the formation of a Schottky barrier. Capitalizing on this insight, we designed and fabricated a real-time gas sensing device, marking a transformative leap in gas detection technology

5:00 PM EL05.08.22
A Scalable Electrochemical Intercalation of Transition Metal Dichalcogenide Powders Nicholas Wilson[1], Manila Valappil[1], Mira Mackintosh[1], Teri Siu[1], Jochen Konieczny[2], Michael Pope[1], Neil Graddage[3] and Franziska E. Muckel[2]; [1]University of Waterloo, Canada; [2]Universität Duisburg-Essen, Germany; [3]National Research Council, Canada

Electrochemical exfoliation of transition metal dichalcogenides (TMD) is a popular method for creating large-sized and well-exfoliated sheets. Cathodic exfoliation using tetraheptylammonium bromide is a promising method for optoelectronics applications due to its ability to retain the semiconducting 2H polymorph. However, this method has several challenges. Expensive single crystals are used, which limits the amount of material generated. Additionally, the crystals expand significantly, causing sporadic and uncontrolled electrical contact to the crystal throughout intercalation. This limits the achievable degree of intercalation of the crystal.

To address these issues, we describe the construction of an electrochemical cell that can be scaled to an arbitrary size and used to intercalate TMD powders. This cell constrains material, applies a homogeneous electrical contact, and enables controlled intercalation using a reference electrode. The intercalated materials can then be easily exfoliated and dispersed by ultrasonication. We also demonstrate that the exfoliated sheets can be assembled into continuous films and coated onto arbitrary flat substrates over large areas using a modified Langmuir-Blodgett method. We use this approach to study the films as photodetectors.

Our work provides a scalable solution for intercalating TMD powders and creating well-exfoliated sheets that can be used in optoelectronics applications.

5:00 PM EL05.08.23
Fabrication of Nanostructured Molybdenum Disulfide (MoS_2) Thin Film–Based Electronic Devices Kevin Qian, Ibraheem Giwa, Fabian Sanchez, Elton Mawire, Sherwood Dong, Eric Smith, Qunying Yuan and Zhigang Xiao; Alabama A&M University, United States

In this study, we report the fabrication of molybdenum disulfide (MoS_2) thin films–based electronic devices. Nanostructured molybdenum disulfide (MoS_2) thin films are grown as the active semiconducting channel material for the fabrication of MoS_2-based field-effect transistors using plasma-enhanced atomic layer deposition (ALD). MoS_2–based electronic devices such as MoS_2 field-effect transistors, inverters, and ring-oscillators are fabricated with the ALD-grown MoS_2 film using the clean room-based micro- and nano-fabrication techniques. Hydrogen sulfide (H_2S) gas is used as the S source in the growth of molybdenum disulfide (MoS_2) while molybdenum (V) chloride ($MoCl_5$) powder is used as the Mo source. The MoS_2 film will be analyzed by the high-resolution tunnel electron micrograph (HRTEM), scanning electron micrograph (SEM), X-ray photoelectron spectroscopy (XPS) analysis and Raman spectrum analysis. The fabricated MoS_2 device wafer will be annealed at high-temperatures (800 – 900 ^oC), and the electrical property of the MoS_2–based electronic devices will be measured before and after the high-temperature annealing and will be compared. The characterization results of the nanostructured molybdenum disulfide (MoS_2) thin films and the measurement results on the fabricated MoS_2–based electronic devices will be reported in the 2024 MRS Spring Meeting.

High Performance GQD/Graphene Heterostructure Field Effect Phototransistor with Efficient Photoinduced Effects Muhammad Shehzad Sultan[1], Ernesto Espada Nazario[1], Bianca S Umpierre Ramos[1], Daniela D Negron Negron[1], Amanda M. Gracia Mercado[1], Wojciech Jadwisienczak[2], Brad Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico - Río Piedras, United States; [2]Ohio University, United States

Graphene and highly luminescent graphene quantum dots (GQDs) have been widely used in optoelectronic devices as a photoactive material. Graphene Quantum Dots (GQDs) have been widely used for various optoelectronic devices as a photoactive material due to their high absorption coefficient and tunable bandgap. However, the low mobility of GQD films results in poor charge collection and device performance. By combining GQDs with graphene into hybrid GQDs/Graphene field effect transistors, photocarriers from GQDs are transferred to graphene, improving charge collection and transport, drastically increasing the photoresponsivity. In this study, we report the preparation of a GQDs/Graphene heterostructure in order to investigate the effect of GQDs on photoactive response of graphene. Using UV–vis absorption and photoluminescence (PL) spectra, the optical properties of graphene and the GQDs/Graphene heterostructure were measured and compared. Moreover, to investigate their electronic and charge transfer properties, we fabricated field-effect phototransistors (FEPT) on pristine graphene and GQDs/Graphene heterostructure thin films and investigated their photoactive electrical properties. Under illumination, both pristine and GQDs/Graphene FEPT showed an increase in current and carrier mobility. The increased current and carrier mobility of GQDs/Graphene FEPT is due to the presence of a large number of photoexcited charge carriers. The current and carrier mobility in the GQDs/Graphene heterostructure FEPT were also lower than those in the pristine graphene FEPT. This is explained by GQDs' n-type doping effect on graphene, which reduces the accumulation of holes in the active p-channel near the insulating layer and causes charge to be transferred from the GQDs to the graphene. As a result, we discovered a charge transfer effect in the GQDs/Graphene heterostructure, which could be used in optoelectronic devices.

SESSION EL05.09: Memory Devices II

Neuromorphic Circuits and Devices Based on MoS_2 Andras Kis; Ecole Polytechnique Federale de Lausanne, Switzerland

Machine learning and signal processing on the edge are poised to influence our everyday lives with devices that will learn and infer from data generated by smart sensors and other devices for the Internet of Things. The next leap towards ubiquitous electronics requires increased energy-efficiency of processors for specialized data-driven applications. I will present here how we realised an in-memory processor fabricated using a two-dimensional materials platform can potentially outperform its silicon counterparts in both standard and non-traditional Von Neumann architectures for artificial neural networks. The circuits are based on a flash memory array with a two-dimensional channel using wafer-scale MoS_2. Simulations and experiments show that the device can be scaled down to sub-µm channel length without any significant impact on its memory performance. I will then present our latest work with large-scale integrated vector-matrix multiplier circuits with over 1000 memories based on MoS_2.

9:00 AM *EL05.09.02
Compute-in-Memory Hardware based on 2D Materials for Convolution Neural Networks Kah-Wee Ang; National University of Singapore, Singapore

The exponential growth of data storage and computation requirement has imposed severe power consumption challenges for digital computers built on traditional von Neumann architecture. New computing systems using the compute-in-memory (CIM) concept could offer a potential solution to overcome the inherent energy consumption and latency issues. In particular, CIM based on analog memristors is promising to enable a low latency and energy-efficient approach for performing data-intensive tasks such as image processing by means of neural network training. Here, we demonstrate memristive crossbar arrays (CBA) using transition metal dichalcogenides for implementing convolution neural network (CNN) hardware. The memristor achieves a small switching voltage, low switching energy, and improved variability in addition to the ability to emulate synaptic weight plasticity. The CBA successfully implements both neuromorphic and matrix-heavy workloads in neural networks, including artificial-synapse-based ANN, multiply-and-accumulate (MAC) operations, and convolutional image processing with high recognition accuracy. Moreover, the column-by-column MAC operation manifests a highly parallelized computing ability, opening a route to enable hardware acceleration of machine learning algorithms for emerging artificial intelligence applications.

9:30 AM EL05.09.03
Transfer-Free Wafer-Scale Graphene Electronics on Sapphire Oliver Fenwick[1], Zhichao Weng[1], Sebastian Dixon[2], Lok Yi Lee[2], Colin Humphreys[1,2], Ivor Guiney[2], William Gillin[1], Robert Wallis[2], Bryan Wingfield[2], Paul Evans[2], Piotr Baginski[2], Jaspreet Kainth[2], Andrey Nikolaenko[2] and Joanna Baginska[2]; [1]Queen Mary University of London, United Kingdom; [2]Paragraf Ltd., United Kingdom

The realisation of commercial graphene solid-state electronics devices has been held back by challenges of processing high-quality monolayer graphene at scale. In this work, we used wafer-scale graphene as the electrode in selected electronic devices, notably OLEDs and memristors. The graphene was grown by Paragraf Ltd using their proprietary growth process to produce high quality, monolayer graphene grown directly onto 50 mm sapphire wafers in batches of up to 37 wafers in metal-organic chemical vapour deposition (MOCVD) reactors. All processes in device production are compatible with semiconductor production lines, and we find graphene to be remarkably robust to these processes.

Graphene memristors in non-volatile memory or neuromorphic computing applications could offer high integration density as well as robustness against common memristor degradation mechanisms. The latter includes oxygen vacancy diffusion into the electrode and unwanted metal ion diffusion from the electrodes, both of which are prevented by the in-plane covalent bonding of graphene. Wafers containing 2520 memristors of different sizes with graphene electrodes were fabricated. The as-fabricated graphene memristors showed a high *ON/OFF* ratio of $10^7 \sim 10^8$ when under a bias pulsing rate of 0.5Hz – 1Hz, robust endurance (switching remained stable after >2700 cycles), stability (no device degradation after 1.8 hrs of switching at 26Hz – 46Hz) and low voltage operation (low V_{set} ~1.6V and V_{reset} ~-1.55V).

Graphene is considered as a promising material for replacing ITO, which has long term supply issues due to its limited elemental abundance, but for this to become possible. The as-grown graphene was patterned using photolithography and its conductivity was enhanced by doping with nitric acid prior to deposition of the OLED stack. The electrical and optical performances of the as-fabricated graphene-based OLEDs were identical to control devices with conventional ITO anodes [1].

9:45 AM EL05.09.04
Ultrathin $Sb_2Te_3/Ge_4Sb_6Te_7$ Superlattices for Low-Power and High-Speed Phase Change Memory Xiangjin Wu[1], Asir Intisar Khan[1], Huairuo Zhang[2,3], Heshan Yu[4,5], Albert Davydov[2], Ichiro Takeuchi[4], H.S. Philip Wong[1] and Eric Pop[1]; [1]Stanford University, United States; [2]National Institute of Standards and Technology, United States; [3]Theiss Research, Inc., United States; [4]University of Maryland, United States; [5]Tianjin University, China

The demand for robust and low-power nonvolatile memory is on the rise due to the rapid growth of big-data, high-performance computing, and data-centric artificial intelligence applications. Phase-change memory (PCM) based on chalcogenides has the potential to bridge the performance gap between existing storage solutions like flash and dynamic random-access memory. Traditional PCM materials suffer from issues such as high switching power and resistance drift over time [1,2]. Superlattices (SLs) made of nanometer-thin phase change materials arranged in alternating layers can overcome some of these challenges by lowering switching current and resistance drift [3,4]. However, the operation speed of these SL-PCM devices has remained slow, ~ hundreds of ns [4].

Here, we present nanoscale PCM devices (~ 40 nm bottom electrode diameter) based on Sb_2Te_3/GST467 superlattices. Unlike traditional PCM materials, GST467 contains coherent SbTe nanoclusters within the Ge-Sb-Te matrix, enhancing crystallization and lowering the melting temperature. These nanoclusters act as precursors for crystallization, boosting the switching speed of GST467. By incorporating GST467 into our superlattice PCM devices, we achieved remarkable results, including a record-low switching power density of approximately 5 MW/cm^2, an ultra-low switching voltage of around 0.7 V, sub-1.5 pJ switching energy, rapid switching speed of about 40 ns, low resistance drift with 8 distinct resistance states, and high endurance of ~ 2×10^8 cycles.

The performance of our devices is attributed to strong heat confinement within the superlattice interfaces and their nanoscale dimensions. Additionally, the unique microstructural properties of GST467, coupled with its higher crystallization temperature, contribute to faster switching speeds and improved stability, surpassing some of the fundamental trade-offs observed in conventional PCM. Importantly, this study combines bottom-up natural interfaces in the nanocomposite with top-down superlattice interfaces in the same memory material, resulting in superior device performance.

Growth of Semiconducting Graphene Nanoribbons and Single-Crystal Graphene on Germanium Robert M. Jacobberger; University of Wisconsin-Madison, United States

The chemical vapor deposition of graphene on germanium (Ge) and germanium-on-silicon (Ge-on-Si) substrates provides a scalable, industry-compatible route for integrating graphene-based devices on traditional semiconductor platforms. Here, we will discuss our work on the wafer-scale synthesis of aligned semiconducting graphene nanoribbon arrays and single-crystal semi-metallic graphene films on Ge wafers.

First, we have discovered how to drive graphene crystal growth kinetics into a highly anisotropic regime, enabling the synthesis of graphene nanoribbons with tunable sub-5-nm widths, nearly atomically defined armchair edges, atomic thickness, and unidirectional alignment on Ge(001) and vicinal Ge(001).[1,2,3,4] This precise control over the nanoribbon width and edges transforms graphene into a semiconductor with technologically useful bandgap > 0.5 eV. The nanoribbons also exhibit high performance in field-effect transistors in terms of their on-state conductance (~10^3 μS μm^{-1}) and on/off current ratio (~10^4). Initiating the nanoribbon growth from nanoscale seeds significantly reduces ribbon-to-ribbon width polydispersity and provides control over the nanoribbon placement. Such semiconducting nanoribbon arrays with narrow widths and well-defined edges promise to meet the demands of speed, energy efficiency, density, and functionality required for next-generation semiconductor electronics and promise to meet the performance metrics set by the International Roadmap for Devices and Systems for the foreseeable future.

Second, we have elucidated the factors controlling the crystallinity of graphene grown on Ge(110) using advanced dark-field low-energy electron microscopy (DF-LEEM) and micro-low-energy electron diffraction (μ-LEED). This insight is utilized to produce large-area graphene films with minimal rotational misalignment—a major step toward realizing state-of-the-art technologies harnessing the exceptional properties of graphene lacking defective grain boundaries. We have discovered a new phenomenon in which misoriented graphene domains nucleate from the edges of unidirectionally aligned graphene islands when the islands grow over Ge surface steps, increasing polycrystallinity throughout growth. Extensive synthesis studies provide strategies for suppressing this secondary nucleation of misoriented domains to achieve graphene films in which the predominant epitaxial orientation has high coverage > 99% and low rotational spread < 0.6°. These results clarify the varying crystallinity and irreproducibility of graphene grown on Ge(110) reported in the literature, demonstrate the importance of using techniques with high spatial and angular resolution when determining if 2D materials are single crystals, and provide a route towards the large-area synthesis of single-crystal graphene on commercially available and technologically useful substrates.

10:45 AM EL05.10.02

A Method for Extracting 2D Semiconductor Mobility in Transistors with Gate-Voltage-Dependent Contact Resistance Robert K. Bennett[1], Lauren Hoang[1], Connor Cremers[1], Andrew J. Mannix[1,2] and Eric Pop[1,1]; [1]Stanford University, United States; [2]Stanford Institute for Materials and Energy Sciences, United States

Emerging two-dimensional (2D) semiconductors are frequently characterized in terms of their electron and hole mobilities, which quantitatively describe the speed at which these carriers move through a material under an applied electric field. These mobilities are commonly extracted by fabricating and measuring field-effect transistors (FETs) and applying one of several techniques to estimate the 2D semiconductor's electron or hole mobility. Back-gated FETs are often used for these extractions because they can be fabricated in fewer steps and in higher yields compared to top- or dual-gated geometries. However, back-gated FETs experience *contact gating*: the electric field from the gate electrode acts on the transistor's source and drain, causing the contact resistance to decrease as the magnitude of the gate voltage increases [1–5].

Although contact gating increases the drive current that a 2D FET can achieve by minimizing contact resistance in the on-state [1, 3, 6], contact gating also modifies the shape of a transistor's transfer characteristics (i.e., I_D vs. V_{GS} characteristics, where I_D is the drain current and V_{GS} is the gate-to-source voltage). Consequently, conventional mobility extraction techniques can overestimate the mobilities of emerging semiconductors in back-gated FETs by up to an order of magnitude [2–4]. Thus, it was suggested that mobility in back-gated FETs should be estimated only at high $|V_{GS}|$ ($>> |V_T|$, the threshold voltage) to ensure that the channel resistance, rather than contact gating, dominates the FET transfer characteristics [2, 4]. Alternatively, mobility can be accurately extracted from FETs with more complicated geometries and fabrication procedures that allow for the effects of contact gating to be eliminated (such as FETs that incorporate additional terminals to probe the channel [7]). Although these approaches may be viable in some situations, the former method can be unsuitable for transistors that experience early dielectric breakdown, whereas the latter approach can introduce additional experimental complexity during fabrication.

In this work, we propose a method of extracting a semiconductor's carrier mobility that is compatible with back-gated FETs but that does not require the FET to operate in a channel-dominated regime. This method is inspired by the conventional transfer length method (TLM) approach but makes use of a transistor's I_D vs. V_{DS} characteristics (where V_{DS} is the drain-to-source voltage), rather than its I_D vs. V_{GS} characteristics, allowing us to properly account for contact gating in back-gated FETs without having to use complicated geometries to directly probe the channel.

We validate this proposed method using current-voltage characteristics simulated by technology computer-aided design (TCAD). We find that this proposed method offers accurate mobility extraction (< 10% error) in regimes where conventional methods (including the linear extrapolation method, Y-function method, and TLM approach) overestimate mobility by > 50%. Furthermore, we demonstrate that this proposed method is robust to random variation in material quality, and we experimentally validate this method by demonstrating that experimentally-measured current-voltage characteristics of back-gated monolayer tungsten disulfide (WS_2) FETs fit the method well. Overall, we anticipate that the method we propose in this work will allow for the mobilities of emerging semiconductors to be more quickly and easily extracted without requiring sophisticated transistor geometries or complicated fabrication procedures.

Interconnect Technologies in The Ultrathin Limit: Performance of Standard and 2D Barriers and Liners in The Nanometer Thickness Regime Hippolyte P. Astier[1], Muhammed Juvaid Mangattuchali[1], Hao Tan[1], Jing Yang Chung[1], Chandan Das[2], John L. Sudijono[2] and Silvija Gradecak[1]; [1]National University of Singapore, Singapore; [2]Applied Materials Singapore Technology PTE LTD, Singapore

Copper wires in the back-end-of-line (BEOL) interconnects typically require two layers surrounding them: a diffusion barrier preventing Cu from diffusing into the dielectrics, and a liner, ensuring cohesive Cu wires and smooth interfaces. The current industry standards for barrier and liner applications include TaN and Ta, respectively, which then form a bilayer with a typical thickness of ~4 nm. However, with the advent of the 3-nm technology nodes, interconnect half-pitches have reached the scales of 10 nm. Consequently, the barrier/liner bilayer would represent a significant fraction of the wire cross-section and increase the wire resistance and cause significant RC delays. The polycrystalline nature of the conventional TaN/Ta bilayer films prevents formation of a continuous and effective film in the ultrathin regime. Moreover, their performance as a function of the film thickness is poorly understood, especially in ultrathin films.
In recent years, this expected limitation of conventional barriers and liners has motivated intense efforts to replace them with 2D materials, as these can be continuous yet atomically thin. However, no approach reported thus far fulfills the requirements for BEOL integration, namely low temperature (<450 °C), uniform and scalable growth, thickness control and film conformality to the substrate. We have recently developed a novel approach to growing layered films of WS_2 that fulfills all of these requirements. Our WS_2 films function as bifunctional liners and Cu diffusion barriers. We demonstrate these functionalities through electrical measurements that assess Cu film conductivity in the thin film limit, where we see a significant improvement of several orders of magnitude in Cu conductivity for Cu films of 10 nm. Their performance as diffusion barriers was assessed through time-dependent breakdown measurements, where we see the projected device lifetime increases by one order of magnitude through the utilization of single layers of WS_2. To benchmark the performance of this new class of 2D barrier/liner layers, we compare the level of performance as a function of the film thickness both in 2D layered WS_2 films and in polycrystalline TaN films, in regimes from 4-nm thicknesses down to the ultrathin ~1 nm limit. This approach provides an ability to identify and study the thickness regime in which 2D-layer films are expected to outperform the standard TaN layers. We will also discuss measurements and modelling approaches toward evaluation of temperature-dependent diffusion barrier properties for standardized barrier evaluation in the ultrathin film limit.

11:15 AM EL05.10.04
Impact of Substrates on Graphene Sensors Masahiro Ishigami[1], Jyoti Katoch[2] and Michael Lodge[3]; [1]University of Central Florida, United States; [2]Carnegie Mellon University, United States; [3]Truventic LLC, United States

We have measured desorption of atomic hydrogen from graphene devices on hexagonal boron nitride and compared to our results from graphene devices on silicon oxide using transport measurements in ultra high vacuum environment. We found that atomic hydrogen desorbed at much narrower range of

temperatures on hexagonal boron nitride, indicating that chemical interaction was more uniform on hexagonal boron nitride. Our results indicated that hBN could significantly reduce the variability in interaction energies of chemical species on graphene and, as a result, it could be a better substrate for graphene-based chemical sensors.

11:30 AM *EL05.10.05
MOCVD and Device Technology of 2D-TMDC Layers and Heterostructures Holger Kalisch[1], Songyao Tang[1], Yibing Wang[1], Yingfang Ding[1], Hleb Fiadziushkin[1], Amir Ghiami[1], Michael Heuken[1,2] and Andrei Vescan[1]; [1]RWTH Aachen University, Germany; [2]AIXTRON SE, Germany

Two-dimensional transition metal dichalcogenides (2D-TMDC) are attractive materials for various applications such as integration in next-generation highly scaled CMOS technology, neuromorphic computing, (opto)electronic devices and advanced sensors. However, for a successful industrial implementation, reproducible and scalable fabrication processes are required. This includes 2D material synthesis, device processing, and finally circuit integration. Regarding material deposition, MOCVD (metal-organic chemical vapor deposition) is established as a technologically mature method with excellent homogeneity, reproducibility and yield in high-volume fabrication of compound semiconductors on large wafer diameters. Developing MOCVD of 2D-TMDC requires dedicated reactor technology, in-situ monitoring techniques and elaborate deposition processes. Especially for the latter, an in-depth understanding of nucleation and growth mechanisms is a prerequisite. Another advantage of MOCVD is the option to successively deposit 2D-2D heterostructures in a continuous process, avoiding interface contaminations related to mechanical heterostructure stacking.
In many implementation scenarios, 2D integration requires a transfer of 2D films or film stacks from their growth substrates to target wafers. With respect to the atomic thickness and the “surface-only” characteristics of 2D layers, transfer and processing steps demand an even more careful consideration than known for classical bulk semiconductor structures. This especially relates to processing chemicals and all substances coming into contact with the 2D layers.
In this presentation, results of MOCVD process development of 2D materials from the $(Mo,W)(S, Se)_2$ family will be shown. The focus will be on growth kinetics and layer morphology. The different stages of growth starting with film nucleation, continued to lateral growth as well as finally layer coalescence and cool-down stabilization will be discussed. Critical aspects and the interplay between initial nucleation density, monolayer growth time/chalcogen precursor consumption and parasitic bilayer formation before coalescence of the first monolayer will be highlighted. Migration enhancement by reducing metal precursor supply towards coalescence is one approach to suppress premature bilayer formation, especially for W-containing materials. Limits of the parameter window set by the metal adatom migration length and parasitic carbon deposition will be addressed. Using this approach, 2D-2D heterostructures will be presented and compared to counterparts realized by mechanical stacking of monolayers.
Material characterization relies on spectroscopic in-situ reflectance measurements, SEM (scanning electron microscopy), AFM (atomic force microscopy), Raman, photoluminescence (PL) and X-ray photoemission spectroscopy (XPS). Additionally, to especially access e. g. field-effect transistor performance metrics, electrical devices have to be fabricated. In this talk, selected results from transistors and memristors processed on our layers will be presented. This topic includes details on wet and dry transfer of 2D TMDC layers onto target substrates, lithography processing, etching, metallization and device characteristics. Furthermore, first correlations between characteristics of the MOCVD processes and device metrics will be presented.
Finally, an outlook will be given including strategies to improve layer properties (e. g. by additives promoting metal adatom migration), processing steps and finally device performance.

SESSION EL05.11: Growth II
Session Chairs: Chandan Das, Robert Jacobberger, Michael Pope and Hyeon Suk Shin

1:30 PM *EL05.11.01
Wafer-Scale, Thickness-Controlled Growth of Hexagonal Boron Nitride Hyeon Suk Shin; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Since hexagonal boron nitride (hBN) shows unique optical properties in the deep-UV region, mechanical robustness, thermal stability, and chemical inertness, hBN thin films have gained significant attention for various applications, including nanoelectronics, photonics, single photon emission, anti-corrosion, and membranes. Thus, wafer-scale, thickness-controlled growth of hBN films is crucial to enable their industrial-scale applications. To date, considerable efforts have been made to develop continuous hBN thin films with high crystallinity, from those with large grains to single-crystal ones, and to realize thickness control of hBN films by chemical vapor deposition (CVD). However, the growth of wafer-scale high crystalline hBN films with precise thickness control has not been reported yet. The hBN growth is significantly affected by substrate, in particular the type of metals, because the intrinsic solubilities of boron and nitrogen depend on the type of metal. In this talk, state-of-the-art strategies adopted for growing wafer-scale, thickness-controlled hBN are summarized, followed by the proposed mechanisms of hBN growth on catalytic substrates. In addition, how to grow wafer-scale, thickness-controlled growth of hBN on dielectric, sapphire substrate is demonstrated.

2:00 PM EL05.11.02
Manipulating 2D Materials at The Air-Water Interface: Towards Printing on Water Michael A. Pope; University of Waterloo, Canada

Conventional printing or casting approaches involving colloidal dispersions of 2D materials cannot typically yield films or prints less than 0.1 to 1 micron in thickness. On the other hand, the Langmuir-Blodgett approach can create single molecule thick films since the dispersed material is transferred or printed onto water and even after solvent evaporation, the dispersed phase or pigment remains mobile on the liquid water substrate. This mobility allows the floating material to be compressed by the moveable barriers of a Langmuir-Blodgett trough. However, this mechanical approach limits coatings to small areas (~cm^2) and is not amenable to roll-to-roll, high throughput processing. In this talk, I will summarize various works from my group that aim to understand how to use this interfacial mobility to adapt the Langmuir-Blodgett approach to one capable of printing and patterning continuously and over large areas. As an example, we explore the performance of such films comprised of electrochemically exfoliated transition metal dichalcogenides as transistors and photodetectors.

2:15 PM EL05.11.03
Characterization of Hybrid Edge Results in Narrowed Bandgap of Bottom-Up Liquid-Phase Synthesis of Bent N=6/8 Armchair Graphene Nanoribbons Using Scanning Tunneling Mircroscopy and Scanning Tunneling Spectroscopy Hanfei Wang[1], Gang Li[2,3], Michael J. Loes[3], Anshual Saxena[4], Jiangliang Yin[2], Mamun Sarker[3] and Shinyoung Choi[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]The University of Chicago, United States; [3]University of Nebraska–Lincoln, United States; [4]The University of Texas at Austin, United States

Scalable fabrication of graphene nanoribbons with narrow band gaps has been a nontrivial challenge. A unique approach has been developed to access narrow band gaps by using hybrid edge structures. Bottom-up liquid-phase synthesis of bent N=6/8 armchair graphene nanoribbons (AGNRs) has been achieved in high efficiency through copolymerization between an ortho-terphenyl monomer and a naphthalene-based monomer, followed by Scholl oxidation. Through scanning tunneling mircroscopy (STM) characterization, an unexpected 1,2-aryl migration has been discovered, which is responsible for introducing 60 degrees kinked structures to the GNR backbones. Topographical STM scans consistently show asymmetric internal sturcutres in agreement with the bent GNR structure resulted from unexpected competition between the aryl 1,2-migration on the naphlene unit and the direct cyclodehydrogenation during Scholl oxidation. Through model study, we postulate that such 1,2-migration may not occur that frequently during liquid-phase synthesis due to the more rigid C-C bonds in a polymer backbone. Such defects of turns should only take place occasionally, and the AGNRs should maintain close electronic properties to the proposed straight ribbons. The STM topography show, except for a few straight ribbons, most ribbons contain one or two kinks in their backbone. Scanning tunneling spectroscopy (STS) was employed to fully characterize the electronic structure of this GNR. A STS bandgap of 1.7 eV is found across straight and bent AGNRs deposited on hydrogen passivated silicon surface. The STS experimental result of AGNR bandgap is well in the range of 1 eV of the optical band gap and 2.2 eV of the calculated GW band gap. Application of bent N=6/8 AGNRs in efficient gas sensing shows its potential in broad applications of other innovative uses.

2:30 PM EL05.11.04
Inductive Heating a Versatile Process for Large Scale Single-Crystal Cu(111) and Graphene Synthesis : Experiments and Thermochemical Modeling Samir Farhat[1,2], Wafa Alimi[1,2], Ivaylo Hinkov[1,2] and Mourad Cherif[1,2]; [1]Université Sorbonne Paris Nord, France; [2]Laboratoire des Sciences des Procédés et des Matériaux LSPM CNRS, France

Inductive heating (IH) is proposed as a new concept to bring together centimeter-scale single crystal Cu(111) metal catalyst preparation and graphene growth in a combined process. Commercial polycrystalline metal catalyst is first heated by radio frequency (RF) magnetic fields. A nearly uniform magnetic field induced by Helmholtz-like coils penetrates the copper foil generating eddy currents. While the frequency of the current is being rapidly varied, the substrate temperature increases from room temperature to ~1030 °C in ~1 minute. Unlike Roll to Roll (R2R) methods where the copper is continuously passed in a hot furnace region [1], in our approach, the induction coils are moved at a constant speed generating a controlled thermal gradient. The rate of heating and cooling of the metal are hence much faster and gradient surface energy is better modulated. In addition, machine performance and maintenance costs could be reduced due to technological high-speed sealing and thermal constraints in the R2R process. In addition, for scale-up purposes, large oven are necessary to heat the metal foils. This becomes less energy efficient as system size is increased. In contrast, inductive heating only allows the heating of the thin metal films without heating the surrounding gas [2]. In our system, an edge of the Cu sheet was tapered into a tip shape, which ensured the nucleation of a single Cu(111) grain at the tip. The sliding of the coils across the copper foil caused the movement of the grain boundaries between the single crystal and polycrystalline regions and the grain of single crystal Cu(111) reached the width of the copper sheet as confirmed by XRD and EBSD. Consequently, graphene was synthesized using the same inductive heating reactor. From the optical microscopy image, all the hexagonal graphene domains are oriented in the same direction and the Raman spectrum shows the total absence of defects. We take the advantage of such system in order to better understand the mechanisms responsible for graphene growth in a chemical environment represented by a ternary C–H–Ar system. We specifically developed a thermochemical model with gas chemistry and surface reactions through Cu(111) site fraction and surface molar concentrations. The graphene growth rate is obtained by compiling the effects of gas and surface reactions *via* CHEMKIN software. The influence of the total pressure, substrate temperature and H_2, CH_4, Ar contents are obtained from the model and compared to the experiments. There was good agreement between experimental and the modeling results, providing an insight into optimizing CVD graphene growth.

Thin-Film Nanocalorimetry Study of The Melting Transitions in 2D Phase-Change Superlattices Jie Zhao[1], Asir Intisar Khan[2], Mikhail Efremov[3], Zichao Ye[1], Xiangjin Wu[2], H.S. Philip Wong[2], Eric Pop[2,2] and Leslie H. Allen[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Stanford University, United States; [3]University of Wisconsin—Madison, United States

Today's nanoelectronics are reaching the limits of energy and latency for numerous data-intensive applications, including the Internet of Things (IoT) and artificial intelligence (AI). Improving the energy efficiency and speed of data storage remains at the core of tackling this grand challenge. Phase-change memory (PCM) is a storage technology combining the high speed of dynamic random-access memory and the non-volatility of flash memory. By simply stacking ~2 nm Sb_2Te_3 and $Ge_2Sb_2Te_5$ together, superlattice (SL) phase change memory devices demonstrated an 8 times reduction in power consumption, compared to conventional PCM devices [1]. The unexpected device-level success lies in the unique thermodynamic properties of such two-dimensional (2D) heterostructures, which, unfortunately, are inaccessible to conventional characterization methods with limited sensitivity and speed. Thus, the underlying science responsible for success has remained a mystery.
Nanocalorimetry (NanoDSC) [2, 3] is an advanced characterization method with monolayer sensitivity (~1 Å) and fast scanning rate (10^6 K/s). This unique tool allows us to investigate the transitions of 2D heterostructure in its natural form of thin-film stacks as in SL-based PCM devices. In our recent work (2023 Nano Letters [4]), we applied NanoDSC to 65 nm Sb_2Te_3/$Ge_2Sb_2Te_5$ superlattices. An unexpected low-T metastable melting transition is uncovered along with an 8 times reduction in the enthalpy compared to its bulk counterparts. Such a transition provides a thermodynamic insight into the low-current switching of the superlattice PCM and advances the understanding of novel 2D heterostructures. The findings revealed here using the Nanocalorimetry technique will also inspire and enable a systematic material search for new 2D heterostructures for future energy-efficient nanoelectronics.

3:30 PM EL05.11.06
Optimizing Au-Assisted Exfoliation of Layered Materials with (3-Aminopropyl)triethoxysilane (APTES) for Large-Area Monolayers Nicolo Petrini[1,2], Ermes Peci[2], Nicola Curreli[3,1], Francesco Bisio[4,2], Ilka Kriegel[1] and Anjana P. Muraleedharan[5,6]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli studi di Genova, Italy; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [4]CNR, Italy; [5]Instituto Italiano di Tecnologia, Italy; [6]Università Degli Studi di Genova, Italy

Two-dimensional (2D) materials have gained significant scientific interest owing to their exceptional properties and potential applications. Recently, Metal-assisted exfoliation technique has emerged as a valuable method for obtaining large and high-quality 2D monolayers. However, the process efficiency can be hampered by poor adhesion between the metal foil and the substrate. In this study, we address this issue by investigating surface functionalization of the target substrate using (3-Aminopropyl)triethoxysilane (APTES). The introduction of APTES significantly enhances adhesion between monolayers and hydrophilic substrates, overcoming delamination issues associated with the Au-exfoliation method. We perform a comprehensive comparison between APTES-functionalized Au-exfoliated flakes and those obtained through conventional scotch tape exfoliation, evaluating process yield and monolayer quality. Characterization techniques, including ellipsometry, AFM, XPS, Raman spectroscopy, and photoluminescence spectroscopy, confirm the method's effectiveness and superior outcomes in terms of yield and crystal quality. Additionally, we successfully apply this method to obtain high-quality monolayers of other materials, such as BiTeI, which we were able to characterize in terms of SHG, as theoretically predicted. Additionally, we recently refined a Metal-assisted modified exfoliation protocol, allowing for the transfer of the exfoliated flakes onto various flat substrates. This demonstrates the feasibility of achieving extensive exfoliation on rigid substrates (Si, SiO2, ITO, Al2O3) as well as flexible substrates (PET, Kapton).

3:45 PM EL05.11.07
Methodology: Bayesian for Identifying Defects in Two-Dimensional Materials in a Scalable Way. Jun Wang, Na Young Kim and Kyle J. Daun; University of Waterloo, Canada

Two-dimensional transition metal dichalcogenides (TMDCs), including molybdenum disulfide (MoS_2), have many potential applications in electronic and optoelectronic devices, such as light-emitting diodes, photodetectors, and field effect transistors. However, the existence of defects such as sulfur vacancies, impurity atoms, and anti-sites impacts the optoelectronic properties of these materials. Accordingly, there is an urgent need for diagnostics that can identify defects in order to assess the functional performance of TMDC devices for scaling-up production.

In this regard, Raman spectroscopy is a promising approach for quantifying the defect concentration over industrially relevant quantities of monolayer MoS_2 efficiently. In order to obtain quantitative estimates, a measurement model is needed to connect a spectral feature (e.g., Raman shift) to the vacancy concentration, which may be derived numerically using density functional theory (DFT) or experimentally by comparing the Raman shift to the vacancy concentrations measured through other methods. More precisely, a Gaussian distribution curve representing sulfur vacancy concentration probability can be generated according to the Raman peak shift observed in the measurement spectra. In both cases, the measurement model will be subject to uncertainties due to experimental artifacts or aspects of the physical system that are excluded from the DFT simulation. Additional factors, including the number of layers, defect concentration, and doping, may also influence these spectra. Accordingly, there is a need to quantify how these parameters the uncertainty of vacancy concentration estimates, and, ideally, reduce them by incorporating complementary prior information.

Here, we propose a novel methodology that combines Raman data and Bayesian inference to identify the probability of a given concentration of sulfur vacancies which may be applied to various scales of research and production. In this methodology, a prior probability for defect concentration is calculated from the probability distribution of thermodynamic stable defect concentration data sets, which are generated in real cases. The prior probability of defect concentration is then updated with a likelihood derived from a Raman spectrum measured on a MoS_2 monolayer, leading to a posterior probability density function that comprehensively summarizes the uncertainty in the inferred sulfur vacancy.

Rapid Detection of Defects in Monolayer 2D Semiconductors by Polarized Raman Spectroscopy Crystal A. Nattoo, Tara Pena, Koosha N. Nazif, Amalya C. Johnson, Fang Liu and Eric Pop; Stanford University, United States

An outstanding challenge in integrating two-dimensional (2D) transition metal dichalcogenides (TMDs) into future optoelectronics is optimizing high-quality and large-scale growths of these atomically thin materials. Several methods exist for wafer- and chip-scale growths of 2D-TMDs, such as chemical vapor deposition (CVD) and atomic layer deposition (ALD). Still, we see a large degree of variability from growth to growth due to intrinsic and extrinsic factors like defects and humidity [1]. Optimizing the rapid characterization methods used to discern material quality before fabrication is essential to improve the yield of devices produced during research and development, saving time and money.

Raman spectroscopy is a non-destructive and standard characterization technique, to examine various material features such as thickness [2], doping [3], strain [4], and disorder [5, 6]. However, the effect of doping and disorder on the Raman signatures still remains to be examined in some TMD systems (e.g., WSe_2). In this work, we propose using cross-polarized Raman spectra [7] to isolate the in-plane E' mode from the out-of-plane A_1' mode with a 532 nm laser to properly examine defect-induced Raman features in two monolayer TMD materials of broad interest. Based on the phonon dispersion curves, we focus on MoS_2 and WSe_2, because they have the most suitable optical phonon energy and dispersion for this method.

The isolation of the E' mode by cross-polarization is especially effective in the case of WSe_2, which shows a strong degeneracy of the E' and A_1' modes around 250 cm^{-1}, making analysis a unique challenge. Due to the nature of defects interrupting the vibration of atoms in-plane, the transverse and longitudinal modes are the most sensitive to changes in defect density. For this reason, we study the amplitude changes of the in-plane E' mode in relation to the second order M point phonon modes that appear with increasing disorder.

After the data are collected, the spectra are fit with a Gaussian and Lorentzian spectral blend to extract the peak height, position, and full width at half-maximum (FWHM). The ratio between the left shoulder second-order phonon modes and the first-order E' mode is used as a figure of merit to estimate the expected defect density and the majority carrier mobility in the 2D material. Our approach can estimate defect densities down to the order of 10^{11} cm^{-2} using TMD samples procured by different synthesis methods. To compare the method's validity, the same samples are also characterized by conductive atomic force microscopy (c-AFM) and electrical measurements of mobility.

This rapid, non-destructive Raman characterization method can be integrated into commercial growth systems to accelerate TMD research and development for practical applications. Future work is also planned to expand these efforts to other TMDs. The work was supported by an NSF Graduate Fellowship (C.A.N.), an NSF Ascend Fellowship (T.P.), by the SRC SUPREME Center and the Stanford SystemX Alliance.

Towards Large-Area Black Phosphorous Midwave-IR Optoelectronics Ali Javey[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

High-efficiency mid-wavelength infrared (mid-IR, 3–5 µm) optoelectronics, including light emitting diodes (LEDs) and photodetectors, are of high demand for emerging applications in spectroscopy, imaging, and gas sensing. Black phosphorus (bP) has emerged as a unique optoelectronic material for mid-IR applications with performances surpassing those of conventional III-V and II-VI semiconductors of similar bandgap. In this talk, I will present recent advancements on understanding and controlling the radiative and non-radiative recombination rates as a function of bP thickness. We observe higher photoluminescence quantum yields in bP as compared to conventional III-V and II-VI semiconductors of similar bandgaps due to the smaller Auger recombination rate. As a result, bP mid-IR LEDs with external quantum efficiency of >4% are reported, outperforming the state-of-the-art in this wavelength range. Furthermore, device encapsulation and packaging technologies are explored with extrapolated half lifetime of ~15,000 hours based on accelerated lifetime measurements. Finally, I will present strategies for large-area device fabrication and processing.

9:15 AM EL05.12.02
Photo-Gating through Unidirectional Charge Carrier Funneling in 2D TMDC / 2D Perovskite Heterostructure-Photodetectors Leon Spee[1], Julius Konietzka[1], Annika Grundmann[2], Martin A. Schroer[1], Markus Winterer[1], Holger Kalisch[2], Michael Heuken[2,3], Andrei Vescan[2], Gerd Bacher[1] and Franziska E. Muckel[1]; [1]University Duisburg-Essen, Germany; [2]RWTH Aachen University, Germany; [3]AIXTRON SE, Germany

Two-dimensional (2D) van der Waals (vdW) semiconductors, such as transition-metal dichalcogenides (TMDCs), have garnered increasing attention as promising materials for photosensing applications. Their appeal lies in their high oscillator strength, significant electronic mobility, and remarkable mechanical flexibility, promising novel application scenarios for optical sensing in healthcare, optical communication or different lifestyle applications. However, due to their intrinsically limited light absorption, high responsivities and sensitivities are hard to achieve. To enhance photodetectivity, TMDCs are frequently integrated into functional heterostructures with other vdW semiconductors like 2D Ruddlesden-Popper Perovskites to introduce a gain mechanism. However, the processes of energy and charge carrier transfer between TMDCs and 2D Ruddlesden-Popper materials remain subjects of debate, making it challenging to elucidate the fundamental mechanism of device operation.
In this study, we present lateral heterostructure photodetectors composed of MOCVD-grown molybdenum disulfide (MoS2) and solution processed butylammonium lead iodide (BA_2PbI_4) that exhibit significantly enhanced responsivities, reduced dark current, and increased detectivity when compared to devices using MoS_2 or BA_2PbI_4 alone. We provide compelling evidence that this improvement is linked to a gain mechanism facilitated by photo-gating within the MoS_2 channel. This photo-gating results from a unidirectional transfer of holes from MoS_2 to BA_2PbI_4 and the blocking of electrons by butylammonium ions. Our devices exhibit responsivities up to 10 A/W, which corresponds to a gain of 145. This research sheds light on the intriguing performance of heterostructure photodetectors based on 2D materials and their potential for practical device integration.

Graphene-Enhanced UVC-LEDs Wolfgang Mertin, Johanna Meier, Hehe Zhang, Umut Kaya and Gerd Bacher; University of Duisburg-Essen, Germany

In anticipation of their promising applications in the deep-ultraviolet (UVC) spectral range, e.g., for disinfection, AlGaN-based UVC-Light Emitting Diodes (UVC-LEDs) have experienced a lot of attention over the last decade. However, these LEDs still have lower performance regarding Wall Plug Efficiency (WPE) and External Quantum Efficiency (EQE) than blue emitting LEDs [1,2]. One reason is the low electrical conductivity of the p-AlGaN cladding layer, which limits both, current injection in flip-chip geometry, and lateral current spreading for devices in standard geometry.

Graphene combines high electrical conductivity and high optical transparency in the UVC spectral range and has thus the potential to act as low absorbent contact layer in UVC-LEDs. Here we report on a transfer-free low-temperature approach for integrating graphene directly into AlGaN-based UVC-LEDs at temperatures far below 1000°C. We demonstrate functional UVC-LEDs in standard as well as in flip-chip geometry.

Based on our previous work [3,4] we used a plasma-enhanced CVD graphene process to directly grow graphene on the *p*-AlGaN layer of a UVC-LED at 670°C. The graphene has an optical transparency above 90% in the UVC region and an electrical sheet resistance of about 5 kΩ/sq. Using the directly grown graphene as a transparent contact layer, we were able to improve the EQE of UVC-LEDs emitting at 275 nm in standard as well as in flip-chip geometry to over 5%. With these proof-of-principle experiments, we have paved the way to a large-scale integration-friendly process of graphene-enhanced UVC-LEDs.

Bridging Macroscopic and Microscopic Nonlinear Optics with Layered Semiconductors Chiara Trovatello[1], Xinyi Xu[1], Fabian Mooshammer[1], D.

Basov[1], Giulio Nicola Felice Cerullo[2] and P. James Schuck[1]; [1]Columbia University, United States; [2]Politecnico di Milano, Italy

Nonlinear frequency conversion provides essential tools for light generation, photon entanglement, and manipulation. Conventional nonlinear optical crystals display moderate second-order nonlinear susceptibilities and perform well in benchtop setups with discrete optical components. However, such crystals do not easily lend themselves to miniaturization and on-chip integration. Transition metal dichalcogenides (TMDs) possess 10-100x stronger nonlinear susceptibilities and, thanks to their deeply sub-wavelength thickness, offer a unique platform for on-chip nonlinear frequency conversion and light amplification. Recently, such giant nonlinearity has been exploited to demonstrate nonlinear light amplification at the ultimate thickness limit[1]; however, optical gain was still limited by the sub-nm propagation length.

The nonlinear conversion efficiencycould be scaled by increasing the propagation length through the active medium. This is attainable by increasing the number of layers in the TMD sample. However, the nonlinear optical properties of semiconducting TMDs critically depend on their crystallographic symmetry. 2H-TMDs are naturally centrosymmetric, giving an opposite dipole orientation among consecutive layers. This results in a vanishing nonlinear susceptibility ($|\chi^{(2)}| = 0$) for crystals with even number of layers and precludes efficient conversion in multilayers. In contrast, 3R-TMDs naturally combines broken inversion symmetry ($|\chi^{(2)}| \neq 0$) and aligned layering, representing ideal candidates to boost the nonlinear optical gain with minimal footprint.

The nonlinear optical response of 3R-MoS_2 has been explored in some recent pioneering studies[2,3], so far focusing on thinner crystals, reporting the quadratic enhancement with the layer number at the 2D limit, and showing a maximum SHG enhancement of ≈100 occurring at specific thickness windows. Pushing towards general application, however, requires higher nonlinear enhancements and thus larger layer number, which in turn leads to more intricate interferences and interactions within the crystal.

Here we measure SHG from multilayer 3R-MoS_2 crystals with variable thickness. We report the first measurement of the coherence length of 3R-MoS_2 at telecom wavelengths. Our model is able to capture the role of phase-matching, as well as the intrinsic interference effects. At the coherence length (~ 530 nm) we achieve record nonlinear optical enhancement from a van der Waals material, i.e., $>10^4$ stronger than a monolayer, revealing the intrinsic single-pass upper limits of the material[4]. Considering that the reported conversion efficiency of monolayer MoS_2 at FW = 1560 nm is $\sim10^{-10}$, the overall conversion efficiency of MoS_2 at the coherence length thickness will be $\sim10^{-6}$. Further enhancement can then be achieved by regularly engineering larger crystals or waveguides with a periodicity on this length scale, or by exploiting birefringence.

Our results highlight the potential of 3R-stacked TMDs for integrated photonics, providing critical parameters for designing highly efficient on-chip nonlinear optical devices. By virtue of the exceptional nonlinear properties and the possibility of integration and phase matching in waveguide geometries, we foresee ultra-compact devices with extremely high nonlinear conversion efficiency – even exceeding multi-pass state-of-the-art photonic resonators of aluminum nitride – opening new frontiers for engineering on-chip integrated nonlinear optical devices including photonic resonators and optical quantum circuits.

New Form of High-k Dielectrics for 2D Field-Effect Transistors Sean Li[1], Junjie Shi[1], Ji Zhang[1] and Jing-Kai Huang[2]; [1]University of New South Wales, Australia; [2]City University of Hong Kong, Hong Kong

The integration of ultrathin insulators stands as a pivotal factor for the advancement of 2D Field-Effect Transistors (FETs) in cutting-edge technology. Presently, 2D semiconductor devices are yet to realize their complete theoretical potential, primarily due to the unavailability of suitable insulators. These insulators must strike a balance between maintaining minimal leakage currents and enabling a high gate capacitance to achieve superior gate coupling at sub-1nm Equivalent Oxide Thickness (EOT) scales. Furthermore, they must establish well-defined interfaces with the channel, exhibit minimal defect densities, and possess exceptional dielectric stability. This study showcases the power of dielectric engineering in elevating the performance of 2D FETs, offering viable avenues to develop 2D FETs characterized by remarkably low leakage currents, shorter channel lengths, and outstanding power efficiency.

11:00 AM EL05.13.02
Spatial Tuning of Light-Matter Interaction via Strain-Gradient Induced Polarization in Freestanding Wrinkled 2D Materials Chullhee Cho[1,2], SungWoo Nam[3], Zhichao Zhang[2], Jin Myung Kim[3], MD Farhadul Haque[4] and Peter Snapp[1]; [1]NASA Goddard Space Flight Center, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]University of California Irvine, United States; [4]Intel Corporation, United States

Strain engineering is an attractive strategy to design and modulate material properties, via lattice deformation, to improve modern micro and nanoelectronics device performance. To date, due to the challenge of deforming freestanding two-dimensional (2D) materials without fracture, controlled deformation of 2D materials has been demonstrated almost exclusively on substrate-supported structures, where the 2D materials are in contact with an underlying deformable substrate. However, interfacial effects arising from these supporting materials may suppress or alter the unique behavior of deformed 2D materials. To address interfacial effects, we report, for the first time, the formation of a micrometer-scale freestanding wrinkled structure of 2D materials without any encapsulation layers where we observed the enhanced light-matter interactions with a spatial modulation. Freestanding wrinkled monolayer WSe_2 exhibited about a 330% enhancement relative to supported wrinkled WSe_2 quantified through photo induced force microscopy. Spatial modulation and enhancement of light interaction in the freestanding wrinkled structures are attributed to the enhanced strain-gradient effect (i.e., out-of-plane polarization) enabled by removing the constraining support and proximate dielectrics. Our findings offer an additional degree of freedom to modulate the out-of-plane polarization and enhance the out-of-plane light-matter interaction in 2D materials.

11:15 AM EL05.13.03
Simultaneous Strain and Gate Tunability of Moiré Heterostructure Devices Jordan Fonseca[1], John Cenker[1,2], Mai Nguyen[1], Chaowei Hu[1], Wang Xi[1], George Rickey[1], Takashi Taniguchi[3], Kenji Watanabe[3], Jiun-Haw Chu[1] and Xiaodong Xu[1]; [1]University of Washington, United States; [2]Columbia University, United States; [3]National Institute for Materials Science, Japan

Moiré heterostructures of 2D materials have served as a platform for studying and engineering a wide variety of correlated phenomena and many body physics. The atomic thickness of two-dimensional materials and the large effective lattice constant of moiré superlattices make electrostatic gating a particularly effective way to tune carrier density and thereby explore a rich phase diagram of correlated effects. Independently, two dimensional materials exhibit unusually high elasticity and can sustain significant uniaxial strain before yielding. Uniaxial strain breaks rotational symmetry and changes interatomic spacing, altering many material properties in the process. An outstanding challenge, however, is simultaneously and independently tuning uniaxial strain and electrostatic gating in-situ at cryogenic temperatures. In this talk, I will discuss our work to leverage novel approaches for efficient strain transfer to the moiré heterostructure in gateable van der Waals devices. I will show how the ability to traverse the strain-gating phase space for a high-quality transition metal dichalcogenide moiré heterostructure enables exploration of novel features in the photoluminescence spectra and discuss their origin in the underlying optoelectronic properties of this rich material system.

11:30 AM EL05.13.04
Electronic Properties of Quasi-1D Materials, TiS_3 and In_4Se_3 Alexander Sinitskii; University of Nebraska -Lincoln, United States

Two-dimensional (2D) layered materials have received much interest in recent years due to their ease of miniaturization by exfoliation techniques and very diverse physical properties. Quasi-one-dimensional (quasi-1D) materials, while seeing considerably less interest, can express many of the same desirable properties as conventional layered materials, with an added dimension of anisotropy. A representative example of quasi-1D materials is titanium trisulfide (TiS_3), a layered n-type semiconductor composed of chains of trigonal sulfur prisms with Ti^{4+} centers. Because of its moderate bandgap of about 1 eV, which is comparable to that of silicon, and theoretically predicted electron mobilities of up to 10,000 $cm^2 V^{-1} s^{-1}$, TIS_3 is a promising material for electronic applications.
We demonstrate the ease of mechanical exfoliation of bulk TiS_3 crystals accompanied with theoretical calculations and show that these materials exfoliate into few-atomic-layer nanoribbons with very smooth edges. Their characterization by Raman spectroscopy shows a reliable, internally standardized shift of a few cm^{-1} from monolayer to bulk demonstrating tunability typical of conventional layered materials. The TiS_3 field-effect transistors showed an n-type electronic transport with characteristics comparable to those of MoS_2, a popular 2D semiconductor. Their room-temperature mobilities of about 30 $cm^2 V^{-1} s^{-1}$ were two orders of magnitude smaller than predicted theoretically, which we quantitatively explain by polar-optical phonon scattering in TIS_3. We demonstrate that TiS_3 is compatible with the conventional atomic layer deposition procedure for Al_2O_3, and the encapsulation of TiS_3 with alumina resulted in the mobility increase up to 43 $cm^2 V^{-1} s^{-1}$. The quasi-1D TiS_3 chains exhibit an anisotropic photocurrent response to polarized light as well as a gate-tunable metal-insulator transition (MIT) and an access to the charge density wave (CDW) physics.
Many of the conclusions drawn for TiS_3 can be extended to other quasi-1D materials, such as In_4Se_3. In_4Se_3 has a different crystal structure, but it also features covalently bonded quasi-1D chains as its basic building blocks. We successfully exfoliated bulk In_4Se_3 crystals into few-nm-thick flakes with visible signatures of quasi-1D chains, similar to the exfoliated TiS_3 flakes. The In_4Se_3 flakes exfoliated on Si/SiO_2 have anisotropic electronic properties and exhibit field-effect electron mobilities of about 50 $cm^2 V^{-1} s^{-1}$ at room temperature, as well as a polarization dependent photoresponse on a timescale of less than 30 ms. These two examples, TiS_3 and In_4Se_3, demonstrate the promise of quasi-1D materials for emerging electronic applications.

Investigating Magnetic Ordering in Naturally Occurring and Artificially Modified Iron-Rich Phyllosilicates Muhammad Z. Khan[1], Oleg E. Peil[2], Nico Klingner[3], Gregor Hlawacek[3], Sebastian Wintz[4], Christian Teichert[1], Ulrich Kentsch[3], Markus Weigand[4], Daniel Knez[5], Johann G. Raith[6], Andreas Ney[7] and Aleksandar Matkovic[1]; [1]Chair of Physics, Department Physics, Mechanics and Electrical Engineering, Montanuniversität Leoben, Austria; [2]Group of Computational Materials Design, Materials Center Leoben Forschung GmbH, Austria; [3]Institute of Ion Beam Physics and Materials Research, Helmholtz-Zentrum Dresden Rossendorf, Germany; [4]Department of Spin and Topology in Quantum Materials, Helmholtz-Zentrum Berlin, Germany; [5]Institute of Electron Microscopy and Nanoanalysis, Graz Centre for Electron Microscopy, Graz University of Technology, Austria; [6]Chair of Resource Mineralogy, Montanuniversität Leoben, Austria; [7]Institute of Semiconductor and Solid State Physics, Johannes Kepler University, Austria

The modulation of intrinsic 2D ferromagnetism has gained significant attention and shown a great potential for spintronics. Although many two-dimensional (2D) van der Waals materials have been reported to exhibit intrinsic magnetism, there are still challenges when it comes to ambient stability, which is a crucial barrier for their integration into device applications. We propose to overcome this by exploiting naturally occurring iron-rich phyllosilicates. Phyllosilicates offer a unique opportunity to explore complex air-stable layered systems with high concentration of magnetic ions. These naturally occurring layered materials are inherently magnetic and are wide band gap insulators (i.e. 5-6 eV). These minerals integrate local moment bearing ions of iron via magnesium/aluminium substitution in their octahedral sites. Natural capping by silicate/aluminate tetrahedral groups enables air stability of monolayers.[1] Their structure and iron oxidation states are determined via Raman and X-ray spectroscopies. Superconducting quantum interference device magnetometry measurements are performed to examine the long-range magnetic ordering. In-field magnetic force microscopy in the presence of externally applied out-of-plane magnetic field on exfoliated flakes confirms that the paramagnetic response at room temperature persists down to monolayers. We demonstrate correlations between the iron concentration, layer structure, iron oxidation states, and their magnetic response, indicating a path to design materials with higher critical temperatures via oxidation state engineering.[2]
Furthermore, we also demonstrate a scalable approach to control and tune the concentration of magnetic species via ion implantation into pure phyllosilicates crystals. Controlling the amount of implanted magnetic ions, choosing the dopant species or even alloying in the phyllosilicate matrix will open the pathways to engineer the 2D magnetic insulators with high critical ordering temperature.

Tailoring The Rashba-Induced Spin-To-Charge Conversion in 2D Transition Metal Dichalcogenides Interfaced with Oxide Ferroelectrics Oliver Paull[1,2], Khasan Abdukayumov[2], Sylvain Massabeau[1], Céline Vergnaud[2], Luis M. Vicente-Arche[1], Alain Marty[2], Lucia Iglesias[1], Matthieu Jamet[2] and Manuel Bibes[1]; [1]Unité Mixte de Physique, CNRS/Thales, France; [2]Commissariat à l'énergie atomique et aux énergies alternatives, France

The direct and inverse Rashba-Edelstein effect in condensed matter is a viable source of charge-to-spin interconversion, towards the realisation of next-generation spintronic devices. One promising way of creating Rashba spin-orbit coupling (SOC) in an otherwise centrosymmetric material system is to interface it with a ferroelectric crystal, breaking inversion symmetry with the local electric field at the interface.

Two-dimensional (2D) crystals have emerged as a new class of materials that can exhibit a large range of quantum phenomena such as superconductivity, 2D magnetism, and non-trivial topological phases [1], [2]. Of these quantum phenomena, the Rashba effect has gained popularity recently as a result of its applicability to create charge-to-spin interconversion for next-generation spintronics devices. Highly stable $PtSe_2$ is one such 2D material which has a centrosymmetric crystal unit cell and a band-structure that evolves drastically as a function of the number of monolayers deposited, evolving from a high band-gap semiconductor to a semi-metal [3]. Interfacing a 2D material with a ferroelectric (FE) crystal applies a strong local electric field at the interface which breaks the inversion symmetry and triggers the interfacial Rashba effect in the 2D layer. Importantly, the sign of the Rashba spin-orbit coupling depends on the direction of the FE polarisation, such that the spin texture chirality should reverse upon a change in direction of the FE polarisation [4]. This forms the basis of the functionality of a low-power **F**erro**E**lectric **S**pin-**O**rbit (FESO) device.

In this work, we grow 2D materials such as $PtSe_2$ using molecular beam epitaxy and use a wet transfer process to interface them with a variety of ferroelectric surfaces such as $LiNbO_3$ substrates and $BiFeO_3$ thin fims. The spin-to-charge conversion characteristics are then examined using a variety of experimental techniques and compared between samples with different ferroelectric polarisation directions and assessed in the context of a spin-to-charge conversion FESO device.

1:45 PM EL05.14.02
Charge Carrier Balance in Scalable TMDC-Based Light Emitting Devices Tobiloba G. Fabunmi[1], Henrik Myja[1], Annika Grundmann[2], Kalisch Holger[2], Andrei Vescan[2], Michael Heuken[3], Tilmar Kümmell[1] and Gerd Bacher[1]; [1]University of Duisburg-Essen, Germany; [2]RWTH Aachen University, Germany; [3]AIXTRON SE, Germany

2-dimensional transition metal dichalcogenides (TMDCs) such as WS_2 are ultrathin materials with huge oscillator strength, strong in-plane bonds, and in the case of monolayers a direct bandgap. These outstanding properties have stimulated the development of various concepts for light emitting devices [1], often based on micrometer-sized flakes. Recently, a scalable device architecture has been suggested, where wafer-scale TMDCs grown by metal-organic chemical vapor deposition (MOCVD) have been embedded between electron and hole supporting layers to form a vertical p-i-n architecture [2-4]. However, the luminance of TMDC-based LEDs in cw operation at room temperature is still limited to 50 cd/m^{2}for microscale LEDs based on mechanically exfoliated WS_2 [5] and to about 1 cd/m^2 for scalable, 6 mm^2 large devices [2], respectively. One key requirement for optimizing the luminance is a balanced electron and hole injection into the active TMDC layer. In this work, we address the electron-hole balance in scalable WS_2-based LEDs by systematically varying the architecture of electron injection layers (EIL). We fabricated three different LED archetypes: type 1 includes a ZnO EIL, type 2 contains Mg-doped ZnO as an EIL, and type 3 is a reference device without an EIL. At 5V forward bias, we observed a reduction of the current density by a factor of 10 in type 2 devices as compared to type 1. Simultaneously, the EQE was found to increase by an order of magnitude in the type 2 device compared to type 1, and a luminance of up to 3 cd/m^2 was obtained for type 2 devices. We attribute this to an improved electron-hole balance in type 2 devices, caused by a reduced efficiency of electron injection. Our interpretation is supported by device simulations using NextNano, which emphasizes the impact of a balanced electron and hole injection for efficient LEDs based on scalable 2D TMDCs.

A General Modular Assembly Approach to a Library of Hybrid Superlattices Jingyuan Zhou; University of California, Los Angeles, United States

Hybrid superlattices consisting of two-dimensional atomic crystals (2DACs) and self-assembled molecular layers allow to synergistically combine rich physical properties in solid-state 2DACs with designable molecular functionalities. Such hybrid superlattices are generally prepared by a direct chemical or electrochemical intercalation approach, and are often limited to a specific class of 2DACs or molecular systems as dictated by the relative chemical reactivity and electrochemical stability of the constituent building blocks. Self-assembly offers an alternative strategy for efficiently organizing multiple building units into ordered superstructures. In this work, we report a systematic and quantitative study of the underlying governing principle for electrostatic assembly strategy in the context of 2D-molecular hybrid superlattices, and explore it for constructing a broad library of hybrid superlattices with widely variable compositions and tunable structural configurations. By using exfoliated MoS_2 as a model system, we show a series of amines, amino acids, coordination complexes, and polymers can be assembled with MoS_2 monolayers, forming alternatively ordered hybrid superlattices. Our systematic studies reveal that electrostatic assembly process is highly analogous to classical co-precipitation of ionic solids and fundamentally governed by the charge balance and equilibrium between electrostatic repulsion and van der Waals (vdW) interaction, following Schulze-Hardy rule at Debye–Hückel approximation based on Derjaguin–Landau–Verwey–Overbeek (DLVO) colloidal theory. Based on the charge balance rule, the layer number of inclusive molecules in the resulting hybrid superlattices can be precisely tuned. Furthermore, we show this assembly strategy is highly general and can be extended to diverse 2DACs, such as TiS_2, TaS_2, WS_2, $MoSe_2$, SnSe, In_2Se_3, Bi_2Se_3 and Mxenes such as $Ti_3C_2T_x$. The formation of hybrid superlattices with

functional ions or molecules opens a new dimension to tailor and tame the fundamental physical properties of the 2DACs and enables artificial materials with exotic functions. For example, the formation of TaS_2/amine superlattice notably elevates the superconducting transition temperature (T_c). The introduction of chiral amino acids into MoS_2 interlayers effectively incorporates molecular chirality into solid-state superlattices, and the formation of $MoS_2/Co(en)_3Cl_3$ superlattice induces ferromagnetic properties not available in either constituent. Together, our study defines a general modular approach for the rational assembly of hybrid superlattices and artificial solids with designable structural motifs and widely tunable physical properties.

Towards 300 mm 2D Materials Integration: Focus on Performance, Repeatability and Fab Compatibility Salim El Kazzi, Sergej Pasko, Jan Mischke, Simonas Krotkus, Emre Yengel, Apostolia Manasi and Alexander Henning; Aixtron, Germany

To reach the silicon IC-industry, 2D materials need to pass the strict requirements of the semiconductor foundries and manufacturers. At the current stage of 2D materials research, it is critical for the community to develop work on the wafer-scale integration, yield, and reproducibility instead of selecting the best-performing 'champion' device produced on smaller scale. From a growth perspective, layer uniformity and repeatability are critical factors that need to be proven for any materials system considered in the CMOS technology.
Here, we report on the scaling up of 2D materials synthesis to 300 mm substrates. We focus on the different 2D integration schemes, which rely on the growth of 2D materials on amorphous or epitaxial substrates at different temperatures. We then highlight the importance of wafer scale uniformity and run-to-run repeatability for which we try to define for the community the metrology standard of 2D wafer-scale synthesis. Finally, we will address two other key aspects related to cross-contamination and tool cleaning that are being solved to facilitate the entry of these materials into the Si-industry

3:00 PM EL05.14.06
Towards CMOS-Integrated Graphene Hall Sensor Arrays with Individually Tunable Elements for High Sensitivity and Enhanced Uniformity Vasant Iyer, Nishal Shah, Jaeung Ko, A.T.C. Johnson, David Issadore and Firooz Aflatouni; University of Pennsylvania, United States

Graphene Hall-effect sensors exhibit high performance comparable to state-of-the-art devices made from III-V semiconductors, with the added advantage of CMOS-compatible fabrication. These properties make graphene Hall sensors (GHSs) an attractive choice for implementing high-density magnetic sensing arrays for imaging and biosensing applications. [1] The size and effectiveness of GHS arrays are presently limited by a) low uniformity across the array arising from variable doping and fabrication mismatch, and b) the increasing need for co-integrated GHS control and readout electronics as the array size is upscaled. In this work we present and validate strategies to address both challenges, achieving progress towards large-scale GHS arrays.
We first studied the effectiveness of per-device tuning to improve response uniformity between graphene Hall elements. The conventional technique of varying the substrate voltage to tune all devices simultaneously has been shown to improve uniformity, at the expense of overall sensitivity. [2] We hypothesized that individual GHS tuning would greatly relax the tradeoff. An array of 16 GHSs was fabricated on a silicon chip, with an insulated backgate terminal underneath the active region of each sensor (10 mm x 10 mm). 10 nm HfO_2 was chosen as the insulation dielectric to enhance tuning efficacy. A CMOS-compatible voltage range of 5 V was sufficient to access all relevant regions of device operation, including the Dirac point and the maximum sensitivities in the electron and hole regimes. Characterization of multiple devices on the same chip showed non-uniformity in the optimal operating point of each GHS, arising from variations in doping across the chip. Individual backgate tuning was then used to align the responses of the sensors. The post-tuning results confirmed our hypothesis, as individual tuning improved the Hall sensitivity coefficient of variation (CV) by up to 95% compared to the scenario where all sensors shared the same backgate, with a small degradation to sensitivity (9.5%). The best-performing GHS array in our study achieved an average response of 1.17 kΩ/T with a CV of 3.4%.
We then developed techniques to monolithically integrate a GHS array within the back-end-of-line (BEOL) layers of a custom CMOS chip (designed in a 180nm foundry process) for scalable sensor control and readout. Two key challenges in graphene-CMOS BEOL integration are a) surface roughness on the uppermost layers of the chip leading to graphene tears b) surface oxidation on BEOL metals leading to non-ohmic device contacts. [3-4] To circumvent these issues, the entire sensing region of the 1.6mm x 1.2mm chip was covered with a top-metal fill in the design, with a foundry layer added to remove passivation over the top-metal fill. Sensor terminals were defined by instantiating tungsten vias between the top fill and the underlying metal layer. During post-processing, the top-metal fill was removed using a wet etch, leaving behind a planarized surface with exposed oxide-free sensor terminals. After insulating the backgate terminal, CVD-grown graphene was transferred onto the CMOS chip surface and patterned into Hall crosses at the predefined sensing sites. SEM, AFM, and Raman analysis were used to confirm successful patterning of high-quality monolayer graphene. Electrical measurements of 32 sites within the sensing surface were performed through on-chip multiplexing and indicated high yield (75%) with a measured sensitivity of 480 Ω/T. Ongoing measurements using on-chip circuitry for backgate tuning and lock-in detection of the Hall signal will also be discussed.

Ultrathin Quasi-2D Amorphous Carbon Dielectric prepared from Solution Precursor for Nanoelectronics Fufei An[1], Congjun Wang[2], Viet Hung Pham[2], Albina Borisevich[3], Jiangchao Qian[1], Kaijun Yin[1], Saran Pidaparthy[1], Brian Robinson[1], Ang-Sheng Chou[4], Junseok Lee[2], Jennifer Weidman[2], Sittichai Natesakhawat[2], Han Wang[4], Andre Schleife[1], Jian-Min Zuo[1], Christopher Matranga[2] and Qing Cao[1]; [1]UIUC, United States; [2]U.S. Department of Energy National Energy Technology Laboratory, United States; [3]Oak Ridge National Laboratory, United States; [4]Taiwan Semiconductor Manufacturing Company, Taiwan

Integrating crystalline 2D semiconductors and semimetals channels with 3D bulk amorphous metal oxides generally leads to poor interfaces with high concentrations of traps and scattering centers. Low-dimensional amorphous dielectrics could be ideal for 2D-material-based nanoelectronics with their intrinsic ultrathinness and capability to maintain a smooth and homogenous 2D surface. Here we report the wafer-scale synthesis of ultrathin quasi-2D amorphous carbon with thickness down to 1–2 atomic layers from solution-processable carbon-dot precursors directly on non-catalytic substrates. The prepared one layer of coalesced carbon dots is an atomically thin, mechanically strong amorphous film predominantly composted of sp^2 carbon with low surface dangling bond density, and their few-layer assemblies are robust nanodielectrics with low leakage current density and high breakdown field strength.

The thickness of the prepared ultrathin quasi-2D amorphous carbon film was characterized precisely based on high-resolution cross-sectional STEM images, giving a thickness of 0.41 ± 0.04 nm. After each deposition-coalescing cycle, the thickness of the film increased precisely by 0.4 nm, which is comparable to the interlayer spacing of graphite, as measured by both AFM and TEM.

With carbon-dot precursors covalently crosslinked together, the prepared ultrathin quasi-2D amorphous carbon film is mechanically robust enough to be transferred to other substrates as a complete and continuous membrane. The transferred quasi-2D amorphous carbon was firstly suspended as freestanding nanomembranes on TEM grid for imaging. The uniform contrast throughout in the low-magnification ADF-STEM image confirms that the film is macroscopically homogenous, and the SAED patterns show a characteristic diffuse halo, which verifies its amorphous nature.

Their mechanical properties were characterized by AFM nanoindentation performed on atomically thin nanomembranes suspended over 1.2 μm wide and 3 μm deep circular holes, giving an extracted high Young's modulus of 400±100 GPa, which is comparable to that of crystalline graphene and h-BN, further verifies the homogeneity and continuity of the ultrathin quasi-2D amorphous carbon prepared from the assembly and coalescence of carbon dots with strong lateral connections, which are very likely of covalent nature.

The achieved macroscopic uniformity, atomic-level thickness control, and processability allow our quasi-2D amorphous carbon films as dielectric in nanoelectronics devices, where their unique structure and properties were exploited to enable improved device performances. When utilized as gate dielectrics in graphene and 2D metal chalcogenides transistors, compared to amorphous bulk metal oxides, the ultrathin amorphous carbon films with predominant sp^2 carbon content can form clean interfaces with graphene and 2D metal chalcogenides, which leads to enhanced carrier transport mobility and minimum hysteresis. Compared to polycrystalline 2D h-BN, they have better processability and their amorphous atomic structures lead to drastically lower leakage current density ($<10^{-4}$ A/cm^2 with thickness down to three atomic layers of 1.6 nm) with higher dielectric strength (breakdown field above 20 MV/cm) for substantially reduced power consumption and improved device reliability.

The atomic-level thickness and the presence of large-size carbon rings inside the atomic structure of quasi-2D amorphous carbon also make its multilayered assemblies attractive for insulating ion-transport media in memristors. Their intrinsic ultrathinness and distinctive atomic structures composed of heterogeneous carbon rings offer predefined filament formation pathways across atomically thin films, leading to drastically enhanced switching uniformity, reduced energy consumption (<20 fJ per operation), and faster operating speed (<20 ns) as the switching media for electrochemical memristor, without sacrificing endurance and retention.

Large Area Van der Waals MoS_2-WS_2 Heterostructures for Visible-Light Photocatalysis and Energy Conversion Giorgio Zambito[1], Matteo Gardella[1], Giulio Ferrando[1], Francesco Bisio[2], Maria Caterina Giordano[1] and Francesco Buatier de Mongeot[1]; [1]University of Genoa, Italy; [2]CNR-SPIN, Italy

Two-dimensional Transition Metal Dichalcogenides semiconductors (2D-TMDs) have recently collected a strong scientific and technological interest over a broad community due to their peculiar optoelectronic response within a broadband spectrum, and to their tunable bandgap that enables promising optoelectronic and photonic functionalities. Additionally, the superior optical absorption coefficients in the Visible spectrum, enhanced by about two orders of magnitude with respect to conventional bulk semiconductors, qualify TMDs as optimal candidates for photodetection and photoconversion applications [1].
Owing to their atomically smooth surfaces and fully saturated in-plane chemical bonds, an opportunity to further engineer the optoelectronic response of a 2D device is offered by the combination of two different TMDs layers to form a van der Waals heterostructure, in which new optoelectronic properties arise from the band structure coupling of the junction [2].
Here, we demonstrate homogeneous growth of large area 2D-TMDs films by means of a physical deposition process based on Ion Beam Sputtering, followed by high temperature recrystallization in a sulfur enriched atmosphere [3,4]. The fabrication process has been subsequently optimized for the sequential synthesis of vertically stacked large area MoS_2-WS_2 van der Waals heterostructures supported on a large area graphene layer which acts as a transparent conductive window [5]. Vertical stacking of MoS_2-WS_2 heterostructure ensures a type-II staggered band alignment which in turn allows to split excitons across the junction, thus increasing the lifetime of the photogenerated carriers compared to the individual TMD components. Charge separation can be exploited both for energy conversion, since recombination rate is reduced, and for photocatalytic applications, since the separated charges on the surface can boost specific reactions. This is reflected in the superior photodissociation rate of molecular dye probes in solution near the heterostructure sample, and in the photovoltage and photocurrent measured upon illumination of the large area device.
These results show that TMDs van der Waals heterostructures represent optimal building blocks for the fabrication of self-powered photodetectors, by exploiting the charge separation of the photogenerated carriers at the 2D interface without any external bias.

Memristive Circuits based on Two-Dimensional Layered Hexagonal Boron Nitride for Radiofrequency Applications Mario Lanza; King Abdullah University of Science and Technology, Saudi Arabia

Radiofrequency (RF) switches are essential components in modern communication devices, as they enable fast data transmission by driving or blocking electromagnetic signals of high frequencies (typically few/tens of gigahertz). The constant demand for higher data transmission rates requires RF switches capable of operating at higher frequencies, which represents a big challenge for commercial device technologies like field effect transistors and phase-change memristors (which are limited to ~60 GHz). In this talk I will present the fabrication of memristive RF switches, based on multilayer hexagonal

boron nitride (h-BN), capable of operating reliably at frequencies up to 260 GHz. We build the first 2D-materials-based series-shunt device configuration and readily achieve outstanding insertion loss of 0.9 dB and isolation of 35 dB at 120 GHz. We accomplish consistent ambipolar switching with low resistances down to 9.3±3.7 Ω by introducing a low resistance tuning protocol, and achieve high endurances up to 2000 cycles (more than 60 times higher than previous reports on 2D-materials-based RF switches). These achievements represent a significant advancement towards next generation RF switches, as well as to the deployment of 2D materials in the semiconductors industry.

8:30 AM EL05.15.02
Lyotropic Liquid Crystal Phases as Temples for Selective Interfacial Reactions to Asymmetric Functionalization of 2D Nanomaterials at Large Scale Wei Wang; Aramco Americas: Aramco Research Center-Boston, United States

Anisotropic nanomaterials composed of two halves with different structure, chemistry, or polarity, known as Janus nanomaterials, have distinct properties when compared to symmetrically functionalized analogues. These materials have gained significant attention in many applications such as electronic thin films, drug delivery, sensors, optics, oil/water separation membranes, photoactivated micromotors, photocatalysts, and interfacial modification. Two dimensional (2D) Janus nanosheets are especially intriguing considering their interfacial properties as well as their ability to assemble into higher order and hybrid structures. In this research, we describe an approach to asymmetric functionalization of 2D nanosheets at large-scale through selective interfacial reactions using liquid crystal phases as templates. Several liquid crystal systems composed of surfactants, water and organic solvents were studied by birefringence imaging, cryo-TEM, small-angle X-ray scattering (SAXS) and small angle neutron scattering (SANS) to optimize the microstructures and stability for using as “nanoreactor” templates, and the surfactants included cationic, anionic, non-ionic and zwitterionic types. In comparison to interfacial reaction in a conventional biphasic system, the efficiency of interfacial reaction within the liquid crystal temples can tremendously increase by more than million times (in $>10^6$ order), enabling to scale up the synthesis of 2D Janus nanomaterials at industrial scale economically. Several samples of synthesized 2D Janus nanomaterials with different properties for different application have been demonstrated.

Controlled Growth and Integration of 2D Semiconductors for High-Performance Electronics Minsu Seol, Junyoung Kwon, Minseok Yoo, Changhyun Kim, Huije Ryu, Eun-Kyu Lee and Kyung-Eun Byun; SAIT, Samsung Electronics, Korea (the Republic of)

2D semiconductors have received much interest as next-generation channel materials. The ultrathin nature of 2D semiconductors affords notable advantages, including enhanced electrostatic gate control and continued transistor scaling, which are pivotal for advancing electronic devices. In this talk, I am going to present our recent progress related with growth, characterization, and integration of 2D semiconductors. We have successfully grown up to 8-inch wafer-scale MoS2 films on amorphous substrates through Metal-Organic Chemical Vapor Deposition (MOCVD). Furthermore, we have achieved the growth of single-crystalline MoS2 on selected areas. To assess film quality, we have employed non-destructive characterization methods. Through optimized integration processes, we have demonstrated the effective fabrication of field-effect transistors (FETs) on 8-inch wafers, resulting in exceptional uniformity in electrical performance, with a success rate exceeding 90%. Statistical analyses of high-performance 2D FETs, with variations in channel length, will be presented to provide insights into their performance characteristics. Additionally, this talk explores the persisting challenges associated with materials growth and device fabrication in this field, paving the way for future advancements in 2D-semiconductor-based electronics.

9:05 AM *EL05.15.04
X-Ray Photoelectron Spectroscopy Study of 2D MoS2/Oxide Dielectric Interface Manish Chhowalla; University of Cambridge, United Kingdom

The interface between two-dimensional transition metal dichalcogenide (2D TMDs) semiconductors and dielectric has not been as widely studied as the metal/2D TMD junction. The dielectric for 2D TMD devices must be thermodynamically and mechanically stable as well as being chemically inert. The band offset between the conduction and valence bands of the dielectric and 2D semiconductor should be at least 1eV. The 2D TMD/dielectric interface should be clean and free of defects. In this presentation, we present detailed synchrotron XOS study of 2D TMD and oxide interface. Specifically, we have studied the band offsets between MoS_2 and SiO_2, HfO_2, and ZrO_2 using XPS. We find that the dielectrics strongly dope the 2D MoS_2 with significant shift (>1eV) in the Fermi level. Our results provide insight into suitability of different dielectrics for 2D MoS_2 FETs.

9:35 AM EL05.15.05
Sensitivity Enhancement of CO_2 Sensors at Room Temperature based on CZO Nanorods Heterostructure Baktiyar Soltabayev[1], Yessimzhan Raiymbekov[2], Aidarbek Nuftolla[2], Amanzhol Turlybekuly[1], Gani Yergaliuly[1] and Almagul Mentbayeva[2]; [1]PI National Laboratory Astana, Kazakhstan; [2]Nazarbayev University, Kazakhstan

Cobalt-doped ZnO (CZO) thin films were deposited on glass substrates at room temperature by RF magnetron sputtering of a single target prepared with ZnO and Co_3O_4 powders. Changes in crystallinity, morphology, optical properties, and chemical composition of the CZO thin films were investigated by varying sputtering power of 45 W, 60 W, and 75 W. All samples presented a hexagonal wurtzite-type structure with a preferential c-axis at the (002) plane along with a distinct change in strain values through X-ray diffraction patterns. Scanning electron and atomic force microscopy revealed a uniform and dense deposition of nanorod CZO samples with high surface roughness (RMS). Hall mobility and carrier concentration increased with the introduction of Co^+ ions into the ZnO matrix as seen from the Hall effect study. The gradual increase of applied power on the target source heavily affects the morphology of the CZO thin film, which is reflected in CO_2 sensing performance. The best gas response to CO_2 was recorded for CZO-60 W with a response of 1.45 for 500 ppm of CO_2. The distinguishing feature of the CZO sensor is its ability to effectively and rapidly detect CO_2 target gas at 27 °C.

Investigation of Graphene Oxide Using Transmission Electron Microscope: A Study of The Reduction Process Douglas S. Silva, Gustavo A. Viana, Jose M. Silva, Luiz C. Kretly, Tárcio A. Barros and Francisco C. Marques; State University of Campinas, Brazil

Several techniques have been used in the production of graphene, such as direct physical exfoliation of graphite and epitaxial growth of SiC surfaces [1, 2,3]. Regardless of the production process adopted, the resulting GO films are insulators with physical and chemical characteristics very different from those of pure graphene. Due to this, the implementation of processes capable of efficiently removing the presence of oxygen-containing functional groups is important to promote the properties of GO towards those of pure graphene. These processes are called “reduction” and the resulting sample “reduced GO” (rGO). Here we report a study of the reduction process using the transmission electron microscopy (TEM) technique. Variations in the electron energy loss spectroscopy (EELS) signal were also explored. It was observed that plasmon peaks, referring to sp^2 carbon bonds in crystalline structures, are more evident in the rGO sample compared to GO sample. The fine structure at the K edge of carbon shows difference in shape. The difference in the width, convolution and definition of the peaks can be directly linked to the density of states above the Fermi level. This fact indicates that the oxygen eliminated in the effusion spectra, which causes large variations in the electrical resistivity of the films, does not come from adsorbed water but from other sources, such as oxygen-containing functional groups, such as epoxy, carbonyl and carboxyl.

9:45 AM EL05.15.07
Use of Laser-Induced Graphene and Functionalized Magnetite Particles as Anchors in Electrochemical CA 15-3 Detection Devices Gabriela L. Araujo Bernal[1], Ramón Gomez-Aguilar[2] and Hugo Martinez-Gutierrez[3]; [1]Escuela Nacional de Ciencias Biológicas-IPN, Mexico; [2]Unidad Profesional Interdisciplinaria en Ingeniería y Tecnologías Avanzadas-IPN, Mexico; [3]Centro de Nanociencias y Micro Nanotecnologías-IPN, Mexico

Iron oxide particles have been used in in vitro diagnostics and theragnosis for nearly 40 years. Magnetite nanoparticles (MNPs) have become popular as supports for immobilizing biomacromolecules due to their magnetic properties, low toxicity, chemically modifiable surface, and high biomolecule loading capacity which promote constant ionic interaction. Coating magnetic nanoparticles with functional materials, such as silicon oxide (SiO_2), has been shown to improve their stability and enable the addition of various functional groups to their surface without altering their properties. The SiO_2 layer provides a chemically inert surface for the core nanomaterials in biological systems.
An ISFET, or Ion-Sensitive Field-Effect Transistor, is a type of field-effect transistor that measures ion concentration in a solution. It can be used as an immunobiosensor when combined with techniques like antibody or antigen immobilization to detect specific biomolecules such as proteins or antigens. The concentration of target biomolecules in a sample is recorded by measuring the variation of the electrical potential at the gate of the ISFET. The changes in potential are analyzed to establish a correlation between the potential change and the presence and concentration of specific biomolecules. The CA 15-3 cancer-associated antigen has been found in the serum of over 70% of patients with advanced breast carcinoma and in a small percentage of patients with non-breast malignancies. Detecting circulating levels of the CA 15-3 antigen may aid in distinguishing breast carcinoma from other dysplasias.
The upper limit of normal (ULN) for circulating CA 15-3 was set at 40 U/mL, as this threshold most adequately distinguished healthy subjects and patients with metastatic breast cancer. The levels of the antigen CA 15-3 in the serum of 500 patients with non-breast cancer, whose age ranged from 2 to 84 years were studied.
Among metallic particles, functional sable core-shell nanoparticles are promising candidates for electrochemical sensors as they can immobilize various materials of biological significance with proper chemical groups. Even if they show magnetic properties, they enable effective separation through external magnetic field induction. Magnetite, Fe_3O_4, is a prevalent iron oxide that can be converted into particles. They can be dispersed in proper solvents and have the potential to create atomic layers for example oxide surfaces (e.g., silicon or aluminum) with a suitable contact area, which can subsequently be functionalized by joining various bioactive molecules that hold high potential for use in various in vitro and in vivo applications. It is crucial to keep control over the synthesis conditions and surface functionalization of particles to achieve particles with specific dimensions, colloidal stability, and biological properties. Typically, the immobilization of peptides or proteins onto particle surfaces are conducted through the activation of 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide-N-hydroxysuccinimide hydrochloride (EDC-NHS).
This work proposes immobilizing the CA 15-3 ELISA kit antibody using functionalized nanoparticles with a magnetite core and silicon oxide shell (F-NPs) with amine groups that diffuse through an immobilization platform (PI) of LIG. Stable groups are created on the functionalized particles to immobilize proteins. A reactive surface is generated by inserting various concentrations of glucose, which gives rise to an immune neutralization reaction (antigen-antibody) producing ionized species. These species are detected through an ISFET that was built on a flexible substrate and subjected to electrical potentials whose are measured between the drain, source, and gate contacts characterizing them by IV saturation curves. This process obtains a proportional relationship between the decay of the current on the device and the added glucose concentration.

9:50 AM EL05.15.08
Investigating The Influence of Multivalent Transition Metal Dopants and Capping Ligands on The Lateral Growth of Photo-Optical Cu_2MoS_4 2D Nanostructures Using a Colloidal Method Sarika V. Chandoo and Richard A. Taylor; University of the West Indies, Trinidad and Tobago

2D transition metal dichalcogenides (TMDs) is a class of emerging materials due to their unique and unconventional properties which allows them to have a cohort of applications such as for photovoltaics and photoelectrochemical conversion. Of these, ternary TMDs are underexplored and herein, for the first-time metal-doped layered tetragonal copper molybdenum sulfide (CMS) nanostructures using a facile, economically feasible and inexpensive colloidal hot injection method were grown at relatively low temperatures of 100 and 140ºC and short time of 1 hour. The morphology, structure, and optical properties of the nanostructures were analyzed by powder X-ray diffraction, high resolution transmission electron microscopy with energy dispersive X-ray analysis, X-ray photoelectron spectroscopy, Raman spectroscopy, UV-VIS absorption, steady-state and time-resolved and photoluminescence spectroscopy. We demonstrate that colloidal conditions involving fractions of oleic acid in combination with the main capping ligand oleylamine enable lateral growth of highly crystalline 2D CMS nanostructures as hexagonal shaped nanosheets and layered nanorods of approximate dimensions 17 nm and 69 nm respectively. In particular, metal doped nanostructures exhibit a correlation of metal ion fraction and particle morphology implicating impurity ions in lateral growth of high energy facets into larger domain 2D nanostructures. Overall, the data shows a correlation of structure, morphology, and stoichiometry on the optical properties such as the influence of point defects such as sulphur vacancies and dopant (Zn^{2+}, Ni^{2+}, Mn^{2+}) substitutions and interstitials. Collectively, this study provides an avenue for the synthesis of ternary TMD 2D nanostructures primarily with shorter growth time and lower growth temperature and offer the opportunity to simply tailor the reaction conditions to afford materials with tunable properties for photovoltaic applications. Additional elements of the work entail examination of the dynamics of the growth of the 2D nanostructures using *insitu* X-ray characterization such as pair distribution function, small and wide-angle x-ray scattering and x-ray absorption spectroscopy to determine the influence of precursors, capping ligands and growth conditions on preferred edge facets. Such insights will be useful towards pinpointing specific growth factors for more targeted growth of these types of 2D nanostructures.

Longevity and Effectiveness of 2D-MoS2 in Two-Terminal Devices: A Systematic Investigation Shakir Bin Mujib, Sonjoy Dey, Gurpreet Singh and Paul Owiredu; Kansas State University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) are strong candidates for continued scaling of transistors to improve the current Si-based technology and facilitate next-generation nanoelectronic devices such as sensors and field-effect transistors (FETs) due to their band structures and properties. Although countless published studies report the electrical properties of TMDs, many are not attentive to the testing environment or the samples' age, which we have found significantly impacts results. Herein, we utilize 2D TMDs fabricated via different top-down and bottom-up approaches, fabricate two electrode devices, and systemically investigate their longevity and effectiveness. We characterized and compared devices using IV measurements in ambient and inert conditions and found the stability of three months for the device kept at later conditions. As expected, the observed atmospheric and

aging effects have a more pronounced effect on thinner flakes. This work illustrates the importance of understanding the electrical testing environment and the impact of atmospheric aging on TMD materials.

Exploring The Application of Hybrid DFTB-Molecular Mechanics Approach to Computing Optical Properties Ruicheng Li, Gekko Budiutama, Keisuke Kameda, Sergei Manzhos and Manabu Ihara; Tokyo Institute of Technology, Japan

The Density Functional based Tight Binding (DFTB) method has seen a rise in adoption for materials modeling, as it permits electronic structure-level modeling of large molecules, interfaces, nanostructures, etc. with much smaller computational cost and similar accuracy when compared to Density Functional Theory (DFT) methods. The cost reduction in DFTB compared to DFT is achieved by the pre-parameterization of the elements of the Hamiltonian matrix as well as the repulsion potential between all pairs of atoms. However, parameterization for new systems with accuracies competitive with DFT in specific applications requires specialized manpower and large computational resources. This prevents the application of the DFTB method to systems for which it was not parameterized.
In our previous work (J. Chem. Theory Comput., 19, 5189-5198 (2023)), a DFTB-molecular mechanics (DFTB-MM) approach was introduced to expand the applicability of DFTB by modeling the interactions of the missing Slater-Koster parameters with an interatomic interaction potential fitted with machine learning. We have shown that when interactions between the atoms do not critically affect key mechanisms of interaction, we can obtain structures and partial densities of states with a similar accuracy to full DFTB. This in principle allows the use of DFTB in systems where not all pairs of atoms have been parameterized.
Here, we further explore the capability of the DFTB-MM method to the calculation of optical properties with Time-Dependent (TD-) DFTB for the modeling of systems whose optical properties are of interest. TD-DFTB permits calculations that include a large number of excitations, which is required for systems with high densities of states, and would not be feasible with TD-DFT. In particular, we investigate interfacial charge transfer in systems such as TCNQ (tetracyanoquinodimethane) on TiO2, whose spectra are sensitive to the computational approach. We show that key spectral features, in particular transitions that involve the interfacial charge transfer band, are similar in full DFTB and DFTB-MM, indicating that DFTB-MM is a viable approach also for optical properties.

Braiding Lateral Morphotropic Grain Boundary in Homogeneitic Oxides Erjia Guo; Institute of Physics, Chinese Academy of Sciences, China

Interfaces formed by correlated oxides offer a critical avenue for discovering emergent phenomena and quantum states. However, the fabrication of oxide interfaces with variable crystallographic orientations and strain states integrated along a film plane is extremely challenge by conventional layer-by-layer stacking or self-assembling. In this talk, we will discuss the creation of morphotropic grain boundaries (GBs) in laterally interconnected cobaltite [1] and manganite [2] homostructures. Single-crystalline substrates and suspended ultrathin freestanding membranes provide independent templates for coherent epitaxy and constraint on the growth orientation, resulting in seamless and atomically sharp GBs. Electronic states and magnetic behavior in hybrid

structures are laterally modulated and isolated by GBs, enabling artificially engineered functionalities in the planar matrix. Using this method, we are able to creat magnetic nanoislands with minimum size of ~35 nm in diameter, suggesting the highest possible areal density could reach upto ~ 400 Gbit/in^2 [3]. Our work offers a simple and scalable method for fabricating unprecedented innovative interfaces through controlled synthesis routes as well as provides a platform for exploring potential applications in neuromorphics, solid state batteries, and catalysis.

8:45 AM EL03/EL06/MT01.03
MoS_2/VO_2 Based Heterostructure Device for Highly Responsive Infrared Photodetection Malti Kumari[1], Basanta Roul[1,2], S.B. Krupanidhi[1] and Karuna K. Nanda[1,3]; [1]Indian Institute of Science, India; [2]Central Research Laboratory, Bharat Electronics, India; [3]Institute of Physics, India

Vanadium oxide (VO_2) has aroused researchers' curiosity among the transition Metal Oxides (ZnO, TiO_2, Ga_2O_3, V_2O_5, SnO_2, CuO) because of its unique semiconductor-to-metal phase transition (SMT). VO_2 is an n-type semiconductor having room temperature bandgap of 0.5-0.7 eV. It undergoes a structural transformation from semiconductor monoclinic phase (low temperature) to metallic rutile phase (high temperature) at transition temperature T_c ~ 340 K exhibiting ultra-fast, fully reversible, first-order phase transition accompanied by a notable change in electronic and optical properties. Transition Metal Dichalcogenides (TMDs) have also been considerably explored due to their distinctive electronic and mechanical properties. Nowadays, TMDs (such as MoS_2, $MoSe_2$ SnS_2, In_2S_3, etc) are proving to be extremely promising materials because of having tunable bandgaps depending on the number of layers of the material, high carrier mobilities, and strong exciton effects. Attributed to the outstanding properties of 2D layered materials and transition Metal Oxides, these materials are well known to give ultrafast, self-biased, and broadband photodetection. In this work, we deposited VO_2 film on SiO_2 substrates by using Pulsed Laser Deposition (PLD). MoS_2 film was deposited on VO_2 film using PLD form MoS_2/VO_2 heterostructure. For $MoS_2/VO_2/SiO_2$ device, the responsivity was found to be 0.83A/W as compared to 4.42×10^{-4} A/W for VO_2/SiO_2 device at 595.83 mW/cm^2 power density using 1550 nm laser. Clearly, the $MoS_2/VO_2/SiO_2$ device shows higher photodetection and hence gives better performance than VO_2/SiO_2 device.

9:00 AM EL03/EL06/MT01.04
Epitaxial Strain Engineering of Monoclinic Bismuth Vanadate: A Path to Tailoring Optoelectronic and Photoelectrochemical Properties Erwin N. Fernandez[1,2], Daniel Grave[3], Fatwa F. Abdi[4] and Roel Van de Krol[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Technische Universität Berlin, Germany; [3]Ben-Gurion University of the Negev, Israel; [4]City University of Hong Kong, China

Epitaxial strain engineering is a powerful tool to perturb the electronic structure of metal oxide photoabsorbers and to potentially improve its performance [1]. Little is known, however, as to the effects of epitaxial strain on monoclinic bismuth vanadate (m-$BiVO_4$), a transition metal oxide relevant to solar-to-fuels application. In this work, we contribute to the understanding on how epitaxial strain alters the $BiVO_4$ monoclinic lattice and the optoelectronic and photoelectrochemical properties of m-$BiVO_4$. We also reveal how the hydrostatic and deviatoric components of the strain tensor correlates with these properties. Epitaxial films of m-$BiVO_4$ deposited directly on yttrium-stabilized zirconia (YSZ) experiences volume-preserving deviatoric strains that modulate its Tauc bandgaps and polaronic photoluminescence emission [2]. Hydrostatic strains, on the other hand, seem to be more important for epitaxial $BiVO_4$ films deposited on more device-relevant indium tin oxide (ITO)/YSZ. For these fully epitaxial $BiVO_4$/ITO/YSZ films, compressive hydrostatic strains narrow the Tauc bandgaps and enhances the internal quantum efficiencies [3]. Epitaxial strain can thus be exploited to modulate the optoelectronic and PEC properties of $BiVO_4$.

Sub-1nm Wireless Local Interconnect and Photonic Millimeter Wave ULSI with the Optoelectronic Microwave CMOS Technology - Will The Cutoff Frequency and Clock Speed Races Resume? James Pan; American Enterprise and License Company, United States

Traditionally, CMOS is not considered a microwave nor light emitting device. Similar to laser or LED, and microwave devices, Photonic Millimeter Wave CMOS transistors are both light as well as microwave emitting devices. Ultra-low-resistance tunnel lasers, tunnel and avalanche millimeter wave diodes (in the drain region), avalanche photon sensors (in the well and channel regions) and MOSFET are fabricated as one integral transistor. When the MOSFET is on, all other devices are on. When the MOSFET is off, all other devices are also turned off. Potentially, CMOS may outperform these discrete lasers and microwave diodes for better quantum efficiency, reliability, and thermal stability.

Ever since AMD releases the 64-bits Athlon processor in around 2005-2006, the clock speed race for ASIC and processors has been almost stopped. Improvements of performance rely on parallel processing, multiple cores, or 3-dimensional packages. The limitation of clock speed is partially due to the RC and other delays, and electronic design and architecture, while silicon CMOS cutoff frequency may reach as high as 300GHz. With the laser millimeter wave CMOS technology, optical microwave computing may resume the races to extremely high clock speeds, with amplified bandwidth and wireless micro ULSI.

In modern societies, wireless tools, such as computers, printers, and cell phones, are replacing almost all the wired electronic tools. For RF ASICs and ULSI, typically there are many layers of backend metals, and wired local interconnects. Many of these metal wires can be eliminated by wireless designs, using new models simulated with the Photonic Microwave CMOS. The very large number (billions or even a trillion) and multiple layers of metal wires seen in ASICs and ULSI significantly retard the cutoff frequency, signal or clock speeds.

Using microwave photonic CMOS, transistor cutoff frequencies can be extended to beyond 300GHz and well into the Terahertz range. In this report, we will discuss the following:

Process integration and circuit design implementing microwave photonic CMOS to reduce the number of metal wires.
Powered optical waveguides that substantially increase the CMOS output current and speed.
Microwave computing and ASIC - using the polarized, filtered, and multiplexed technologies.
Micro-antenna designs and microwave filters for photonic microwave computing.
SRAM designs - how to design an ultra-fast microwave photonic SRAM for sub-1nm wireless processors.
CMOS VCSEL (Vertical Cavity Surface Emitting Laser) and Millimeter Wave CMOS - how to achieve 3D wireless and optical designs.
How to design logic gates with nonlinear optical materials and optical filters / polarizers.
How wireless microwave photonic CMOS and optical computing may resume the cutoff frequency and clock speed races for terahertz operations, by

replacing many of the metal wires with central micro antennas and microwave filters / polarizers.

We will also illustrate how to design wireless ASICs using negative-resistance tunnel and avalanche microwave CMOS (IMPATT, BARITT). Transferred electronic effects and photon-accelerated avalanche microwave generation significantly improve the CMOS speed and ASIC cutoff frequencies.

Synthesis of Electronic-Grade Quantum Heterostructures Chang-Beom Eom; University of Wisconsin--Madison, United States

Modern quantum materials are inherently sensitive to point defects, and require a new synthesis route to produce epitaxial oxide thin films and interfaces clean enough to probe fundamental quantum phenomena. The recent discovery of robust superconductivity at $KTaO_3$ (111) and $KTaO_3$ (110) heterointerfaces on $KaTaO_3$ bulk single crystals offers new insights into the role of incipient ferroelectricity and strong spin-orbit coupling. Electronic grade epitaxial thin film platforms will facilitate investigation and control of the interfacial superconductivity and understanding the fundamental mechanisms of the superconductivity in $KTaO_3$. The major challenge of research on $KTaO_3$ system is that it is difficult to grow high-quality $KTaO_3$ epitaxial thin films due to potassium volatility. Recently, we have developed the hybrid PLD method for electronic grade $KTaO_3$ thin film growth, which successfully achieves this by taking advantage of the unique capabilities of PLD to instantly evaporate Ta_2O_5 in a controlled manner and evaporation of K_2O to maintain sufficient overpressure of volatile species. We successfully synthesized heteroepitaxial $KTaO_3$ thin films on 111-oriented $KTaO_3$ bulk single crystal substrates with a $SmScO_3$ template by hybrid PLD, followed by a $LaAlO_3$ overlayer. Electrical transport data show a superconducting transition temperature of ~ 1.35K. We anticipate that the ability to synthesize high-quality epitaxial complex oxides such as $KTaO_3$ that contain volatile elements will provide a new platform for exploring new physics and technological applications arising from unique characteristics such as large spin-orbit coupling.

This works has been done in collaboration with Jieun Kim, Jungwoo Lee, Muqing Yu, Neil Campbell, Shun-Li Shang, Jinsol Seo, Zhipeng Wang, Sangho Oh, Zi-Kui Liu, Mark S. Rzchowski, Jeremy Levy.

11:00 AM EL06.01.02
Unconventional Quantum Oscillations in EuO/$KTaO_3$ Heterointerface Km Rubi[1], Dumen Manish[2], Suvankar Chakraverty[2], Mun Chan[1] and Neil Harrison[1]; [1]Los Alamos National Laboratory, United States; [2]Institute of Nano Science and Technology, India

The coexistence of electric-field controlled superconductivity and spin-orbit interaction in two-dimensional electron gas (2DEG) based on complex oxides (e.g., $SrTiO_3$ and $KTaO_3$) hold great promise for advancement in spintronics and quantum computing. However, a comprehensive understanding of the electronic bands that give rise to the multifunctional character of these 2DEGs remains elusive. To address this, we recently investigated quantum oscillations in the magnetoresistance of a $KTaO_3$-2DEG in high magnetic fields (60 T).
$KTaO_3$ is a 5*d* transition metal oxide, exhibiting a lighter effective mass of electrons and a stronger spin-orbit interaction at its conducting surface/interface than its counterpart $SrTiO_3$ [1-2]. A high-mobility spin-polarized 2DEG with the superconducting feature is discovered at the EuO/$KTaO_3$ interface [3]. In this talk, I will present novel insights into the electronic states of the EuO/$KTaO_3$ interface investigated through Shubnikov-de Haas (SdH) oscillations. Remarkably, we observed a progressive increase in cyclotron mass and oscillation frequency with the magnetic field, indicating the presence of non-trivial electronic bands [4]. Besides providing experimental evidence for topological-like electronic states in $KTaO_3$-2DEG, these results shed light on the recent predictions of topological states in the 2DEG based on similar perovskite transition metal oxides.

High-Mobility Two-Dimensional Electron Gases based on Strain Engineered Ferroelectric $SrTiO_3$ Thin Films Ruchi Tomar[1], Tatiana Kuznetsova[2], Srijani Mallik[1], Luis M. Vicente-Arche[1], Fernando Gallego[1], Maximilien Cazayous[3], Roman Engel-Herbert[2,4] and Manuel Bibes[1]; [1]Unité Mixte de Physique, CNRS, Thales, Université Paris-Saclay, France; [2]Pennsyvlania State University, United States; [3]Laboratoire Matériaux et Phénomènes Quantiques, Université de Paris,, France; [4]Paul Drude Institute for Solid State Electronics, Leibniz Institute within Forschungsverbund Berlin eV, Germany

Two-dimensional electron gases (2DEGs) based on the quantum paraelectric $SrTiO_3$ display fascinating properties such as large electron mobilities, superconductivity and efficient spin-charge interconversion owing to their Rashba spin-orbit coupling.[1-3] However, such 2DEGs have almost exclusively been generated in $SrTiO_3$ single crystals, with the few attempts to replace crystals by heteroepitaxial $SrTiO_3$ thin films leading to low carrier mobilities. This is limiting the potential to integrate $SrTiO_3$ 2DEGs in future devices as well as the possibility to introduce additional functionalities specific to $SrTiO_3$ thin films, such as strain-induced ferroelectricity. Here, we use oxide molecular beam epitaxy to grow high quality strain-engineered $SrTiO_3$ films that are ferroelectric up to 170 K. We then generate a 2DEG by sputtering a thin Al layer and demonstrate an increase in both the low and room temperature mobilities by up to factor of four compared to earlier literature. Furthermore, through Raman spectroscopy and magneto-transport measurements, we show that the ferroelectric character is retained after 2DEG formation. These results thus qualify our samples as ferroelectric 2DEGs up to temperatures well above previous results based on Ca-$SrTiO_3$ substrates (~30 K)[4], opening the way towards ferroelectric 2DEGs operating at room temperature.

11:30 AM *EL06.01.04
Multifunctional Oxide-2DEGS for Spin-Charge Interconversion Agnès Barthelemy; Unité Mixte de Physique CNRS/Thales, France

Spin-charge interconversion in systems with spin-orbit coupling offers a new path for the generation and detection of spin currents of great potential for application in spintronics. The Rashba-type spin-orbit coupling linked to the spatial inversion symmetry breaking appearing in the two-dimensional electron gases (2DEG) formed at the interface between $LaAlO_3$ and $SrTiO_3$ [1] or by deposition of Al, Ta or Y on $SrTiO_3$ [2, 3], Ca:$SrTiO_3$ [4] or $KTaO_3$ [5] allows for very efficient spin to charge interconversion [1, 2, 6]. Recently, possibilities to further enlarge or control the functionalities of oxide-2DEGs have emerged. One approach relies on making the 2DEG ferroelectric by exploiting the large electric-field- or Ca-doping-induced ferroelectric character in STO, while the other is by inducing spin polarization in the 2DEG by depositing a magnetic layer on top of the 2DEG. Combining both strategies, multiferroic 2DEGs have been realized, opening an avenue for ferroelectrically controllable chiral spin textures in 2DEGs and providing a new playground for non-volatile spin–orbitronics and non-reciprocal physics. We will review our efforts to obtain such multifunctional 2DEGs [7, 8, 9 , 10].

The Influence of a Polar-Nonpolar Interfaces on Surface Segregation and Interface Termination: The Case of $LaInO_3$/$BaSnO_3$ Martina Zupancic[1], Wahib Aggoune[2], Alexandre Gloter[3], Franz-Philipp Schmidt[4], Georg Hoffmann[5], Daniel Pfützenreuter[1], Anna Regoutz[6], Zbigniew Galazka[1], Houari Amari[1], Oliver Bierwagen[5], Jutta Schwarzkopf[1], Thomas Lunkenbein[4], Kookrin Char[7], Claudia Draxl[2] and Martin Albrecht[1]; [1]Leibniz Institut fuer Kristallzuechtung, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]Université Paris-Saclay, France; [4]Fritz-Haber-Institut, Germany; [5]Paul Drude-Institut für Festkörperelktronik, Germany; [6]University College London, United Kingdom; [7]Seoul National University, Korea (the Democratic People's Republic of)

Interfacial polar discontinuities are a unique way to manipulate charge states at interfaces and to create novel two-dimensional electron states. One recent example for this phenomenon is the interface between AlN and GaN, where a discontinuity in the spontaneous polarization leads to the formation of two-dimensional electron (2DEG) or hole gas (2DHG). The polar-nonpolar interface between ABO_3 perovskite oxides offers new degrees of freedom to tune the interface states by the accessibility of mixed valence states. The accepted model explaining the formation of a 2DEG is based on the concept of charge transfer between the layers terminating the polar-nonpolar interface. To realize a 2DEG or a 2DHG control of the interface is a prerequisite. When growing the heterostructures, it is a commonly assumed that the surface termination of the non-polar layer controls the interface properties. In this contribution we provide experimental evidence demonstrating that the compensation of the polar discontinuity can drive surface segregation and consequently, control the interface termination.
We study the interface formation between the cubic wide band gap semiconductor $BaSnO_3$, and orthorhombic $LaInO_3$, by combining analytical scanning transmission electron microscopy (S)TEM, photoelectron spectroscopy and density functional theory (DFT) calculations. The samples were grown by plasma-assisted molecular beam epitaxy on $DyScO_3$ substrates at 835°C using a mixture of Sn and SnO_2 as a SnO source. While TEM experiments of $BaSnO_3$ bulk crystals and DFT agree that BaO is the most stable surface termination of $BaSnO_3$ over wide range of chemical potentials, we find that the interface between $BaSnO_3$ and $LaInO_3$ is terminated by SnO_2. This is consistent with the presence of a 2DEG, but also with our DFT calculations, which show this interface to be the most energetically favorable. STEM and PES show the presence of BaO on the surface of thin $LaInO_3$ films indicating Ba surface segregation. Based on our DFT calculations we find that the driving force for Ba segregation is the compensation of the polar discontinuity at the interface. This compensation is an effect of the gradual reduction of the octahedral tilt from the orthorhombic $LaInO_3$ to the cubic $BaSnO_3$ and the polar and non-polar distortions at the interface. In the case of the n-type SnO_2 interface, this leads to an expansion of the out-of-plane lattice spacing at the interface, which most efficiently compensates for the discontinuity. At the p-type BaO terminated interface it leads to non-polar distortions in the $BaSnO_3$, while polar distortions remain mainly in the $LaInO_3$, which compensate the polar discontinuity less efficiently. This shows that in perovskites in addition to surface energy and strain, the response of the system to compensate for the polar discontinuity must be considered as an additional driving force for segregation that can control the interface termination.

Orbital Engineering in Trigonal $CrVO_3$ Superlattices Simon Mellaerts[1], Wei-Fan Hsu[1], Claudio Bellani[1], Adolfo del Campo[2,3], Jesús López-Sánchez[2,3], Mariela Menghini[4], Michel Houssa[1,5], Jin Won Seo[1] and Jean-pierre Locquet[1]; [1]KU Leuven, Belgium; [2]Instituto de Cerámica y Vidrio – Consejo Superior de Investigaciones Científicas, Spain; [3]Instituto de Ciencia de Materiales de Madrid, Spain; [4]IMDEA Materials Institute, Spain; [5]IMEC, Belgium

Complex oxides form a fertile ground for a rich variety of functional phenomena that can be controlled upon doping, strain, interfacial charge transfer, confinement, and many others. Tuning these parameters often involves complex architectures such as heterostructures, superlattices or nanocomposites, with the ultimate aim to bring these quantum phenomena towards device applications. Moreover, many of the explored complex oxides are perovskites ABO_3 hosting the common high-temperature cubic structure, while materials with trigonal and hexagonal symmetry have remained largely unexplored.

In this work, we study corundum $CrVO_3$ (V_2O_3/Cr_2O_3) superlattices with symmetric periodicities ranging from 1 to 14 monolayers (ML) grown by oxide molecular beam epitaxy (MBE). By means of transport and optical spectroscopy, it is shown how the strong electron correlations in V_2O_3 are suppressed by quantum confinement. While infrared and Raman spectroscopy prove that this is accompanied by the absence of the monoclinic ground state at low temperature. By combining density functional theory (DFT) and Raman spectroscopy, it is shown that this dimensional crossover can be largely explained by a change in the orbital states dictating the phase diagram of V_2O_3.

In a second part, we focus on the 1ML limit of superlattices, which can be considered as a new ordered ilmenite structure (R-3) and is predicted to be a ferromagnetic insulator by DFT methods. Furthermore, the capability to grow these corundum materials in a monolayer fashion unlocks a complete new set of ABO_3 materials with a trigonal symmetry (R3, R-3, R3c) where both A and B are transition metals. Finally, we also propose a way to grow these materials in the polar ordered (R3c) structure where the existence of two magnetic sublattices promises new high-temperature multiferroicity, motivating the search for novel ordered trigonal materials.

Hot Complex Oxides--Turning up The Heat for Adsorption Control Darrell G. Schlom[1,2,1]; [1]Cornell University, United States; [2]Leibniz-Institut für Kristallzüchtung, Germany

It has long been known that molecular-beam epitaxy works best for materials that can be grown in an adsorption-controlled regime where thermodynamics automatically provides composition control. This is where MBE started—for GaAs and other compound semiconductors—and underlies its success for producing semiconductor films with the highest purity and mobility. The same holds for the growth of thin films of complex oxides by MBE, but the issue has been that it has not been possible to grow that many oxides in such a regime. In this talk I will describe how high substrate temperature opens the door to this desired growth regime for the growth of complex oxide thin films. Using a powerful CO_2-laser capable of heating to substrate temperatures of 2000 °C, we have grown an increasing number of complex oxides in an adsorption-controlled regime by MBE. In this talk I will show multiple examples, but concentrate on the growth and characterization of (Ba,Sr)TiO_3 films grown by MBE at substrate temperatures in the 1200-1500 °C range.

2:30 PM EL06.02.04

$SrMoO_3$ is the most conducting perovskite oxide (~5.1 at room temperature),[1] about 40 times more conductive than $SrRuO_3$. This makes it an attractive material as a bottom electrode for perovskite heterostructures, particularly for the high-*K* dielectric $Ba_xSr_{1-x}TiO_3$.[2] Unfortunately, the synthesis of molybdates by traditional MBE is difficult due to the low vapor pressure of molybdenum.[3] In contrast to elemental molybdenum, its oxide MoO_3 has a very high vapor pressure, which makes it a suitable candidate for a variant of MBE where a molecular beam of a metal oxide rather than its elemental counterpart is used.[4] One challenge of using MoO_3 as a source, however, is its tendency to reduce to non-volatile MoO_2 in an ultrahigh vacuum environment. This challenge was recently circumvented by injecting a steady flow of oxygen directly into the crucible, enabling the growth of $SrMoO_3$ films using the stable flux of MoO_3 molecules emanating from a MoO_3 source in conjunction with the flux of strontium atoms emanating from a strontium source, both of which were containing within MBE effusion cells.[3] The properties of oxide conductors often depend strongly on composition, where off stoichiometry can increase the room-temperature resistivity and dramatically decrease the residual resistivity ratio . This disorder is presumably responsible for the lowest room-temperature resistivity values obtained to date for $SrMoO_3$ films grown by conventional MBE and pulsed-laser deposition being 24 and , respectively,[2,5] which is a factor of 5 higher than the best $SrMnO_3$ single crystals.[1] Here we report the growth of $SrMoO_3$ in an adsorption-controlled regime where thermodynamics automatically controls film composition. To achieve this adsorption-controlled regime, substrate temperatures above 1100 °C are needed, which are unattainable in conventional oxide MBE systems. At the PARADIM thin film facility, we can reach substrate temperatures up to 2000 °C with a CO_2-laser substrate heater, allowing us to capitalize on the volatility of SrO at ~1100 °C. The resulting phase-pure epitaxial $SrMoO_3$ thin films are characterized by narrow rocking curves, room-temperature resistivities under and residual resistivity ratios higher than the best $SrMoO_3$ single crystal.[1] We additionally map the band structure of these high-quality $SrMoO_3$ films with angle-resolved photoemission spectroscopy.

Growth of Superconducting Sr_2RuO_4 Thin Films via Thermal Laser Epitaxy Brendan D. Faeth[1,2], Varun Harbola[2], Felix V. Hensling[2], Lena N. Majer[2], Y. Eren Suyolcu[2], Yu-Mi Wu[2], Hans Boschker[3], Peter A. van Aken[2], Wolfgang Braun[2,3] and Jochen Mannhart[2]; [1]Cornell University, United States; [2]Max Planck Institute for Solid State Research, Germany; [3]Epiray Gmbh, Germany

Thermal laser epitaxy (TLE) is a novel technique for thin film deposition which employs continuous wave lasers to simultaneously heat both the substrate and elemental sources. This laser heating approach allows for evaporation or sublimation of nearly all elements from the periodic table, ultrahigh substrate temperatures exceeding 2000 C, and broad compatibility with process gases at a wide range of pressures from UHV up to 1 Torr, among other benefits. As a result, TLE dramatically expands the parameter space available for thin film synthesis compared to existing epitaxy techniques. However, to date it has proven experimentally challenging to achieve simultaneous control of multiple laser based elemental sources with the flux stability and systematic fidelity necessary for the growth of ternary or multernary systems of interest such as complex oxides.

In order to establish the capabilities of TLE for the growth of such complex materials, we demonstrate here the successful epitaxial synthesis of several Ruddlesden-Popper phases of the Sr-Ru-O ternary oxide system via TLE. Near instant thermalization of both source elements and substrates from laser heating allows the process of thermodynamic phase control to be achieved rapidly during film deposition without the need for physical shuttering of sources. Additionally, we find that the "n=1" phase Sr_2RuO_4 can be reliably synthesized at substrate temperatures in excess of 1200 C and in a background environment of pure molecular oxygen, within an adsorption-controlled growth window that is inaccessible to conventional MBE approaches. We show that Sr_2RuO_4 films grown under these conditions demonstrate extremely high structural, electronic, and chemical quality, as evidenced by the appearance of superconductivity at relatively high critical temperatures. In particular, the higher growth temperatures and elemental source fluxes afforded by laser heating allow us to achieve phase pure 214 without higher-N intergrowths typically observed in MBE-grown films, and growth rates more than 10 times faster than MBE. A detailed accounting of the experimental approach, growth thermodynamics and film characterization will be discussed.

This work not only demonstrates the feasibility of TLE for the synthesis of high-quality complex oxide thin films, but also suggests new routes to achieving thin film growth in other materials systems that remain as-yet inaccessible to conventional epitaxy techniques.

Fe Substitution Suppresses Oxygen Vacancy Formation and Stabilizes High-Valence Ni in Epitaxial $La_{0.5}Sr_{0.5}Ni_{1-x}Fe_xO_{3-\delta}$ Thin Films Le Wang[1], Bethany Matthews[1], Xu He[2], Mark Bowden[1] and Yingge Du[1]; [1]Pacific Northwest National Laboratory, United States; [2]Université de Liège, Belgium

Recent discovery of superconductivity in $Nd_{0.8}Sr_{0.2}NiO_2$ has inspired further exploration of nickelates to gain insights into the origins of high-temperature superconductivity. However, the synthesis of Sr- or Ca-doped nickelate thin films is challenging due to the instability of high-valence Ni and the competition between perovskite and Ruddlesden–Popper (RP) phases. Our recent study revealed that Sr doping in $LaNiO_3$ thin films significantly reduces the Ni valence from Ni^{3+} to Ni^{2+} and results in the formation of numerous RP phases as the Sr doping level increases from 0% to 100%. Furthermore, DFT simulations on the $La_{1-y}Sr_yNiO_{3-\delta}$ perovskite structures indicated a substantial decrease in the oxygen vacancy formation energy from 2.96 to 1.85 eV as y varies from 0 to 0.5. In our current work, we synthesized a series of epitaxial $La_{0.5}Sr_{0.5}Ni_{1-x}Fe_xO_{3-\delta}$ (LSNFO) thin films on LSAT(001) substrates using oxide MBE. We found that partial Fe substitution for Ni in $La_{0.5}Sr_{0.5}NiO_{3-\delta}$ significantly enhances the structure quality and stabilizes the perovskite structure. Ni *L*-edge XAS results reveal an increase in the Ni valence of LSNFO films, approaching Ni^{3+} as x increases from 0 to 0.5. At x = 0.75, the Ni valence is even higher than Ni^{3+}. This is in contrast to the $LaNi_{1-x}Fe_xO_3$ (LNFO) system (without Sr), where the average Ni valence decreases with increasing Fe content due to charge transfer from Fe to Ni. STEM measurements confirm that the x = 0.75 sample remains in the perovskite phase but exhibits lots of RP faults and defects. On the other hand, Fe *L*-edge XAS results indicate that films of all Fe content show a nominally higher Fe oxidation state than a $LaFeO_3$ (Fe^{3+}) reference. In-plane transport measurements demonstrate that the resistivity increases with Fe content in the LNFO system, but decreases initially in the LSNFO system, reaching the lowest value at x = 0.375, before rising again with x greater than 0.375. The metal-insulator transition in the LSNFO system strongly depends on Fe content, increasing with x, similar to the LNFO system. Further theoretical investigations are necessary to elucidate the influence of Fe doping on the electronic structure of the LSNFO system. In summary, these findings provide valuable insights into the design of perovskite structures featuring high-valence Ni and Fe, crucial for developing effective electrocatalysts for water splitting, as well as the creation of advanced electronic devices for solid oxide fuel cells.

Metal-Insulator Transition and Novel Ground States in Epitaxially Strained $SmBaMn_2O_6$ Thin Films Yorick Birkholzer[1], Anna S. Park[1,1], Noah Schnitzer[1], Evan Krysko[1], Jacob Steele[1], Hebatalla Elnaggar[2], Jelle Ruiters[3], Koen Draijer[4], Masoud Lazemi[4], Qijun Che[4], Shigeki Yamada[5], Taka-hisa Arima[6], Frank de Groot[4], David Muller[1,1,1] and Darrell G. Schlom[1,1,7]; [1]Cornell University, United States; [2]Sorbonne Université, France; [3]University of Twente, Netherlands; [4]University of Utrecht, Netherlands; [5]Yokohama City University, Japan; [6]University of Tokyo, Japan; [7]Leibniz-Institut für Kristallzüchtung, Germany

For the realization of the next generation of fast, energy-efficient nanoelectronics, there is a great need for new materials whose electrical and optical conductivities can be sensitively tuned between high (on) and low (off) states by altering a thermodynamic control parameter such as strain or temperature. Unfortunately, most materials are either metallic or insulating and their conductivities cannot be changed substantially. Materials exhibiting a metal-insulator transition (MIT) above room temperature are quite rare, limiting their applicability in devices.

One noteworthy example of such a material is the A-site layer-ordered double perovskite $SmBaMn_2O_6$. While its synthesis in bulk form was reported by Yamada *et al.* [1], the successful growth of $SmBaMn_2O_6$ thin films remained elusive for over a decade. Here, we demonstrate the growth of untwinned epitaxial thin films of phase-pure $SmBaMn_2O_6$ on various single-crystalline oxide substrates using molecular-beam epitaxy (MBE), exploring a wide range of tensile to compressive biaxial strains. The latter has been predicted to host a different ground state based on first-principles calculations by Nowadnick *et al.* [2].

To stabilize the A-site layer-ordered double perovskite phase, we employ a two-step approach as originally described by Millange *et al.* for $LaBaMn_2O_6$ bulk crystals [3]. The key elements are, first, a high-temperature synthesis step of a brownmillerite-like, oxygen-deficient precursor, and second, a topotactic oxidation at low temperature. Notably, the former requires temperatures higher than 1100 °C that are unattainable in conventional oxide MBE systems. In this study, we utilize a recently installed, high-power CO_2-laser-based substrate heater at the PARADIM user facility at Cornell University, which allows growth temperatures up to 2000 °C.

Ongoing efforts entail the comprehensive investigation of the structural and spectroscopic properties of epitaxial $SmBaMn_2O_6$ thin films as a function of temperature and strain. To this end, we are employing an ensemble of X-ray, optical, and electrical transport techniques, alongside scanning transmission electron microscopy and electron energy-loss spectroscopy. Our aim is to elucidate potential hidden ground states and coupled structural, magnetic, and electronic phase transitions in this MIT compound.

Structure and Properties of Low Dimensional Epitaxial Oxides; Interfaces and Superlattices Gertjan Koster[1,2]; [1]University of Twente, Netherlands; [2]MESA+ Institute for Nanotechnology, Netherlands

In complex oxide materials the occurrence of ferroelectric, ferromagnetic or other properties are for the most part determined by the detailed (oxygen) coordination of metal cations. More specifically, in the case of perovskite-type materials ABO3, where A and B are metal cations, by the BO6 octahedral orientations and rotations. At interfaces in epitaxial oxide hetero structures, for example magnetic junctions or capacitive structures, this oxygen sub-lattice is found to be different from its bulk counterpart.
I will briefly introduce the status of the often-used technique to fabricate epitaxial layers, 'atomically controlled PLD', as well as give a few examples of oxygen sub-lattice and interface engineering achieved by controlled thin film parameters such as, composition, digital thickness variation, polar discontinuous interfaces or the insertion of oxide buffer layers that influence the perovskite-type BO6 sub-lattice or related structures. I will further elaborate on the effects of such thin film parameters on the structure and properties of various model systems that have been subsequently studied by in situ characterization techniques, high resolution scanning transmission electron microscopy. More practically, often-encountered problems due to dead-layer effects and interfacial issues when integrating oxides with technical platforms such as Si or GaN, will be discussed.

SESSION EL06.03: Poster Session
Session Chairs: Aiping Chen, Woo Seok Choi and Megan Holtz
Tuesday Afternoon, April 23, 2024
Flex Hall C, Level 2, Summit

Lithium Incorporation in (111)NiO Epitaxial Layers Grown by Pulsed Laser Deposition Technique Bhabani P. Sahu, Santosh K. Yadav, Simran Arora and Subhabrata Dhar; India Institute of Technology Bombay, India

Wide bandgap oxides such as ZnO, Ga_2O_3 and In_2O_3 have tremendous potential in UV-optoelectronics, yet the unintentional generation of certain donor type of defects in the film during growth make it challenging to achieve stable p-type doping in these materials. Nickel oxide (NiO) is a wide bandgap semiconductor of bandgap ranging from 3.6 - 4 eV. It is one of the few oxide semiconductors that exhibits stable p-type conductivity and antiferromagnetic properties with Neel temperature of 525K. The material also has high chemical and thermal stability. All these characteristics have made NiO a potential candidate for wide range of device applications such as exchange bias systems, field effect transistors, transparent hole conducting films, spintronics, UV-photodetectors and UV-LEDs. It has to be noted that stoichiometric NiO is an insulator, and p-type conduction in the film can be ascribed to the presence of nickel vacancies. However, controllable p-type doping with native defects is difficult to accomplish due to the formation of other unintentional compensating defects in the film. Intentional doping with monovalent atoms such as lithium will be interesting to explore. Keeping in mind that epitaxial films will give better device performance, there are efforts to grow epitaxial layers of NiO on different substrates such as c-sapphire, MgO and yttria-stabilised zirconia. In fact, the growth of NiO films with high epitaxial qualities have been reported by various techniques such as pulsed laser deposition (PLD), mist chemical vapour deposition, RF magnetron sputtering and molecular beam epitaxy.
Here, we study the incorporation of Li in (111) NiO epitaxial layers grown by PLD technique on c-sapphire substrates as a function of growth conditions. The structural, morphological, electrical and optical properties of the films have been systematically investigated. It has been found that the crystalline quality of these films deteriorates as the growth temperature is lowered. Surface morphology of the films, studied by atomic force microscopy (AFM) and field emission gun secondary electron microscopy (FEGSEM) shows smooth and continuous nature of the films with surface roughness lying between 0.4 - 1.4 nm. It has been found that the conductivity of the layers increases as the growth temperature is decreased. The enhancement of conductivity has been ascribed to the increase in density of nickel vacancy with the reduction of temperature. The investigation further suggests that there is a miscibility limit of Li in NiO. Li-clusters are detected in the films beyond a critical concentration of lithium. Further, it has been found that lithium inclusion results in hydrostatic tensile strain in the NiO lattice leading to the reduction of the bandgap. The study also shows that Li incorporation, which has also been verified by secondary ion mass spectroscopy (SIMS) and x-ray photoelectron spectroscopy (XPS), improves the electrical conductivity of the layers.

Potentiometric Detection of Serum Creatinine Utilizing Lead Dioxide and Carbon Nanotubes in a Single-Enzyme Reaction Sung Min Jeon, Dayeong Choi, Han Been Lee and Gi Hun Seong; Hanyang University, Korea (the Republic of)

Creatinine (CRE) serves as the end product of creatine, responsible for energy release in skeletal muscle. The baseline concentration of serum creatinine (SCr) typically ranges from 45 μM to 90 μM in females and 60 μM to 110 μM in males. Elevated SCr levels are commonly utilized in diagnosing acute kidney injury. Ongoing research focuses on developing reliable techniques for estimating SCr due to its critical role as a biomarker of significance. The Jaffe reaction, a colorimetric method utilizing picric acid, has traditionally been employed for clinical analysis of creatinine (CRE). However, this method presents several drawbacks, including the need for pH adjustment, interference issues, and, notably, the toxicity and explosiveness of picric acid. A prominent trend in CRE detection involves electrochemical enzyme sensors, offering enhanced sensitivity and selectivity. The inclusion of creatinine deiminase (CD) in the enzymatic approach addresses the aforementioned challenges, thereby improving sensor performance and selectivity. In this enzymatic method, CD reacts with CRE to produce NH_3, subsequently converted to NH_4^+ and OH^- in an aqueous solution. The NH_4^+ ion selective sensor and pH sensor then measure the concentration of CRE.
Single-walled carbon nanotubes (SWCNTs) are widely acknowledged for their outstanding electrical properties, characterized by high carrier mobility and current-carrying capacity, coupled with impressive chemical, thermal, and mechanical attributes. Surface modification techniques can be applied to introduce diverse functional groups on the SWCNT surface, enhancing their suitability for various applications. The incorporation of metal oxide deposits can impart electrical, electrochemical, and biocompatible properties, making them valuable in sensor manufacturing. Among the diverse applications, electrochemical pH sensors stand out, and metal oxide modification presents several advantages. These include notable sensitivity, rapid response times, prolonged operational lifespan, minimal interference with other ions, cost-effectiveness, ease of maintenance, and adaptability for miniaturization in flexible systems. While various metal oxide pH sensors such as IrO_2, RuO_2, TiO_2, WO_3, and SnO_2 have been reported in recent years, their production often involves intricate and high-temperature processes. Lead dioxide (PbO_2) emerges as a noteworthy choice for pH sensors due to its excellent electrochemical properties and straightforward fabrication method. However, PbO_2-based pH sensors may exhibit deficiencies in oxygen or an excess of lead within the PbO_2, potentially impacting electrochemical reactions.
In this investigation, we produced a thin film of lead dioxide deposited on carbon nanotubes (PbO_2/CNT) and developed a PbO_2/CNT ion-selective electrode (PbO_2/CNT/ISE). These sensors served as highly sensitive potentiometric biosensors for CRE, capitalizing on the one-step selective conversion of creatinine by creatinine deiminase. We conducted the detection of OH^- and NH_4^+ in an aqueous solution, generated through an enzymatic reaction, utilizing PbO_2/CNT as a pH sensor and PbO_2/CNT/ISE as an NH_4^+ selective electrode. The obtained results reveal a remarkable sensitivity of -75.56 mV

log[CRE]$^{-1}$ and 64.62 mV log[CRE]$^{-1}$, with a calculated limit of detection of 0.06 μM and 0.13 μM, respectively, within the range of 10 to 400 μM. A selectivity test demonstrated robust discrimination against interfering materials in human serum, and the repeatability and long-term stability of our sensors were confirmed, indicating their high-level stability. Furthermore, recovery tests for CRE concentrations (10, 25, 50, 70 μM) in spiked human serum yielded results of 104%, 98%, 103%, and 96% for PbO_2/CNT, and 104%, 92%, 110%, and 97% for PbO_2/CNT/ISE. These findings underscore the reliability and reproducibility of our sensors in detecting CRE for clinical applications.
