High Performance of Ferroelectric Synaptic Device in $Hf_{0.7}Zr_{0.3}O_2$ (HZO)/$La_{0.7}Sr_{0.3}MnO_3$ (LSMO)/$SrTiO_3$ (STO) Heterostructure by Optimizing Defect-Mediated Ferroelectric Switching Dynamics Hojin Lee[1], Joonbong Lee[1], Hyungseok Kim[2], Kyungwho Choi[3], You Seung Rim[1] and Taekjib Choi[1]; [1]Sejong University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

High-performance artificial synaptic devices with linear synaptic weight and high precision are in high demand for hardware neural network (HNN) implementation. Hf-based ferroelectric memristor has robust stable non-volatile analog resistive switching driven by its gradual polarization reversal. However, the high linearity and precision of the synaptic weight update are required to improve the accuracy of the neuromorphic chip application. Here, we demonstrate the high performance of ferroelectric synaptic device in $Hf_{0.7}Zr_{0.3}O_2$ (HZO)/$La_{0.7}Sr_{0.3}MnO_3$ (LSMO)/$SrTiO_3$ (STO) heterostructure, showing the high linearity (α=0.5), effective multiple conductance states (> 40), and low cycle-to-cycle variation (2.06%). The synaptic characteristics of the device are dominantly attributed to the inhomogeneous domain nucleation, ultimately affecting the precision and linear weight update achievable in continuous polarization switching. As an artificial synapse, experimental results with electrical pulse modulation closely mimic the neuro-inspired signal process dependent on spike timing and spike rate. These results supposed that oxygen vacancy engineering in ferroelectric synaptic devices is a powerful approach to improving effective precision and overcoming the limitations nonlinear synaptic behavior for the implementation of HNN. In addition, when applied to a hardware neural network with a crossbar array (20X20), the recognition accuracy of MNIST handwriting data was recorded as 94.8%.

High-Resolution Uncooled Detector of Thermal Radiation with Resistivity Engineering Yuhang Cai and Junqiao Wu; University of California, Berkeley, United States

Uncooled infrared bolometers have become the technology of choice for applications such as thermography, firefighting, and night vision. These microbolometers detect thermal radiation from an object based on the Stefan–Boltzmann law with a thermal sensitivity, named as noise-equivalent differential temperature (NEDT). Existing methods to advance NEDT of the uncooled detectors are focused on the engineering side, with the efforts approaching the end of the roadmap. In this work, we take a distinct appoach on the material side and improve the key parameter, known as temperature coefficient of resistance, by 3 times over a wide temperature range. The abrupt change of resistance comes from the metal-insulator transition of vanadium dioxide while the broad working temperature range is realized by creating a gradient-doped tungsten-doped vanadium dioxide where the tungsten fraction is judiciously graded across a thickness comparable to real products.

Effects of Temperature on Ruthenium Oxide Thin Films Using Pulsed Laser Deposition Tyffani Royal; North Carolina Agricultural and Technical State University, United States

Within this report, experiments were conducted to determine what effects temperature has on thin film composition, crystalline orientation, and roughness. Ruthenium Oxide (RuO2) thin films were grown using pulsed laser deposition on substrates at different temperatures (100C, 200C, 300C). The properties of the thin films were observed using X-Ray diffraction, scanning electron microscopy, and atomic force microscopy measurements. It has been observed that the increase in temperature causes an increase in density, and roughness. The RuO2 thin films made at 500C are able to form on a substrate with strong crystalline orientation. This information can become vital in how thin films are made for their intended purpose.

Pulsed Laser Deposition and Characterization of Titanium Nitride and Oxynitride Thin Films for Alternative Energy Applications Brooke Smith[1], Jacob Som[1,2] and Dhananjay Kumar[1]; [1]North Carolina A&T, United States; [2]Cornell University, United States

TiN_xO_y (TiNO) thin films have been grown using a pulsed laser deposition process with a wide range of x and y realized by varying the oxygen pressure. X-ray diffraction, scanning electron microscopy, and atomic force microscopy measurements have been carried out to evaluate the phase purity and microstructures of TiNO films. The electrocatalytic activities of these films were performed in KOH solution for oxygen evolution reaction. It has been observed that the electrocatalytic activities of these films depend on the growth conditions. Films grown under low oxygen partial pressure (5 mTorr) showed an overpotential of 340 mV to achieve a current density of 10 mA/cm^2, whereas the TiNO film grown under high oxygen partial pressure of 25 mTorr displayed the lowest overpotential of 290 mV at the same current density. This range of overpotential observed in this study is among the lowest values reported for any oxynitride systems.

5:00 PM EL06.03.07
Quantifying Oxygen Diffusion Rates at The Nanoscale in Epitaxial $SrTiO_3$ Films Keon Sahebkar, Nathan Ardnt, Sihang Hui, Brooke Lastinger, Morgan Congdon and Ryan Need; University of Florida, United States

Oxygen ion migration is an increasingly viable route to control electronic and magnetic phase transitions in nanoscale oxide thin films and harness those phase transitions for next-generation, energy-efficient electronics [1]. Nanoscale oxygen migration is central to the operation of promising emerging information technologies like resistive random-access memory and magnetoionic memory [2,3]. Heterostructure design elements like strain, interface symmetry, and layer stacking can all control the ion diffusion rates and energy barriers that underpin the operation of these devices. However, due to the difficulty of measuring small concentrations of oxygen ions (~1 at%) moving nanoscale distances, we do not have a framework for how these heterostructure design elements can be tuned to improve and optimize device functionality. This project aims to address this by developing a methodology to quantitatively determine oxygen diffusion rates and migration energy barriers in nanoscale thin films using reflectometry techniques.

Nanoscale “oxide diffusion couples” are fabricated from epitaxially grown $SrTiO_3$ (STO) and a sputtered metal cap, then annealed in vacuum to drive oxygen from the epitaxial oxide layer into the metal. X-ray reflectometry (XRR) scans are taken before and after vacuum annealing and used to establish an oxygen concentration depth profile from changes to the interface roughness between the STO and metal layers. These concentration profiles are then fit to

known diffusion couple solutions to Fick's Second Law and used to calculate an oxygen diffusion coefficient for each annealing study [4]. This poster will further explain our proposed methodology and preliminary results.

Topochemical Synthesis and Optical Properties of Epitaxially Strained $SrCo(O,F)_{3-x}$ Thin Films Tessa D. Tucker, Zongmin Yang, David Bugallo and Steven J. May; Drexel University, United States

Transition metal oxides (TMOs) are attractive in materials science for their structural versatility and property tunability. This tunability can be further expanded by incorporating a second anion, such as F or N, to alter the metal-anion bond ionicity or the metal charge density. In this work, we report on vapor-based fluorination of epitaxial $SrCoO_{2.5}$ films. The films are grown by oxygen-assisted molecular beam epitaxy (MBE) under conditions that result in the brownmillerite structure. Topochemical fluorination was conducted on the as-grown films at 200°C using a quartz tube furnace under Ar gas flow with poly(vinylidene fluoride) (PVDF) as the fluorine source. Fluorination reactions were performed on $SrCoO_{2.5}$ films synthesized on STO, LAO, LSAT and GSO substrates to understand the impact of substrate-induced strain on fluorine incorporation. Fluorine incorporation was confirmed via depth-dependent elemental analysis performed with X-ray photoelectron spectroscopy (XPS). Fluorine incorporation results in an expansion of the *c*-axis parameter as determined by X-ray diffraction. Optical absorption spectra, obtained through spectroscopic ellipsometry, reveals a blue-shift of the low-energy absorption edge by 0.1 - 0.3 eV depending on the substrate. This result is attributed to a widening of the band gap due to the increased ionicity of the Co-anion bonds.

High-Throughput Combinatorial Approach to The Synthesis of a Lead-Free Relaxor Ferroelectrics System Di Zhang[1], Katherine Harmon[2], Michael Zachman[3], Ping Lu[4], Doyun Kim[5], Qing Tu[5] and Aiping Chen[1]; [1]Los Alamos National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]Oak Ridge National Laboratory, United States; [4]Sandia National Laboratories, United States; [5]Texas A&M University, United States

Developing novel lead-free nontoxic ferroelectric materials is crucial for the next-generation microelectronic technologies in regard to clean energy and environmental sustainability. However, materials discovery and properties optimization have usually been a frustratingly slow process due to the limited throughput in traditional synthesis methods. In this work, using a high-throughput combinatorial synthesis approach, we fabricated lead-free ferroelectric superlattices and solid solutions of $(Ba_{0.7}Ca_{0.3})TiO_3$ (BCT) and $Ba(Zr_{0.2}Ti_{0.8})O_3$ (BZT) phases with compositional gradients. The high-resolution X-ray diffraction and scanning transmission electron microscopy (STEM) revealed the good film quality and well-controlled compositional gradient throughout the samples. Ferroelectric and dielectric properties identified the "optimal property point" achieved at the morphotropic phase boundary (MPB) with the composition of BZT-52BCT. The displacement vector maps revealed the tunable ferroelectric domain sizes by varying the single layer thickness of the $\{BCT/BZT\}_n$ superlattices. This high-throughput synthesis approach can be applied to many other materials systems to expedite novel materials discovery and property investigations.

Tailoring Dielectric Permittivity in $Gd_xCe_{1-x}O_{2-\delta}$ Films by Ionic Defects Alessandro Palliotto, Nini Pryds and Daesung Park; Danmarks Tekniske Universitet, Denmark

Fluorite-based crystalline materials have the general chemical formula AX_2 (A = Ca, Hf, Zn, Zr, Ce, while X = F, O) and find wide application in fuel cells, electroceramics, oxygen sensors and exhaust reduction systems. Despite their rather simple and prototypical crystallographic structure, "fluorites" remain the subject of much academic research and unexpected scientific discoveries [1], such as ferroelectricity in HfO_2-based thin films or large electromechanical coupling in polycrystalline Gd-doped CeO_{2-x} (CGO) ceramics/films [2]. Moreover, a recent discovery has demonstrated the potential to induce significant piezoelectric effects in nominally centrosymmetric CGO by breaking symmetry through the control of ionic defects, specifically oxygen vacancies (V_O) [2]. It was found that the motion and redistribution of defects induced by an electric field results in notable changes in the dielectric permittivity of the system, which are closely associated with the magnitude of the electromechanical effects [3]. Hence, controlling the dynamic V_O in the CGO and similar oxides is key for achieving significant permittivity and electromechanical effects. In this work, we effectively tuned the V_O contents in epitaxial CGO(001) films grown on Nb-doped $SrTiO_3$(001) single crystal using pulsed laser deposition. Our findings show that the control of V_O contents in the epitaxial films is highly limited, regardless of the oxygen environment (oxygen partial pressure, P_O), during high-temperature growth (e.g., T = 700 °C). In contrast, an effective control of V_O contents in the epitaxial films was achieved by utilising a two-step growth technique. Subsequently, we noted a strong variation in the V_O content in the engineered CGO films and the emergence of significant apparent dielectric permittivity, thus enabling the generation of substantial electromechanical coupling and piezoelectric effect.

Enhancement of Alkaline Hydrogen Evolution in $BaRuO_3$ Thin Film via Surface Self-Reconstruction Do Hyun Kim, Jegon Lee and Woo Seok Choi; Sungkyunkwan University, Korea (the Republic of)

Hydrogen production through water splitting presents a promising avenue for carbon-free energy generation. Transition metal oxides (TMOs) are pivotal electrocatalysts known for their remarkable activity and tunability. Among TMOs, perovskite Ruthenates stand out due to their significant electrocatalytic potential in driving the hydrogen evolution reaction (HER). However, the precise influence of the surface chemistry of Ruthenates in alkaline solutions on their catalytic performance in HER remains a subject of ongoing exploration.
In this investigation, we concentrate on the dynamic chemical and structural transformations occurring on the surface of cubic perovskite BaRuO3 (3C BRO) during the HER cycle and their direct impact on HER activity. To facilitate our analysis, we utilized epitaxial thin films, meticulously crafting atomically precise crystalline surfaces. This approach allowed us to elucidate the fundamental role of the surface in catalytic activity.

Remarkably, the HER activity of the 3C BRO epitaxial thin film experiences a substantial boost through cycling in an alkaline environment. Specifically, after the initial cycle, the HER overpotential decreased from 210 to 60 mV, reflecting an impressive ~70% improvement. With continued cycling, the initially high HER activity gradually wanes, ultimately reaching a saturation overpotential similar to that of RuO2 catalysts after approximately 50 cycles. Examination via X-ray photoelectron spectroscopy reveals that the highly active state of 3C BRO retains a similar bulk stoichiometry to the pristine 3C BRO within the thin film region. However, a noticeable reduction in the Ba/Ru ratio (~0.75) becomes apparent on the surface. Complementary observations using scanning transmission electron microscopy indicate the expansion of the Ba-deficient region across the entire film as the heightened activity diminishes. Our interpretation suggests that the initial significant activation arises from the presence of a highly active local Ba-deficient surface stabilized on the pure 3C BRO film. Subsequently, as the overall 3C BRO film loses Ba, the catalytic activity gradually diminishes. These findings offer fundamental insights into the underlying mechanisms governing the formation of a highly active catalytic surface and its stabilization strategy."

Enhancing High-Speed Artificial Neuron Functionality via Vanadium Oxide Resistive Switching on Perovskite Substrates Nicholas Cucciniello[1,2], Sundar Kunwar[2], Alessandro Mazza[2], Pinku Roy[2], Di Zhang[2], Aiping Chen[2] and Quanxi Jia[1]; [1]University at Buffalo, United States; [2]Los Alamos National Laboratory, United States

This study confronts the urgent challenge of rising energy consumption in the realm of information technology and the constraints imposed on conventional computing by issues like the Memory wall, Heat wall, and Moore's law. In response to this, there is a growing demand for a novel, energy-efficient computing paradigm inspired by the human brain, known as neuromorphic computing. These neuromorphic systems are composed of artificial synapses and neurons, with the intention of replicating the brain's nonlinear operations and its capacity for in-memory computing. Although progress has been made in creating memristive devices to mimic adaptable synaptic weights, the development of artificial neuron devices is still in its nascent stages. The use of vanadium oxide-based resistive switching is particularly promising due to its unique attributes, such as reversible phase transitions and impressive electrical conductivity, positioning it as a candidate for the development of energy-efficient, brain-inspired computing systems. This research centers on the exploration of VOx thin films grown on $La_{0.7}Sr_{0.3}MnO_3$-buffered (111) perovskite substrates, with the aim of achieving low-energy consumption, a crucial advancement in the field of neuromorphic computing.

5:00 PM EL06.03.13
Characterizing Ferroelectric *a*/b Domain Fluctuations in BaTiO3 through Coherent X-Ray Scattering Pooja Rao, Roopali Kukreja and Nanna Zhou Hagström; University of California, Davis, United States

Ferroelectrics are a class of functional materials which exhibit spontaneous and switchable polarization. To minimize electrostatic and elastic strain energy, ferroelectrics tend to form nanodomains of different polarization directions. Due to the stability of polarization with temperature, ferroelectrics can be considered for applications such as non-volatile memory and neuromorphic computing. However, in order to directly tune ferroelectrics for these purposes, it is important to understand fluctuation characteristics of their domains. Using x-ray photon correlation spectroscopy, we quantify timescales and length scales of fluctuations in heterogeneities of BaTiO3. For a thin film of BaTiO3 at nearly zero strain, the Landau-Ginzburg-Devonshire theory predicts a domain transition near 55°C from in-plane (a/b) domains to alternating in-plane and out-of-plane (a/c) domains. We focus on the diffuse scattering peaks from the a/b domain walls near the BTO (103) peak for a temperature range between 35°C to 70°C. We observed that the domains tend to remain stable at temperatures above and below the transition. However, as the transition temperature is approached, the fluctuation dynamics speed up in order to reorganize as new domains. This shows us interesting behavior of ferroelectric domains which have not been investigated yet in BaTiO3.

5:00 PM EL06.03.14
Escalated Phase Separation Driven Enhanced Magnetoresistance in Manganite/Iridate Epitaxial Heterostructures Pinku Roy[1], Aiping Chen[1] and Quanxi Jia[2]; [1]Los Alamos National Laboratory, United States; [2]University at Buffalo, The State University of New York, United States

Phase separation in manganites leads to unique magnetic and electronic properties. 50% Ca-doped $LaMnO_3$ (LCMO), at the boundary of ferromagnetic (FM) and antiferromagnetic (AFM) states in $La_{1-x}Ca_xMnO_3$ ($0 \leq x \leq 1$), is an ideal system to study phase separation behavior. Here, we have investigated the effect of a 5*d*-metal perovskite $SrIrO_3$ (SIO) on the phase separation, magnetic, and magnetoresistance (MR) properties of LCMO. The MR, and colossal magnetoresistance (CMR), observed in LCMO/SIO bilayers were two orders and an order of magnitude (in %) larger, respectively than that in the single-layer film. We found the coexistence of FM and AFM/CO phases was responsible for the CMR and MR enhancement in the LCMO/SIO bilayer, pointing towards the importance of the phase separation and competition of both the individual materials in enhancing their magnetic and electronic properties.

5:00 PM EL06.03.15
Functional Tin-Based Nanostructures Engineering Poting Liu[1,2], Anna Makarova[3], Katharina Freiberg[2], Stephanie Lippmann[2], Dave Grinter[4], Sergey Turishchev[5] and Vladimir Sivakov[1]; [1]Leibniz Institute of Photonic Technology, Germany; [2]Friedrich-Schiller-University Jena, Germany; [3]Free University Berlin, Germany; [4]Diamond Light Source, United Kingdom; [5]Voronezh State University, Russian Federation

Tin (Sn) –based nanostructures have attracted very much attention because of their superior physical and chemical properties such as high electron mobility and wide bandgap [1]. Herein, a metal organic chemical vapor deposition (MOCVD) technique is reported for the growth of unique Sn/SnO_{2-x} nanostructures with phases control by varying deposition conditions and using nanostructured/planar initial Si surfaces. Herein, we are going to discuss possible nano-engineering using nanostructured and planar silicon surfaces to create functional nanostructures with new physical and chemical properties and their characterization using large-scale synchrotron radiation based techniques. Theoretical calculations, extensive surface and bulk characterization techniques such as electron microscopy, XRD, and synchrotron radiation based XPS and NEXAFS techniques were applied to study the formation mechanisms of the unique tin-based nanostructures. An intensive oxygen exchange reaction between the planar silicon surface and a thin layer of tin (IV) oxide during the MOCVD process is observed at a tiny temperature window of 725-735 °C resulting a unique $Sn:SiO_2$ composite formation with the nature-similar shape of "volcanos" and "craters". The growth mechanism of the "volcano-like" nanostructures is related to the efficient oxygen retraction between the tin(IV) oxide and the silicon surface, leading to the formation of thermodynamically unstable Sn(II) oxide, which immediately disproportionates to metallic tin and SnO_2 phases localized in the SiO_2 matrix. The observed phenomenon of thin film growth at the nanoscale has similar principles to the formation of volcanos in nature, which reflects the unique relationship between the laws of nature in the nanometer and macroscale world. From another side, when the silicon nanowires (SiNWs) are used as deposition matrix, it is found a phase of Sn(0), Sn(II) and Sn(IV) distribution effect along SiNWs with controllability by varying the SiNWs matrix [2,3]. According to the detailed destructive/non-destructive surface characterization results, the significant thermal conductivity difference between bulk Si and SiNWs is responsible for a temperature gradient along SiNWs during MOCVD process and result in the reduction of Sn from precursor byproducts. These discoveries give us a new way to realize the phase-selective deposition of Sn-based functional materials and expected to adjust its functional properties in different scenarios such as photocatalyst, Li(Na) –based batteries and energy conversion and storage.

Richness of Spiral Magnetic States in Strontium Ferrite Thin Films Jennifer Fowlie; Stanford University, United States

Perovskite strontium ferrite, $SrFeO_3$, hosts a variety of spiral magnetic phases at low temperature including multi-q states of different proper screw and/or cycloid ordering [1]. Among them is a phase believed to support topologically-protected magnetic structures and may explain an observed finite-field anomaly in Hall effect [2].
$SrFeO_3$ is a fascinating material because, unusually, these effects exist despite the centrosymmetry of the crystal structure. Instead of a Dzyaloshinskii-Moriya interaction, the helimagnetism has been suggested to arise due to an interplay of electronic interactions [3].
We have optimized the growth and stability of epitaxial thin films of $SrFeO_3$ grown by pulsed laser deposition. Then, using resonant soft x-ray scattering, we study how these complex magnetic orderings depend on the biaxial strain state, which potentially influences the electronic structure.

Properties of Barium Bismuthate Layers on Si: Molecular Beam Epitaxy Study Islam Ahmed[1,2], Maxim Korytov[1], Olivier Richard[1], Patrick Carolan[1], Stefanie Sergeant[1], Thomas Nuyyten[1], Thierry Conard[1], Stefan De Gendt[1,2] and Clement Merckling[1,2]; [1]IMEC, Belgium; [2]KU Leuven, Belgium

With slowing down of Moore's law, related to scaling of integrated circuits, alternative technologies such as quantum computing require research efforts for pushing the limits of new generation of electronics. A promising approach to realize fault-tolerant quantum computations is to build qubits that are intrinsically protected against quantum errors thanks to the topological nature of the used materials. Such computations are realized when Majorana fermions are detected and manipulated. Topological superconductors are the perfect solid state material system for hosting Majorana bound states. Equivalently, an interface between a superconducting and a topological insulating layer is also expected to host such states, based on the proximity effect. Barium bismuthate (BBO) is a relevant material system because when hole-doped with potassium, it is a superconductor with a critical temperature of 29.8 K. In addition, with the spin-orbit coupling of bismuth considered, fluorine-doped BBO is predicted to be a topological insulator according to density functional theory (DFT) studies.
The work presented is related to material development and characterization of the parent compound utilizing oxide molecular beam epitaxy (MBE) process. In our work, we integrate $BaBiO_x$ on Si(001) substrate, using an epitaxially grown strontium titanate $SrTiO_3$ single-crystalline buffer layer. It is demonstrated that the epitaxy of $BaBiO_x$ is only achieved in excess of oxygen plasma because of the volatile nature of bismuth molecules reaching the substrate. Due to the high vacuum environment in the oxide chamber of the MBE machine that can reach below 10^{-8} torr as base pressure, ordered oxygen vacancies are created within the perovskite layers, forming a mixture of brownmillerite and perovskite phases. The mixed phase is demonstrated based on transmission electron microscopy (TEM) images. A method, in function of oxide MBE process parameters, to retrieve fully perovskite phase (with no ordered oxygen vacancies) is presented.
Due to the breathing distortion within its lattice, barium bismuthate is a Peierls insulator with an optical band gap of 1.96 eV. Optical conductivity is measured using spectroscopic ellipsometry, showing a peak centred around 2 eV. The Raman response of BBO observed at 570 cm^{-1} is attributed to the breathing distortion of BiO_6 octahedra, which is in resonance with a laser wavelength of 633 nm. In our studies, thickness dependence of the presence of the breathing distortion is studied. In the upcoming study, a light will be shed on the band structure of fluorine-doped by measuring it using angle-resolved photoemission spectroscopy (ARPES) to detect the existence of topological states.

9:30 AM EL06.04.03
Effect of Stoichiometry on The Atomic Microsctructure of Thin Film $BaTiO_3$ Ashley Cavanagh, Larissa Little, Charles M. Brooks, Julia Mundy and Robert Westervelt; Harvard University, United States

Synthesis and characterization of thin film barium titanate is of great interest due to its promise for use in electro-optic modulators [1]. These devices require a thin film with a high electro-optic coefficient that can operate at low voltages and integrate into photonic circuits, so barium titanate's strong nonlinearity makes it an attractive candidate material. Barium titanate's ferroelectricity means that it is also of interest for applications in nonvolatile ferroelectric memories. For use in photonic devices, we must understand how variations in film stoichiometry affect the electro-optic properties, local atomic structure, and ferroelectric structure of thin film barium titanate. We use molecular beam epitaxy (MBE) to grow high quality thin films of barium titanate with a high degree of stoichiometry control. In this talk, we use high-resolution scanning transmission electron microscopy (STEM) to compare the atomic microstructure of barium titanate films of varying stoichiometries grown on strontium titanate. High-resolution electron microscopy imaging allows us to evaluate atomic-level variations in crystal structure, local defects, and electrical polarization in thin films of barium titanate. By understanding the effect of stoichiometry on these variations, we can understand the degree of stoichiometry control needed to grow barium titanate thin films that are of sufficient quality for electro-optic device applications.

Tunable Electromagnetic Properties of Epitaxial Mo(d^2)-Doped SrRu(d^4)O_3 Thin Films Rahma D. Prasetiyawati[1], Taehee Lee[1], Sungkyun Park[2],

Tuson Park[1] and Woo Seok Choi[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of)

4*d* transition metal oxides (TMOs) offer various intriguing physical behaviors resulting from the strong interplay among charge, spin, lattice, and orbital degrees of freedom. Their electronic structure is influenced not only by the on-site Coulomb interaction (*U*) and spin-orbit coupling (SOC) but also by Hund's coupling (J_H). There have been several studies conducted to construct the correlated electronic phase diagram by varying the degree of those interaction parameters. One of the renowned 4*d* TMOs is the ferromagnetic $SrRuO_3$ (SRO) with $4d^4$ configuration having abundant electronic states including non-Fermi liquid and Weyl semimetal states. The intrinsic SOC coupled with its ferromagnetism is important for the emergence of the Dzyaloshinskii – Moriya interaction beneficial for the observation of exotic quantum phenomena, such as the skyrmion formation and resultant topological Hall effect [1, 2]. On the other hand, $SrMoO_3$ (SMO) with $4d^2$ configuration is the other reported metallic 4*d* TMO influenced by Hund's coupling. However, its electronic transport mechanism is less understood compared to SRO despite its extremely small room-*T* resistivity with Fermi-liquid behavior [3]. Different from SRO, SMO is reported to have *T*-independent magnetic susceptibility exhibiting Pauli paramagnetic behavior.
Previously, several attempts have been made to dope SRO thin films with 3*d* and 5*d* TM ions through Ru-site chemical substitution which results in the suppression of the ferromagnetism and emergence of metal-insulator transition in the electronic transport. In this study, we investigated the effect of Mo($4d^2$)-doping on SRO thin films by manipulating the degree of electronic and magnetic correlations through chemical substitution. We grew the epitaxially stabilized $SrRu_{1-x}Mo_xO_3$ (SRMO, $x = 0 – 0.5$) thin films using pulsed laser epitaxy by alternately ablating two targets, SRO and SMO. The Mo concentration was selectively controlled by adjusting the laser pulse numbers according to the deposition rate of each target on (001) $SrTiO_3$ substrates. The high quality of the resulting SRMO thin films has been confirmed by using x-ray diffraction accompanied by a systematic lattice compression per the increase in the Mo concentration. The modification of the complex $4d^4$ electronic structure by the $4d^2$-doping is apparent in the hybridization between Ru 4*d* and O 2*p* orbitals, inducing systematic changes in the electric and magnetic properties of SRMO epitaxial thin film. Our results present further insights into understanding the systematic changes in the electromagnetic properties of epitaxial SRMO thin films useful for spintronic device applications.

Giant Topological Hall Effect and Tunable Chiral Symmetry in a Localized Asymmetric Oxide Heterostructure Xiaofang Zhai; ShanghaiTech University, China

Topological Hall effect (THE) provides the electrical detection of topologically protected chiral spin structures such as skyrmions and has attracted intensive attentions due to the potential application in future information technology. Here we found the asymmetric ruthenate/titanate heterostructure exhibiting a giant THE resistivity in striking contrast to zero anomalous Hall effect (AHE) because of localization and the quantum interference induced real space Berry phase. We further present a new technique – magnetic-field angle dependent resistance (MAR) measurement – capable to reveal emergent chiral symmetries from different chiral spin textures. Our findings reveal the localization regime to be a new playground for exploring exotic chiral spin phenomena, and demonstrate the MAR as a new technique providing evidence of real space spin chirality.

Correlated Topological Oxide Heterostructures for Energy-Efficient Quantum Microelectronics Ho Nyung Lee; Oak Ridge National Laboratory, United States

Complex oxides are known to possess the full spectrum of fascinating properties, including magnetism, colossal magnetoresistance, superconductivity, ferroelectricity, ionic conductivity, and more. The breadth of remarkable properties is the consequence of strong coupling among charge, spin, orbital, and lattice degrees of freedom. Spurred by recent advances in the synthesis of such artificial materials at the atomic scale, the physics of oxide heterostructures containing atomically smooth layers of such correlated electron materials with abrupt interfaces is a rapidly growing area. We have established a growth technique to control complex oxides at the level of unit cell thickness by pulsed laser deposition. The atomic-scale growth control enables to assemble materials from atoms to functional systems in a programmable manner, yielding many intriguing physical properties that cannot be found in bulk counterparts. In this talk, examples of complex oxide thin films and heterostructures grown by advanced pulsed laser deposition and their correlated and topological properties will be presented, highlighting the importance of precision synthesis for heterostructuring, interfacing, and straining. The main topics include (1) oxide Dirac semimetals with extreme high mobility that exhibit fractional occupation of the Landau level and (2) corrected metal Pd-based delafossites as an extreme metal that may revolutionize interconnects in the next generation of microelectronics by their excellent electronic conductivity combined with Mottness.

Model-Based Artificial Quantum Materials Realized in Oxide Heterostructures and Superlattices Jian Liu; University of Tennessee, United States

The complex interplay between the quantum degrees of freedom in oxides is known to cause intriguing emergent states. While the underlying physics is usually captured by model Hamiltonian, most of the known models, such as the Hubbard Hamiltonian, are difficult to resolve theoretical. This challenge calls for toy-model-based design and synthesis of novel structures for complex oxide materials synthesis. In this talk, I will discuss our recent work on experimental realization of artificial iridate superlattices that simulate the correlation-topology interplay with engineered complex hopping. While the electronic correlation stabilizes an antiferromagnetic Mott insulating ground state, their intermediate coupling strength allows significant longitudinal spin fluctuations, which allow the SU(2) symmetry-preserving and breaking components of the complex hopping to manifest as anomalous magnetoresistance and anomalous Hall effect, respectively. The latter also leads to an exceptionally large Ising anisotropy which is captured as a giant magnon gap and is an imprint of electronic topology. I will also discuss another example in pyrochlore heterostructures which simulate the spin-ice fluctuation-mediated charge transport.

Phonon Decoupling in Double Perovskite Oxides Yeongrok Jin and Jaekwang Lee; Pusan National University, Korea (the Republic of)

In general, a slight displacement of an atom from its equilibrium position affects the forces on the rest of the atoms simultaneously. That's why the phonon has been considered a collective excitation in the periodic arrangement of atoms in solids. Here, using first-principles density functional theory calculations, we first demonstrate that, contrary to typical collective phonons, oxygen-octahedral and oxygen-tetrahedral phonons can be fully decoupled across the entire phonon spectrum, especially in double perovskite oxides. This decoupled oxygen tetrahedral phonon would be strongly localized and can greatly induce band flattening along a specific crystal orientation, enabling unusual site-selective control of the unit cell width domain wall.

Understanding Electron and Crystal Structure Roles in Electronic Transitions of Complex Oxides: Insights Across Scales and Machine-Learning Aided Discovery of Novel Materials Alexandru Georgescu; Indiana University, Bloomington, United States

In this talk, I will discuss three main areas in the study of correlated electron materials:
1) Differentiating the influence of crystal structure and valence electrons in symmetry-breaking phase transitions, resolving a longstanding question in the field.
2) Using layered material structures as a lens to study electronic transitions at the nanoscale, backed by practical thin-film examples.
3) Harnessing machine learning throughout the quantum materials discovery process, from identification to synthesis.
I'll wrap up by highlighting how these advances impact the discovery and application of new quantum materials and may lead to novel applications.

Quantifying 3D Chemical and Structural Order/Disorder in Thin Film Complex Oxides with Multislice Electron Ptychography James M. LeBeau; Massachusetts Institute of Technology, United States

Determining chemical and structural order/disorder within functional oxides is often key to understanding the properties of these materials, for example, relaxor ferroelectrics. Conventional techniques such as X-ray, neutron, or electron diffraction are often used to study these features via diffuse scattering, but only offer insights into the global and average local structure of a sizable material volume. While recent advances in phase contrast imaging techniques in scanning transmission electron microscopy (STEM), such as iDPC, have helped to reveal connections between local polar and chemical order, these approaches are constrained by the ability to capture only a 2D projection of the structure within a thin TEM sample. Consequently, the origins of the exceptional piezoelectric properties of these materials continue to be a subject of debate.

In this presentation, I will explore how multislice electron ptychography can be leveraged to provide nanoscale structural, chemical, and polar variations in functional oxides in 3D. First, I will present the analysis of the reconstructed phase from the thin film paraelectric Pb2MgWO6. I will highlight how the approach provides access to the three-dimensional structure and chemistry of inclined anti-phase boundaries in this material. The comprehensive characterization offers deeper insights into their impact on local polarization, namely stabilizing antiferroelectric distortions at the boundaries. Second, I will discuss our study of the prototypical relaxor ferroelectric Pb(Mg1/3Nb2/3)O3-PbTiO3 (PMN-PT) using ptychography, where structural distortions of the cation and anion sublattices across slices are used to measure polar order in 3D. The results will be compared against conventional HAADF and iDPC imaging from the same region to provide an understanding of the sampling volume of those techniques. Finally, I will discuss how multislice ptychography offers to play a pivotal role in unraveling the intricate relationships between defects, structure, and the influence of intrinsic and extrinsic factors on the behavior exhibited by functional oxides.

Unravelling The Effect of Nitrogen Doping on The Structure of $LaFeO_3$ Epitaxial Thin Films Krishna Prasad Koirala[1], Shan Lin[2], Le Wang[1], Minju Choi[1], Erjia Guo[2], Peter V. Sushko[1], Scott A. Chambers[1], Chongmin N. Wang[1] and Yingge Du[1]; [1]Pacific Northwest National Laboratory, United States; [2]Institute of Physics, Chinese Academy of Sciences, China

Heteroatom doping has proven to be an effective approach for fine-tuning the electronic and magnetic properties, as well as enhancing the electrocatalytic performance in ABO_3-type perovskite oxides. Beyond the conventional cation doping at A or B-sites, partial replacement of oxygen anions in perovskite oxides by other elements, such as nitrogen (N), sulfur (S), and fluorine (F), has also been explored to modify their structure and properties. In this study, we aim to advance our understanding of how N doping in $LaFeO_3$ films, influences their composition and structure, subsequently affecting their electronic and electrochemical properties. High-quality N-doped $LaFeO_3$ (LFON) epitaxial thin films with different doping levels were grown on (001)-oriented Nb:$SrTiO_3$ substrates using nitrogen-plasma-assisted pulsed laser deposition. Our X-ray diffraction and scanning transmission electron microscopy (STEM) measurements revealed that while the films are coherently strained in plane, with no observed dislocations at the interface, there is a notable, up to 4% lattice expansion in the out-of-plane direction. By employing an integrated differential phase contrast (iDPC) imaging technique in STEM, we examined orthorhombic relaxation in both undoped and doped samples. We found no significant differences in octahedral tilting between them, while the doped LFON sample exhibited a higher prevalence of two orthogonal in-plane rotated structural domains. Moreover, atomically resolved electron energy loss spectroscopy (EELS) indicated that the Fe valence remains as Fe^{3+} after N doping, suggesting that the generation of oxygen vacancies serves as a compensatory mechanism for the charge difference between nitride and oxide ions. However, DFT calculations indicated that oxygen vacancies and substitutional N had little impact on the out-of-plane lattice parameter. Further experimental and theoretical investigations are necessary to uncover the underlying cause of the 4% lattice expansion in the out-of-plane direction. In summary, these findings provide a crucial guide for understanding how N

doping affects the structure and properties of complex oxides, essential for designing novel electrocatalysts for water splitting.

4:15 PM EL06.06.03
Nearly Epitaxial ZrO_2-Co Vertically Aligned Nanocomposites Thin Film with Tunable Magnetic and Optical Anisotropy Yizhi Zhang[1], Jiawei Song[1], Ping Lu[2], Julia Deitz[2], Di Zhang[3], Hongyi Dou[1], Jianan Shen[1], Zedong Hu[1], Xinghang Zhang[1] and Haiyan Wang[1]; [1]Purdue University, United States; [2]Sandia National Laboratories, United States; [3]Los Alamos National Laboratory, United States

Metamaterials have gained great research interest recently owing to their potential for property tunability, multifunctionality, and property coupling. As a new group of hybrid metamaterials, vertically aligned nanocomposite (VAN)-based thin films exhibit significant anisotropic physical properties and a broad range of property tailorability, such as optical anisotropy, magnetic anisotropy, and hyperbolic dispersion. In this work, self-assembled ZrO_2-Co hybrid thin films, with high epitaxial quality and ultra-fine vertically aligned metallic Co nanopillars (with an average diameter of ~ 2 nm) embedded in a ZrO_2 matrix, were successfully fabricated using a pulsed laser deposition (PLD) method. The Co pillar planar density can be effectively tuned, without changing the pillar size, by varying the Co concentration in the target, which results in tunable optical properties and magnetic properties. Specifically, a high saturation magnetization of 100 emu*cm^{-3}, strong out-of-plane magnetic anisotropy and tailorable magnetization properties were achieved. Coupled with hyperbolic optical dispersion from 950 nm to 1500 nm in wavelength, plasmonic Co metal nanopillars, and the unique dielectric ZrO_2 matrix, this new nanoscale hybrid metamaterial shows great potential for future integrated optical and magnetic device designs.

4:30 PM *EL06.06.04
Epitaxial Memristors: Preparing for The New Generation Devices Beatriz Noheda; University of Groningen, Netherlands

The search for devices that can emulate the behavior or neurons and synapses, in order to be used in brain-inspired, in-memory or on-edge computing, is extending among different research fields with an increasing number of materials scientists involved in the quest. However, the number of materials that have been considered as the key elements for these devices is restricted to the few that are compatible with CMOS integration. The need to process at low temperatures often produces polycrystalline or amorphous materials, limiting the control of the materials properties. Luckily, the emergent efforts towards epitaxial growth of complex oxides by ALD at low temperatures[1] allows us to dream of a future of epitaxial oxide microelectronics for which we want to be prepared. In this talk, we will show an example of epitaxial material that show interesting neuromorphic features, namely, self-oscillating behavior and generation of voltage spikes in epitaxial $TbMnO_3$, a material that does not undergo a meta-insulator transition, and can be used as a compact neuristor[2].

Exploring Opportunities and Challenges in Free-Standing Epitaxial Oxide Nanomembranes Bharat Jalan; University of Minnesota, United States

With a rapidly growing family of vdW materials, the role of dielectric and metals have become more important than ever. In this talk, I will present challenges associated with the synthesis of atomically-precise three-dimensional (3D) perovskite nanomembranes followed by our group's effort to address them. Using hybrid molecular beam epitaxy that employs a metal-organic precursor, titanium isopropoxide (TTIP), to supply both Ti and oxygen (without the need for additional oxygen), epitaxial $SrTiO_3$ (STO) films were grown directly on a graphene layer transferred on to bulk STO substrate. Films were then successfully exfoliated and transferred onto other substrates. Using Raman spectroscopy and high-resolution X-ray diffraction, we show that the transferred STO membrane is single-crystalline and can be integrated with other vdW materials. I will also present sacrificial layer route to create oxide membranes resulting in room temperature dielectric constant of ~ 300. Finally, I will present several opportunities for materials physics and devices engineering using 3D nanomembranes.

9:15 AM EL06.07.02
Periodic Wrinkles in Freestanding Complex Oxide Membranes Minyong Han, Tiffany C. Wang and Harold Y. Hwang; Stanford University, United States

A stiff film bonded to an elastic substrate shows a universal tendency to form periodic wrinkles upon application of compressive force [1]. This design principle has been employed to produce wafer-scale wrinkles in polycrystalline metal films on polydimethylsiloxane (PDMS) for applications in *e.g.* optical gratings or strain sensors [2]. When a single crystalline film is processed similarly in a non-planar morphology, a spatially gradated strain state with continuously varying lattice constant can be realized. In the regime of extreme bending, the strain gradient therein is known to generate significant modifications in mechanical and electromagnetic properties of the material [3,4]. The recent development of water-soluble oxide buffer layer enables viable lift-off of complex oxide membranes to be transferred onto an arbitrary elastic substrate [5]. In this study, we adopt this technique to prepare single crystalline oxide membranes on PDMS and fabricate a variety of periodic wrinkles in a fully programmable fashion using compression amplitude and membrane thickness as control parameters. Under large compressive force, the degree of bending extends to the limit where the membrane thickness is a few percent in size compared to the radius of curvature of wrinkles. In addition, we introduce our unique sample packaging methods to characterize electrical properties of wrinkled membranes while maximally preserving the overall sample geometry and the associated strain state.

Maintaining The Structural Integrity of Wet-Transferred Graphene to Achieve Successful Exfoliation of BTO in Heterostructures Grown through Pulsed Laser Deposition (PLD) Asraful Haque, Suman K. Mandal, Shubham K. Parate and Srinivasan Raghavan; Indian Institute of Science, India

The epitaxial growth of functional oxides on graphene-coated substrates presents a promising avenue for producing self-standing epitaxial nanomembranes, thereby facilitating advanced scientific investigations, applications, and sustainable substrate reutilization. However, the conventional use of aggressive oxidizing conditions in the growth of epitaxial oxides can jeopardize the integrity of the graphene layer. This study introduces a systematic approach to safeguard graphene during the epitaxial growth of BaTiO3 (BTO) on SrTiO3 (STO) substrates coated with graphene. Our method involves an initial BTO growth phase using a laser source with a controlled aperture, thereby adjusting the growth rate to minimize damage to the underlying graphene layer. Additionally, a precisely regulated chemical vapor deposition (CVD) process is employed to grow graphene with larger grain sizes, thereby enhancing the crystalline quality of the remotely epitaxially grown BTO film. Gradual strain relaxation is observed in the resulting BTO films upon the incorporation of multiple graphene layers. The use of bilayer graphene facilitates the easy exfoliation and transfer of the BTO film to various substrates, including Si. These findings pave the way for the heterogeneous integration of different functional oxides, holding significant implications for the commercialization of perovskite oxides in flexible electronics.

Ferroelectric Vortex State in Twisted $BaTiO_3$ Membranes Jacobo Santamaria; Universidad Complutense de Madrid, Spain

The wealth of complex polar topologies recently found in nanoscale ferroelectrics result from a delicate balance between the materials' intrinsic tendency to develop a homogeneous polarization and the electric and mechanical boundary conditions imposed upon them. Recently, new methods have been developed, for the realization of freestanding perovskite films, the so called oxide membranes. Membranes can be manipulated and deterministically placed on any substrate thus bypassing the limitations of conventional epitaxy. Moreover, freestanding layers can be piled up to form twisted homo bilayers. In this talk I will show that the stacking of freestanding ferroelectric perovskite layers with controlled twist angles opens an unprecedented opportunity to tailor topological polar landscapes in a way determined by the lateral strain modulation associated to the twisting. Interestingly, we find that a peculiar pattern of polarization vortices and antivortices emerges from the flexoelectric coupling of polarization to strain gradients. This finding opens exciting opportunities to create two-dimensional high density vortex crystals that would allow us to explore novel physical effects and functionalities.

Freestanding Oxides: Paving The Way for Advanced Functional Materials Nini Pryds; Technical University Denmark, Denmark

Combining different materials into heterostructures stands as a foundational pillar in modern materials science. Notable instances include the advent of 2D materials and the development of van der Waals heterostructures. This presentation talks about new ways to make very thin oxide films that are almost 2D stack and twist them. These new methods open up many exciting possibilities for using these oxide materials in novel functionalities. I will in my talk focus on how these oxides freestanding membranes work and interact at their interfaces and surfaces. This research highlights the transformative potential of these materials in reshaping our understanding and approach to modern science and materials technology.

11:15 AM EL06.07.06
Transfer of Epitaxial Strained Multiferroic Thin Films on Millimeter Scale Using Rigid Substrate Epoxy Method James P. Barnard[1], Jianan Shen[1], Benson Tsai[1], Max R. Chhabra[1], Jiho Noh[2,3], Hyunseung Jung[2,3], Aleem Siddiqui[2], Raktim Sarma[2,3], Chloe Doiron[2,3] and Haiyan Wang[1,1]; [1]Purdue University, United States; [2]Sandia National Laboratories, United States; [3]Center for Integrated Nanotechnologies, United States

Multiferroic oxide thin films have diverse applications in the fields of integrated photonics, acoustic sensors, and memory devices. These devices are typically fabricated on substrates such as fused silica, lithium niobate, and silicon. However, these substrates can pose significant challenges for epitaxial growth due to their lattice structures. Pulsed Laser Deposition (PLD), a well-known technique for epitaxial thin film growth, is heavily limited by substrate selection due to its lattice parameter matching requirements, usually leading to growths being performed on $SrTiO_3$ (STO) or $LaAlO_3$ (LAO) substrates. However, a novel approach to enabling other substrates has attracted attention in recent years: film transfer. In this method, the insertion of a water-soluble layer of $Sr_3Al_2O_6$ (SAO) allows for epitaxial film growth while also enabling liftoff through dissolution of this sacrificial layer. The film of interest can be supported during release and transfer by attaching flexible polymer layers such as polypropylene carbonate (PPC) or poly(dimethylsiloxane) (PDMS) before dissolving the sacrificial layer. After adhering the film to the new substrate, the polymer layers can be removed. However, challenges associated with epitaxial strain have not yet been solved. Namely, when a highly strained film is released from the growth substrate, the substrate clamping effect is lost, allowing the film to wrinkle or curl to relax the strain. These deformations of the surface lead to cracks in the final transferred film, limiting the area of continuous film that can be successfully transferred. In this work, we report a new process where the rigid target substrate is adhered to the film, in this case the multiferroic $Bi_3Fe_2Mn_2O_x$ (BFMO) material, using epoxy prior to releasing the film from the growth substrate. This creates a "sandwich" with the BFMO film between the original substrate and new substrate. The sacrificial layer is then dissolved, leaving the film attached to the new substrate. Since the film is not allowed to flex at any time during the process, the strain cannot be relaxed to cause surface deformation, resulting in large crack-free areas of transferred film—on the scale of several millimeters rather than several hundred microns as achieved by the polymer transfer method with strained films. Finally, we will demonstrate that the transfer process preserves crystal quality and therefore the multiferroic properties of the film.

11:30 AM *EL06.07.07
Single-Crystalline Rutile Oxide Nanomembranes: Versatile Platform to Overcome Lattice Mismatch Junwoo Son; Seoul National University, Korea (the Republic of)

The demand for high-performance electronics and photonics calls for the integration of heteroepitaxial oxide films with perfect crystallinity to fully exploit emerging phenomena (e.g., metal-insulator transition, high-electron mobility) from the ionic crystals. However, the requirement of the lattice matching between epilayer and dissimilar substrates drastically limits high-quality epitaxial growth, which in turn degrades the unique properties from functional oxides; this fundamental obstacle of the heteroepitaxy prevents the unrestricted integration of the single-crystalline oxide films onto any desired substrates. To overcome this fundamental limitation, here, I present our research group efforts to demonstrate the heterogeneous integration of single-crystalline rutile oxide nanomembranes with steep phase transition onto arbitrary substrates. First, we discovers new combination of sacrificial layer and mild etchant by exploiting selective oxidation and transformation to layered structure, which could be exfoliated and dispersed in the solution to release millimeter-scale TiO_2 nanomembrane with any deterioration of crystal quality. Interestingly, nearly perfect single-crystallinity of transferred TiO_2 nanomembrane as a template for epitaxy permits the heterogeneous integration of single-crystal VO_2 films on silicon; indeed surprising sharp transition and the highest modulation of resistivity ratio ever reported was remarkably achieved even in the ultrathin VO_2 films on silicon, which is not achievable via direct growth [1]. Moreover, I will also present our epitaxial oxide nanomembrane as an versatile platform for steep phase transition even above critical thickness for lattice mismatch using the concept of pseudo-compliant substrates and emerging devices using single-crystalline oxide heterostructure (e.g., VO_2/PMN-PT heterostructure) [2]. Our finding will create new paradigm for the unrestricted application of emerging phenomena in oxide heterostructures on main-stream microelectronics.

This work was performed in collaboration with Dr. Dong Kyu Lee, Dr. Yunkyu Park, Sung Won Lee, Hyeji Sim, Dr. Younghak Kim, Dr. Gi-Yeop Kim and Prof. Si-Young Choi.

1:30 PM *EL06.08.01
Nanoscale Control of The Ionic Evolution within Complex Oxides Pu Yu; Tsinghua University, China

Over the last decades, ionic evolution emerges as a powerful tuning knob to manipulate the material functionalities of complex oxides. In this talk, we will present a few new strategies to explore ionic evolution at the nanoscale, including the scanning probe tip-induced ionic evolution and electron beam illumination induced chemical reduction. For the tip-induced hydrogen evolution, the Pt-coated scanning probe serves as an efficient hydrogen catalyst, leading to a hydrogen spillover across the nano junction between the probe and sample surface. Furthermore, the application of positively-biased voltage through the junction drives protons into the sample, while negative voltage extracts protons out, giving rise to reversible proton evolution. Due to the associated electron filling, this method can then offer an exciting opportunity to harvest advanced functions such as insulator-metal transition through the tip-induced proton evolution. Furthermore, through the electron-beam illumination with a commercial scanning electron microscope, we also demonstrated locally controlled oxygen vacancy migration in the model system of VO_2, and achieved a nano-scale structural transformation into V_2O_3. In this approach, the electron beam induces both surface oxygen desorption through radiolytic process and positively charged background through secondary electrons, which contribute cooperatively to facilitate the vacancy migration from the surface toward the sample bulk, leading to nanoscale chemical reduction through oxygen vacancy formation. We envision that these two approaches can be readily applied for other material systems, providing a promising strategy to manipulate and design novel functionalities in various materials.

2:00 PM *EL06.08.02
Solid-State Electrochemical Thermal Transistor based on Oxygen Sponge $SrCoO_x$ ($2 \leqq x \leqq 3$) Hiromichi Ohta; Hokkaido University, Japan

Thermal transistors are devices that can electrically switch “heat flow” on and off, like a semiconductor transistor that switches “electric current” on and off. We can reuse waste heat exhausted to the environment using devices composed of thermal transistors such as thermal shutters and thermal displays [1]. Although several thermal transistors have been demonstrated thus far, the use of liquid electrolytes (or ionic liquids or ion gels) may limit the application from the viewpoint of reliability or liquid leakage [2–4]. Very recently, we demonstrated a solid-state thermal transistor that can electrochemically control the heat flow with an on-to-off ratio of the thermal conductivity (κ) of ~4 without using any liquid [5]. The thermal transistor is composed of a multilayer film composed of an upper electrode (Pt), strontium cobaltite ($SrCoO_x$), solid electrolyte (YSZ), and bottom electrode (Pt). An electrochemical redox treatment at 280 °C in air repeatedly modulates the crystal structure and κ of the $SrCoO_x$ layer. The fully oxidized perovskite-structured $SrCoO_3$ layer shows a high κ ~3.8 W m^{-1} K^{-1}, whereas the fully reduced defect perovskite-structured $SrCoO_2$ layer shows a low κ ~0.95 W m^{-1} K^{-1}. We believe that all-solid-state electrochemical thermal transistors have the potential to become next-generation devices for future thermal management technology, and we are currently working on improving their characteristics [6, 7].

Effect of Strain on The Proton Conduction in Multi-Oriented $BaZr_{0.9}Y_{0.1}O_{3-\delta}$ Thin Film Artur Braun[1], Muhammad S. Saleem[1] and Qianli Chen[2]; [1]Empa, Switzerland; [2]Shanghai Jiao Tong University Joint Institute, China

For proton-conducting ceramic fuel cells, $BaZr_{0.9}Y_{0.1}O_{3-\delta}$ (BZY10) is an attractive material due to its high proton conductivity and stability. The

physical and chemical fundamentals of proton conduction in sintered pellets and thin films and their heterostructures have been explored in several studies. The search for the effect of crystallographic orientation, grains, and grain boundaries on proton transport is yet an ongoing quest. We present a study [1] on the proton conduction in a self-assembled multi-oriented BZY10 thin film grown on top of a (110) NdGaO3 substrate. The multiple orientations are composed of different lattices, which provide a platform to study the lattice-dependent conductivity through different orientations in the vicinity of grain boundary between them and the substrate. The crystalline stacking of each orientation is determined by X-ray diffraction analysis and scanning transmission electron microscopy. The transport measurements are carried out under different gas atmospheres. The highest conductivity is 3 mS/cm at 400 °C and found under a wet H2 environment along with an increased lattice parameter of 4.208 Å, while under O2 and even reducing Ar atmosphere, the film shows lower conductivity and smaller lattice parameter. Our findings not only demonstrate the role of crystal lattice for conduction properties but also illustrate the importance of self-assembled strategies to achieve high proton conduction in BZY10 thin films.

Polar Vortices at mmWave Frequencies Florian Bergmann[1,2], Peter Meisenheimer[3], Bryan Bosworth[1], Nick Jungwirth[1], Ramamoorthy Ramesh[4] and Nate Orloff[1]; [1]National Institute of Standards and Technology, United States; [2]University of Colorado Boulder, United States; [3]University of California, Berkeley, United States; [4]Rice University, United States

$PbTiO_3$-$SrTiO_3$ superlattice films form Polar Vortices under the right lattice periodicity conditions. Experiments at kHz and THz frequencies have already shown emergent properties of these superlattice films like negative permittivity and collective lattice dynamics. However, data in the GHz range are sparse. Measurements in this frequency range are both interesting for the fundamental understanding of Polar Vortices and for potential electronic applications of the films. Here, we report on broadband measurements from 70 kHz to 110 GHz using Coplanar Waveguide devices. We extract the permittivity of a $PbTiO_3$-$SrTiO_3$ superlattice film on a $DyScO_3$ substrate and compare the results to those from co-fabricated $PbTiO_3$ and $SrTiO_3$ films. For all samples, we characterize the complex in-plane permittivity in two perpendicular orientations and as a function of bias voltage. Based on our results, we discuss the potential of Polar Vortex films for mmWave applications.

Multimodal X-Ray Studies of Remote Epitaxy of Functional Oxides and Enhanced Functionalities on Graphene Hua Zhou, Xi Yan, Hui Cao, Yan Li, Hawoong Hong, Liliana Stan, Nathan Guisinger and Dillon D. Fong; Argonne National Laboratory, United States

Future technologies are likely to exploit flexible heterostructures exhibiting multifunctional properties constructed from multiple materials. One technique for the synthesis of such systems relies on remote epitaxy, which is a novel synthesis technique that allows for the fabrication of thin, freestanding single crystals and nanomembranes. It relies on a sacrificial layer (e.g. graphene) between a thin film and a single-crystalline substrate: during film deposition, the electronic interactions across the graphene are strong enough to enable epitaxial growth but weak enough to allow mechanical release of the film. Others have demonstrated methods for the fabrication of freestanding structures, but the procedures are often materials-specific in terms of the interlayer permitting epitaxial growth. The remote epitaxy technique can be used to create single crystal heterostructures comprised of stacked epitaxial films, their properties optimized by minimizing incompatibilities between the different materials. Details regarding nucleation and growth via remote epitaxy remain unknown, however, due to the many difficulties in studying synthesis in the growth environment with atomic-scale resolution. This necessitates *in situ* studies sensitive to the atomic-level structure conducted in the growth environment. *In situ* measurements are particularly important for the synthesis of complex oxides such as perovskite oxides, where small changes to the degree of oxygen incorporation can impact the properties of the film/interface as well as degrade the graphene interlayer.

Here, in this talk, we will firstly demonstrate an *in situ* synchrotron X-ray investigation of perovskite oxide (e.g. $SrTiO_3$ and $LaNiO_3$) thin film growth by molecular beam epitaxy onto graphene few layer coated $SrTiO_3$ (001) substrates. X-ray phase retrieval methods were used to reconstruct the electron density profiles from X-ray crystal truncation rods measured under different growth conditions. Our *in situ* observations combined with post-growth spectroscopy provide a number of key insights regarding graphene in the synthesis environment and the resulting effects on the complex oxide/graphene heterostructure. Furthermore, we show that the graphene buffer layer could also enchance the physical propeties of a functional oxide thin film grown by the remote epitaxy. We will present the study conducted on epitaxial VO_2 thin films to assess to the effect of remote epitaxy on the metal–insulator transition (MIT). The epitaxial VO_2 heterostructures were synthesized on both bare Al_2O_3 (0001) substrates and Al_2O_3 substrates coated with a bilayer graphene. While both systems exhibit the MIT, the film grown by remote epitaxy on graphene demonstrates improved transport properties. Electrical transport measurements show that the on/off ratio is enhanced by a factor of ~7.5 and the MIT switching temperature window is narrower for VO_2 thin films grown on graphene. By characterizing the heterostructures with a suite of X-ray structural, chemical, and spectroscopic tools, we find that the graphene interlayer inhibits oxygen vacancy diffusion from Al_2O_3 (0001) during the VO_2 growth, resulting in improved electrical behaviors at the MIT.

3:45 PM EL06.08.06
Scanning Oscillator Piezoresponse Microscopy: New Tools to Explore Domain Wall Dynamics Neus Domingo Marimon, Shivaranjan Raghuraman, Kyle Kelley and Stephen Jesse; Oak Ridge National Laboratory, United States

Dynamics of ferroelectric domain walls associated to domain wall switching are known to depend on bulk structure, being very sensitive to defects, chemical and structural pinning sites, as well as environmental conditions, modifying the electronic boundary conditions associated with screening dynamics. However, domain walls also show a sub-coercive field dynamics as a reversible motion, with vibrational states that strongly couple to local structure and composition of the domain wall. In this presentation, we will show a novel microscopy mode based on a multifrequency approach which allows us to quantify domain wall oscillations under applied sub-coercive electric field, while simultaneously disentangle electrostatic from net eletromechanical signals, which can introduce severe distortions on the net piezoelectric response around neutral domain walls. This technique allows quick visualization of domain wall displacement, their velocities and dependence on pre-existing domain configurations and defects. When applied to lead titanate, this technique shows significant oscillations of the 180° domain walls between the antiparallel c+/c- domains. Further, the displacement and velocities distinctly depend on existing a-c domain structures and relative orientations of domains. This technique can be readily applied to other heterostructures under a wide range of stimuli such as light, heat, force and bias.

4:00 PM *EL06.08.07
Unprecedented Electromechanical Response in Antiferroelectric Thin Films Lane W. Martin; Rice University, United States

Antiferroelectrics, long considered the somewhat less exciting cousin of ferroelectrics, are having their moment. These materials, which possess antipolar order (*i.e.*, antiparallel alignment of polarization at zero field), can be switched to polar (parallel) order by an external electric field thus producing a reversible antiferroelectric-to-ferroelectric phase transition and a characteristic double polarization-electric-field hysteresis loop. Such a unique field-induced antipolar-to-polar transition endows antiferroelectrics with properties that are of great interest for a range of applications including nonlinear dielectrics, capacitive-energy storage, electrothermal-energy conversion, and electromechanical actuation. While these materials have been known for many decades, they remain relatively less well studied and understood as compared to their ferroelectric relatives. To better understand the nature of such phase transitions in antiferroelectrics and to finely engineer the polarization properties for targeted applications requires that one can fabricate high-quality versions of antiferroelectric materials. In this spirit, recent years have seen a growth in efforts to study these materials, particularly as thin films. Epitaxial films offer researchers the opportunity to finely control and manipulate the structure, orientation, strain, and much more. In turn, we are offered unprecedented insights into the nature and evolution of these complex and, at times, poorly understood physical phenomena.

Here, we apply the lessons of thin-film epitaxy to the study of antiferroelectrics. This talk will provide an overview of our recent efforts to synthesize, control, and study antiferroelectric perovskite oxides. Our attention will focus on classic, prototypical antiferroelectric materials such as $PbZrO_3$ and $PbHfO_3$ and solid solutions and multilayers derived from these parent materials. In turn, we will demonstrate how epitaxy, strain, and buffer layers can allow us to finely control the orientation of the resulting orthorhombic films and, in turn, how this orientation control affects the manifestation of properties. In particular, we will explore how antiferroelectrics offer a pathway to overcome traditional limitations in the achievement of large electromechanical responses in thin-film materials. We will explore an unconventional coupling of the field-induced antiferroelectric-to-ferroelectric phase transition and the substrate constraints in these materials. A detilting of the oxygen octahedra and lattice-volume expansion in all dimensions are observed commensurate with the phase transition, such that the in-plane clamping further enhances the out-of-plane expansion. In turn, an abnormal thickness scaling is realized wherein an ultrahigh electromechanical strain (1.7%) is produced from a model antiferroelectric $PbZrO_3$ film of just 100 nm thick. The exceptional performance and novel mechanism provide a promising pathway to develop high-performance micro-/nano-electromechanical systems. Ultimately, antiferroelectrics represent a relatively understudied realm of ferroic materials, ripe for the application of thin-film epitaxy to accelerate our understanding and use of these interesting materials.

4:30 PM *EL06.08.08
Voltage-Gated Hybrid Ferroelectric-Superconductive Quantum Devices Maria Badarne[1], Mohammad Suleiman[1], Martin Sarott[2], Morgan Trassin[2] and Yachin Ivry[1]; [1]Technion, Israel; [2]ETH Zürich, Switzerland

The increasing demand for data storage and manipulation urges technological developments outside the silicon arena. Superconductors are promising for enabling low-power and quantum computing that addresses the data-consumption growth. A prominent advantage of these materials is the lack of dc electric resistance, which in turn allows zero-energy loss while transmitting electric currents. Nevertheless, following Ohm's law, the lack of resistance makes voltage biasing impossible. Thus, as opposed to voltage-gated semiconducting transistors, superconducting devices are operated with magnetic fields and RF signals, imposing large device footprint and hence hindering device miniaturization and high-density scaling. Here, we used a ferroelectric-superconducting bilayer to demonstrate voltage-gated superconducting quantum devices. Films, wires and superconducting quantum interference devices (SQUIDs) were fabricated and characterized. The ferroelectric polarization was used to produce controllable surface charge at the bilayer interface, which in turn induced changes in the quantum properties, including 54% change in the device switching current. Thus, non-volatile voltage-tunable memory hybrid quantum devices were introduced.

SESSION EL06.09: Oxide Electronics—Devices and Computing
Session Chairs: Aiping Chen and Sundar Kunwar
Friday Morning, April 26, 2024
Room 343, Level 3, Summit

8:30 AM EL06.09.01
Dynamic Processes of Oxygen Ion Exchange in Strontium Cobaltite Bilayer Thin Films Driven by Oxidation and Reduction Jill Wenderott[1,2], Eric M. Dufresne[1], Yan Li[1], Hui Cao[1], Qingteng Zhang[1], Narayanachari Kondapalli[3], D. Bruce Buchholz[3], Supratik Guha[4,1] and Dillon D. Fong[1]; [1]Argonne National Laboratory, United States; [2]Drexel University, United States; [3]Northwestern University, United States; [4]The University of Chicago, United States

Transition metal oxides (TMOs) possess variable oxygen stoichiometry which can be the cause of distinct changes to physical and electronic properties. As an example, the well-studied TMO strontium cobaltite ($SrCoO_x$), has two structurally and electrically distinct phases – the insulating orthorhombic brownmillerite ($SrCoO_{2.5}$ – BM-SCO) and conducting cubic perovskite ($SrCoO_{3-\delta}$ – PV-SCO) – that reversibly transition via a topotactic pathway with the insertion or removal of oxygen. In the thin film form, this topotactic transition occurs while preserving high quality epitaxial films, making this material system of interest for ionotronic devices. Here, BM-SCO/PV-SCO (001) (15 nm/15 nm) heterostructures on strontium titanate (STO) (001) and the exchange of oxygen ions across this bilayer are investigated in order to understand changes to the interface under oxidizing and reducing conditions.[1] X-ray diffraction (XRD) and X-ray photon correlation spectroscopy (XPCS) studies reveal strongly asymmetric behavior with slower dynamics appearing during reducing versus oxidizing conditions and similar dynamics in the $SrCoO_{2.5}$ layer as compared to those near the heterointerface. Our results demonstrate a stable and reversible heterointerface, showcasing $SrCoO_x$ as a model system for study of ionotronic behavior.

8:45 AM EL06.09.02
What We Have Learned So Far from Phase-Field Modeling of Epitaxial Thin Films of Orthorhombic $K_xNa_{1-x}NbO_3$ Bo Wang[1,2], Mengjun Zhou[3], Ce-Wen Nan[4] and Long-Qing Chen[2]; [1]Lawrence Livermore National Laboratory, United States; [2]The Pennsylvania State University, United States; [3]Wuhan University of Technology, China; [4]Tsinghua University, China

Epitaxial ferroelectric thin films often exhibit unique polymorphic phases, domain structures, and physical properties dissimilar from their bulk counterparts due to the modification of mechanical and electrical boundary conditions. While extensive knowledge has been acquired for epitaxial thin films of bulk tetragonal (such as $BaTiO_3$ and $PbTiO_3$) and rhombohedral ferroelectric materials (such as $BiFeO_3$), much less is known for the thin films of bulk orthorhombic ferroelectrics such as $K_xNa_{1-x}NbO_3$. In this talk, I will review our recent progress in the development and employment of thermodynamic theory and phase-field modeling for understanding the phase stability and transformation, domain and domain wall structures, and

dielectric and piezoelectric properties of KNN thin films. I will highlight the computational establishment of anisotropic misfit strain-temperature phase diagrams, theoretical prediction and experimental validation of the formation condition and configuration of two types of superdomains, and the strong domain size-dependent piezoelectricity. I will also outlook potential topics unique for the epitaxial thin films of the orthorhombic ferroelectrics.
Part of this work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

9:00 AM *EL06.09.03
Rare Earth Nickelates for Neuromorphic Computing Applications Olivia Schneble[1,2], Christopher Muzzillo[1], Mirzo Mirzokarimov[1], Michelle Smeaton[1], Jeramy D. Zimmerman[2] and Marshall B. Tellekamp[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

As global information consumption continues to grow, the energy required to support computations is consuming a significant portion of the global energy supply. Data centers alone will consume 4.5% of all energy by 2025,[1] with computing demands doubling every 3–4 years.[2] Neuromorphic computing promises an energy-efficient solution based on the naturally efficient mechanisms that drive human thought and memory; it was recently calculated to outperform other technologies, including quantum computing, by at least 10,000x in terms of energy per solution.[3] Spiking neural networks (SNNs) are extremely efficient, encoding information based on the time between voltage spikes defined by multiple *local* inputs. The dynamic nature of the spiking processes can be simulated in conventional semiconductors at the cost of energy efficiency,[4,5] however a more attractive solution utilizes materials that natively produce such dynamic behavior.
Materials with an insulator-metal transition (IMT) are ideal for accessing nonlinear transport properties that could be useful in SNNs. In addition, IMTs can be highly sensitive to structure, defects, and environmental factors. Coupling fundamental mechanisms to stimuli such as electric field, electrochemical gating, and optical stimuli is an attractive way of encoding adaptive behavior that is a function of multiple input variables. Recently, IMT materials such as VO_2 and NbO_2 have been used to replicate the Hodgkin-Huxley action potential in pull-up/pull-down neuristor circuitry.[6–8] The IMT of NbO_2 is at 1080 K, too high for energy-efficient use, while the IMT of VO_2 is at 330 K (with doping up to 370 K)[9], meaning active cooling is required for operation with silicon CMOS, which typically operate around 400 K. Meanwhile, RNOs have a tunable IMT from 100–600 K, with known sensitivity to many inputs.[10] Therefore, it is attractive to improve our understanding of RNO synthesis, control the IMT, and leverage it for neuromorphic computing applications.
In this invited talk, I will overview our efforts to controllably synthesize RNO compounds (R = Gd, Eu, Sm, Nd, La) and leverage them for neuromorphic computing applications. I will first discuss synthesis of high-quality heteroepitaxial nickelate layers and bilayer stacks by RF magnetron sputtering, including successful stabilization of $EuNiO_3$ by RF sputtering which we have not seen reported elsewhere. I will also focus on the connection between uncontrollable synthetic parameters such as target aging and resulting film properties. In addition to RF sputtering, I will discuss synthesis of heteroepitaxial layers and bilayer stacks by pulsed laser deposition (PLD) while connecting deposition parameters to measured properties. In particular, I will present $EuNiO_3/LaNiO_3$ bilayers with a residual resistivity ratio ~ 7 orders of magnitude.
Finally, I will conclude with a discussion of our efforts to fabricate devices using nickelate bilayers, including a discussion of challenges and possible approaches to creating vertical devices for scalability. I will discuss our recent results of electrically-driven IMTs in $NdNiO_3$ and $NdNiO_3/LaNiO_3$ bilayers which show strong negative differential resistance (NDR) – the key electrical characteristic leveraged in neuristor circuits.

Emerging Self-Assembled Oxide–Metal Nanocomposite Thin Films with Coupled Multifunctionalities Di Zhang[1], Shikhar Misra[2], Jijie Huang[2], Bruce Zhang[2], Matias Kalaswad[2], Robynne Paldi[2], Bethany Rutherford[2], Xuejing Wang[2], Jiawei Song[2], Aiping Chen[1] and Haiyan Wang[2]; [1]Los Alamos National Laboratory, United States; [2]Purdue University, United States

Beyond oxide-oxide functional nanocomposite films which have been widely explored in the past two decades of this century, oxide-metal nanocomposites films have attracted increasing interests in recent years owing to their wide range of functionalities, such as metamaterials with plasmonic and hyperbolic optical properties, and ferroelectric, ferromagnetic and multiferroic behaviors. In this talk, I will focus on introducing the recently explored oxide-metal vertically aligned nanocomposite (VAN) thin films showing exotic optical, electrical, and magnetic properties coupling effect. Detailed transmission electron microscopy (TEM) and X-ray diffraction (XRD) characterization work revealed the film epitaxy and crystallographic lattice matching relation at metal/oxide interfaces. The anisotropic film morphology results in the corresponding anisotropic physical properties such as plasmonic hyperbolic dispersion and magnetism anisotropy. In situ TEM heating experiment clarified the excellent thermal stability of the oxide-metal nanocomposite thin film. The unique physical properties and coupled functionalities of the VAN films enable them to have great potential in nanoelectronic and nanophotonic devices applications.

10:30 AM EL06.09.05
Stochastic Oscillations of $LaCoO_3$ Memristor for True Random Number Generator Kyung Seok Woo[1,2], Timothy D. Brown[1], Alan Zhang[1], Elliot J. Fuller[1], R. Stanley Williams[1,2] and Suhas Kumar[1]; [1]Sandia National Laboratories, United States; [2]Texas A&M University, United States

In the era of Internet of Things, information security has become significantly important. Hardware-based true random number generator (TRNG) is a crucial component of security that relies on unpredictability, and the physical stochasticity of memristors has been implemented for TRNG. Here we demonstrate $LaCoO_3$ memristor capable of generating random numbers using its stochastic self-oscillations. We utilized Scanning Transmission X-ray Microscopy to confirm a low to high electron-spin-state transition in the Co^{3+} ion during the insulator-metal-transition (IMT). Our $LaCoO_3$-based TRNG requires only one flip-flop to produce binary bits and generates the highest bit generation speed among reported volatile-memristor-based TRNGs. It successfully passed the NIST randomness test without any post-processing. Unlike Mott-transition-based memristors, such as VO_2 and NbO_2 devices, which have abrupt temperature-driven IMT, the spin-state transition of $LaCoO_3$ undergoes the IMT with a gradual temperature increase, leading to high endurance. This work demonstrates the advancement of memristor-based hardware security, providing a major step toward a simple, fast, and stable system.

10:45 AM EL06.09.06
Reconfigurable Cascaded Thermal Neuristors for Novel Computing Erbin Qiu, Yuan-Hang Zhang, Massimiliano Di Ventra and Ivan Schuller; University of California, San Diego, United States

In our work, we explore a novel class of spiking oscillators termed "thermal neuristors". These neuristors function and communicate exclusively through thermal processes, utilizing the insulator-to-metal transition in vanadium dioxide. We showcase a diverse range of reconfigurable electrical behaviors that closely resemble those of biological neurons, including phenomena like the all-or-nothing law, type-II neuronal rate coding law, spike-in and DC out effect, spike-in and spike-out effect, and stochastic leaky integrate-and-firing law. Remarkably, inhibitory capabilities are achieved using just a single oxide device, and the transmission of cascaded information occurs solely through thermal interactions without any intricate circuits. This research serves as the groundwork for scalable and energy-efficient thermal neural networks, advancing the field of brain-inspired computing.

11:00 AM EL06.09.07
Harnessing The Competing Roles of Charge to Design Ferroelectric-Gated Mott Transistors Yifei Hao[1], Xuegang Chen[1], Le Zhang[1], Myung-Geun Han[2], Wei Wang[2], Yue-Wen Fang[3], Hanghui Chen[3], Yimei Zhu[2] and Xia Hong[1]; [1]University of Nebraska - Lincoln, United States; [2]Brookhaven National Laboratory, United States; [3]New York University Shanghai, China

The device concept of ferroelectric-gated Mott field effect transistors (FETs) has been intensively studied for the past three decades as a promising building block for developing energy-efficient nanoelectronics that can transcend the scaling limits of conventional semiconductor technology. The nearly metallic density of carriers within the Mott channel, however, imposes a major bottleneck for achieving substantial field effect modulation via a solid-state gate. In this study, we report a record high room temperature resistance switching in a rare earth nickelate (RNiO$_3$) channel controlled by a ferroelectric PbZr$_{0.2}$Ti$_{0.8}$O$_3$ (PZT) gate. We have systematically studied the ferroelectric field effect in RNiO$_3$ (R = Sm, Nd, La) to identify the optimal channel materials for constructing nonvolatile Mott transistors. For single-layer RNiO$_3$ channels, the resistance switching ratio $\Delta R/R_{on}$ peaks near the electrical dead layer thickness and then decreases abruptly due to strong depolarization in PZT. Switching the polarization of PZT induces a metal-insulator transition in the 4 uc single-layer LaNiO$_3$ channel. At 300 K, the highest $\Delta R/R_{on}$ of 1,619% is observed in 2 unit cell (uc) LaNiO$_3$ channels as it possesses the smallest electrical dead layer thickness. Devices with RNiO$_3$/La$_{0.67}$Sr$_{0.33}$MnO$_3$ (LSMO) composite channels exhibit up to three orders of magnitude higher $\Delta R/R_{on}$ compared with the single layer channel FETs with the same channel thickness. A record high $\Delta R/R_{on}$ of 38,540% is observed in the 2.5 uc LaNiO$_3$/2 uc LSMO bilayer channel at 300 K. Such an enhancement has been attributed to the interfacial charge transfer between RNiO$_3$ and LSMO, which reduces the net carrier density in RNiO$_3$ without compromising the screening of depolarization field in PZT. First principles calculations reveal about 0.1 electron/Mn transfer from interfacial Mn to Ni layers (or hole transfer from Ni to Mn). Both the magnitude and length scale of the charge transfer have been confirmed by atomically resolved EELS mapping. We have also studied the retention and cycling behaviors of the PZT/LaNiO$_3$/LSMO FETs, which reveal superior device performance compared with those of single-layer Mott channels and FeFETs exploiting polycrystalline PZT gates. Our study addresses one of the critical material challenges that limit the application potential of epitaxial ferroelectric-gated Mott transistors.

This work was primarily supported by National Science Foundation (NSF) Grant No. DMR-1710461 and EPSCoR RII Track-1: Emergent Quantum Materials and Technologies (EQUATE), Award No. OIA-2044049, and Semiconductor Research Corporation (SRC) under GRC Task Number 2831.001

11:15 AM EL06.09.08
Piezo-Strain-Controlled Phase Transition in Single-Crystalline Mott Switches for Threshold-Manipulated Leaky-Integrate-And-Fire Neurons Dong Kyu Lee, Sungwon Lee, Yunkyu Park, Si-Young Choi and Junwoo Son; Pohang University of Science and Technology, Korea (the Republic of)

Correlated oxides with strong correlations between the charge, spin, lattice, and orbital degrees of freedom present a wide array of emergent properties, such as metal-insulator transition, ferroelectricity, and superconductivity. These exotic functionalities give an opportunity to overcome the limitations of electronic devices; thus heteroepitaxial growth have been employed to synthesize these functional ionic crystals. However, unrestricted integration of emergent functionality from single-crystal oxide films is inhibited owing to the limited platforms to grow epitaxial films. Therefore, unrestricted integration of single-crystal oxide films has been of great interest to exploit emerging phenomena in artificial heterostructure.
Here, we demonstrate a new strategy to integrate single-crystal (002) VO_2 thin films on highly lattice-mismatched (002) PMN-PT converse piezoelectric substrate (f_a > 10 %) by utilizing freestanding oxide nanomembrane (NM) as epitaxial template [1]. By selective dissolution of VO_2 sacrificial layers from TiO_2/VO_2 heterostructure grown on TiO_2 substrate by H_2O_2 solution, millimeter-size TiO_2 single-crystalline layers are integrated on PMN-PT substrate. After subsequent epitaxial growth of VO_2 films on the transferred TiO_2 NM, we create single-crystalline VO_2/PMN-PT heterostructures with excellent sharpness of metal-insulator transition ($\Delta\rho/\rho > 10^3$) even in ultrathin (<10 nm) VO_2 films. Moreover, piezoelectric-mediated reversible strain modulation of single-crystalline VO_2 films showed unprecedented modulation of T_{MI} (5.2 K) and isothermal resistance of VO_2 ($\Delta R/R\ (E_g)$ = 20 % at 300 K) via effective stran transfer, which is not possible using directly grown VO_2/PMN-PT heterostructure. Owing to the steep phase transition near the phase boundary and effective strain transfer, small changes in the lattice parameters can cause the strain induced abrupt phase transition in our VO_2 films on TiO_2 NM/PMN-PT substrate ($\Delta R/R\ (E_g) \approx$ 18000% at 315K). The massive and reversible strain modulation of VO_2 epitaxial films by the VO_2/PMN-PT heterostructure offers a new type of artificial neurons with a real-time-tuned threshold values. Our strategy to utilize freestanding oxide NMs as epitaxial template for realizing single-crystalline artificial heterojunction will provide an unique opportunity to investigate unprecedented exotic functionlity for novel interfacial physics and next-generation devices.

Resistive Switching Oxide Nanocomposite Thin Films for Sustainable Artificial Intelligence Markus Hellenbrand[1], Ming Xiao[1], Babak Bakhit[1], Hongyi Dou[2], Megan Hill[1], Nives Strkalj[1], Adnan Mehonic[3], Quanxi Jia[4], Haiyan Wang[2] and Judith MacManus-Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]Purdue University, United States; [3]University College London, United Kingdom; [4]University at Buffalo, The State University of New York, United States

Artificial intelligence (AI) applications are increasingly affecting many areas of our lives. However, they are mostly being implemented in the conventional von Neumann computing architecture, which suffers from the memory bottleneck, i.e., a bottleneck in shuttling data between the memory and processing parts of the von Neumann architecture. This leads to immense power consumption due to AI applications, because with billions of parameters, they are very memory-heavy. New approaches to AI computing are thus necessary to enable a sustainable future.

One of the most promising approaches are resistive switching (RS) materials, where information is stored as the resistance state of a memory cell, rather than as charge on a capacitor as in conventional computer memory. RS materials hold promise to realise hardware neuromorphic networks, for example in the form of crossbar arrays, which make it possible to combine memory and processing into in-memory computing and thus circumvent the memory bottleneck. We developed oxide nanocomposite thin films which are based on a self-assembled phase separation on the nanoscale, and which demonstrate highly uniform and stable multi-level resistive switching. They are deposited at industry-friendly temperatures of ≤400 °C and demonstrate great promise in all standard figures of merit for resistive switching. In different materials systems, we achieve ≥10 000 switching cycles across a large number of devices, stable retention of up to ≥300 days, up to ≥500 resistance states, spike-timing-dependent plasticity, and fast switching down to 20 ns. These data will be presented together with compositional and structural analyses of the underlying films and the corresponding RS mechanisms.

SESSION EL06.10: Oxide Electronics—Synthesis and Characterization
Session Chairs: Nicholas Cucciniello, Megan Holtz and Yachin Ivry
Friday Afternoon, April 26, 2024

1:30 PM *EL06.10.01
Structural and Optical Properties of Compositionally Disordered Perovskite Metal Oxide Films Zachary Corey[1,2], Ping Lu[3], Guangran Zhang[4], Yogesh Sharma[2], Bethany Rutherford[5], Samyak Dhole[1], Pinku Roy[1,2], Zhehui Wang[2], Yiquan Wu[4], Haiyan Wang[5], Aiping Chen[2] and Quanxi Jia[1]; [1]University at Buffalo, United States; [2]Los Alamos National Laboratory, United States; [3]Sandia National Laboratories, United States; [4]Alfred University, United States; [5]Purdue University, United States

Perovskite metal oxides offer a wide range of functionalities owing to their rich compositional diversity. Experimental results have shown that much-enhanced physical properties could be achieved by forming multicomponent or high-entropy perovskite oxides. In this talk, we discuss our efforts in the design and synthesis of compositionally disordered epitaxial perovskite metal oxide films with multiple A-site cations. Using rare-earth aluminum perovskite oxide with an equiatomic ratio ($La_{0.2}Lu_{0.2}Y_{0.2}Gd_{0.2}Ce_{0.2}$)$AlO_3$ as the model system, we show that a high entropy oxide system with equiatomic A-site cations allows for the achievement of desired optical luminescence observed in mixtures and/or doping of RE aluminates while maintaining a highly crystalline single-phase. The high crystallinity of these materials paves the way for exciting new research of high precision scintillating applications.

2:00 PM EL06.10.02
Vector Substrates: How to Grow Epitaxially Impossible Heterostructures Yu-Jung Wu[1], Varun Harbola[1], Felix Hensling[1], Hongguang Wang[1,2], Peter A. van Aken[1,2] and Jochen Mannhart[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]Stuttgart Center for Electron Microscopy, Germany

Substrates play a crucial role in thin film deposition, but they do not always align with the specific requirements of a particular experiment or application. For instance, they might be expensive or unavailable with a desired crystal lattice structure. To address this, we introduce the novel concept of "vector substrates." In this approach, the template layer for growing thin films is both chemically and structurally independent from the main substrate. Vector substrates are fabricated by transferring a membrane, which serves as the template layer and is grown on a reusable parent substrate, onto a carrier substrate. The template and carrier layers can be independently chosen and optimized, which reduces material costs and offers more flexibility. We validate the feasibility of this technology by presenting sets of vector substrates for high-quality epitaxial film growth and by demonstrating a clean interface between the transferred membrane and the carrier substrate. The vector substrate concept is in its early stages of development but holds significant promise to supplement conventional substrates and drives future advancements in substrate technology and the deposition of films and heterostructures.

Heterogeneous Nucleation of YBCO Film Deposited by MOD: Experimental Verification of a Thermodynamic and Kinetic Model Valentina Pinto[1], Michele De Angelis[2,1], Achille Angrisani Armenio[1], Andrea Augieri[1], Giuseppe Celentano[1], Andrea Masi[1], Silvia Orlanducci[2], Alessandro Rufoloni[1] and Massimo Tomellini[2]; [1]ENEA, Italy; [2]Tor Vergata University, Italy

The deposition of superconducting $YBa_2Cu_3O_{7-\delta}$ (YBCO) thin film can be performed through physical and chemical methods, being the latter ones really advantageous in terms of cost-effectiveness, versatility, and simplicity. Therefore, within the last decade, the use of chemical solution deposition method, in particular the metal organic decomposition (MOD) approach, for producing epitaxial YBCO films has played an increasing role in the development of scalable processes.
In recent years, the need for a quantitative model for the YBCO heterogeneous nucleation emerged in order to better control the parameters affecting the formation of epitaxial film deposited by fluorine based MOD process. In fact, despite the great number of articles on YBCO deposition, the nucleation has been scarcely studied in the literature and only at qualitative level. However, it is a crucial step because the best superconducting properties are exhibited by YBCO film with the *c*-axis orientation. Recently, a thermodynamic and kinetic study on the heterogenous nucleation of YBCO film has been proposed in [1]. The model focused on fluorine based MOD deposition on $SrTiO_3$ (STO) single crystal and was developed on the basis of the classical nucleation theory providing an estimate of *c*-axis grain fraction as a function of water partial pressure and temperature. This latter calculation could constitute a useful tool to *a priori* define the proper experimental conditions for depositing highly epitaxial *c*-axis film when low crystallization temperatures may be necessary.
In the present work, the experimental verification of the model is proposed. The deposition of YBCO films on STO single crystal has been performed at different crystallization temperatures and water partial pressure values. The prepared samples have been fully characterized through the analysis of microstructure, morphology, and superconducting properties. The *c*-axis fraction has been derived by x-ray diffraction analysis and the experimental data have been described by the theoretical curves calculated from the model.
The deposition on a different substrate, namely $LaAlO_3$ (LAO), has been also carried out to study the effect of the substrate on YBCO nucleation kinetics. In fact, the expression for the free energy barriers includes the work of adhesion of the YBCO/substrate interface. The preliminary results obtained for YBCO/LAO samples evidenced the critical importance of this quantity and its technological implications.
In general, the present study shows that a deeper comprehension of the nucleation mechanism can lead to the improvement not only of the YBCO superconducting properties, but also of the process robustness and reproducibility.

Bridging Thin Films Growth and Advanced Electron Microscopy to Uncover Structure-Property Correlations in Oxide Electronics Robert Winkler[1], Alexander Zintler[2], Oscar Recalde[1], Déspina Nasiou[1], Lambert Alff[1] and Leopoldo Molina-Luna[1]; [1]TU Darmstadt, Germany; [2]University of

Antwerp, Belgium

Reactive Molecular Beam Epitaxy (RMBE), among other Physical Vapor Deposition (PVD) techniques, can precisely fabricate high-quality semiconductor heterostructures necessary for complex oxide electronics [1]. Their composition and crystallinity can be engineered through careful selection of growth parameters [2], [3], however are subject to the underlying layer. Here, miscut, composition and lattice mismatch impact texture transfer and thus the resulting microstructure [4].
Typically, RMBE is used to grow epitaxial thin films, yet textured thin films with defects might be more promising in oxide electronics applications like superconductors or emerging memories like resistive random access memory (RRAM). In our study, we investigated the texture relationship of TiN grown on c-cut sapphire by combining ion channeling contrast imaging (ICCI) with pole figure mapping. In addition, textured HfO_2 has been in situ grown on optimized TiN layers to investigate the impact of extended defects on RRAM performance by using atom probe tomography (APT) and operando electron microscopy. Our results indicate that a certain miscut of c-cut sapphire promotes distinct types of extended defects, which, as confirmed by elemental composition investigations using APT, are essential for RRAM operations.
Combining synthesis, macroscopic and microscopic investigation, and device characterization can bridge the information gaps required to further oxide electronics.

Phase Change Material VO_2/Iridium/Yttria-Stabilized Zirconia Heterostructures on Silicon Christina Bestele and Helmut Karl; University of Augsburg, Germany

External parameters like temperature, strain and electric fields can be employed to control the metal-insulator phase transition (MIT) of the strongly electron-correlated material vanadium dioxide (VO_2). This MIT is accompanied by an enormous decrease in electrical resistivity and optical transmittance in the infrared spectral region and especially the telecom window. VO_2 is thus a very promising material for hybrid optoelectronic integrated circuits [1,2]. In order to use its properties for introducing new functionality in integrated circuits based on silicon, high quality thin VO_2 films on dielectric and metallic layers are of importance.
In this work, we demonstrate epitaxial growth of VO_2 on yttria-stabilized zirconia (YSZ) and a layer stack of iridium/YSZ epitaxially grown on (001)-silicon, where the iridium layer forms a backside metallization that is used as a capacitor plate and areal contact to the VO_2 layer on top. The heterostuctures were fabricated in the following way: at first, a dielectric and electrically insulating YSZ template-layer was grown epitaxially on a (001)-silicon substrate [3], followed by the growth of the VO_2 thin film, both deposited by pulsed laser deposition. Similarly, the VO_2/Iridium/YSZ heterostructure was grown, except that the iridium layer was grown ex-situ by e-beam evaporation [4,5]. The iridium layer provides a highly electrically conducting electrode allowing building capacitor structures with VO_2 to control the MIT by electric fields and to build vertical electronic switching devices for very fast sensing applications and current control.
The YSZ template-layer inhibits silicide formation by blocking diffusion of the cations to the YSZ/Si interface. Pole figures, reciprocal space maps and temperature dependent µ-Raman spectroscopy measurements reveal (010)-oriented VO_2 layers with 30° in-plane rotated crystallites and high symmetry grain boundaries on both the (001) iridium/YSZ double layer and YSZ template-layer.
Based on these multilayers metal/VO_2/iridium capacitor structures on silicon were fabricated and the effect of an electric field on the MIT were studied by µ-Raman spectroscopy and spectral reflectivity measurements.

Emergent Electronic and Structural Landscapes in a Novel Valence Ordered Thin-Film Nickelate prepared by Topochemical Reduction Aravind Raji[1,2], Zhengang Dong[3,4], Victor Porée[2], Alaska Subedi[5], Guillaume Krieger[6], Xiaoyan Li[1], Bernat Mundet[7,8], Lucia Varbaro[7], Claribel Domínguez[7], Marios Hadjimichael[7], Bohan Feng[3,4], Daniele Preziosi[6], Alessandro Nicolaou[2], Jean-Pascal Rueff[2,9], Danfeng Li[3,4] and Alexandre Gloter[1]; [1]Laboratoire de Physique des Solides Orsay, France; [2]Synchrotron SOLEIL, France; [3]City University of Hong Kong, Hong Kong; [4]City University of Hong Kong Shenzhen Research Institute, China; [5]Ecole Polytechnique, France; [6]IPCMS UMR, CNRS, Université de Strasbourg, France; [7]University of Geneva, Switzerland; [8]Ecole Polytechnique Fedéralé de Lausanne (EPFL), Switzerland; [9]LCPMR, Sorbonne Université, CNRS, France

The on-demand design of transition-metal oxides (TMO) with emerging properties is imparted by the multivalent nature of the transition-metal ions and the accessible complexity of lattice structures [1, 2]. One can access a wide range of electronic landscapes by varying the structure and constituent elements in TMO. The oxygen dynamics in the system determines the resulting structure, and thereby their electronics. The metal hydride based topochemical reduction is one of the oxygen (de-) intercalation methods and it has been employed to synthesize otherwise difficult systems such as the infinite-layer nickelates (IL-nickelates), which was found to be superconducting upon doping [3].
In this path, from topochemical reduction of a perovskite $SmNiO_3$ thin-film, we obtain a novel valence-ordered and tri-component coordinated nickelate phase [4]. This new phase, with the chemical formula of $Sm_9Ni_9O_{22}$ ($SmNiO_{2.44}$) is formed by intricate planes of $\{303\}_{pc}$ (subscript pc refers to pseudocubic) apical oxygen vacancies (Vo) from the parent perovskite as revealed by four-dimensional scanning transmission electron microscopy (4D-STEM). Transport measurements indicated this phase to be highly insulating, over the measured temperature range (30K - 400K). A coherent analysis between ab-initio simulations and Synchrotron based X-ray spectroscopy techniques that evidenced a strong orbital polarization elucidated that this nickelate hosts multi-valent Ni sites that are in NiO_5 pyramidal, NiO_4 square-planar, and NiO_6 octahedral coordinations. The resonant inelastic x-ray

scattering (RIXS) measurements at the O-K edge also revealed this system to be having a strong carrier localization, marked by the disappearance of a ligand-hole configuration at low temperature. The periodicity of these polyhedral ordering, that can also be interpreted as valence ordering, follows the periodicity of the apical Vo ordering. The NiO_4 square-planar sites forms at the intersection of the families of $\{303\}_{pc}$ apical Vo planes, indicating a route to the infinite-layer phase.
Apart from these, this phase being an intermediate between the perovskite ABO_3 and infinite-layer ABO_2, it could have been present as a defect in many IL-nickelate samples, and caused complexity in identifying their pristine properties. The ongoing debate on the (1/3, 0, 1/3) r.l.u. Charge ordering reported in IL-nickelates is one such prototypical example [5- 10]. Our STEM-EELS analysis found quasi-2D nanodomains of $(303)_{pc}$ apical Vo ordering in a charge ordered IL-nickelate, and its absence in a sample without charge ordering [8]. Later on, another group also reported similar Vo ordering combining with resonant x-ray scattering that directly corroborated our idea [9]. It is evident from the measurements in those thin-films and with that of $Sm_9Ni_9O_{22}$ that the nano-domains of $(303)_{pc}$ ordering there was in fact the presence of nano-domains of $Sm_9Ni_9O_{22}$ phase as a defect. This directly questions the intrinsic nature of (1/3, 0, 1/3) r.l.u. Charge ordering reported in IL-nickelates.
This new nickelate compound provides another example of previously inaccessible materials enabled by topotactic transformations and presents a unique platform where mixed Ni valence can give rise to exotic phenomena.

Evidence for Phase Transitions in $CoFe_2O_4$ and $NiCo_2O_4$ Thin Films in Temperature Dependent X-Ray Photoelectron Spectroscopy Arjun Subedi, Detian Yang, Xiaoshan Xu and Peter Dowben; University of Nebraska–Lincoln, United States

The temperature dependent X-ray photoelectron spectroscopy (XPS) of the $CoFe_2O_4$ thin film showed that core level binding energies decreased with increasing temperature. The large binding energy shifts of the Co $2p_{3/2}$ and Fe $2p_{3/2}$ core levels of $CoFe_2O_4$ thin film, observed at room temperature, are due to large photovoltaic surface charging. The large binding energy shifts of the Co $2p_{3/2}$ and Fe $2p_{3/2}$ core levels, in the X-ray photoelectron spectroscopy of $CoFe_2O_4$ thin film, decreased with increasing temperature. However, above 455 K, during annealing of the sample, shifts in the core level binding energies ceased to decrease. This shows that the prepared $CoFe_2O_4$ thin film can be dielectric at room temperature but more metallic at elevated temperatures. The dielectric nature of the film was restored only when the film was annealed in sufficient oxygen, indicating that the oxygen vacancies play a role in the transition of the film from dielectric (or insulating) to conducting. In contrast, similar studies on $NiCo_2O_4$ thin film showed that annealing of $NiCo_2O_4$ thin film, which was observed to be conducting, could make $NiCo_2O_4$ thin film insulating, and the original more metallic character of the $NiCo_2O_4$ thin film could be restored only when the sample was annealed in sufficient oxygen. A model that governs the core level binding energy changes, as a function of temperature, is proposed. Furthermore, restoration of the original properties or phases of the thin films after undergoing a metal-to-insulator transition illustrates routes to regulate the surface metal-to-insulator transition, especially in the case of insulating $NiCo_2O_4$ thin film which can undergo reversible metal-to-insulator transition with temperature. This work provides a better fundamental understanding of defect mediated surface phases for thin film oxides and opens avenues for defect assisted and/or temperature dependent future beyond CMOS devices.

XANES Analysis of Mn-Alloyed TiO_2 Coatings Grown by Atomic Layer Deposition: Probing The Crystallization Behavior Devan Solanki[1], Deyu Lu[2] and Shu Hu[1]; [1]Yale University, United States; [2]Brookhaven National Laboratory, United States

TiO_2 is a nontoxic, wide bandgap semiconductor with many excellent physical properties such as high chemical stability in acids and bases and good optical transparency to visible light, making it an excellent candidate for photoelectrocatalysis. Atomic Layer Deposition (ALD) enables synthesis of conformal coatings on various substrates by its layer-by-layer, surface-growth mechanism. However, controlling the crystal structure, which can modulate properties such as the band gap and band edge positions, remains a challenge as TiO_2 is often amorphous as deposited but can be annealed into multiple polymorphs such as anatase, rutile, and brookite. Despite progress in understanding the reaction mechanisms and intermediates associated with the deposition of binary materials via ALD, there are still many questions surrounding the structure-processing relationship of ternary materials. For example, the role that dopants or alloying agents play in determining key properties such as oxidation state and crystal structure remain open questions.
Methods:
The X-Ray Absorption Spectroscopy (XAS) and X-ray Absorption Near Edge Structure (XANES) measurements were conducted at the Inner Shell Spectroscopy beamline of the National Synchrotron Light Source II (NSLS-II) at Brookhaven National Lab. The data was collected at room temperature with the energy calibrated using a Ti foil. The Athena software package was used to calibrate the energy and normalize the data using the recommended parameters. XAS was collected in fluorescence mode with $\mu(E) = If / I0$ where If is the fluorescence intensity and I0 the incident intensity. Each spectrum is flattened so that the overall spectrum has an asymptotic behavior approaching 1.
Results:
The primary pre-edge feature in the TiO2 sample, centered at 4968 eV is due to the oxygen vacancies and resultant undercoordinated Ti. The absorption maximum of that pre-edge feature is unchanged after the incorporation of Mn. However, there is a narrowing of the peak in TiMnOx samples relative to the TiO2 and an enhancement of the shoulder peak that appears at 4972 eV. The separation between the apex of the first and second pre-edge feature corresponds to the crystal field splitting energy of the Ti 3d states. This indicates that the incorporation of Mn, while not having an effect in the oxidation state of the Ti, does perturb the local steric coordination environment. Quantitative analysis of this feature was not possible due to the background variation between the different samples and the low absolute intensity of the peak. Analysis of the Mn K-edge reveals that the oxidation state of Mn in the as-grown TiMnOx is independent of Mn concentration. One explanation for this fractional oxidation state could be the incorporation of Mn into multiple different sites. The pre-edge feature is comparable to experimental and computational Mn3O4 spectra. The position of the white line can be explained either by the electrostatic model or as continuum resonances. In the electrostatic model, as the oxidation state increases, the electrons are more tightly bound to the nucleus, requiring higher energy to be excited. The continuum model considers both the excited atom and the surrounding ones, and as the absorber-scatter distance gets shorter, the energy of the continuum state increases with 1/r2 . As higher oxidation states result in shorter bond lengths, the energy increases as oxidation state increases. In addition, the intensity of the white line intensity is proportional to the filling of 3d orbitals. As the 3d orbitals gets more occupied, the intensity of the white line goes down due to the reduction in possible population states. As the position of the white line remains constant between the as grown TiMnOx samples, the increase in sharpness of the K-edge in the 16:1 sample relative to the 2:1 sample could be explained by the combination of a slightly increased oxidation state and longer Mn-O bond.

4:15 PM EL06.10.09
Accelerating Metal Nanoparticle Exsolution by Exploiting Tolerance Factor of Perovskite Stannate Yujeong Lee, Daseob Yoon, Yeon-seo Nam, Sangbae Yu, Chaesung Lim, Hyeji Sim, Yunkyu Park, Jeong Woo Han, Si-Young Choi and Junwoo Son; Pohang University of Science and Technology, Korea (the Republic of)

Perovskite oxide (ABO_3) with catalytically active metal nanoparticles (NPs) has the potential as a promising application such as solid oxide fuel cell operated at high temperature, electrochemical reaction, energy conversion, photocatalysis and syngas conversion. In particular, *in-situ* exsolution is emerging method that metal NPs are segregated from an oxide matrix to a surface under a reducing atmosphere for enhancing the interfacial adhesion between metal NPs and the perovskite support with high electrical conductivity [1, 2].
In this presentation, we demonstrate a novel method to control a density of Ni metal NPs on surface of A-site deficient perovskite stannate matrix ($A_{0.9}Sn_{0.9}Ni_{0.1}O_{3-\delta}$, A = Ca, Sr, Ba) by manipulating distortion of SnO_6 octahedron by diffusion kinetics of Ni metal during exsolution process. Remarkably, the density of Ni NPs increases from 47 particles um^{-2} ($Ba_{0.9}Sn_{0.9}Ni_{0.1}O_{3-\delta}$) to 304 particles um^{-2} ($Ca_{0.9}Sn_{0.9}Ni_{0.1}O_{3-\delta}$) by decreasing the Goldschmidt tolerance factor of perovskite stannate epitaxial films. *Q*uantitative analysis using ambient pressure X-ray photoemission spectroscopy (APXPS) during *in-situ* exsolution process experimentally confirmed that Ni diffusion is enhanced with decreasing the tolerance factor of perovskite stannates. Experimental characterization combined with theoretical calculation shows that Goldschmidt tolerance factor of perovskite stannate promote the Ni diffusion kinetics from the oxide matrix to surface by manipulating the A-O bonding strength. Motivated by the high density of Ni NPs on perovskite stannate support, *in-situ* CO oxidation was also performed using APXPS to identify the effect of the catalytic activity of perovskite stannate support with exsolved Ni NPs. This new strategy on the manipulation of tolerance factor for promoting exsolved metal diffusion kinetics can be exploited to enhance the density of populated metal nanoparticles for emerging catalytic applications.

Emergent Dipolar Textures and Properties in All-Ferroelectric Superlattices Lane W. Martin; Rice University, United States

Emergent topological dipolar textures including vortices, dipolar waves, skyrmions, merons, hopfions, and more have generated considerable interest in the ferroelectrics and wider condensed-matter physics communities. The delicate balance of electric, elastic, and gradient energies of ferroelectrics can be tailored in low-dimensional forms and nanostructures to manipulate the order parameters. Exotic functional properties (*e.g.*, coexistence of phases, chirality, negative capacitance, and emergent ultrafast dynamical responses) make them interesting candidates for devices. Ferroelectric-dielectric superlattices such as $(PbTiO_3)_n/(SrTiO_3)_n$ have been widely studied as a model system in part due to the high depolarizing field boundary condition provided by the $SrTiO_3$ layer. Such layers, however, limit the incorporation of such heterostructures into devices that could use the electronic characteristics of these polar topologies.

Looking to expand upon this rich design space, we ask a simple question: can similar emergent dipolar textures be produced in all-ferroelectric (and other) heterostructures while providing additional tunability based on the susceptibilities of the constituent layers? Here, we demonstrate the formation of polar

vortices in all-ferroelectric $Pb_{1-x}Sr_xTiO_3/PbTiO_3/Pb_{1-x}Sr_xTiO_3$ trilayer and $(Pb_{1-x}Sr_xTiO_3)_n/(PbTiO_3)_n$ superlattice structures wherein $0.5 < x < 1$ grown on $DyScO_3$ (110) substrates. Unlike their counterparts with $SrTiO_3$, the $Pb_{1-x}Sr_xTiO_3$ layers exhibit robust, in-plane ferroelectric polarization and domain structures, but still provide the appropriate boundary condition for the formation of polar vortices in the $PbTiO_3$ layers. We describe the manifestation of complex polar order in these structures that combines traditional ferroelectric order with emergent dipolar textures. Reciprocal space mapping studies reveal that the strontium content in the $Pb_{1-x}Sr_xTiO_3$ provides a fine control knob over the vortex periodicity; as supported by molecular-dynamics simulations. Furthermore, while recent studies on in-plane ferroelectric switching of polar vortices showed classical bistable switching, here, the in-plane polarization component of the vortices in the $PbTiO_3$ layers and the ferroelectric domains in the $Pb_{1-x}Sr_xTiO_3$ layers exhibit strong elastic and dipolar coupling, leading to a coercivity enhancement of the trilayer stack upon decreasing the strontium content of the $Pb_{1-x}Sr_xTiO_3$. Phase-field simulations further explain the polarization arrangement in the trilayer and the system's subsequent collective switching pathway of the two order parameters. Formation of such in-plane domains in the $Pb_{1-x}Sr_xTiO_3$ leads to the formation of a labyrinthine vortex arrangement, unlike the highly unidirectional vortices observed in $(PbTiO_3)_n/(SrTiO_3)_n$ superlattices. Further, we have explored the coupling between different emergent dipolar heterostructures of the from $Pb_{1-x}Sr_xTiO_3/PbTiO_3/Pb_{1-x}Sr_xTiO_3/SrTiO_3/PbTiO_3/SrTiO_3$. Therein, the thickness of the $SrTiO_3$ layer separating the two vortex structures controls the strength of the elastic and electric fields that extend between layers, affecting the sequence in which each trilayer would switch and the number of switching events. The result is an ability to produce low-field multi-state, four-step switching with robust retention and fatigue performance. Finally, in $(Pb_{1-x}Sr_xTiO_3)_n/(PbTiO_3)_n$ superlattices we have explored the dielectric tunability and out-of-plane switching and find improved tunability as a function of the chemistry of the $Pb_{1-x}Sr_xTiO_3$ layer, antiferroelectric-like switching due to an unraveling of the vortex phase upon application of the electric-field, and strong back switching on releasing the same leading to improvements in the low-field energy storage as compared to $(PbTiO_3)_n/(SrTiO_3)_n$.

Novel Hexagonal Ferroelectric $LuGaO_3$ Jesse Schimpf[1], Megha Acharya[1] and Lane W. Martin[2,1]; [1]University of California, Berkeley, United States; [2]Rice University, United States

The presence of simultaneous ferroelectric and magnetic order in hexagonal $LuFeO_3$ has made it a promising candidate for next-generation microelectronics. At the same time, the metastable nature of this phase makes it an interesting case study for the synthesis of novel epitaxial materials. Its utility, however, is limited by its low polarization (<10 $\mu C/cm^2$) and often poor film quality. Recent first principles predictions have identified a new hexagonal ferroelectric, $LuGaO_3$, which is isostructural to $LuFeO_3$ but is predicted to be thermodynamically stable and exhibit a higher polarization than $LuFeO_3$. While nonmagnetic, the enhanced polarization in $LuGaO_3$ could make it a more suitable ferroelectric, and alloying it with $LuFeO_3$ may serve to enhance the magnetic character while retaining more robust ferroelectricity. Overall, understanding the synthesis of newly predicted materials provides an important opportunity to verify and correct computational models, making them more reliable for future materials predictions.

Here, we demonstrate the synthesis of epitaxial, hexagonal $LuGaO_3$ via pulsed-laser deposition, which has not yet been reported. Extensive X-ray diffraction-based structural studies verify the hexagonal nature of this phase, while piezoresponse force microscopy studies show indications of stable, ferroelectric switching. While first principles calculations predict this phase to be thermodynamically stable (energy above hull = 0), the bulk material separates into Lu_2O_3 and $Lu_3Ga_5O_{12}$ phases. Film synthesis is even more complex and highly sensitive to growth conditions and epitaxial constraints. While (111)-oriented yttria-stabilized zirconia is the preferred substrate for hexagonal ferroelectrics like $LuGaO_3$, it is also closely lattice matched with Lu_2O_3, which forms epitaxially with surprisingly high quality under a wide range of conditions, with excess gallium being segregated to large precipitates on the surface of the film. Energy dispersive X-ray spectroscopy shows a large gallium deficiency (as much as 30% off from the target stoichiometry) in these phase-separated films, likely reducing the stability of the perovskite phase. Depositing the films at room temperature and subsequently annealing them circumvents the gallium loss enough to stabilize the hexagonal phase in extremely thin (~5 nm) films, while depositing in abnormally high oxygen partial pressures (1 Torr or more) has the same effect for thicker films, enabling more extensive structural and dielectric characterization which confirms the presence of a hexagonal, ferroelectric phase. We further examine the structure and dielectric properties as a function of synthesis conditions as the material transforms from predominately nonpolar Lu_2O_3 to ferroelectric hexagonal $LuGaO_3$. We then compare this to $LuFeO_3$, which does not exhibit the same phase separation and largely maintains the hexagonal phase regardless of the synthesis conditions. Finally, we examine the influence of alloying and multilayering of both materials to understand their stability and produce a more robust multiferroic. Interestingly, providing a thin (as little as 1-2 nm) buffer layer of $LuFeO_3$ is enough to stabilize hexagonal $LuGaO_3$ where it would otherwise phase separate on a bare substrate, further demonstrating the importance of epitaxy in phase selection. Extending this to a multilayer or solid solution has a similar effect. While such mixtures maintain robust ferroelectricity, a small degree of phase separation still persists and will likely require further tuning of the gallium chemistry to fully correct. Nevertheless, this work represents an important step toward finding a more robust hexagonal perovskite multiferroic and offers valuable insight on metastable materials synthesis.

11:15 AM EL07.01.05

Van der Waals Growth of Ferroelectric GeTe Thin Films by Industrial Magnetron Sputtering for Large-Scale Integration Pierre Noé[1], Nicolas Bernier[1], Damien Térébenec[1], Jules LaGrave[1], Alexandre Oysel-Mestre[1], Jean-Baptiste Dory[1], Théo Frottier[2], Salvatore Teresi[2], Jean-Philippe Attane[2], Laurent Vila[2] and Françoise Hippert[3]; [1]Univ. Grenoble Alpes, CEA, LETI, France; [2]Univ. Grenoble Alpes, CNRS, CEA, SPINTEC, France; [3]Univ. Grenoble Alpes, CNRS, Grenoble INP, LMGP, France

Chalcogenide materials have attracted a lot of attention over the years due to their wide range of applications. Among them, some compounds such as Ge-Sb-Te based alloys exhibit a unique portfolio of properties, which has led to their wide use for non-volatile phase-change memory applications [1,2]. In addition to memory applications, the GeTe phase-change alloy is also very promising for RF switches [3], for thermoelectrics [4,5], and offers numerous opportunities for optical applications[6] and photonics[7] as well as for the emerging field of spinorbitronics [8]. GeTe has also been the subject of numerous studies, , due to the ferroelectric character of the stable rhombohedral α phase and the existence of a reversible structural transformation (around 430°C) between the rhombohedral α phase and the cubic paraelectric cubic b phase. The rhombohedral α-GeTe phase can be described as a deformed rocksalt structure that has undergone shearing along a cube diagonal ([111] or equivalent direction), with a relative displacement of the Ge and Te atoms along this direction, which is . responsible for the ferroelectric properties. In the α-GeTe phase a Ge atom is surrounded by six Te atoms forming a distorted octahedron with three short and three long Ge-Te bonds. This splitting is interpreted as resulting from a Peierls distortion. These properties have sparked interest in GeTe as a ferroelectric Rashba semiconductor, combining semiconductivity, strong spin-orbit coupling and non-volatility. In addition, GeTe has recently attracted renewed interest with the demonstration of non-volatile ferroelectric control of spin-charge conversion in epitaxial germanium telluride films deposited by molecular beam epitaxy [8]. The sign of the charge current can be controlled by the orientation of the ferroelectric polarization, which can be switched by an electric gate despite the high intrinsic carrier density of GeTe. In this context, the successful deposition of high-quality epitaxial ferroelectric GeTe films using a large-scale industrial deposition process could open up a new field of applications based on the non-volatile electrical control of spin currents in semiconducting GeTe. In this presentation, I will show that the van der Waals growth of high structural quality ferroelectric GeTe thin films using industrial magnetron sputtering could be achieved, demonstrating that this material could be monolithically integrated on silicon for devices beyond CMOS such as reconfigurable spin-based and in-memory computing devices.

Key words: chalcogenide, GeTe, phase-change material, van der Waals epitaxy, ferroelectric

SESSION EL07.02: Ferroelectrics II
Session Chairs: Yen-Lin Huang and Ruijuan Xu
Tuesday Afternoon, April 23, 2024
Room 342, Level 3, Summit

1:30 PM *EL07.02.01
Coexistence of Ferro- and Antiferroelectric Behavior Dennis Meier; Norwegian University of Science and Technology, Norway

Ferroelectric domain walls are a rich source of emergent electronic properties and unusual polar order. For example, recent studies showed that the polarization configuration of ferroelectric walls can go well beyond the conventional Ising-type structure, exhibiting Néel-, Bloch-, and vortex-like polar patterns.

In my talk, I will present novel types of anti-polar domain walls and discuss their structure and unusual physical properties. In the first part of my talk, I will show that charged domain walls arise in $K_3[Nb_3O_6(BO_3)_2]$. The domain wall bound charges arise from a finite canted moment associated with the material's antiferroelectric-like order, leading to distinct local piezoelectric and electrostatic responses. In the second part, I will talk about the emergence of anti-polar order at domain walls in $Pb_5Ge_3O_{11}$. The domain walls are highly mobile and exhibit an energetically costly antiparallel ordering of dipoles along the longitudinal direction, which we attribute to the hyperferroelectric nature of the system. The results provide new insight into the complex polar textures of domain walls, expanding previous studies towards anti-ferroic phenomena.

2:00 PM *EL07.02.02
Dynamic Mechanical Writing of Ferroelectric Bubbles Chan-Ho Yang; KAIST, Korea (the Republic of)

Topological ferroelectric structures offering novel functionalities due to peculiar distributions of polarization and charge with long retention have been increasingly explored in a variety of dielectric systems, such as superlattices, strained films, and nanoscale islands. The polar structures, protected by topological constraints such as boundary conditions, appear as metastable states due to the interplay between strain, depolarization and gradient energies, but their precise control is still challenging. In this study, we demonstrate the observation of skyrmion-like centre-type polar bubble domains in supertetragonal $BiFeO_3$ thin films. These polar textures are mechanically generated by dynamic elastic force of vibrational tapping using scanning probe microscope tips. The formation of bubble domains is accompanied by emergence of strain-driven morphotropic phase boundaries wherein two competing structural phases coexist. The bubble domains can be accurately written, mechanically or electrically erased, and remain stable for longer than ~500 days. Vibrational tapping can bidirectionally switch out-of-plane polarization by exerting strong tapping force onto the elastically soft surface driven by the morphotropic phase transition, which may be attributed to non-linear flexoelectric effects in the large strain-gradient regime beyond the conventional flexoelectrical concept. Our study presents insights into dynamic mechanical switching of polarization and provides a unique pathway into topological polar structures for next-generation energy-efficient electronic applications.

2:30 PM EL07.02.03
Real-Time Imaging of Nonequilibrium Domain Evolution into a Multiferroic Phase Jan Gerrit Horstmann[1], Yannik Zemp[1], Ehsan Hassanpour Yesaghi[1], Thomas Lottermoser[1], Mads Weber[2] and Manfred Fiebig[1]; [1]ETH Zurich, Switzerland; [2]Le Mans Université, France

The properties and functionalities of multiferroic materials are governed by the microscopic domain structures of coexisting ferroic orders and their mutual coupling. Active control over multiferroic domains via external stimuli is desirable, with prominent examples in magnetoelectric inversion or transfer of domain patterns. These approaches typically harness electric or magnetic fields to affect the thermodynamically stable domain configuration within a multiferroic phase. Optical or thermal quenches through phase transitions can be used to transfer structural features between distinct phases, creating novel and potentially functional domain structures unattainable in thermal equilibrium. The impact of such transitions on multiferroic domain patterns and their dynamic evolution, however, remains a largely open subject.

In this work, we combine real-time Faraday imaging at kHz frame rates with fast optical excitations to investigate the evolution of domains across spin-reorientation transitions and into the multiferroic phase of $Dy_{0.7}Tb_{0.3}FeO_3$. We find that optically-induced thermal quenches of the system can be harnessed to imprint the characteristic bubble domain pattern of the weak ferromagnetic order at elevated temperatures onto the low-temperature multiferroic phase. We identify the quenching rate across the different spin reorientation transitions as the decisive parameter governing the domain memory and the formation of metastable domain states forbidden under equilibrium conditions. Our results highlight the potential of optical stimuli for the switching and control of multiferroic domain structures, enabling the creation of new functional states via nonequilibrium pathways.

Mapping Polar Distortions with Nanobeam Electron Diffraction Using A Cepstral Approach Megan E. Holtz; Colorado School of Mines, United States

Understanding local polar ordering is key to understanding ferroelectricity in thin film systems, especially for systems with small domains or significant disorder. Scanning nanobeam electron diffraction (NBED) combined with new high speed, pixelated scanning transmission electron microscopy (STEM) detectors make it possible to measure a diffraction pattern (k_x, k_y) at every scan position (x, y). This opens doors to investigate lattice parameters, local

fields, polarization directions, and charge densities with relatively low beam dose over large fields of view. However, quantitatively extracting both the magnitude and direction of polarization vectors is still challenging. Here we use a cepstral approach, similar to a 2D pair-correlation function, to measure these local polar displacements that drive ferroelectricity. In this presentation, we will discuss the application and limits of this technique and map polar distortions across a thin film of $PbTiO_3$ and in relaxor ferroelectrics.

Nanoscale Design of Polarization Using Lattice Chemistry Engineering in Layered Ferroelectrics Ipek Efe[1], Alexander Vogel[2], Elzbieta Gradauskaite[1], William S. Huxter[1,1], Christian Degen[1,1], Marta D. Rossell[2], Manfred Fiebig[1] and Morgan Trassin[1]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Nanoscale electrostatic control of oxide interfaces enables physical phenomena and exotic functionalities beyond the realm of the bulk material, including superconductivity, multiferroicity, and topological properties promising for future nonvolatile memory applications. Here, by exploiting spontaneously forming charged interfaces in layered materials, we control the electrostatic boundary conditions in ferroelectric oxide heterostructures. We directly access the polarization dynamics of the layered ferroelectric model system Aurivillius $Bi_5FeTi_3O_{15}$ (BFTO) films during growth using in-situ optical second harmonic generation (ISHG). We identify the characteristic Aurivillius antipolar ordering of the dipoles along the growth direction, which leads to an oscillating intensity of the ISHG signal during the layer-by-layer deposition. In combination with reflection high-energy electron diffraction monitoring, we show how the polarization orientation of the films consistently changes from out-of-plane during the growth of perovskite blocks, to fully in-plane upon the completion of the unit cell with the fluorite-like $(Bi_2O_2)^{2+}$ planes. Finally, we incorporate various functional perovskite units into the Aurivillius layered-crystal structure using the direct access to structure-dependent polarization dynamics during growth. Our work thus expands the limits of engineering the properties of layered oxide films to the sub-unit-cell-scale for the development of energy-efficient oxide electronics.

3:45 PM EL07.02.06
A Strain-Enabled Novel Multiferroic State in Barium Hexaferrite through Suppression of Quantum Paraelectricity Zhiren He[1,2] and Guru Khalsa[1]; [1]University of North Texas, United States; [2]Cornell University, United States

Barium hexaferrite ($BaFe_{12}O_{19}$) is predicted to harbor a novel multiferroic phase within which frustrated antiferroelectricity and ferrimagnetism coexist. However, experimental studies have shown that in bulk barium hexaferrite, quantum fluctuations instead lead to a quantum paraelectric ground state at low temperature [1-2]. Strain is a popular method for tuning functional properties in epitaxial thin films and has previously been used to coax ferroic electric dipole order, for example in $SrTiO_3$ [3]. Similarly, recent theoretical exploration has suggested that strain may enhance antiferroelectricity in barium hexaferrite [4]. In this theoretical work, we combine first-principles calculations with quantum Monte Carlo simulations to explore the temperature- and strain-dependent properties of barium hexaferrite. We find good agreement between our model and available bulk experimental data. In the investigation of strained barium hexaferrite, we find that a modest compressive strain of approximately 1% enables the transition to a frustrated antiferroelectric phase with a critical temperature of greater than 10 K. Our results suggest that further investment in epitaxy and development of compressive substrates for hexaferrites may provide a promising route towards room temperature multiferroics.

4:00 PM EL07.02.07
Relaxor-Like Ferroelectric Behavior in Epitaxial $NaNbO_3$ Films for Capacitive Energy Storage Kevin J. Crust[1,2], Aarushi Khandelwal[2,1], Ruijuan Xu[3] and Harold Y. Hwang[2,1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]North Carolina State University, United States

Electrostatic energy storage based on dielectric capacitors has garnered significant interest due to its fast charge-discharge speeds and high power density relative to electrochemical energy storage, but applications have been limited due to large leakage currents, relatively low energy storage density, and the presence of lead in materials[1,2]. $NaNbO_3$ is a lead-free alternative which has received much research attention in the last decade but work has primarily focused on its bulk form, with $NaNbO_3$-based systems displaying both antiferroelectric and relaxor ferroelectric behaviors at room temperature with promising energy storage properties[2,3]. Using pulsed laser deposition and selective etching, we have synthesized metal-insulator-metal heterostructures of $La_{0.7}Sr_{0.3}MnO_3$ and $NaNbO_3$ with high crystalline quality and coherent epitaxial strain across a range of thicknesses. Both strain and thickness have previously been noted to greatly affect the properties of $NaNbO_3$ due to the close proximity of its antiferroelectric and ferroelectric ground states[4,5]. Through careful optimization of the growth conditions, we achieve minimal leakage current even under large external electric fields and can observe relaxor-like ferroelectric behavior in both our thinnest samples (below 50 nm of $NaNbO_3$) and our thickest samples (above 150 nm). This allows us to achieve improvements in both recoverable energy-storage density W_{rec} and energy efficiency η compared to previous $NaNbO_3$ thin films[6,7]. This work demonstrates the potential of $NaNbO_3$ for dielectric energy storage and the advantages of epitaxial, single-crystal films for electrical characterization.

***In Situ* X-Ray Nano-Imaging of Heterogeneous Structural Response in a Relaxor Ferroelectric** Aileen Luo[1,2], Tony Chiang[3], Tao Zhou[2], Ziming Shao[1], Yifei Sun[1], Benjamin Gregory[1], Martin V. Holt[2], John T. Heron[3] and Andrej Singer[1]; [1]Cornell University, United States; [2]Argonne National Laboratory, United States; [3]University of Michigan–Ann Arbor, United States

Magnetoelectric multiferroics transduce electrical and magnetic energy, which is critical for the development of new materials for sensors, motors, and computation devices. Composite heterostructures of a magnetostrictor coupled to a piezoelectric, such as the promising epitaxial FeGa on $0.7[PbMg_{1/3}Nb_{2/3}O_3]$ - $0.3[PbTiO_3]$ (PMN-PT), enable electric field control of magnetic polarization, while offering additional device utility compared to

rare single-phase multiferroics. Such systems have been studied at the micron scale, but nanoscale strain distribution changes during switching are not well characterized. We use in situ hard x-ray nanodiffraction to simultaneously measure real and reciprocal space of devices under applied DC electric field, which allows us to attribute strain and lattice rotation information at the nanoscale. By applying non-linear least squares modeling of the phase coexistence across the morphotropic phase boundary in this multiferroic heteroepitaxial system, we correlate the local strain behavior in the direction of the applied field and along the domain polarization axes. We analyze the phase distribution as a function of electrical bias and demonstrate the potential for real-time analysis in advanced microelectronics characterization.

4:30 PM EL07.02.09
Understanding Fatigue and Wake-Up in Ultra-Thin Ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ Capacitors Using Cryogenic Measurements Balreen Saini[1], Chanyoung Yoo[2], John D. Baniecki[2], Wilman Tsai[1] and Paul C. McIntyre[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The need for logic and memory devices that are smaller, faster, and more energy-efficient is constantly growing. This has intensified the demand for innovative materials capable of scaling down and aligning with current CMOS processes. A next generation memory solution is non-volatile memories that are energy efficient and can enable new computing architectures. For high performance computing systems such as quantum computing, cryogenic embedded memories are essential that would have an added benefit of eliminating thermally induced performance degradation mechanisms. One material that shows promise for nonvolatile memory applications is HfO_2-based ferroelectric materials and research in this area has surged due to potential memory applications such as 1T1C ferroelectric random-access memory (FeRAM) and ferroelectric field-effect transistors (FeFET).
The HfO_2-based ferroelectric materials exhibit an increase (wake-up) or decrease (fatigue) of the remnant polarization with switching cycles which causes major reliability issues in device applications. Mechanisms such as field-induced phase evolution, domain depinning and defect redistribution with field cycling are reported to cause the observed polarization evolution with field cycling. The thermally activated nature of the above-mentioned mechanisms may produce a significant change in polarization endurance when the measurement temperature is varied. In our present work, we explore the effect of measurement temperature on the functional properties of ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ (HZO) capacitors to further the understanding of mechanisms responsible for the observed endurance characteristics. Measurement are performed in a cryogenic probe station, which has the capability to reach extremely low temperatures as low as 10 Kelvin.
HZO capacitors of varying thickness (ranging from 4 nm to 10 nm) and with both Mo and TiN electrodes are examined. The HZO films have different crystalline phase fractions in the as-deposited (pristine) state. For HZO capacitors that exhibit electrical characteristics expected of films with majority ferroelectric orthorhombic phase (O-phase) in the pristine state, a decrease in remnant polarization and an increase in coercive voltage are observed as the measurement temperature is decreased from room temperature to 10 K. The polarization reduction is recovered by increasing the temperature back to room temperature, suggesting a strong effect of thermally activated domain wall motion at low temperatures. No fatigue during voltage cycling to switch the polarization is observed at low temperatures. On the other hand, pristine HZO capacitors with pinched polarization hysteresis (P-V) loops at room temperature and that, therefore, are expected to have majority non-ferroelectric tetragonal phase (T-phase), show negligible loop pinching and a large increase in switchable remanent polarization at cryogenic temperatures. This suggests that modulating the phase fraction in HZO films can change the temperature dependence of polarization switching and field cycling endurance. The rate of wake-up for these samples is reduced at low temperatures. Synchrotron X-ray diffraction measurements are performed to further understand the temperature dependence of functional properties of HZO capacitors and their relation to crystalline phase fraction.

4:45 PM EL07.02.10
Non-Zero Remnant Polarization of Anti-Ferroelectric $Hf_{0.1}Zr_{0.9}O_2$ revealed by First Order Reversal Curves (FORC) for Non-Volatile Memory Min-Hung Lee[1] and Z.-X. Li[2]; [1]National Taiwan University, Taiwan; [2]National Taiwan Normal University, Taiwan

The data retention is one major issue of requirements for non-volatile memory (NVM) application, i.e. non-zero remnant polarization (P_r) of Ferroelectric random-access-memory (FeRAM) application at standby (bias-free) [1][2]. Recently, antiferroelectric $HfZrO_2$ (AFE-HZO) under built-in bias of fixed charge (Q_f) and/or interface dipole by Al_2O_3 interlayer leads applicable P_r [3][4]. Furthermore, AFE-HZO exhibits intrinsic capability of high-speed response and long endurance [5]. However, the validation of bilayer of AFE and dielectric (DE) is lack for further discussion. In this work, the technique of First-Order Reversal Curve (FORC) [6][7] will be employed to reveal the built-in bias based coercive field (E_c) distribution for AFE/DE.
The FORC diagram can determine the distribution of the E_C by multiple P-E loops measurement. The FORC distribution function ρ (E_r, E) shows the concentration of E_C, and the procedure can be achieved as following. The initial field of the waveform is the saturation field (E_{sat}), sweeping from the E_{sat} to the reversal field (E_r) and then back to the E_{sat}. Then the step is repeated and E_r range is from E_{sat} reversing gradually to $-E_{sat}$. The metal/ferroelectric/metal (MFM), metal/antiferroelectric/metal (MAFM) and metal/antiferroelectric/insulator/metal (MAFIM) were prepared for FORC analysis. The MFM shows typical FE-behavior and $2P_r > 60$ mC/cm^2. For MAFM, the $2P_r$ almost zero due to polarization compensation at 0 MV/cm. For MAFIM, the "FE-like" characteristic is presented due to built-in bias. The origins of the built-in bias with Al_2O_3 are unbalance of surface energy for interface dipole and insufficient bonding for positive or negative fixed charge [8][9]. The single E_C distribution of MFM by FORC diagram indicates the typical FE behavior and it concentrates at ~1.2 MV/cm. For MAFM, there are two Ec distributions at ~ -0.5 MV/cm and 2.5 MV/cm, and this is attributed to the multi-peak of Ec for AFE. For MAFIM, the single Ec distribution is occurred at ~1.5-2 MV/cm. The FORC methodology is employed to validate the built-in bias existence and non-zero Pr for AFE/DE system.
The authors are grateful for the funding support by Ministry of Science and Technology (NSTC) 112-2218-E-A49-013-MBK, 112-2221-E-002-252-MY3, 111-2221-E-002-203-MY3, and process supported by TSRI & NFC, Taiwan.

Combining Superlattices with Co-Doping -- Toward BEoL Compatible Ferroelectric Materials with Improved Reliability at Bias and Temperature Stress David Lehninger, Ayse Sünbül, Shruthi Subramanian, Konrad Seidel and Maximilian Lederer; Fraunhofer IPMS, Germany

Interest in the concept of ferroelectric memory has been revived by the discovery of ferroelectricity in thin doped hafnium oxide films. Zirconium doped hafnium oxide (HZO) crystallizes at low temperatures (400°C and below), which makes it a compelling material for back-end of line (BEoL) implementation. Metal-ferroelectric-metal (MFM) capacitors are essential building blocks for realizing BEoL-compliant ferroelectric memory concepts. Placed in BEoL, these devices can be connected to the gate or drain contact of a standard logic device to achieve a one-transistor-one-capacitor (1T1C) ferroelectric field-effect transistor (FeMFET) or a 1T1C FeRAM, respectively. [1]

Since the discovery ferroelectricity in hafnium oxide, scientists have been working to improve key properties of these materials, including remanent polarization, endurance, retention, imprint, and wake-up. Common methods of improvement include exploring different dopants, dopant concentrations, film thicknesses, and stacking options such as interface/electrode materials and superlattices [2].

Despite significant advancements, some reliability challenges persist, such as operation under high bias and temperature stress (BTS). Especially the automotive industry's strict demands for resilience and reliability under challenging BTS conditions exacerbate the issue. Currently, the Automotive Electronic Council's quality requirements for Integrated Circuits (AEC-Q100) serve as the minimum standard for car manufacturers. Fulfilling the Grade 0 specifications, which demand stable performance within the temperature range of -40°C to 150°C, presents a major challenge for ferroelectrics with a fluorite structure.

Recently, two methods have been reported that significantly improve the stability under BTS: (1) using ferroelectric [HfO_2/ZrO_2] superlattices with relatively thick sublayer thicknesses [3], and (2) co-doping, which introduces a small amount of an additional dopant [4].
Herein, we utilize both techniques to achieve optimal reliability properties. Analytical and electrical methods were used to characterize co-doped [HfO_2/ZrO_2] superlattices with various stacking options. To gain a deeper understanding of the structural properties, X-ray diffraction (XRD) and time-of-flight secondary-ion mass spectrometry (ToF-SIMS) were conducted. Additionally, polarization versus electric field characteristics were measured to explore the electrical properties under various BTS conditions. Finally, endurance and retention characteristics under BTS conditions will be utilized to evaluate compatibility with the requirements specified by the automotive industry.

5:00 PM EL07.03.03
Tuning the Structure, Bringing The Phase Transition Temperature and Ferroelectricity Near Room Temperature in $Na_2Nb_{4-x}Ta_xO_{11}$ (x = 0,1,2,3 and 4) Bulk Material for Nanogenerator Applications Udhayakumar S[1], Sumit Khatua[2], Patro L.N[2] and Kamala Bharathi Karuppanan[1]; [1]SRM Institute of Science and Technology, India; [2]Department of Physics, SRM University AP, India

In recent times, development in health monitoring devices technology is rapidly increasing to monitor the blood pressure, body electrolyte, body temperature and breath rate due to the viral fevers especially after Covid-19. Almost all the devices are larger in size, mechanically rigid and they have longer response time. Flexible, wearable and self-powered devices such as Piezoelectric Nanogenerators (PNGs) and Triboelectric Nanogenerators (TNGs) are welcomed for the health monitoring applications [1-2]. To develop materials for low cost piezoelectric nanogenerator device applications, we made an attempt to develop a series of lead-free piezoelectric material $Na_2Nb_4O_{11}$ (x= 0 to 4) and explore their structural, ferroelectric, dielectric, electronic and piezoelectric properties. $Na_2Nb_4O_{11}$ is one of the ferroelectric materials which is not explored much due to its high phase transition temperature nearly 393 K which is paraelectric to ferroelectric transition [3]. In order to bring down the transition temperature to room temperature (RT), we have prepared a series of $Na_2Nb_{4-x}Ta_xO_{11}$ (x= 0 to 4) material using solid state reaction method and explored their structural, electrical, piezoelectric and electronic properties. X-ray diffcation (XRD) and Raman spectra analysis confirms the formation of $Na_2Nb_4O_{11}$ material in monoclinic structure with space group of C2/c. With increasing Ta concentration, the monoclinic system changes into rhombohedral system with the space group of R-3c. The boundary between monoclinic and rhombohedral change lies in between x= 0 to 0.5. HRSEM images shows that particles are spherical in shape in micron size and decreases with increasing Ta concentration. From the real part of the dielectric constant vs temperature measurements, the phase transition for pure sample is observed at 373 K and decreases to 328 K for x= 1 sample. The bandgap value of $Na_2Nb_{4-x}Ta_xO_{11}$ (x= 0 to 4) sample is seen to increase from 3.69 eV to 4.45 eV with increasing Ta concentration. The piezoelectric measurements show excellent piezo-response for the pure and Ta doped samples, which can be utilized for fabricating the nanogenerator devices. Nanogenerator devices of 1 x 2 cm are fabricated by mixing the $Na_2Nb_4O_{11}$ (x= 0 to 4) with PVDF and the piezo-response is measured using oscilloscope. Induced voltage is seen to be in the order of 500 mV to 1 V, which can be very much applicable for the health monitoring devices.

$HoFeO_3$-$BaTiO_3$ Nanofiber Heterostructure: Impressive Nanogenerator Performance Smita Chaturvedi[1,2,1], Priyank Shyam[3], Supriya Sahoo[1], Mihir Iyer[1], Shivshankar Jokare[1], Avinash S. Kumbhar[1], Boomishankar Ramamoorthy[4] and Satishchandra Ogale[2]; [1]Savitribai Phule Pune University, India; [2]IISER Pune, India; [3]Aarhus University, Denmark; [4]IISER, India

$HoFeO_3$-$BaTiO_3$ (HFO-BTO) nanofiber multiferroic heterostructure showcase fascinating properties due to the coexistence of ferroelectric and ferromagnetic ordering. The nanofiber heterostructure is synthesized by combining the ferromagnetic component $HoFeO_3$, and the ferroelectric component $BaTiO_3$ via the electrospinning technique. The heterostructure exhibits phase fraction 3:7 of orthorhombic (Pbnm) HFO: tetragonal (P4mm) BTO. The

heterostructure indicates the possibility of tunable magnetic and ferroelectric properties by tuning the phase fraction. Inclusion of HFO-BTO heterostructure into PDMS renders impressive nanogenerator performance. This trait in the heterostructure indicates that three main factors namely structure, morphology, and composition play crucial role in tuning the properties of the compound: (i) Structure: orthorhombic and tetragonal mixed phase contributes to the distortion of TiO6 octahedra in heterostructure: in-plane O–Ti–O angle sharply decreases as Ti atom shifts from inversion centre, giving rise to greater ferroelectric polarization. The increase in average Fe–O–Fe angle in heterostructure is 141° as compared to uncoupled HFO (139°), affects the Fe–O–Fe exchange coupling (ii) Morphology: the nanofiber heterostructure has (a) the interface induces strain field due to interface of BTO and HFO, and (b) the surface- induced strain field intrinsically present in nano-systems due to large aspect ratio (iii) Composition: The ferroelectric BTO and ferromagnetic HFO parent compounds are stabilised in heterostructure and exhibit enhanced magnetic and ferroelectric properties as compared to the individual parent compounds. Under the influence of electric as well as mechanical field, the response of HFO-BTO heterostructure based nanogenerator is superior in terms of polarization, output voltage, current density and power density.

5:00 PM EL07.03.05
Distortion of Inversion Symmetry in Biaxial Van der Waals Layered Oxide Leading to Negative Capacitance (NC) Effect and Intrinsic Ferroelectricity Rahul Mitra[1,2,3], Unnikrishnan Manju[2,3] and Yongxiang Li[1]; [1]RMIT, Australia; [2]CSIR-IMMT, India; [3]AcSIR, India

Piezoelectric materials find applications in a diverse array of devices, such as sensors, resonators, motors, actuators, high-resolution ultrasound devices, and microscopic filters for cellular communications. The synthesis of single-phase α-MoO_3 (MO) with a biaxial van der Waals (vdW) gap revealed orthorhombic *Pmcn* symmetry featuring a layered ABAB sequence with mirrored A and B layers. Applying a force magnitude of 0.5 N unveiled a force-driven dielectric constant of 12.5 in MO, showcasing distinctive dielectric saturation behavior. Ferroelectric investigations, conducted with a 10 kV/cm external electric field, demonstrated an efficiency peak of 46%, while the Berlincourt technique yielded a piezoelectric modulus (d_{33}) of 30 pC/N. Negative capacitance (NC) effects, correlated with inductive reactance and ferroelectric-induced emf per Lenz's law, were observed. Combining these characteristics, a piezoelectric energy harvester (PEH) was engineered, achieving a peak voltage of 4 V under repeated finger tapping. When subjected to a resistive load of 100 MΩ, the PEH exhibited a power density of 7.32 x 10^{-1} μW/cm^2. These findings position α-MoO_3 as an exceptional piezoelectric candidate in the realms of sensing and energy harvesting, contributing to the advancement of the Internet of Things (IoT) and Industry 4.0.

SESSION EL07.04: Magnetoelectrics

8:30 AM *EL07.04.01
Sensing The Antiferromagnetic State of Multiferroics Using Spin Hall Measurements Ramamoorthy Ramesh; Rice University, United States

Over the past decade the oxide community has been exploring the science of ferroic materials as crystals and in thin film form by creating epitaxial heterostructures and nanostructures. Among the large number of materials systems, there exists a small set of materials which exhibit multiple order parameters; these are known as multiferroics, particularly, the coexistence of ferroelectricity and some form of ordered magnetism (typically antiferromagnetism). The scientific community has been able to demonstrate electric field control of both antiferromagnetism and ferromagnetism at room temperature. There are some very intriguing new developments in SOT based manipulation of magnets. Particularly, the role of epitaxy and electronically perfect interfaces has been shown to significantly impact the spin-to-charge conversion (or vice versa). Current work is focused on ultralow energy (1 attoJoule/operation) electric field manipulation of magnetism with both voltage and current, as the backbone for the next generation of ultralow power electronics. We are exploring many pathways to get to this goal. In this talk, I will describe our progress to date on this exciting possibility.

9:00 AM *EL07.04.02
Polar Magnetic Metals by Design Pu Yu; Tsinghua University, China

Polar metal with a combination of conflicting polarization and metallicity attracts great research interests recently with promising functionalities. Numerous searches have been carried out particularly in complex oxides with many exciting discoveries. Inspired by the promising magnetoelectric coupling in multiferroic systems with coupled polarity and magnetism, it is of fundamental interest to introduce magnetism (remove time-reversal symmetry) into polar metals to access exotic phases that might emerge through the coupled magnetic and polar orders. The difficulty in realizing a polar magnetic metal lies in circumventing the mutually exclusive requirements of polarity and metallicity, and at the same time incorporating suitable electron correlation effects to form magnetism. In this talk, I will present our recent effort to design and explore novel complex oxides with the breaking of both spatial-inversion and time-reversal symmetries, while maintaining robust metallicity. We further demonstrate that the strong coupling between the polarity and magnetism of these metallic system produces a collection of exotic properties, including the intrinsic magnetochiral anisotropy with exotic magnetic field-free nonreciprocal electrical resistivity, and an emergent Hall effect. We envision that these materials and their derivatives will serve as a model family to probe the rich spectrum of emergent states in complex oxides.

9:30 AM *EL07.04.03
Engineering Multiferroic Garnet-Perovskite and Spinel-Perovskite Nanocomposites Caroline A. Ross; Massachusetts Institute of Technology, United States

Nanocomposite oxide thin films consist of two phases that grow epitaxially on a substrate. Of particular interest are multiferroic nanocomposites consisting of pillars of a ferrimagnetic spinel such as CoFe2O4 (CFO) within a matrix of a ferroelectric perovskite such as BiFeO3 (BFO) grown on a perovskite substrate. BFO/CFO nanocomposites exhibit magnetoelectric coupling mediated by strain transfer at the vertical interfaces. We first discuss how patterning of substrates enables control of the locations and geometry of the self-assembled pillars. In particular, we describe the fabrication, microstructure and ferroic properties of ‘sideways multilayers’ consisting of parallel fins of CFO and BFO grown on (111) and (110)-oriented substrates patterned using a focussed ion beam process, including the magnetic and ferroelectric domain structure. We then demonstrate nanocomposites made from perovskites and garnets. Iron garnets (IGs) are ferrimagnetic insulators of composition R3Fe5O12, where R is Y, Bi or a rare earth. They exhibit a range of useful magnetic properties including spin orbit torque switching, relativistic domain wall velocities of km/s, spin wave-driven domain wall motion, and magnetooptical activity. The garnet structure is incompatible with a perovskite substrate, and deposition of garnet compositions onto perovskite substrates leads to the formation of Fe-rich orthoferrites RFeO3. Instead, we use a garnet substrate patterned with a thin seed layer of a perovskite or nanosheets of perovskite-structured Ca2Nb3O10. Growth of garnet on these heterogeneous substrates produces IG over the bare garnet substrate and Fe-rich orthoferrite over the

perovskite seed, with vertical garnet/perovskite interfaces, where both phases have the same composition. The ferroic properties of these structurally-modulated films will be described, as well as their utility in magnetooptical and magnonic devices.

Schlom[1]; [1]Cornell University, United States; [2]Leibniz-Institut fur Kristallzuchtung, Germany; [3]Pennsylvania State University, United States; [4]University of North Texas, United States; [5]Rice University, United States; [6]Spelman College, United States; [7]Princeton University, United States; [8]The Pennsylvania State University, United States

Multiferroics with coupled magnetic and electric orders, although rare, hold potential for low-energy-consumption materials for logic and memory capable of electric-field control of magnetism. Barium hexaferrite ($BaFe_{12}O_{19}$), the most common refrigerator magnet, is predicted to gain electric polarization order at room temperature in addition to its robust ferrimagnetism under in-plane, biaxial, compressive strain [1]. The recent realization of single-crystal substrates of $Sr_{1.03}Ga_{10.81}Mg_{0.58}Zr_{0.58}O_{19}$ (SGMZ) [2], an insulator that is isostructural to $BaFe_{12}O_{19}$, enables straining $BaFe_{12}O_{19}$ as SGMZ has a ~1.1% smaller in-plane lattice constant. In addition to strain, to induce the ferroelectric state, an epitaxial bottom electrode is needed to control the electric state for this hexaferrite multiferroic candidate. $SrCo_2Ru_4O_{11}$ is a metallic ferromagnetic oxide [3], belongs to the same hexaferrite family as $BaFe_{12}O_{19}$, and has small (~0.3%) in-plane lattice mismatch to the SGMZ substrate. Consequently, a coherent $SrCo_2Ru_4O_{11}$ epitaxial thin film on the SGMZ substrate would be ideal for straining $BaFe_{12}O_{19}$ and serving as the bottom electrode of a metal-insulator-metal structure to test for ferroelectricity in this predicted strain-induced multiferroic.

Here we show that a 1.1% in-plane biaxial compressive strain from SGMZ substrates can be imposed on up to 27.5 nm thick $BaFe_{12}O_{19}$ films. The full width at half maximum (FWHM) of the X-ray diffraction rocking curve of the 00$\underline{20}$ peak in w ranges from 0.006° to 0.009°, the smallest ever reported. Scanning transmission electron microscopy (STEM) multislice ptychography results on a commensurately strained film clearly show local electric polarization arising from the off-center displacement of Fe^{3+} ions in the trigonal bipyramid sites, locally breaking the mirror-plane symmetry perpendicular to the c-axis of $BaFe_{12}O_{19}$. Second harmonic generation (SHG) proves the symmetry breaking on a larger scale from 6/*mmm* (bulk paraelectric $BaFe_{12}O_{19}$) to 6*mm* (fully strained $BaFe_{12}O_{19}$). Commensurately strained $BaFe_{12}O_{19}$ containing 95% enriched Fe^{57} has been synthesized. Mössbauer measurement will be made on this sample to quantify the splitting between the two sites of the iron cations in the trigonal bipyramid sites.

Films of $SrCo_2Ru_4O_{11}$ were grown by MBE on (0001) SGMZ substrates in an adsorption-controlled regime. With matching substrates and adsorption-controlled growth, we have grown epitaxial, fully strained $SrCo_2Ru_4O_{11}$ thin films with even lower resistivity than $SrCo_2Ru_4O_{11}$ single crystals [3]. Our next step is to grow a commensurately strained metal-insulator-metal $BaFe_{12}O_{19}/SrCo_2Ru_4O_{11}$/SGMZ stack to test for ferroelectricity.

10:45 AM EL07.04.05
Manipulation of Isolated Spins in Ferroelectric Oxides from First Principles Elizabeth Nowadnick[1], Bradford Barker[1], Nabaraj Pokhrel[1], Md Kamal Hossain[1], Katherine Inzani[2,3] and Sinead M. Griffin[3]; [1]University of California, Merced, United States; [2]The University of Nottingham, United Kingdom; [3]Lawrence Berkeley National Laboratory, United States

Electric field control of single spins can probe the fundamental atomic-scale limits of multiferroic behavior. One possible platform to explore this scenario is to form isolated spin centers in ferroelectric materials via inclusion of dilute concentrations of magnetic dopants. The preferred orientation of a spin is connected to its local crystallographic environment via the spin-orbit interaction, and is described by the magnetocrystalline anisotropy energy (MCAE). In a ferroelectric material, the local crystallographic environment can be modified by structural changes that occur during polarization switching under applied electric fields, which provides a path towards electric field control of the MCAE and a magnetic dopant's spin directionality. Although the diverse properties and functionalities of ferroic complex oxides have been the subject of extensive research over the past decades, they have so far received little attention as potential platforms for electric field-based single spin processing, which is of central interest to several modern technological applications. In this work, we combine group theoretic analysis with density functional theory calculations to explore two examples of tuning the spin orientation of isolated magnetic dopant atoms in ferroelectric oxide hosts. We first consider an isolated Fe^{3+} dopant in the tetragonal, orthorhombic, and rhombohedral phases of the prototypical ferroelectric oxide $BaTiO_3$. We investigate how the MCAE and preferred Fe^{3+} spin orientation evolves as the material traverses these structural phases of different crystalline symmetries, linking these changes to evolution in the electronic structure. Second, we explore an isolated Fe^{3+} dopant in the low-dimensional Aurivillius ferroelectric Bi_2WO_6, tracking how the MCAE and the preferred spin orientation evolve throughout ferroelectric switching. We find that the Fe^{3+} spin aligns along a spin-easy axis in Bi_2WO_6 and that a 90° switch of the polarization direction leads to a 112° reorientation of this spin-easy axis. This work advances our understanding of electric field control of single spins, which has potential implications in the fields of spintronics and quantum computing.

11:00 AM *EL07.04.07
Designed Magnetic Texture for Spin Transport in a Multiferroic Oxide Peter Meisenheimer[1], Maya Ramesh[2], Sajid Husain[3,1], Isaac Harris[1,3], Shiyu Zhou[4], Lucas M. Caretta[4], Darrell G. Schlom[2], Paul Stevenson[5], Zhi Yao[3] and Ramamoorthy Ramesh[6]; [1]University of California, Berkeley, United States; [2]Cornell University, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Brown University, United States; [5]Northeastern University, United States; [6]Rice University, United States

Antiferromagnetic-based spintronics are growing in popularity for potential applications in next-generation computational technologies due to their speeds and robustness to external fields. A key challenge in this area, however, is the control of antiferromagnetic order on the nanometer scales applicable to solid-state technologies. Bismuth ferrite ($BiFeO_3$) is a multiferroic material that exhibits both ferroelectric and antiferromagnetic properties at room temperature, making it a unique candidate in the development of electrically controllable magnetic devices. In $BiFeO_3$, the magnetic moments are arranged into a long-range spin cycloid, resulting in a unique set of magnetic properties that are intimately tied to the ferroelectric order. To date, however, understanding of this coupling between magnetism and ferroelectricity has generally relied on average, mesoscale measurements to infer the magnetic structure and behavior.

Using high-resolution nitrogen vacancy (NV) diamond-based scanning probe magnetometry, we show that this spin cycloid can be deterministically controlled with an electric field. The underlying energy landscape of the spin texture is shaped by both the ferroelectric degree of freedom and strain-

induced anisotropy, where electric fields drive magnetoelectric switching in predictable ways that can be engineered. Through precise control of the crystal structure using thin film techniques, the magnetic structure of $BiFeO_3$ can be tuned to control magnon transport in the material, opening the door for efficient, electrically controllable magnonic devices.

11:30 AM EL07.04.08
From Magnetostrictive Composites to Precision Magnetoelectric Field Sensing Lukas Zimoch, Stefan Schroeder, Eric Elzenheimer, Soeren Kaps, Thomas Strunskus, Franz Faupel, Michael Hoeft, Gerhard Schmidt and Rainer Adelung; University of Kiel, Germany

The demand for magnetic field sensors is rapidly increasing due to various factors, including the requirements for navigation, orientation, and motion tracking systems, as well as their growing utilization in the automotive sector and notably in biomedical applications. There are two magnetoelectric (ME) sensors discussed in this context. The first employs a magnetostrictive polymer composite (MPC) as its magnetosensitive material, which consists of ferromagnetic particles embedded within a soft polymer matrix. This capacitive sensor, featuring an electret [1], is specifically well suited for biomedical applications due to its low resonance frequency, typically around 100 Hz. To evaluate the sensor's performance, three measurements were conducted. Subsequently, a DC magnetic bias field measurement was carried out to identify the optimal operating point. In the final measurement, the sensor operated at its resonance frequency with the optimal bias field. In each measurement, the amplitude of the resonance frequency was systematically reduced to determine the minimum field the sensor can reliably detect. The resonance frequency is in the range of 50-150 Hz, largely influenced by the MPC's geometry. The sensor requires a bias field of several mT. Furthermore, these measurements confirmed that no remagnetization occurs within the sensor during the bias sweep. Even without optimization, the sensor displayed linear behavior across four orders of magnitude. The magnetic characterization of the sensor revealed that it fundamentally operates as intended, with its magnetic properties remaining stable when exposed to magnetic fields. The sensor could provide valuable insights into the common challenge faced by all magnetic field sensors, which is noise. The mechanical characteristics of the sensor are derived from the polymer matrix, while the magnetic properties are predominantly determined by the particles. Both components can be independently adjusted or altered, allowing an investigation of the individual noise components. To understand all the mechanics of the sensor a second simplified approach was adopted.
The second sensor is the most elementary version of the first sensor, where only two macroscopic ferromagnets are used emulating two particles in the composite, to understand the underlying mechanisms of the MPC. One of these magnets is mounted to a silicon cantilever, while the other remains fixed beneath it. The magnets oppose each other. When an external magnetic field is applied, superposition takes place, and the cantilever starts to oscillate. On the top part of the cantilever a piezoelectric AlN thinfilm is placed between two electrode layers. The mechanical stress of the oscillation is transduced into an electrical voltage and generates a signal proportional to the applied magnetic field. In this composition magnetic noise amplitude densities as low as 47 $pT/\sqrt{Hz}$ have been measured [2]. It is possible to measure within the earth's magnetic field without sacrificing any performance. The sensor shows a sensitivity of 2170 V/T and doubles as an energy harvester. Without any optimization it was possible to generate 1.31 $\mu W/cm^3Oe^2$ with a magnetic AC field of 20 µT in resonance.

11:45 AM EL07.04.09
Impressive Nanogenerator Application Using Nanoscale $LuFeO_3$: Role of Structure and Morphology Smita Chaturvedi[1,2], Priyank Shyam[3], Sachin Kumar Singh[4], Avinash S. Kumbhar[1], Gopalan Srinivasan[5] and Satishchandra Ogale[2,6]; [1]Savitribai Phule Pune University, India; [2]IISER Pune, India; [3]Aarhus University, Denmark; [4]Delhi University, India; [5]Oakland University, United States; [6]TCG CREST, India

In the domain of multiferroicity, Lutetium orthoferrite ($LuFeO_3$) represents a potentially interesting material owing to the fact that it exhibits orthorhombic (o) and hexagonal (h) structures, which significantly differ in terms of lattice symmetry and the symmetry of the surroundings of the individual cations. This difference in structural symmetry contributes to unusual changes in physical properties. In o-LFO canting of Fe moments towards c direction gives rise to weak ferromagnetism below Néel Temperature (620 K), while, ferroelectricity is unexpected due to symmetry of lattice. On the other hand, weak ferromagnetism is not allowed in h-LFO unless the moments are along the 'a' axis. Present work is intended to realize the co-existence of o-LFO and h-LFO to achieve ferroelectricity and ferromagnetism simultaneously in a single nanostructure of two different morphologies i.e. nanoparticles and nanofibers. In multiferroic $LuFeO_3$ the hexagonal (-h) phase is an intermediate metastable phase encountered during the amorphous to orthorhombic (-o) transformation and is ferroelectric in nature. So far h-phase has only been stabilized in a substrate-supported layered ultrathin film form. Herein we show that the surface-induced strain field intrinsically present in nano-systems can self-stabilize this phase and the hexagonal to orthorhombic phase constitution ratio depends on the shape of the nanomaterial. Thus, nanofibers (nanoparticles) strain-stabilize the o : h ratio of about 23 : 77 (75 : 25). The inclusion of nano-$LuFeO_3$ into PDMS renders impressive nanogenerator performance, consistent with the ferroelectric phase content. This trait in the biphasic $LuFeO_3$ is attributed to: (i) Structure: Orthorhombic and hexagonal mixed phase: wherein the lattice dynamics change with temperature (both in case of nanoparticles and nanofibers), (ii) Morphology: (nanoparticles and nanofibers): wherein the dynamics of interparticle interactions would differ for nanoparticles and nanofibers.

Strain Manipulation of Ferroelectricity and Flexoelectricity in Freestanding Membranes Harold Y. Hwang[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The ability to create and manipulate materials in two-dimensional (2D) form has repeatedly had transformative impact on science and technology. We have developed a general method to create freestanding complex oxide membranes and heterostructures using epitaxial water-soluble buffer layers, with millimeter-scale lateral dimensions and nanometer-scale thickness. This facilitates many new opportunities; here we will focus on the use of membrane dimensions, tensile strain, and strain gradients to control the ferroelectric and flexoelectric response of oxide membranes.

2:00 PM *EL07.05.02
Synthesis and Properties of Single Domain $BiFeO_3$ Thin Films and Free-Standing Membranes Chang-Beom Eom and Pratap Pal; University of Wisconsin--Madison, United States

$BiFeO_3$ (BFO) is positioned for success as a magnetoelectric material system, but its optimum usage in faster and more energy-efficient magneto-logic devices require advances. Most importantly, a ferroelastic and antiferromagnetic monodomain state with single-step deterministic switching is desirable for reliable low-power magnetoelectric devices with reproducibility and scaling using $BiFeO_3$. This would allow deterministic and robust control of both the internal magnetoelectric coupling in $BiFeO_3$ and the exchange coupling of its antiferromagnetic order to a ferromagnetic overlayer.

We have fabricated epitaxial (001) and (111) BFO thin films with both ferroelectric and antiferromagnetic monodomain states. Additionally, we have fabricated freestanding membranes of ferroelastic and ferroelectric monodomain $BiFeO_3$ using an $Sr_2CaAl_2O_6$ (SCAO) sacrificial layer. The membranes exhibit deterministic switching over a hundred thousand electric field cycles with lower voltage and faster switching dynamics than their thin-film counterpart. This progress is promising toward energy-efficient magnetoelectric memory devices. We will discuss additional multiferroic applications of these BFO membranes.

This work has been done in collaboration with J. L. Schad, K. J. Lee, Y. Yao, A. M. Vibhakar, R. D. Johnson, P. G. Radaelli M.S. Rzchowski and C.B. Eom.

Anomalous Hall Effect and Topological Hall Effect in $NiCo_2O_4$ Thin Films and Free-Standing Membranes Xia Hong; University of Nebraska-Lincoln, United States

The inverse spinel ferrimagnetic $NiCo_2O_4$ possesses high Curie temperature and high spin polarization, making it a promising material candidate for spintronic applications. The magnetic state of $NiCo_2O_4$ films depends sensitively on the strain and disorder effects, which can lead to unconventional spin transport. In this talk, I will discuss our recent studies of the magnetotransport anomalies in epitaxial $NiCo_2O_4$ thin films and free-standing $NiCo_2O_4$ membranes, including linear magnetoresistance, anomalous Hall effect (AHE), and topological Hall effect (THE). $NiCo_2O_4$ films deposited on (001) $MgAl_2O_4$ substrates exhibit strong perpendicular magnetic anisotropy down to 1.2 nm (1.5 unit cell) thickness, while the (110) films possess in-plane magnetic anisotropy. Films with high crystallinity show quasi-linear magnetoresistance in magnetic fields up to 17 T with weak temperature dependence. The AHE exhibits a nonmonotonic temperature dependence and sign reversal driven by both temperature and film thickness, revealing the intricate interplay between the impurity spin scattering, band intrinsic Berry curvature, and correlation effect. THE has been observed in (110) $NiCo_2O_4$ films and (001) $NiCo_2O_4$ membranes at low temperatures. The former has been correlated with magnetic bubble domain formation, as revealed via magnetic force microscopy, suggesting the emergence of bimeron spin textures. The latter can be sensitively tuned by magnetic field cooling. Our study provides effective material strategies for designing spin transport in $NiCo_2O_4$ via strain and disorder, paving the path for its technological implementation.
This work was primarily supported by NSF through Grant No. DMR-1710461 and EPSCoR EQUATE Award No. OIA-2044049.

4:00 PM *EL07.05.05
Atomic Scale imaging of Topotactic Phase Transitions in Freestanding Strontium Cobaltite Membranes Seung Sae Hong[1], Hudson Shih[1], Rohan Dhall[2] and Yayoi Takamura[1]; [1]University of California, Davis, United States; [2]Lawrence Berkeley National Laboratory, United States

Topotactic phase transitions (TPTs) are structural phase changes that involve the significant loss or gain of oxygen atoms while preserving the crystalline framework of the lattice. In perovskite oxides, TPTs have recently emerged as innovative pathways for designing complex oxide materials. These transitions induce dramatic alterations in metal oxidation states and atomic coordination, enabling a wide range of electromagnetic ground states, from magnetic ordering to unconventional superconductivity. Moreover, the reversible nature of TPTs holds promising implications for practical applications such as neuromorphic computing devices, garnering significant attention in both fundamental physics and device applications.

Despite the growing research interest in TPTs in recent years, the microscopic details of these transitions, encompassing both structural changes and ionic transport, remain largely unexplored. This is partly due to the constraints imposed by the thin film heterostructure geometry, which limits our ability to directly visualize the transition through conventional means. In this report, we present recent advancements in freestanding oxide membranes that enable the local nature of TPTs to be visualized using electron microscopy. As a model system to comprehend the local structure of TPTs, we examined strontium cobaltite ($SrCoO_{3-\delta}$), which can transition between a ferromagnetic metal (perovskite) and an antiferromagnetic insulator (brownmillerite). Transmission electron microscopy studies of $SrCoO_{3-\delta}$ membranes unveiled the formation of anisotropic domains in the midst of the transition. Furthermore, atomic-scale images revealed the intricate nature of strains and crystallographic symmetries that dictate the domain patterns. Freestanding oxide membranes offer an ideal platform for in-situ and in-operando studies of TPTs, providing insights into the predictable design of switching phenomena in oxide materials.

4:30 PM EL07.05.06
Intrinsic Properties of Ferroic Materials Independent of Substrate Effects Varun Harbola, Yu-Jung Wu, Felix Hensling, Hongguang Wang, Peter A. van Aken and Jochen Mannhart; Max Planck Institute for Solid State Research, Germany

Substrates are essential in thin-film deposition, yet they do not always meet the specific requirements of a given experiment or application and, in some cases, may even hinder in intrinsic measurements of epitaxial thin films. For example, $SrTiO_3$, one of the most widely used substrates, goes through an

antiferrodistortive transition at 105 K which can lead to substrate artefacts extrinsic to the thin film properties grown atop the substrate. However, the bulk of the substrate in its single crystal form is not required to support epitaxy, as only the top few unit cells near the surface define the epitaxial template for thin film growth. We introduce the novel concept of "vector substrates" where the template layer for epitaxy can be chosen independently of the bulk of the substrate. Thus, by choosing the right combination of a bulk carrier substrate and the template layer, we can reduce, if not eliminate artefacts resulting from the behaviour of the bulk substrate. The fabrication of vector substrates leverages thin-film membrane technology by growing a template layer on a parent substrate and then transferring it onto a carrier substrate, thereby generating the vector substrate. By comparing the magnetism of $La_{0.67}Sr_{0.33}MnO_3$ grown on a conventional $SrTiO_3$ substrate and a $SrTiO_3$-on-sapphire vector substrate, we show that we can indeed eliminate the extrinsic antiferrodistortive artefact on a vector substrate. Therefore, the concept of vector substrates can provide a platform to measure ferroic thin films and the characteristics independent of substrate effects.

Fabrication of Hybrid Particles with Dual-Functionality for EMI Shielding and Heat Dissipation Yeonju Park, HyeRyeong Oh, Hyeongkeun Kim and MyongJae Yoo; Korea Electronics Technology Institute, Korea (the Republic of)

Semiconductor packaging technology and industry are developing toward higher performance, higher integration, thinner thickness, and miniaturization. Consequently, there is a problem in that the amount of heat generated from the device increases and electromagnetic interference (EMI) occurs inside the PIM semiconductor. Therefore, packaging requires both high heat dissipation and EMI shielding performance.
In this study, an insulating and heat dissipating thin film was deposited on the surface of the magnetic particles. The deposited thin film composition was analyzed through elemental analysis. The insulating properties of the fabricated particle were measured and it was confirmed that the resistance increased. Heat dissipation properties and EMI shielding properties of the fabricated particles were measured by manufacturing composite film. Our results achieved 13% increased thermal conductivity properties compared to films manufactured using pristine particles. EMI shielding characteristics were measured in the Ka band (26.5-30 GHz), and reflection and absorption performance were calculated and analyzed.

Magnetic Entropy Changes in Rare-Earth Tetraborides (RB_4, R = Dy, Ho, and Tm) Beongki Cho[1] and Songhee Han[2]; [1]GIST, Korea (the Republic of); [2]Mokpo National Maritime University, Korea (the Republic of)

The RB_4 (R = Gd, Tb, Dy, Ho, and Tm) compound presents an intriguing system with simultaneous magnetic ordering and geometrical frustration, leading to a strong interaction within the matarial. The interaction manifests in consecutive magnetic transitions at temperatures $T = T_{N1}$ and T_{N2} (where $T_{N1} > T_{N2}$) and results in a highly anisotropic magnetic configuration when in an ordered state. In this study, we systematically investigate the anisotropic entropy chnage (ΔS_{AN}) of single crystals of RB_4 (R = Dy, Ho, and Tm). Our findings reveal distinct behavior: the negative entropy change above T_{N1} follows conventional field-dependence, while a positive entropy change below T_{N1} follows anomalous field-dependence. Notably, ErB_4 (T_{N1} = 15.5 K) and TmB_4 (T_{N1} = 11.7 K) demonstrate $I\Delta S_{AN}I$ values of ≈ 11.6 J/(K kg) and 10.2 J/(K kg), respectively, at $T > T_{N1}$ and for H = 50 kOe, accompanied by relative cooling power (RCP) values of ≈ 237.1 J/kg and 225.9 J/kg. Interestingly, DyB_4 (T_{N1} = 20.5 K) exchibits a significant $I\Delta S_{AN}I$ value of 18.8 J/(K kg) near $T = T_{N2}$ (= 13.0 K) and an RCP value of ≈ 208.39 J/kg for H = 50 kOe. These $I\Delta S_{AN}I$ and RCP values demonstrate the potential of these comounds for applications in refrigeration using rotational magnetocaloric effect (RMCE). Additionally, HoB_4, ErB_4 and TmB_4 exchibit also promising behavior for RMCE even at temperatures of $T < T_{N1}$ and particularly during low-field cooling (H < 50 kOe). This work highlights the suitability of RB_4 compounds as effective materials for RMCE cooling, covering a broad temperature range above and below the antiferromagnetic Néel temperature. Specifically, the anisotropic entropy change observed in DyB_4 near $T= T_{N2}$ holds considerable potential for RMCE applications, such as hydrogen liquefaction due to its occurrence which a limited temperture range, accompanied by large $I\Delta S_{AN}I$ and RCP values.

5:00 PM EL07.06.03

Tuning of Orientation and Magnetic Properties of Ferromagnetic Aerogels produced through a Magnetic-Field Assisted Synthesis Rosemary L. Calabro[1,2], Alexander D. Ciampa[1], Edward Tang[1], Kennedy V. Munz[1], Olivia S. Raykhman[1], Malina O. Hatton[1], Zachary T. Bone[1], Felita W. Zhang[1], Kelsey M. Healy[1], Peter H. Chapman[1], Stephen F. Bartolucci[2], Joshua A. Maurer[2] and John Burpo[1]; [1]United States Military Academy, United States; [2]U.S. Army DEVCOM Armaments Center, United States

Ferromagnetic aerogels possess many desirable properties such as low densities, high porosities and surface areas, and interesting magnetic properties which allow opportunities in a wide range of applications including sensing, energy storage, switches, theranostics, catalysis, and many others. In a majority of these applications, the aerogels consist of some type of host material such as silica or a polymer that is doped with a ferromagnetic nanomaterial. However, ferromagnetic aerogels that consist only of the magnetic material without a host are highly desirable because they allow higher magnetizations per unit mass, better exposed surfaces, and simpler structures. We have prepared magnetic nanowire aerogels using a magnetic-field assisted synthesis which allows formation of magnetic nanowire aerogels in a fast, simple, and scalable manner. In a typical synthesis, a metal salt such as iron or cobalt chloride was placed inside a magnetic field, and sodium borohydride was added dropwise as a reducing agent. This resulted in rapid formation of gels that could then be supercritically dried into aerogels or conformed into thin films depending on the desired application. The applied magnetic field strength was varied from 0 mT to 150 mT and had impact on the nanowire aspect ratios and orientation, the magnetization and coercivities of the aerogels, the mechanical properties, and the observed surface areas and porosities. Typically, low applied field strengths showed low ordering and small aspect ratios while higher applied fields increased the orientation and aspect ratios of the nanowires. Bimetallic iron-nickel aerogels were also prepared and the influence of the metal counterion was studied. The counterion not only impacted the rate of the reaction, but also the shape of the nanostructures within the formed aerogels. The iron-to-nickel ratio also influenced the nanowire length and magnetic properties. The magnetic field assisted synthesis strategy allowed rapid formation of template free ferromagnetic aerogels and can be expanded to achieve a wide range of bimetallic materials.

5:00 PM EL07.06.04
Engineering Reliability and Crystallographic Orientation by Al Doping of Ferroelectric Hafnium-Zirconium Oxide Ayse Sünbül[1], David Lehninger[1], Konrad Seidel[1], Lukas Eng[2] and Maximilian Lederer[1]; [1]Fraunhofer IPMS, Germany; [2]Institute of Applied Physics, Technical University Dresden, Germany

Due to its scalability and CMOS compatibility, ferroelectric hafnium oxide (HfO_2) has attracted attention since its discovery in 2011 [1, 2]. Many elements can be used as dopant [3, 4] to stabilize the ferroelectric (FE) orthorhombic phase of HfO_2. Especially Zr doping of HfO_2 (HZO) has some advantages for back-end-of-line (BEoL) integration, due to its low crystallization temperature [5].
FE materials can be used in memories such as ferroelectric field-effect transistors (FeFETs) that are non-volatile and applicable in low-power systems. Good endurance and retention, high remanent polarization, and high-temperature resilience are required for embedded FE memories and the automotive industry requires high-temperature operation (up to 150 °C specifications given by the Automotive Electronics Council) which is not fulfilled by current HZO devices.
Al can be co-doped into HZO (HZAO) to overcome the reliability challenges of HZO such as high-temperature, high-bias operation, endurance, and imprint limitations [6]. In this study, different Al concentrations (up to 3 at. % Al) were doped into HZO and various crystallization annealing conditions (400 °C, 650 °C, and 800 °C) were investigated.
Increasing Al concentration and increasing annealing temperature in HZAO resulted in more antiferroelectric-like behavior. Additionally, endurance at high temperatures (up to 150 °C) and high-bias conditions (up to 5 MV/cm applied electric fields) were drastically improved in HZAO compared to HZO. A correlation between crystallographic phases and electrical results (coercive field E_c and remanent polarization P_r) was made. The ratio of (111)/(002) diffraction peak intensities increases with lower Al concentrations. Increase in P_r and E_c is observed with increasing ratio of (111)/(002) diffraction peak intensities. Consequently, this work will discuss the tuning of electrical properties (such as P_r, E_c, and endurance) depending on application requirements by controlling anneal conditions and Al doping concentration. It will investigate the impacts of Al concentration and anneal conditions on reliability aspects such as enhanced endurance, reduced leakage and high temperature resilience.

Deep UV Photo Emission Electron Microscopy to Spatially Probe Work Function in Oxygen Vacancy Reduced $Hf_xZr_{(1-x)}O_2$ Fernando J. Vega Amaya[1], Alex M. Boehm[2], Andrew R. Kim[2], Samantha Jaszewski[2], Jon F. Ihlefeld[3], Taisuke Ohta[2] and Thomas Beechem[1]; [1]Purdue University, United States; [2]Sandia National Laboratories, United States; [3]University of Virginia, United States

Oxygen vacancies are known to both stabilize the ferroelectric orthorhombic phase of $Hf_xZr_{(1-x)}O_2$ (HZO) and promote leakage pathways limiting endurance of devices based on this material. For this reason, the energy states of oxygen vacancies were investigated using photoemission electron microscopy (PEEM) as their concentration was varied via laser exposure. Following a controlled oxygen vacancy (V_O) reduction via incremental and areal laser dosing on HZO, 213nm deep-ultraviolet (DUV) photoemission electron microscopy (PEEM) was used to spatially probe the resulting modification in work function. Work function was found to increase monotonically with the laser-induced reduction in oxygen vacancy concentration culminating in a total increase near 70 meV. The change implies a Fermi-level shift toward the valence band as the total available charge states are reduced as oxygen vacancies are removed. A reduction in charge states is also supported by the observed reduction in photo emission yield after laser dosing. Beyond the quantitative change, the smooth monotonic change in work-function and photoemission yield suggest the presence of a “defect band” that forms in HZO due to the presence of vacancies rather than a single discrete state.

5:00 PM EL07.06.06
$La_{1-x}Sr_xCoO_3$ Perovskite: Antimicrobial Properties and PVDF Based Piezoelectric Nanogenerator Through Self-Induced Polling and Sensory Application S M Anyet Ullah Shohag, Luke Franco, Adhira Tippur, Ahmed Touhami, Swati Mohan and Jasim Uddin; The University of Texas Rio Grande Valley, United States

Global demand of sustainable and efficient energy sources continues to rise of research of novel materials and their application in energy harvesting. Sr^{2+} doped Lanthanum Cobaltite ($La_{1-x}Sr_xCoO_3$) perovskite stands out as a promising candidate due to its unique properties and versatility as piezoelectric material as well as in antimicrobial properties. Piezoelectric Nanogenerators (PENGs), which can produce electrical energy from mechanical energy via ferroelectric effect, are one of the ambient sources of green energy. PENGs have gathered a huge attention due to cost-effectiveness, mechanical stability, and easy installation process. In this work,1synthesized$^+$ doped Lanthanum Cobaltite ($La_{1-x}Sr_xCoO_3$) perovskite, a ferroelectric material, was synthesizes by sol-gel- molten-salt process and then characterized by X-ray diffraction, and scanning electron microscopy ensures the uniform morphology of nanoparticles. Further poly (vinylidene difluoride) (PVDF), N,N-dimethylformamide and acetone solution were used to make a flexible composite film using $La_{1-x}Sr_xCoO_3$ nanoparticles by spin coating, self-induced polling process and curing. Fourier transform infrared spectroscopy (FTIR) investigation ensures that self-induced polling process was effective to identify the structural β phase. PVDF/ $La_{1-x}Sr_xCoO_3$ composite film is then placed in between two copper sheets to fabricate the piezoelectric nanogenerator. The 7.5wt% PENG demonstrates the open-circuit voltage of 2.5V. The peak-to-peak voltage and peak to peak current values were also reported for all different weights, frequencies, and doping range. Finally, the PENG was used as a smart weight sensor and motion sensor to operate low-power electronic devices. Beside this we also observed antimicrobial properties of $La_{1-x}Sr_xCoO_3$ nanoparticles by the Kirby Bauer testing method, our synthesized $La_{1-x}Sr_xCoO_3$ nanoparticles showed much better activity against *Escherichia coli* and two other Bacillus species as well. This work explores $La_{1-x}Sr_xCoO_3$ nanoparticles potential as antimicrobial properties and piezoelectric nanogenerator for mechanical energy harvesting, contributing to greener and more sustainable energy solutions.

Wake-up, Retention and Fatigue in Wurtzite Ferroelectric Films Susan E. Trolier-McKinstry; The Pennsylvania State University, United States

Ferroelectric wurtzite films typically show large polarizations of 70 – 140 μC/cm^2, coupled with coercive fields of 2 – 6 MV/cm. These films are appealing for non-volatile memory elements in ferroelectric random access memories, ferroelectric tunnel junctions, and ferroelectric diodes. It has been found that $Al_{0.93}B_{0.07}N$ and $Zn_{1-x}Mg_xO$ thin films often undergo a wakeup process associated with development of mobile interfaces on bipolar cycling. The number of cycles required for wakeup is a strong function of the switching frequency and field, with more cyles required for wakeup as the excitation frequency increases. The activation energies for wake-up typically exceed those for the activation energy for the coercive field of a fully woken-up sample. Both types of films showed excellent retention of the stored polarization state. For example, in opposite state (OS) measurements even after 3.6×10^6 sec (1000 hr.) at 200°C, the OS signal margin still exceeded 200 μC/cm^2 in $Al_{0.93}B_{0.07}N$. The predicted OS retention is 82% after 10 years baking at 200ºC. $Zn_{1-x}Mg_xO$ is even more robust in opposite state retention. A key challenge is to increase the cycle lifetime by prevention of premature dielectric breakdown events.

8:45 AM EL07.07.01
Multilayered Thin Film Ferroelectric Wurtzites Robert J. Spurling[1], Chloe Skidmore[1], John Hayden[1], Josh Nordlander[1], Joseph Casamento[1,2], Kyle Kelley[3] and Jon-Paul Maria[1]; [1]The Pennsylvania State University, United States; [2]Massachusetts Institute of Technology, United States; [3]Oak Ridge National Laboratory, United States

We report on observations of ferroelectric switching in multilayered sputtered thin films based on wurtzite $Zn_{1-x}Mg_xO$ and $Al_{1-x}B_xN$. Ferroelectric switching is achieved in thin film stacks containing ferroelectric and polar non-ferroelectric layers. Total polarizations indicate switching is achieved across the entire film stacks, suggesting propagation of ferroelectric domains across interfaces between layers. We investigate switching pathways and wake-up behavior in these films as characterized through an array of structural and property measurement techniques. We also discuss synthesis controls in $Zn_{1-x}Mg_xO$ sputtered thin films, with an emphasis on connections between structure and electrical properties. We focus on the effect of oxygen chemical potential and temperature on film microstructure and resistivity.

9:00 AM EL07.07.03
Developing Phase Field Models for The Physical Vapor Deposition of Ferroic Doped AlN John Wellington-Johnson[1], Roxanne Ware[1], Remi Dingreville[2] and Lauren M. Garten[1]; [1]Georgia Institute of Technology, United States; [2]Center for Integrated Nanotechnologies, United States

While unique functionalities, such as ferroelectricity and ferromagnetism, have been observed in transition metal doped AlN thin films, the addition of these dopants can negatively impact the films crystalline quality. Avoiding phase segregation, surface faceting, or crystallite missorientation are critical to ensure that the full ferroic potential of these materials can be reached. Further insight into the microstructural evolution of AlN in the presence of transition metal dopants is necessary to understand the impact of these dopants on film growth and ferroelectricity.
In this work, phase field models are developed for physical vapor deposition, microstructural development, and ferroelectric response of transition metal doped AlN thin films. These models are then compared to doped AlN thin films grown by pulsed laser deposition (PLD) and sputtering. Doped AlN thin films were deposited onto platinized silicon substrates via ultra-high-vacuum PLD, RF or DC sputtering. The substrate growth temperatures ranged from 200 °C to 800 °C with an incident laser energy from 100 to 300 mJ and a laser repetition rate of 10 Hz for PLD growth. Increasing the growth temperature decreases the full width, half maximum of the predominant (002) X-ray diffraction peaks, indicating an increase in orientation which is corroborated by the model. Atomic force microscopy and scanning electron microscopy show the evolution of the surface morphology and microstructure with changing processing conditions. Increased surface faceting is observed with increased dopant concentration and segregation as determined by X-ray photoelectron spectroscopy (XPS). There is also a clear correlation between the deposition conditions and the ferroelectric response, with increased electrical breakdown for DC sputtered films compared to RF sputtering and pulsed laser deposition. Overall, these results illustrate that the ferroelectric properties highly sensitive to the growth conditions and resulting microstructure.

9:15 AM EL07.07.04
Impact of Electrodes and Interfaces in Ferroelectric Switching of Sub-100nm $Al_{1-x}Sc_xN$ Vamshi Kiran Gogi[1], Christopher Chae[2], Jinwoo Hwang[2] and Rashmi Jha[1]; [1]University of Cincinnati, United States; [2]The Ohio State University, United States

Ferroelectric materials have garnered huge research interest in the last 50+ years as these materials possess a variety of interactions between electrical, mechanical, and thermal properties that can enable multiple functionalities. The reports of ferroelectric behavior in Aluminum Scandium Nitride ($Al_{1-x}Sc_xN$) has widened the potential use of ferroelectric functionality in microelectronics beyond HfO_x based ferroelectrics. Particularly, Ferroelectric Field Effect Transistor (FeFET) is a compelling application of these materials that can enable novel logic and memory devices. However, most studies have reported Ferroelectricity in thick AlScN films and more work is needed to understand their behaviour in sub-100 nanometer thickness regime. Additionally, role of electrodes and interfacial layers when AlScN is integrated in FeFETs is not well-known. This work reports the role of electrodes in Ferroelectric Switching of sub -100 nm $Al_{1-x}Sc_xN$ ($x\approx22\%$) films. Sub-100nm $Al_{0.78}Sc_{0.22}N$ has been deposited via reactive co-sputtering and impact of electrodes such as W, Ti/Ru and Sc has been studied in metal-insulator-metal and metal-insulator-p-Si configurations. We demonstrate the effects of rapid thermal annealing and its impact on polarization in these thin films. Notably, RTA can alter the film properties and modify interfaces. On Silicon substrates, we also report the role of oxynitride formation aided defect structures in ferroelectric switching of these III-V nitrides. True Ferroelectric switching has also been investigated through PUND (Positive Up and Negative Down) analysis accounting for leakage current induced effects on these AlScN thin films grown on different metals. The film microstructures have been investigated using TEM and EDX analysis that has been correlated with electrical test data on polarization. We believe this work is important for tailoring AlScN materials and interfaces to achieve the desired FeFETs performance.

9:30 AM EL07.07.05
Synthesis of New Nitride Material Manganese Cobalt Nitride by RF Co-Sputtering Sita Dugu[1], Rebecca Smaha[1], Shaun O'Donnell[2], Andrew Treglia[2], Stephen Lany[1] and Sage Bauers[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado State University, United States

Transition metal (*TM*) nitrides have historically been used as cutting tools due to their outstanding properties such as high hardness and strength, excellent thermal conductivity, and unique electrochemical properties. In 2019, Sun *et al.* [1] constructed a stability map of inorganic ternary metal nitrides using high-throughput computational methods based on a data-mined structure prediction algorithm. While this work predicted hundreds of new ternary nitrides, only one new chemical space was predicted to contain a previously unknown compound comprising nitrogen and two *TM*s: $MnCoN_2$. In this study, a series of Mn-Co-N thin films are synthesized by RF magnetron sputtering and characterized for structural and magnetic properties.
Combinatorial Mn-Co-N thin films are deposited using reactive co-sputtering at different temperatures ranging from 25 – 450ºC and various process pressures. The phase of the as-grown material is checked by X-ray diffraction. Survey density function theory total energy calculations are performed in

parallel on six prototype structures based on zincblende or rocksalt lattices. Comparing the calculated structures with experimental diffraction patterns, the synthesized films better match the rocksalt-derived structures, which also exhibit lower formation energy than the zincblende candidates. However, only the primary diffraction peaks are seen, suggesting a large amount of cation anti-site disorder. Manganese and cobalt concentrations are measured by X-ray fluorescence and nitrogen concentration by Rutherford backscattering spectrometry, confirming nearly 1:1:2 concentrations of Mn:Co:N with some reduced N due to O impurities. Scanning electron microscopy and energy dispersive x-ray spectroscopy are also performed, which illustrated the presence of all elements at their respective energy levels. Magnetic properties for $MnCoN_2$ films have been studied by SQUID magnetometry, which demonstrates that the film possesses a weak moment of remanant magnetization 0.01 emu/gm and coercive field of 0.5 T. The study of moment vs temperature shows a transition temperature at ~10 K and overall antiferromagnetic correlations. To better understand the origin of the magnetic moment in the compound and its correlation with structure and stoichiometry (both anion and cation), we perform X-ray Absorption Spectroscopy (both near edge and extended fine structure). Our experimental confirmation of this new TM_1–TM_2–N ternary nitride motivates renewed effort in new materials prediction and discovery in similar ternary spaces, which we are actively pursuing. For example, in our ongoing computational search, several more TM_1–TM_2–N have been predicted as new stable nitrides.

Hybrid Molecular Ferroelectrics, a Promising System with Unique and Outstanding Electromechanical Properties Yuzhong Hu[1,2,3], Marin Alexe[2], Hongjin Fan[3], Junling Wang[4] and Pooi See Lee[3]; [1]University of Heidelberg, Germany; [2]University of Warwick, United Kingdom; [3]Nanyang Technological University, Singapore; [4]Southern University of Science and Technology, China

Organic-inorganic hybrid ferroelectrics (OIHFs) is a novel member of ferroelectrics family comprised of both organic and inorganic parts as its building block. Since the year of 2014, tens of OIHF structures have been explored with striking progress made in electromechanical properties such as high ferroelastic strain output and piezoelectricity. Recently, giant d33 (1540 pC/N) and strain output (21.5%) were reported in this ferroelectric system, which are much higher (by around three times and two orders of magnitude, respectively) than those of lead zirconate titanate (PZT). These enmerging outstanding properties indicates their bright future as lightweight and high-performance electromechanical materials. Different with the widely used piezoelectric enhancement methods such as morphotropic phase boundary (MPB) effect in oxide perovskite, the strain/piezoelectricity enhancement strategies for OIHF are involved with special molecular engineering. In addition, the bond engineering in OIHF show bright future for high-performance soft piezoelectrics. With our works, I will report: 1. The space-confinement structure enables giant strain output of 21.5% and d35 of 4800 pm/V in an OIHF. 2. The bond weakening strategy renders high-performance soft piezoelectrics, in which the materials show orders of magnitudes higher power output (11W/m2) than general piezoelectric ceramics and simultaneously, excellent mechanical softness (0.8 GPa) better than PVDF (2 GPa). These results promise OIHF unique positions in ferroelectrics family, especially in actuator and in soft electronics applications.

First-Principles Studies of Hafnia Ferroelectrics -- In a Class of Their Own Jorge Iniguez[1,2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]University of Luxembourg, Luxembourg

Hafnia ferroelectrics hold great promise for the development of nano-devices that may take advantage of their permanent and switchable electric polarization. Hence, their technological interest has made them a focus of attention. But that is not all: surprisingly, these materials are proving to constitute a ferroelectric class of their own, displaying many intrinsic behaviors that seem genuinely unprecedented and certainly lay outside the "standard model" of soft-mode ferroelectricity in perovskite oxides. In this talk I will present first-principles results to discuss and explain some of those intriguing properties. In particular, I will discuss the evidence for (im)proper ferroelectricity -- and a possible soft-mode behavior -- in these compounds. I will also address the question of whether hafnia should be consider a triaxial, biaxial or uniaxial ferroelectric, explaining how the last option may be sufficient (and convenient) to account for the behavior of many woken-up samples. I will then show that, within such a uniaxial picture, it is possible to identify a centrosymmetric reference phase that yields a straightforward description of all the known low-energy polyrmorphs of these materials, evidencing how they are structurally connected. Finally, I will discuss the piezoelectric response of hafnia ferroelectrics, emphasizing the various unique features it presents (e.g., sign tunability). Time permitting, I will summarize other recent results of my group, e.g., on hafnia-based superlattices.

Work done in collaboration with Hugo Aramberri, Sangita Dutta, Binayak Mukherjee and Natalya S. Fedorova (Luxembourg Institute of Science and Technolgoy). Funded by the Luxembourg National Research Fund through Grant INTER/NWO/20/15079143/TRICOLOR.

Memristive Devices with Ferrolectric Materials Beatriz Noheda; University of Groningen, Netherlands

The field of neuromorphic computing has recently broaden with the emergence of memristive devices as key elements that allow both processing and storage of information in the same unit. One of the materials classes that attract interest is ferroelectrics, as they offer non-volatile memory but also have been demonstrated to behave as memristive devices, allowing muliple resistance values and opening the possibility of their use as artificial synapses in hardware artificial neural networks, as well as in analogue information processing. I will present our work in this direction with different ferroelectric

materials (HfO2, BiFeO3 an BaTiO3) and their differnet synaptic characteristics.

11:30 AM EL07.08.03
The Impact of Crystallinity on Ferroelectric Properties of Epitaxial Rhombohedral $Hf_{0.5}Zr_{0.5}O_2$ Films Ji Soo Kim[1], Maximilian Becker[1], Nives Strkalj[1,2], Megan Hill[1,3], Ziyi Yuan[1] and Judith MacManus-Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]Institute of Physics, Croatia; [3]Lund University, Sweden

Ferroelectric hafnium oxide is of great interest in the semiconductor industry due to its complementary metal-oxide-semiconductor compatibility and scalability. It has potential to be used as actuator, sensors, transducers, memories, etc. Out of all the dopants studied, zirconium doped hafnium oxide, $Hf_{0.5}Zr_{0.5}O_2$ (HZO), has been the most promising and widely investigated composition with reported remanent polarisation (P_r) of ~ 20 μC/cm2 and coercive field (E_c) of ~ 1 MV/cm. However, there are limitations with ALD-grown ferroelectric HZO films in terms of wake-up effect, endurance and tuning of P_r and E_c for specific application such as ferroelectric random-access memory (FeRAM), ferroelectric field effect transistor (FeFET), negative capacitance field effect transistor (NCFET), and many more. In this work, model systems of HZO films were deposited by pulsed laser deposition (PLD) in which the epitaxial rhombohedral ferroelectric phase was stabilised. All the films show wake-up free ferroelectric behaviour with $P_r > 7$ μC/cm^2. With increase in laser fluence from 0.5 to 1.3 J/cm^2, EC increased from ~ 2.7 MV/cm to ~ 3.3 MV/cm. In order to understand the origin of such change in ferroelectric properties, we separate out individual influences of O content, strain and microstructure via x-ray photoelectron spectroscopy, x-ray diffraction, and scanning tunnelling electron microscopy.

11:45 AM EL07.08.04
Polar Orthorhombic Phase Stabilization of $Hf_{0.5}Zr_{0.5}O_2$ by inserting Seed Layer of HfO_2 and ZrO_2 Yong chi Su and Yen-Lin Huang; National Yang Ming Chiao Tung University, Taiwan

Ferroelectric materials exhibit electrically switchable polarization states that can be utilized in non-volatile memory components such as ferroelectric random access memory (FeRAM), ferroelectric FET (FeFET), and ferroelectric tunnel junctions (FTJs). Among various ferroelectric materials, $Hf_{0.5}Zr_{0.5}O_2$ (HZO) has attracted significant interest owing to its potential for thickness scalability and compatibility with CMOS technology.
However, hafnia-based ferroelectric materials still have some difficulties needing to be overcome. For example, hafnia-based materials have many polymorphs, including monoclinic phase, tetragonal phase, and orthorhombic phase. Among all the phases, only the orthorhombic phase with space group ($Pca2_1$) exhibits the ferroelectricity, yet it is a metastable phase for HZO. Therefore, how to stabilize the orthorhombic phase formation at a limited thickness regime is the central issue for a large-scale application of HZO. Another issue is that hafnia-based materials often suffer from the wake-up effect, which may result from the defect accumulation or the transformation from non-polar phase into polar phase. This issue is also related to the orthorhombic phase stabilization and the quality of thin films.
To address these drawbacks and improve the ferroelectric performance of HZO thin films this study proposes another approach by inserting an ultra-thin layer of HfO_2 or ZrO_2 serving as the polar phase stabilizer. This reduces the lattice mismatch between the bottom electrode ($La_{0.7}Sr_{0.3}MnO_3$) and the HZO layer. We found that by optimization of the insertion layer the pure polar phase of HZO can be realized in a larger growth window. We conducted the ferroelectric measurements by piezo force microscopy and ferroelectric tester to analyze the micro/marco ferroelectric properties. The wake-up and imprint effect can be measured by pulse switching measurement and first order reversal curves (FORCs) respectively. Also, by using a brand-new X-ray nano diffraction (XND) technique, it can differentiate the t-phase and o-phase with high energy resolution, which can help to prove the phase transformation from t-phase into o-phase after wake-up cycle.
Our results offer new insights into the stabilization of ferroelectric HZO and the development of wake-up-free hafnia-based devices, with the hope of paving the way for next-generation non-volatile memory applications.

$Hf_{1-x}Zr_xO_2$-Based Ferroelectric Heterostructures for Non-Volatile Memories and Artificial Synaptic Devices Yuewei Yin and Xiaoguang Li; University of Science and Technology of China, China

The rapid development of information technology requires memory devices with fast speed, low power consumption, high density, *etc*. HfO_2-based ferroelectric thin films are promising for the advanced information memory devices, especially due to the good silicon compatibility and intrinsic advantages of ferroeelctricity. Recently, we used atomic layer deposition to construct high-quality $Hf_{1-x}Zr_xO_2$ (HZO) ferroelectric thin film heterostructures and investigated corresponding prototype memory devices, including ferroelectric capacitors for FeRAM and ferroelectric tunnel junctions for neural network computing. The ferroelectric endurance properties of TiN/HZO/TiN capacitor were studied, and it was found that the ferroelectric fatigue severity increases first and then decreases with increasing pulse voltage or width. Accordingly, a recovery method by introducing wake-up effect was utilized to realize a weaker fatigue, a sufficient switched polarization (7–12 μC/cm^2) by 100 ns voltage pulses, and especially an enhanced endurance of $>1.01\times10^{12}$ ($>5.0\times10^{13}$ in expectation). On the basis of growing high-quality HZO heterostructure, ferroelectric tunnel junctions (FTJs) based on a SiO_2/HZO composite barrier and both conducting electrodes were designed and fabricated on Si substrates. The FTJ achieves the fastest write speed of 500 ps under 5 V or 10 ns speed at a low voltage of 1.5 V, low write current density ~1.3×10^4 A/cm^2, and 8 discrete states. Interestingly, in the FTJ-based memristive synapse, gradually tunable nonvolatile conductance states (128 states) with high linearity were obtained, and by inputting the corresponding experimental results into an online neural network simulation, a high accuracy in recognizing fashion product images was achieved. These results indicate that silicon-compatible HfO_2-based ferroelectric heterostructures are important candidates for high-performance nonvolatile memory and artificial synaptic devices.

2:00 PM EL07.09.02
Ferroelectric Tunneling Junctions Based on Yttrium Doped Hafnium Dioxide Wei Chen Hung[1], Yen-Lin Huang[1] and Chun-Wei Huang[2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Feng Chia University, Taiwan

Hafnium dioxide (HfO_2)-based thin films are considered promising ferroelectric materials for modern semiconductor integration. Various methods have been explored to induce ferroelectricity in hafnium oxide-based thin films, including atomic layer deposition, chemical doping, and solid solution techniques. Among the diverse doping species, yttrium-doped hafnium dioxide (YHO) stands out as a novel candidate due to its robust ferroelectric

polarization, reliability, and scalability.

In this study, we are going to utilize the high ferroelectric polarization value of YHO, approximately 50 μC/cm^2, to showcase ferroelectric polarization modulation of tunneling resistance. We also propose the device structure of ferroelectric tunneling junctions using YHO as the tunneling layer. We fabricate high quality epitaxial YHO thin films using pulsed laser deposition on single crystal $SrTiO_3$ (110)/(001) (STO) substrates. The crystal orientations of YHO were analyzed using X-ray diffraction, confirming the presence of the ferroelectric orthorhombic ($Pca2_1$) phase with two structure domains. Ferroelectric tests were carried out on our YHO films by a ferroelectric tester and piezoresponse force microscopy and ferroelectric tester.

Subsequent to the ferroelectric measurement, we utilized conductive atomic force microscopy and piezoresponse force microscopy to measure variations in polarization direction and tunneling resistance. Ultimately, we showcase the high-quality Pt/YHO/$La_{0.7}Sr_{0.3}MnO_3$ devices and measure the resistance hysteresis loops. This innovative material holds significant potential for improving the performance and efficiency of ferroelectric tunnel junctions.

2:15 PM EL07.09.03
Influence of Stack Design on The Electrical Performance of $HfZrO_2$ Ferroelectric Charlene Chen[1], Ray Meck[1], Jared McWilliams[1], Navnidhi Upadhyay[1], Mario Laudato[2] and Nguyen Vu[1]; [1]EMD Electronics, United States; [2]Western Digital Corporation, United States

Hafnium-zirconium oxide (HZO) ferroelectrics have been attracting growing interest in different memory applications owing to their complementary metal oxide semiconductor (CMOS) compatibility and scaling capability [1]. Unlike their perovskite and wurtzite ferroelectric counterparts, HZO retains an excellent leakage and decent ferroelectric response at very low thicknesses [2]. This work highlights the role of bottom and top electrodes on the electrical performance of thin film HZO such as remnant polarization, endurance, and leakage. Crystallinity, thickness, and roughness of the electrodes are found to play critical roles in improving the film quality, reducing the thermal budget, and ultimately improving the electrical response of HZO films. Wake-up free sub 100 Å thick HZO films with back-end-of-line compatible annealing conditions exhibiting high remnant polarization ($2Pr \approx 54$ μC/cm^2) and low leakage (10^{-5} A/cm^2 at 1 MV/cm) are achieved. The trade-off between polarization and the coercive field is also discussed for achieving the desired ferroelectric performance for different memory applications.

2:30 PM EL07.09.04
Integrated Ultrathin Ferroelectrics in Negative Capacitance Transistors towards Energy-Efficient High-Performance Computing Nirmaan Shanker[1], Suraj Cheema[1] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

With the exponentially increasing demand for high-performance computing, the energy efficiency of transistors must continue to improve [1]. In particular, negative capacitance (NC) [2] in ferroelectric materials has emerged as a route to increase the gate capacitance, i.e. lower equivalent oxide thickness (EOT), of a transistor which can reduce the operating voltage and therefore power. However, integration of NC gate oxides in advanced silicon transistors requires ferroelectric stabilization in the ultrathin (sub-2 nm) regime on silicon, which is a significant materials challenge for conventional ferroelectrics. To overcome this, we stabilized ferroelectricity on silicon down to 1 nm [3-4] and 0.5 nm [5] in doped HfO_2 and undoped ZrO_2, respectively, which are the high-κ dielectrics used in today's advanced logic and memory devices. Notably, these ultrathin ferroelectrics demonstrate signatures of ultrathin-enhanced polarization [3-5], in strong contrast to conventional perovskite oxide-based ferroelectrics.

Next, we leveraged the competing atomic-scale antiferroelectric-ferroelectric orders to design NC in 1.8-nm HfO_2-ZrO_2 superlattices [6-8] and 1-nm ZrO_2 [9], the thicknesses used in today's advanced transistors and future node transistors, respectively. In contrast to the conventional ferroelectric-dielectric picture for NC stabilization, the microscopic origin of NC in these gate oxides is mixed antiferroelectric-ferroelectric order, which broadens the materials space for NC realization. Furthermore, this work establishes the first demonstrations of capacitance enhancement [6-9] in the technologically-relevant HfO_2-ZrO_2 system, resulting in record-low EOT down to 5 Å [6-9]. Accordingly, when these NC gate oxides were integrated within transistors [6-9], due to the increase in gate capacitance without degradation in carrier velocity and reliability [6-7], record high ON current and transconductance was obtained at 90 nm channel lengths [8-9]. Additionally, there are early indications of industrial adoption as the 1.8-nm HfO_2-ZrO_2 superlattice gate stack has successfully been integrated within a US Defense CMOS R&D Foundry [8] and an advanced FinFET transistor process in an industrial semiconductor foundry [10]. Overall, the materials breakthroughs in this work—ultrathin ferroelectricity and negative capacitance—in the simple CMOS-compatible HfO_2-ZrO_2 material system provides a new route towards energy-efficient computing.

2:45 PM BREAK

3:15 PM EL07.09.05
300-mm Wafer-Scale Deposition of Ferroelectric $HfZrO_2$ for High Electrical Performance with Back-End-Of-Line Compatible Conditions Jared McWilliams[1], Charlene Chen[1], Ray Meck[1], Randall Higuchi[1], Ruben Waldman[2] and Nguyen Vu[1]; [1]EMD Electronics, United States; [2]Applied Materials, Inc., United States

Atomic layer deposition (ALD) of hafnium oxide and zirconium oxide has been extensively studied to replace SiO_2 as dielectrics in complementary metal oxide semiconductor (CMOS) technology [1]. Since the discovery of ferroelectricity in Hafnia-based oxides in 2011 [2], there has been growing interest in developing an ALD process to achieve good ferroelectrics within the required thermal budget for back-end-of-line CMOS. This work will discuss the advantages of using ALD precursors with wide ALD windows for achieving high-quality ferroelectric $HfZrO_2$ films. The crystallinity of the as-deposited films can be tuned to reach the desired electrical performance by adjusting the substrate temperature within the ALD windows. A 300-mm wafer-scale deposition of $HfZrO_2$ with excellent uniformity across the wafer is demonstrated. The role of different underlying layers for the growth of $HfZrO_2$ is also

discussed. Different metals with a wide range of thicknesses are found to have an impact on the nucleation of the ligands at the surface, which affects the growth per cycle and the leakage of the films. We anticipate our results will broaden the understanding of the ALD process of ferroelectric hafnia-based oxides and bring the technology closer to manufacturing.

3:30 PM EL07.09.06
Characterizing Negative Capacitance in Ultrathin Ferroelectric HfO_2-ZrO_2 Towards Energy-Efficient Advanced Transistors Qinyuan Xue[1], Nirmaan Shanker[1], Suraj Cheema[1] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Negative capacitance (NC) [1] has emerged as a promising solution to overcome fundamental energy-efficiency limits in conventional electronics, in which internal ferroelectric order within the gate stack of a field-effect transistor can enable low-power operation. In particular, by swapping the conventional high-κ dielectric with a negative-κ ferroelectric gate stack, enhanced gate capacitance, i.e. lower equivalent oxide thickness (EOT), can be realized in advanced Si transistors, resulting in key performance benefits in transistors compared to established semiconductor foundry benchmarks [2-3]. We have previously stabilized NC in sub-2-nm HfO_2-ZrO_2 heterostructures [2-3], where we observe a capacitance enhancement, definitive proof of NC stabilization, over the SiO_2 interlayer [2-3] via small-signal capacitance measurements. However, the full internal polarization-electric field (P-E_{FE}) relation was not extracted for these NC gate oxides.
In this work, ultrafast pulsed I-V measurements are used to map the 'S'-shaped P-E_{FE} relation in various ultrathin (sub-2-nm) HfO_2-ZrO_2 NC gate stacks towards realizing both EOT and physical thickness scaling for power- and dimensional-scaling, respectively. The extracted P-E_{FE} relation shows a negative dP/dE_{FE} region, a clear signature of NC stabilization. Additionally, by integrating the P-E_{FE} relation, the characteristic ferroelectric double-well energy landscape was extracted and modelled with a Landau-Ginzburg-Devonshire framework. Both P-E_{FE} and energy landscapes were then used to quantify the degree of NC stabilization across the various gate stacks. Overall, this work further confirms NC stabilization in ultrathin HfO_2-ZrO_2 heterostructures via large-signal pulsed I-V measurements (as opposed to small-signal capacitance measurements) and provides a methodology to quantify the degree of NC stabilization.

3:45 PM EL07.09.07
High Thermal Stability of Negative Capacitance HfO_2-ZrO_2 Superlattice Gate Stack Towards Improved Reliability and Work Function Engineering Yejin Hong[1], Nirmaan Shanker[1], Suraj Cheema[1] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Negative capacitance (NC) [1] gate oxides have emerged as a new route towards energy-efficient transistors as it can increase the gate capacitance, i.e. lower equivalent oxide thickness (EOT), which reduces the operating voltage and therefore power. We have previously demonstrated a 1.8 nm ferroelectric-antiferroelectric HfO_2-ZrO_2 superlattice (HZH) gate stack boasting a capacitance enhancement over the 8 Å SiO_2 IL layer via the NC effect [2]. Furthermore, once the HZH gate stack was integrated into 90 nm L_g silicon-on-insulator (SOI) nMOS transistors, gate leakage, electron mobility, and the PBTI reliability were unchanged relative to a conventional high-κ dielectric HfO_2 gate stack [2,3].
In this work, we investigate the thermal stability of the NC HZH gate stack at high temperatures. In particular, in advanced transistor processing, the gate oxide is subjected to several high temperature (>900°C) rapid thermal anneals in order to, for example, diffuse metal dopants (e.g. La) to adjust the effective work function, generate oxygen vacancies in the high-κ layer to lower effective work function, and improve device reliability [4,5]. After the NC HZH gate stack capped with TiN/amorphous silicon was subjected to high temperature rapid thermal anneals, we observe the EOT is unchanged before and after the high-temperature anneal, suggesting that the mixed ferroelectric-antiferroelectric structure is unaffected by the high temperature anneal and the interfacial SiO_2 did not increase in thickness. Additionally, a corresponding decrease in effective work function, consistent with prior work with high-κ HfO_2 [5], is observed, likely due to the generation of oxygen vacancies.
Overall, this work confirms the high-thermal stability of the NC HfO_2-ZrO_2 superlattice gate stack and that conventional high-κ work function tuning and reliability enhancement strategies are also compatible with the NC HZH superlattice gate stack. This takes a key step towards the integration of NC HZH superlattice gate stack in advanced transistors in semiconductor foundries.

4:00 PM EL07.09.08
Low Temperature Characterization of Negative Capacitance HfO2-ZrO2 Superlattice Transistors Towards Cryo-CMOS Aditya D. Varma[1], Nirmaan Shanker[1], Suraj Cheema[1], Mohamed Mohamed[2] and Sayeef Salahuddin[1,3]; [1]University of California, Berkeley, United States; [2]Massachusetts Institute of Technology, United States; [3]Lawrence Berkeley National Laboratory, United States

Cryogenic CMOS, where CMOS systems operate at liquid nitrogen temperatures, is an attractive option to reduce the energy consumption of computing as the operating voltage can be aggressively scaled due to lower subthreshold swing in transistors [1]. To realize this, several performance boosters are required, including increasing the gate capacitance of transistors without degradation in carrier transport. We have previously demonstrated a 1.8-nm ferroelectric-antiferroelectric HfO_2-ZrO_2 superlattice (HZH) gate stack boasting a capacitance enhancement over the 8 Å SiO_2 IL layer [2] via the NC effect [3] and have successfully integrated it into a 90 nm US Defense CMOS R&D technology [4]. Additionally, since no SiO_2 interfacial layer (IL) scavenging was performed, the carrier transport is not affected, resulting in a significant increase in on-current and intrinsic transconductance at room temperature [2, 4].
In this work, we characterize 90-nm L_g nMOS and pMOS transistors integrating the NC HZH gate stack down to 77 K. From cryogenic RF characterization, we observe that the capacitance enhancement is maintained, suggesting that the mixed ferroelectric-antiferroelectric structure is stable at 77 K. Additionally, due to enhanced injection velocity at cryogenic temperatures, we observe 35% and 25% improvement in transconductance for nMOS and pMOS devices, respectively, at 77 K. Overall, this work confirms that NC is stabilized in the HZH gate stack down to cryogenic temperatures and can be an attractive option to realize cryo-CMOS systems.

4:15 PM EL07.09.09
Enabling Low Coercive Voltage in $Hf_{0.5}Zr_{0.5}O_2$/$BaTiO_3$ Heterostructure via Double Ferroelectric Coupling Yen cheng Chiu and Yen-Lin Huang; National Yang Ming Chiao Tung University,Department of Materials Science and Engineering, Taiwan

In recent years, hafnium-based binary oxides, particularly $Hf_{0.5}Zr_{0.5}O_2$ (HZO), have garnered significant attention due to their stable ferroelectric properties at the nanoscale and compatibility with Complementary Metal-Oxide Semiconductor (CMOS) devices. However, maintaining ferroelectricity at extremely thin thicknesses is often hindered by a substantial coercive field, limiting the applicability of ferroelectric HZO in low-power applications. Typically, reducing the operating voltage compromises the stability of ferroelectric polarization. In this context, we introduce a novel approach to achieve lower operating voltage by creating a heterostructure consisting of perovskite/fluorite ferroelectric layers. When compared to fluorite ferroelectrics, perovskite ferroelectrics, such as $BaTiO_3$ (BTO) thin films, exhibit a significantly lower coercive field. In our study, we showcase the high-quality heterostructure of BTO/HZO, which is fabricated by pulsed laser deposition, and we characterize the ferroelectric properties through piezo force microscopy and a ferroelectric tester. By incorporating the low-voltage switchable BTO layer, we have the potential to induce critical domain nucleation in the BTO layer, leading to a lower switching voltage for the HZO layer. This innovative approach leverages the advantages of both materials to address the challenges associated with high switching voltages in HZO and the integration of perovskite ferroelectrics into the CMOS process. Our findings may pave the way for enhanced performance and efficiency in ferroelectric-based devices, such as Ferroelectric Field-Effect Transistors (Fe-FETs) and Ferroelectric Tunnel Junctions (FTJs).

4:30 PM EL07.09.10
Load Line Analysis of The Memory Window in Amorphous Indium-Gallium-Zinc Oxide-Based Ferroelectric Thin-Film Transistor Jae Hoon Lee[1,2], Yong Hee Lee[1], Joon-Kyu Han[1,3] and Cheol Seong Hwang[1]; [1]Seoul National University, Korea (the Republic of); [2]SK Hynix Semiconductor Inc., Korea (the Republic of); [3]Sogang University, Korea (the Republic of)

Ferroelectric thin-film transistors (FeTFTs) attract a great deal of interest for their potential to reduce operating voltage and enhance durability in non-volatile memories by minimizing the interfacial layer through the use of amorphous oxide semiconductors (AOS) instead of silicon (Si). Especially, FeTFTs with amorphous indium-gallium-zinc oxide (*a*-IGZO) channels offer high on-off ratios, fast operation speed, and compatibility with complementary metal-oxide-semiconductor (CMOS) technology. The Memory Window (MW) of FeTFTs holds significant importance, particularly in applications such as multilevel cell non-volatile memory and neuromorphic systems. However, there have been limited reports on the MW achievable with n-type *a*-IGZO, primarily due to the scarcity of hole carriers necessary for polarization switching.
This study investigates the attainable MW through load line analysis in FeTFTs. Load line analysis is a widely used technique that enables a comprehensive graphical representation of the intricate operation of solid-state circuits with nonlinear charge-voltage or current-voltage responses. In contrast to ferroelectric field-effect transistors (FeFETs) based on Si, which can secure an MW at the twice coercive voltage ($2V_c$) level, the inherent characteristics of FeTFTs based on AOS material result in an inevitably smaller MW due to the absence of an inversion mode.
Furthermore, the influence of various process conditions in FeTFTs is explored, including the atomic layer deposition temperature of the aluminum-doped hafnium oxide (HAO) ferroelectric layer, rapid thermal annealing temperature for crystallization of the HAO layer, and the thickness of the *a*-IGZO channel. Aluminum is selected as the impurity for hafnium oxide due to its thermal stability and compatibility with CMOS processes. The impact of these process variables on ferroelectric performance in metal-ferroelectric-semiconductor-metal capacitors and the FeTFT structures is analyzed by evaluating polarization-voltage, capacitance-voltage, and current-voltage characteristics under various conditions. In addition, load line analysis is performed at each process condition based on these characteristics. These findings can potentially guide the development of high-performance FeTFTs with optimized MW for various applications.

4:45 PM EL07.09.11
Large Electromechanical Coupling in Zr-Doped Ceria Maxim Varenik[1], Boyuan Xu[2], Tali Pechersky-Savich[1], Junying Li[3], Ellen Wachtel[1], David Ehre[1], Prahlad Routh[3], Sergey Khodorov[1], Anatoly Frenkel[3], Yue Qi[2] and Igor Lubomirsky[1]; [1]Weizmann Institute of Science, Israel; [2]Brown University, United States; [3]Stony Brook University, United States

We have investigated the electrostriction (ES) effect in Zr-doped ceria ($Zr_xCe_{1-x}O_{2-\delta}$) ceramics. ES is a second order electromechanical response, *i.e.*, strain, $\boldsymbol{u}$, is proportional to $\mathbf{M}*\mathbf{E}^2$, where $\mathbf{E}$ is the applied electric field and $\mathbf{M}$ is the longitudinal electrostriction strain coefficient. Large ES in ceria has generally been associated with oxygen vacancies (V_o) which provide charge compensation for aliovalent dopants or for cerium reduction (Ce^{3+}). The ES induced by V_o is restricted to frequency <1 Hz and low saturation strain ($|u_{sat}|$ <15 ppm).
Doping CeO_2 with Zr results in a large ES strain coefficient, reaching $|M|=10^{-16}$ m^2/V^2 for x=0.1. This effect persists to frequency ≥3 kHz with $|u|$ ≥220 ppm, making $Zr_{0.1}Ce_{0.9}O_2$ competitive with the best commercial electrostrictor (PMN-PT15), but with ~100 times lower dielectric permittivity and three-fold higher elastic modulus. XAS data, DFT modelling and *ab initio* molecular dynamics (AIMD) calculations demonstrate that elastic dipoles formed by Zr-doping are dynamic. In the absence of an E-field, [ZrO_8]-local bonding units remain, on average, centered with respect to the second (cation) coordination shell. Due to bond anharmonicity displacement of Zr by an E-field requires less energy than displacement of the host cations, resulting in a large dynamic elastic dipole. This polarizable elastic dipole gives rise to large electrostrictive strain and constitutes the first example of non-classical electrostrictors (NCES) relying solely on substitutional point defects.
|**M**| of Zr-doped ceria increases exponentially with Zr content for x=0-0.1, suggesting that the contribution of Zr-ions to electrostrictive strain may not be simply additive. Zr-doping also increases the relative dielectric permittivity, from ~26 (x=0), to ~220 (x=0.1) and lowers the elastic modulus from 227GPa (x=0) to 214GPa (x=0.1), even though the number of chemical bonds remains unchanged. AIMD calculations report that stiffness for moving [CeO_8]-local bonding units is essentially isotropic and is 2-2.4 times higher than for [ZrO_8]. Stiffness for moving [CeO_8] first nearest neighbor to Zr, is only slightly decreased from that in the bulk. These results can provide the theoretical basis for the reduction of the Young’s modulus and increase in the dielectric permittivity with Zr doping.
When the concentration of Ce^{3+} is ≥ 100 ppm in $Zr_xCe_{1-x}O_{2-\delta}$, accompanied by the formation of oxygen vacancies (V_O) for charge compensation, ES is suppressed. In addition, by co-doping $Zr_{0.1}Ce_{0.9}O_2$ with 0.5mol% of aliovalent cations - Ca, Sc, Yb or La - we observed that the aliovalent dopant reduces the electrostriction strain coefficient by more than an order of magnitude and restores the values of Young’s modulus and dielectric permittivity to values close to those of undoped ceria. Since all these co-dopants, irrespective of valence and ionic radius, lead to a similar result, we concluded that the species responsible for the suppression of electrostriction in Zr doped ceria must be the oxygen vacancies. This finding is supported by XAS measurements and AIMD calculations. Fourier transform of Zr K-edge EXAFS spectra reveal that, even though the molar ratio Zr_{Ce}:V_O is 40:1 in the co-doped compounds, oxygen vacancies nevertheless succeed in introducing enhanced disorder into the second coordination shell (cation) of Zr. DFT modelling predicts that a [ZrO_7-V_O] local bonding unit is stiff and asymmetrically distorts adjacent unit cells, leading to an elastic interaction length in the lattice between Zr-ions ≥ two-and-a-half-unit cells, which, in the absence of oxygen vacancies, can allow limited collective motion. However, such collective motion does not lead to

a phase transition even at 123 K, implying that interaction between Zr-ions is neither sufficiently strong nor sufficiently long-range to produce freezing of the displacement, an effect that has been observed for perovskite relaxors.

SESSION EL07.10: Poster Session III

5:00 PM EL07.10.01
Strain-Driven Solid−Solid Crystal Conversion in Chiral Hybrid Perovskites with Paramagnetic-To-Ferromagnetic Transition Haining Zheng and Kian Ping Loh; National University of Singapore, Singapore

Hybrid organic−inorganic perovskites (HOIPs) are promising stimuli-responsive materials (SPMs) owing to their molecular softness and tailorable structural dimensionality. The design of mechanically responsive HOIPs requires an in-depth understanding of how lattice strain induces intermolecular rearrangement that impacts physical properties. While chirality transfer from an organic cation to an inorganic lattice is known to influence chiral-optical properties, its effect on strain-induced phase conversion has not been explored. As opposed to achiral or racemic organic cations, chiral organic cations can potentially afford a new dimension in strain-responsive structural change. Herein, we demonstrate that mechanical strain induces a solid phase crystal conversion in chiral halide perovskite single crystals (*R*/*S*)-$(FE)_2CuCl_4$ (FE = (4-Fluorophenyl)ethylamine) from a 0D isolated CuCl4 tetrahedral to 1D corner-sharing $CuFCl_5$ octahedral framework via the incorporation of Cu...F interaction and N−H...F hydrogen bonding. This strain-induced crystal-to-crystal conversion involves the connection of neighboring 0D $CuCl_4$ tetrahedra via Cu^{2+}−Cl^-−Cu^{2+} linkages as well as the incorporation of an F-terminated organic cation as one of the X atoms in BX_6 octahedra, leading to a reduced band gap and paramagnetic-to-ferromagnetic conversion. Control experiments using nonchiral or racemic perovskite analogs show the absence of such solid phase conversion. To demonstrate pressure-sensitive properties, the 0D phase is dispersed in water-soluble poly(vinyl alcohol) (PVA) polymer, which can be applied to a large-scale pressure-induced array display on fibrous Spandex substrates via a screen-printing method.

5:00 PM EL07.10.02
Filterless Visible-Range Color Sensing and Wavelength-Selective Photodetection Using Bandgap Engineered Ferroelectric Ceramics Vasilii Balanov[1], Filipp Temerov[1], Vladimir Pankratov[2], Wei Cao[1] and Yang Bai[1]; [1]University of Oulu, Finland; [2]University of Latvia, Latvia

Photosensors, photodetectors, or color sensors are key components for various optical and optoelectronic applications. Semiconductor-based photodetection has been a dominator which is excellent at measuring the photon intensity of incident light. However, the wavelength of the incident light to be measured must be known beforehand and it mostly depends on auxiliary methods to filter unknown wavelengths. In this work, an alternative but simple mechanism that is using a monolithic, bandgap-engineered photoferroelectric ceramic to blindly determine the wavelength and intensity of incident light at the same time is demonstrated. The photoferroelectric compound is Ba- and Ni-codoped $(K,Na)NbO_3$ exhibiting a direct band gap of ≈2 eV and a spontaneous polarization of ≈0.25 C/m^2. The band–band charge carrier transition is confirmed by multiple characterization methods of photoluminescence, photodielectric spectroscopy, and photoconductivity. The existent optoelectrical cumulative effect enabled by the simultaneous narrow bandgap and strong ferroelectricity allows to reliably distinguish the wavelengths of 405, 552, and 660 nm as well as the power density ranging from ≈0.1 to 10 W/cm^2, with the photoresponsivity of up to 60 μA/W.

First Principles Insights into Phase Transitions, Disorder and Electronic Properties of Lead-Free Ba-Based Tetragonal Tungsten Bronzes Benjamin A. Williamson, Nora S. Løndal and Tor Grande; Norwegian University of Science and Technology, Norway

Tetragonal tungsten bronzes (TTBs), with the general formula $A2_4A1_2C_4B1_2B2_8O_{30}$, are a family of ferroelectric materials, which, due to their broad compositional space and structural flexibility make them a suitable framework for tuneable lead-free oxide ferroelectrics.

The Ba-containing TTBs such as $Ba_4Na_2Nb_{10}O_{30}$ (BNN) with a T_c of ~560ºC[1] is of particular interest in high temperature applications where there is a lack of suitable materials. Previous experimental work on substituting the A-site Na cation with larger alkali metals: K and Rb, show a systematic decrease in Tc in addition to uncovering the integral role that cation disorder plays on the structural parameters of these systems.[1]

However, there is little in terms of mechanistic understandings of these compositions using first principles characterisation techniques. In this work, density functional theory (DFT) calculations using both standard and hybrid functionals are performed on BNN-based compositions: $Ba_4A_2M_{10}O_{30}$ (A = Na, K, Rb ; M = Nb, Ta). In particular, we probe the origin of the high Tc as well as the thermodynamics of disorder. In particu

and the trends associated with the compositional engineering, as well as the thermodynamics of disorder and its effect on structural and electronic properties. The effects of this study are discussed in line with experimental work done in parallel as well as implications for the future direction of these materials.

Chlorine Substituted Organic Linker in Two-Dimensional Halide Double Perovskite Ferroelectric with Directional Dependence Properties Shubham A. Rajput, Sudhadevi Antharjanam and Aravind Kumar Chandiran; Indian Institute of Technology Madras, India

Ferroelectric materials have garnered significant interest due to their unique electrical and structural properties, holding immense promise for diverse electronic applications. This study introduces a novel 2D layered halide double perovskite ferroelectric material denoted as $Cl_{1.14}Br_{2.86}PA_4AgInBr_8$ (CPAIn). Through the strategic substitution of halogenated A-site organic linker 3-chloropropylammonium, CPAIn demonstrates exceptional non-centrosymmetric properties and remarkable ferroelectric behaviour, with a Curie temperature (Tc) of 197°C. One of the key findings of this research is CPAIn's anisotropic ferroelectric behaviour, characterized by a notably high spontaneous polarization (Ps) of 6.25 $\mu C.cm^{-2}$ along the perpendicular orientation to the octahedral layers. This observation underscores its potential for applications requiring precise control over polarization direction. Notably, the material exhibits differential resistivity along distinct crystallographic axes, with resistance measuring 9.71 MΩ.cm along the parallel direction

and 18.81 MΩ.cm along the perpendicular direction. This variance is attributed to the role of organic cations as insulators, modulating charge transfer dynamics within the material. As demonstrated by CPAIn, the ferroelectric characteristics present intriguing opportunities for future development and construction of advanced electronic devices. This endeavour represents a noteworthy advancement in tapping into the complete capabilities of ferroelectric materials for a diverse array of technological uses. The distinctive qualities of CPAIn outlined in this investigation render it an attractive contender for further research and pragmatic integration into cutting-edge electronic devices.

Synthesis and Characterization of Tellurium Doped Tin Sulfide (SnSTe) Bamidele O. Onipede[1], Hui Cai[1,2] and Matthew E. Metcalf[1]; [1]University of California, United States; [2]Lawrence Berkeley National Laboratory, United States

The presence of a spontaneous electric dipole even in the absence of an applied external electric field defines ferroelectric materials. By symmetric requirements, this is possible only in non-centrosymmetric structures where non-zero net polarization is possible. Bulk 2D Tin sulfide (SnS), an exciting member of the group IV-VI semiconductor materials with ferroelectric properties exhibits centrosymmetry which can be broken by doping. In this work, we successfully synthesized tellurium doped SnS, achieving different doping concentrations via the traditional chemical vapor deposition method. The samples were characterized via Optical microscopy, Raman spectroscopy, X-Ray Photoelectron spectroscopy and Atomic Force Microscopy. By tuning the growth parameters, we have been able to determine optimal growth parameters for these doped crystals, thus precise control has been achieved. Hence, this work would open fresh opportunities for bulk ferroelectric 2D SnS with future potential use in high quality, scalable, tunable, and high-performance technological applications.

5:00 PM EL07.10.06
Zwitterion-Based Organic High-k Dielectric Materials Simranjeet Kaur[1], Renita M. D'Souza[2], Timothy L. Kelly[2], Vance E. Williams[1] and Loren G. Kaake[1]; [1]Simon Fraser University, Canada; [2]University of Saskatchewan, Canada

Most high-k dielectrics known are based on inorganic materials, where large polarization is due to the slight separation of positive and negative charges in response to an applied field. Organic materials on the other hand, tend to have very low dielectric constants because of the low atomic number of their constituents. However, organic materials offer many advantages including easy of processing and mechanical flexibility. Zwitterionic molecules have charged groups that can be spatially separated by tens of angstroms. However, they are underexplored as dielectric materials. We report the synthesis of a novel zwitterionic molecule which melts below 100 °C. The compound was blended with poly(methyl methacrylate) and its dielectric properties were studied. The frequency-dependent capacitance depends strongly on the amount of zwitterion in the film and on the temperature of the device. At low concentrations of zwitterion and low temperatures, the film shows small capacitance (~3 nF/cm^2). Above a specific concentration and temperature, capacitance is greater than 10 μF/cm^2, consistent with electrostatic double layer formation. In order to achieve this high of a capacitance value, the bulk of the film must be field-free. As such, we suggest that zwitterions exhibit strong electrostatic correlation behaviour. This interpretation is supported by grazing incidence wide angle x-ray experiments which show evidence of zwitterion crystallization only at high concentrations. The demonstrates a non-electrolyte dielectric with a very high capacitance and illustrates the importance of the nanoscale electrostatic environment on the properties of this class of materials.

5:00 PM EL07.10.07
Depolarization Field Driven Photovoltaic Effect in 2D Ferroelectric α-In_2Se_3 Shahriar Muhammad Nahid[1], SungWoo Nam[2] and Arend M. van der Zande[1]; [1]University of Illinois Urbana Champaign, United States; [2]University of California Irvine, United States

The ultimate limit of bulk photovoltaic energy conversion efficiency in ferroelectrics at the nanoscale depends on the mechanism of electron and hole separation. Understanding the underlying mechanism will enable new design principles for utilizing the bulk photovoltaic effect (BPVE) in next generation optoelectronic devices, such as self-powered photodetectors or solar cells. In contrast to conventional ferroelectrics, 2D ferroelectric α-In_2Se_3 has two advantages for BPVE based solar cells. First, the band gap is 1.3 eV, close to the ideal value for utilizing the solar spectrum, and much smaller than most wide bandgap ferroelectric oxides. Second, they naturally exist at nanoscale dimensions with stable ferroelectricity down to a monolayer. The key goals are to characterize the thickness dependent BPVE in α-In_2Se_3 and understand the dominant mechanism.
Here, we fabricate graphene-α-In_2Se_3-graphene heterostructures, where the thickness of α-In_2Se_3 varies between 18-50 nm, and characterize the transport under illumination. We use scanning photocurrent and photovoltage microscopy to map the short-circuit current density (J_{sc}) and open-circuit voltage (V_{oc}). We also measure the transport under varying intensities.
The photocurrent and photovoltage maps show that both the J_{sc} and V_{oc} prevails only in the region overlapped by the top and bottom graphene. The J_{sc} is antiparallel to polarization. All these observations confirm the BPVE in the heterostructures. The transport measurements under illumination show that the J_{sc} and efficiency decay exponentially with thickness. The direction of the photocurrent and its exponential decay with thickness confirm the depolarization field as the origin of the photovoltaic effect in α-In_2Se_3. We also find that the depolarization field is inversely proportional to thickness and reaches 158 KV/cm for 18 nm α-In_2Se_3. Moreover, the depolarization field model allows us to predict a nonmonotonic trend of photoconductivity with thickness where it is expected to peak for 6 nm thick α-In_2Se_3. The transport measurements depict that $J_{sc} \propto \text{Intensity}^{\beta}$ where β varies from 0.6 to 1.2 with increasing thickness. The photoresponsivity reaches 1.8 mA/W under 1 W/cm^2 intensity for 18 nm α-In_2Se_3. This is comparable to other 2D ferroelectrics and almost 4 to 2200 times higher than conventional bulk ones.
Our study demonstrates the relative importance of depolarization field in 2D ferroelectrics over other mechanisms, such as shift current or Schottky barrier effect, and provides design principles for optimizing the efficiency of BPVE based energy harvesting.

SESSION EL07.11: Emerging Ferroics II

Ferroelectric Control of Conduction in The $Pb(Zr_{0.2}Ti_{0.8})O_3/Bi_2O_2Se$ Heteroepitaxy Ying-Hao Chu; National Tsing Hua University, Taiwan

The search for 2D semiconductors with excellent electronic performance and stability in the ambient environment is urgent. Bi_2O_2Se, an air-stable layered oxide, has emerged as a promising new semiconductor with excellent electronic properties. Studies demonstrate that its layered nature makes it ideal for fabricating electronic devices down to a few atomic layers. The Bi_2O_2Se-based top-gated field-effect transistor device shows

excellent semiconductor device properties, including high carrier mobility (~28,900 cm2/Vs at 1.9 K and 450 cm2/Vs at room temperature) and superior current on/off ratio with the almost ideal subthreshold swing. In addition, the moderate bandgap (~0.8 eV) of Bi_2O_2Se makes its device suitable for room temperature operation while requiring only a relatively low operation voltage. These fascinating properties, chemical stability in the ambient environment, and easy accessibility make Bi_2O_2Se a promising semiconductor candidate for future ultra-small, high-performance, and low-power electronic devices. Moreover, as the Bi-O layer in Bi_2O_2Se is structurally compatible with many perovskite oxides with interesting physical phenomena, it is feasible to fabricate heteroepitaxy/superlattices between Bi_2O_2Se and perovskite oxides to pursue novel emergent physical phenomena in hybrid heterostructuresThethe study combines an epitaxial ferroelectric $Pb(Zr_{0.2}Ti_{0.8})O_3$ (PZT) layer with the Bi_2O_2Se layer. The ferroelectric polarization of the PZT layer serves as a control parameter to modulate the semiconducting behaviors of the Bi_2O_2Se layer. The as-grown polarization leads to charge depletion and, consequently, low conduction. Switching the polarization direction results in charge accumulation and enhances the conduction at the Bi_2O_2Se layer. The origin of this modulation is attributed to a change in the electronic structure due to the ferroelectric polarization states, evidenced by X-ray photoelectron spectroscopy and cross-sectional scanning tunneling microscopy/spectroscopy. Control of the conduction at this new heterostructure delivers a pathway of non-volatile controlling on layered semiconductors for next-generation transistors.

9:00 AM EL07.11.01
Giant Optical Second Harmonic Generation from SnS with Ferroelectric Stacking Redhwan A. Moqbel[1,2,3], Ryo Nanae[4], Satsuki Kitamura[4], Chi-Cheng Lee[5], Kosuke Nagashio[4] and Kung-Hsuan Lin[2]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan; [3]Taiwan International Graduate Program, Taiwan; [4]The University of Tokyo, Japan; [5]Tamkang University, Taiwan

In recent years, substantial attention has been directed towards two-dimensional SnS, a member of the group IV monochalcogenides, owing to its exceptional physical properties. Theoretical predictions have emphasized the potential of SnS monolayer to display significant second harmonic generation (SHG) due to its in-plane ferroelectricity. However, the synthesis of monolayers with considerable lateral dimensions remains challenging due to the formidable inter-layer forces between SnS layers. For a large SnS bulk crystal, the layers are typically stacked with an antiferroelectric order (AB stacked), and the ferroelectric property disappears. In this work, we successfully fabricated a sizable flake (approximately 8x8 μm) consisting of a few layers of SnS with ferroelectric stacking (AC stacking), which enables optical measurement feasible. We found giant SHG from AC-SnS, surpassing that of MoS_2 monolayers by 50 times. The SHG susceptibility was experimentally estimated as 85 pm/V, which is much stronger than the value (~2 pm/V) of a typical nonlinear crystal such as BBO and KTP crystals. We have also investigated the angle-resolved SHG patterns and found there is good agreement between experimental and theoretical data. We further developed angle-resolved SHG microscopy as a tool for identifying single or multiple domains in SnS flakes. Orientations of polarization in different domains have been clearly obtained by this technique. From the results of cross-sectional transmission electron microscopy, we found some region that the stacking order of layers is neither AB nor AC stacking. We have also investigated the effect of stacking disorder to the angle-resolved SHG patterns.

9:15 AM EL07.11.03
Defects and Domain Walls in Soft Ferroelectric $CsGeX_3$ (X = Cl, Br, I) Kristoffer Eggestad, Benjamin A. Williamson, Dennis Meier and Sverre M. Selbach; Norwegian University of Science and Technology, Norway

Conductive domain walls (DWs) hold promise for nanoscale, energy-efficient multi-level diodes and neuromorphic circuitry. In $CsGeX_3$, caesium and halogen vacancies are intrinsic point defects that can induce electrons and holes, respectively. Controlling the formation and position of vacancies can in principle give switchable local n-type or p-type conductivity at DWs and enable new concepts for DW-based circuitry. This requires a material where mobile point defects of both positive and negative charge can accumulate at DWs. $CsGeX_3$ is here chosen as our model system due to the possibility of having mobile caesium and halogen vacancies.

We use density functional theory (DFT) to study intrinsic point defects and DWs in $CsGeX_3$. Using *hybrid* DFT we investigate electronic structure and defect formation energies in bulk, showing highly mobile holes and free electrons, as well as relatively shallow defect levels. Additionally, a study on point defect mobility in bulk, reveals exceptionally mobile anion vacancies with migration barriers comparable to Li vacancies in the best solid-state electrolytes. Furthermore, we investigate possible DWs and show that parallel and head-to-tail Y-type 71-degree DWs are the most stable DWs. Moreover, the mobility of DWs, with and without point defects in their vicinity, has been studied, showing extremely mobile DWs, implying that polarisation can easily be switched. Finally, the possibility of reversible p- and n-type conductivity in DWs in $CsGeX_3$ and other similar materials is discussed.

9:30 AM EL07.11.04
Two-Dimensional MOF-Based High-Performance Ferroelectric Field-Effect-Transistors with an Ultralow Off-State Current Jiangyu Li; Southern University of Science and Technology, China

Two-dimensional (2D) ferroelectrics open a new realm of nonvolatile memory and computing devices, while metal-organic framework (MOF) materials offer tremendous possibilities to design and optimize ferroelectric performance. Building a ferroelectric field effect transistor (FeFET) by integrating a 2D MOF ferroelectric gate with a 2D semiconducting channel provides new strategies towards ultralow power nonvolatile memory devices, yet no 2D MOF was found to be ferroelectric yet. Here we successfully develop 2D ferroelectric MOF nanosheets, {CuIIL2}n-MOF, and confirm its ferroelectricity down to 7 nm. A large polarization of ~14.2 μC/cm2, a small coercive field of ~33.3 V/um, and excellent endurability >10^6 cycles are found in 2D {CuIIL2}n-MOF nanosheets. This enables us to fabricate FeFETs using 2D {CuIIL2}n-MOF as the gate and MoS2 as the channel, achieving an on/off ratio of 10^7 with the ultralow low off-state current of 100 fA and tunable memory window, making it exceptional among known FeFETs and very promising for next-generation ultralow power memories and computing devices.

9:45 AM EL07.11.05
Understanding The Formation of Ferromagnetic $CuCr_2Se_4$ Nanocrystals Samantha Harvey, Jonathan DeStefano, Jiun-Haw Chu, Daniel R. Gamelin and Brandi M. Cossairt; University of Washington, United States

Spinels (AB_2X_4) are a unique class of materials that exhibit a range of magnetic, optical, and magnetooptical properties tunable through choice of A and B site cations. While many of the oxides have been synthesized at the nanoscale, research into nanocrystalline chalcogenide spinels is lacking. Amongst these the copper chromium chalcogenides are of particular interest for their high Curie temperatures (>350K) and large magneto-optical Kerr effects. Only a handful of reported syntheses for these materials exist, with conflicting magnetic properties (e.g. superparamagnetic vs. ferromagnetic), minimal mechanistic understanding, and no optical data. Here, we delve deeper into the synthesis of this material. Binary copper selenide forms as an intermediate followed by Cr diffusion into the lattice. Upon ramping the reaction temperature, magnetism is slow to turn on as evident by magnetic susceptibility measurements. After approximately 40 minutes at 340°C ferromagnetic ordering appears concurrently with a change in lattice parameter, crystallite size, and stoichiometry suggesting annealing and cation diffusion. Magnetic circular dichroism data of nanocrystal films is similar to magnetooptical Kerr rotation spectra of single crystals exhibiting a NIR feature that overlaps with telecommunications wavelengths.

Current and future directions involving doping, cation exchange, and spectroelectrochemistry are also discussed.

10:30 AM *EL07.12.02
Increasing Magnetic Anisotropy at The Nanoscale for Micromagnetic Actuators Amal El-Ghazaly, Yulan Chen and Ludovico Cestarollo; Cornell University, United States

When scaled down to micrometer dimensions, magnetic actuators along with other micromagnetic devices strongly depend upon their nanoscale behavior. For example, magnetorheological elastomers (MREs), which are composites of a polymer matrix and a magnetic filler, will stretch, bend, and generally behave in a manner that is intrinsically linked to the properites of the magnetic filler. However, the extent by which a magnetic material can bend and deform is proportional to its elasticity and inversely proportional to the cube of its thickness. Thus, high-resolution actuation and bending of MREs at the microscale requires an MRE of thickness similarly at the microscale and a magnetic filler that is much smaller – on the order of nanometers.
In this talk, we will present a direct comparison of actuation by microparticle-filled and nanoparticle-filled elastomer thin films, illustrating that higher actuation response at small applied magnetic fields (<100 mT, typical of integrated devices) can be achieved by the nanoparticle films [1]. Therefore, MRE microactuators using magnetic nanoparticles are desirable. However, magnetic particles are known to lose their anisotropy and ferromagnetic behavior as the dimensions are reduced to the nanoscale. Thus, nanoparticle MRE actuation can be further increased with improved nanostructures having increased remanent magnetic moment.
We will show that synthesis of high saturation magnetization $Fe_{65}Co_{35}$ (230 emu/g) magnetic nanoparticles addresses this obstacle head on, bringing both anisotropy and strong ferromagnetism down to this size regime and achieving *6x higher remanent magnetization* than conventional ferrous magnetic nanoparticles (maghemite, steel, and pure Fe). Furthermore, synthesis of self-assembled Fe-Co nanochains (theoretical 1-dimensional nanostructures) doubles the nanoscale anisotropy by adding shape anisotropy to the existing magnetocrystalline anisotropy [2, 3]. Of particular importance is that these nanochain structures with aspect ratios exceeding 10:1 can be synthesized in high concentration solutions without the need for an external field, thereby simultaneously allowing yield to increase while simplifying the synthesis process.
Finally, these anisotropic 1-dimensional nanostructures, i.e. nanochains, are hypothesized to produce the maximimum actuation response from the MRE microactuators when the filler concentration is optimized. We will present our experiments that show that an optimal volume concentration of nanochains in the elastomer matrix exists, at 6 vol.%, such that it minimizes the antiferromagnetic chain-to-chain interactions while maximizing remanence ($0.43*M_s$). Capitalizing on these results, an optimized soft actuator was made with the nanochains and shown to provide large actuation at fields <100 mT. Multiple modes of actuation will be illustrated including, lateral bending, twisting, and vertical bending.

11:00 AM EL07.12.01
Amplifying Spin-Orbit Torque Efficiency via a Crystallographic Approach Chi-Yen Huang, Chao-Yao Yang and Yen-Lin Huang; National Yang Ming Chiao Tung University, Taiwan

Currently, transition-metal-oxide based spintronics have sparked a tremendous research interests thanks to their non-trivial properties in solid-state physics and soon become potential candidates to participate into the spin-orbit torque (SOT) technology in the third generation of magnetoresistive random access memory.Recent studies have highlighted the ability of epitaxially grown $SrIrO_3$ to generate a spin current with remarkable charge-to-spin conversion efficiency. However, a comprehensive study of crystallographic dependence of SOT effect in single crystal $SrIrO_3$ thin films remains lacking.To address this gap, we prepare $SrIrO_3(001)/La_{0.7}Sr_{0.3}MnO_3(001)$ epitaxial bilayers on the $SrTiO_3$ single crystal substrates by using pulsed laser deposition technique. The $SrIrO_3$ layer serves as a spin generator with orthorhombic symmetry, facilitating the study of anisotropic SOT effects, while LSMO functions as a ferromagnetic layer with in-plane magnetic isotropy for spin detection. Employing a loop-shift method on Hall bar devices with different crystallographic orientations, we observed that applying current along the [110] direction of SrIrO3 resulted in nearly five times higher SOT efficiency compared to applying current along the [100] direction, as indicated by the peak shift (H_{eff}) relative to the sensing current amplitude. This outcome reveals a robust correlation between the crystal structure and the SOT effects, offering an ideal platform for manipulating SOT properties in TMO-based spintronic devices.

11:15 AM EL07.12.03
High Aspect Ratio Magnetostrictive Particles for Structurally Integrated Sensors and Transducers Andrew Charles[1,2], Andrew Rider[1], Sonya Brown[2] and Chun Wang[2]; [1]Defence Science and Technology Group, Australia; [2]University of New South Wales, Australia

Magnetostriction is a property of many magnetic materials whereby they exhibit a deformation in response to a change in magnetization, which is thus applicable to various sensor, actuators and transducer applications. Terfenol-D, $Tb_xDy_{1-x}Fe_2$ ($x \approx 0.3$), exhibits the largest known room temperature magnetostriction of >2000 ppm, followed by Galfenol, $Fe_{1-x}Ga_x$ ($x \approx 0.2$), with magnetostriction values of up to 400 ppm.

The use of these alloys in particulate form is particularly advantageous, as the combination with a supporting matrix allows the production of active devices of complex geometries with tailorable properties. Notably, the use of a non-conductive polymer matrix drastically reduces eddy current losses in produced composites, allowing for operational use at high frequencies. This has enabled the exploitation of these alloys in various strain-coupled magnetoelectric applications through use of a piezoelectric matrix. Tailoring of the polymer and magnetostrictive phases can also yield improvements in mechanical properties, which is particularly useful for structurally integrated sensor and transducer applications.

Through the use of flake-shaped particulates, shape anisotropy can be exploited to bring about enhancements in the specific strain of these magnetostrictive phase/polymer composite systems. To further these efforts, in this work we explore the production of these flake-shaped geometries using high-energy ball milling and quantify the effects this technique has on the crystal structure of polymer embedded Galfenol and Terfenol-D particulates. The work provides

useful insights into the material processing requirements to optimize the performance of these alloys in multi-functional composite applications such as structurally integrated sensors and transducers.

11:30 AM EL07.12.04
Understanding Magnetic Nanochain Interactions for Reconfigurable Soft Actuators Yulan Chen[1], Karthik Srinivasan[2], Marcus Choates[3], Ludovico Cestarollo[1] and Amal El-Ghazaly[1]; [1]Cornell University, United States; [2]Boise State University, United States; [3]The Pennsylvania State University, United States

Reconfigurable soft actuators hold great promise for applications ranging from mobile electronics to medicine, but they require more in-depth studies to improve the extent and efficiency of their actuation. Magnetic soft actuators are attractive candidates for these applications due to the extent of their deformation in external magnetic fields and the speed of their response. However, relatively little attention has been devoted to the influence of the shape and concentration of the magnetic filler (typically in the form of microparticles or other microstructures) on the properties of the assembled actuator. Here, we study the importance of these parameters and observe their influence on the actuator's properties, ranging from its magnetic to its mechanical characteristics.
In particular, this study delves into the potential of magnetic nanochains to offer soft actuators both the benefits of magnetic responsiveness and the additional feature of reconfigurability due to their enhanced anisotropy. We synthesized iron-cobalt nanostructures including nanoparticles and self-assembled nanochains using a magnetic field-free assembly method. The nanostructures were investigated to understand their individual and collective magnetic behaviors. After synthesis, an external magnetic field was applied to align the nanostructures. Nanochains largely remained in their single-particle-wide form but organized into longer lines of chains separated by regular distances; the synthesized nanoparticles, on the other hand, formed multi-particle-wide elongated strands with the width of a few micrometers. In both cases, alignment of the nanostructures led to an augmentation of their collective magnetic properties compared to when they were randomly oriented. However, the nanochains demonstrated a more pronounced enhancement (2x increase) in magnetic remanence compared to the case of nanoparticles. To further investigate the magnetic behavior of the nanochains and their potential as a filler for soft magnetic actuators, their properties were systematically studied as a function of filler concentration, i.e., spatial density. It was discovered that there exists a threshold concentration where the interactions between nanochains transition from ferromagnetic coupling to antiferromagnetic coupling. This resulted in a trend of initially increasing and subsequently decreasing remanence and coercivity as the concentration was increased. The maximum remanent concentration for a collective magnetic nanochain system was achieved at a filler concentration of 6 vol%, which yielded an M_r/M_s ratio approaching 0.5.
Furthermore, we successfully fabricated a reconfigurable magnetic composite film by incorporating the optimal concentration of magnetic nanochains into an elastomer matrix. A soft actuator was made with two separate magnetic panels. The panels could be either encoded with the same magnetization orientation or opposite magnetization orientation to achieve various actuation modes. Subsequent reprogramming could be achieved through the application of a magnetic field to one or both panels. This actuator exhibited shape-morphing behaviors in the form of S-shaped twisting or either lateral or vertical U-shaped bending, respectively, in response to the magnetic field and could be repeatedly reprogrammed. Thus, we demonstrated the construction of reconfigurable magnetic soft actuators capable of large, efficient deformation in small actuation fields (less than 400 Oe). This research emphasizes the potential of magnetic nanochains as effective magnetic fillers and determines the optimal concentration of this magnetic filler for the development of reconfigurable, highly-elastic actuators.

SESSION EL07.13: Bulk Ferroics
Session Chairs: Kevin Crust and Aileen Luo
Friday Afternoon, April 26, 2024
Room 342, Level 3, Summit

1:30 PM EL07.13.01
Energy Storage Properties of Samarium-Doped Bismuth Sodium Titanate-Based Lead-Free Ceramics Xuyao Tang[1], Zimeng Hu[1], Vladimir Koval[2], Bin Yang[3], Graham Smith[3] and Haixue Yan[1]; [1]Queen Mary University of London, United Kingdom; [2]Slovak Academy of Sciences, Slovakia; [3]University of Chester, United Kingdom

Due to worldwide environmental regulations, lead-free relaxors, namely $Bi_{0.5}Na_{0.5}TiO_3$–$6BaTiO_3$ (BNT-6BT) are being extensively studied as an alternative candidate for energy storage applications. Here, Sm was introduced at different A sites of the relaxor system; specifically, the Sm-doped BNT-6BT system was designed to replace Bi (BNT-Bi), Na (BNT-Na), and both the Bi and Na ions (BNT-BiNa) by Sm ions. It was found that the BNT-Bi sample possesses high piezoelectricity (d_{33}=117.3 pC N^{-1}), whereas the BNT-Na and BNT-BiNa ceramics show exceptionally high values of the energy storage density and efficiency. To define the energy storage performance, a new concept based on determining the recoverable energy storage intensity is proposed in the present work. This allows bypassing the high applied electric fields in determining the value of the energy storage density. An ultrahigh recoverable energy storage density (4.41 J cm^{-3}), excellent energy storage efficiency (83.96%) and superhigh recoverable energy storage intensity (19.17×10-3 J kV-1 cm^{-2}) were achieved in the BNT-BiNa ceramics simultaneously. Furthermore, the energy storage characteristics exhibit an excellent stability over a wide temperature range from 25 °C to 150 °C. Thus, the developed Sm-doped BNT-6BT ceramics show great potential for piezoelectric and high-power energy storage applications.

This paper has been published in Chemical Engineering Journal 473 (2023) 145363, https://doi.org/10.1016/j.cej.2023.145363

1:45 PM EL07.13.02
Field Sensitive $Ba_{1-x}Sr_xTi_{0.89}Hf_{0.11}O_3$ Ceramics with Super High Dielectric Tunability Wanting Hu, Haixue Yan, Xuyao Tang, Samrawit D. Hailu and Isaac Abrahams; Queen Mary University of London, United Kingdom

Barium strontium titanate($Ba_{1-x}Sr_xTiO_3$, BST) is a promising candidate for tunable components but the turnability of BST is relatively low and the mechanisms of turnability and the impact of electric fields on the dielectric properties of BST ceramics require more comprehensive research. Here, by introducing Hf and adjusting the content of Sr, the transition in BST ceramics turn to the diffuse phase There are at least two distinct polar structures, which is suggested by different current peaks in current-electric field loops. The developed ceramics show super high dielectric tunability (up to 68%) which can be attributed the different polar structures having significantly sensitive to applied electric fields. Compared to pure BST ceramics or other doped variants, the designed BST exhibit nearly twice the increase in dielectric tunability and hold great potential for widespread use in tunable devices including phase shifters, resonators, filters, voltage-controlled oscillator.

Facile Mechanochemical Synthesis of Lead-Free Piezoelectric Perovskite Potassium Sodium Niobate Incorporated with Tungsten Latha Nataraj, Anthony Roberts, Scott Walck, Tucker Moore, Kenneth Strawhecker and Kristopher Darling; US ARL, United States

A quest for non-toxic alternatives to conventional lead-based ferroelectric and piezoelectric materials has led to avid research in complex perovskite oxides and systems characterized by morphotropic phase boundary due to the abrupt increase in the dielectric and piezoelectric constants occurring in this region. Niobate perovskites like the (K,Na)NbO3 (KNN) family have emerged as some of the most important lead-free ferroelectric and piezoelectric materials. Engineering of facile, economical, and environmentally safe synthesis methods for such materials pose challenges to ensuring chemical homogeneity and achieving desired structures. Further, it has been demonstrated that doping positively influences properties such as morphology, texture, crystalline structure, and polarization of KNN. Here, we report solvent-free mechanochemical synthesis of single-phase lead-free piezoelectric perovskite oxide (W-KNN) of KNN incorporated with Tungsten (W), using a simple high-energy ball-milling process with shorter processing times and lower calcination temperatures than those reported in literature. The characterization of the derived powder confirms the structure, morphology, crystallinity, and chemical composition of the material synthesized. Local piezoelectricity is confirmed on the synthesized material for various application-specific device configurations. The presented method could also pave the way for a rapid, facile, and faster synthesis mechanisms at lower processing temperatures for other promising functional oxides.

Novel Photocaloric Effects in Archetypal Ferroelectrics for Solid-State Cooling Applications Claudio Cazorla; Universitat Politècnica de Catalunya, Spain

Solid-state cooling represents an energy efficient and ecologically friendly solution to the environmental problems posed by conventional refrigeration technologies based on compression cycles of greenhouse gases [1-3]. Upon small and moderate magnetic, electric and/or mechanical field shifts, promising caloric materials experience large adiabatic temperature variations ($|\Delta T|$~1-10 K) as a result of phase transformations entailing large isothermal entropy changes ($|\Delta S|$~10-100 J $K^{-1}kg^{-1}$). Solid-state cooling relies on such caloric effects to engineer multi-step refrigeration cycles. Nevertheless, conventional magneto-, electro- and mechano-caloric effects present a series of critical drawbacks that keep hindering their practical implementation in commercial refrigeration devices. For example, operation temperature conditions should be close to zero-bias transition points, since otherwise the required driving fields grow unfeasibly too large, but these only serendipitously occur at ambient conditions. Here, we will show, based on advanced first-principles simulation methods, that macroscopic light-driven phase transitions in ferroelectrics have the potential to overcome such a materials selection limitation. In particular, we demonstrate for the archetypal ferroelectric $KNbO_3$ the existence of giant photocaloric effects (i.e., $|\Delta T|$~10 K and $|\Delta S|$~100 J $K^{-1}kg^{-1}$), that is, induced by light absorption, over a vast temperature span of several hundreds of Kelvin containing room temperature. Our results can be qualitatively generalized to other ferroelectrics displaying similar types of ferroelectric to paraelectric phase transitions [4].

2:30 PM EL07.13.06
Light-Induced Color Change and Negative Photoconductivity in Bandgap Engineered Lead Titanate Ceramics Yang Bai[1], Suhas Yadav[1], Ofir Rudich[2], Or Shafir[2] and Ilya Grinberg[2]; [1]University of Oulu, Finland; [2]Bar-Ilan University, Israel

Motivated by the principle of above-bandgap photovoltage and thus the theoretical possibility of breaking the Shockley-Queisser limit, research interest in bandgap engineering of conventional ferroelectric materials is on the rise. Due to the reduced bandgaps and the resultant interaction between the incident photon energy and the unit cells and domains, many fundamentally interesting phenomena have been observed in ferroelectrics under visible light, including photo-excited domain switching and photoferroelectric cumulative effect. These phenomena could result in optical and optoelectrical applications far beyond the bulk photovoltaic effect. This talk will report a newly synthesized $PbTiO_3$-based ceramic that is modified to achieve a narrow band gap, which has been predicted via calculations by the density functional theory (DFT). This new material changes its color from maroon to brown when exposed to visible light, accompanying with negative photoconductivity. A hypothesis to explain the phenomena could be that the photo-excited electrons might reduce Ti^{4+} to Ti^{3+}, causing the color change. Meanwhile, the leftover photo-excited holes might contradict the pristine n-type conduction and thus decreasing conductivity under illumination. This interesting phenomenon may be useful for optical or optoelectronic components requiring property change under visible light, such as photo-sensitive membrane, photosensor, and photo-resistive switch.

2:45 PM EL07.13.07
Enhanced Spontaneous Ferroelectric Polarization in Sm-Doped $BaFe_{0.2}Ti_{0.8}O_3$ Ceramics Anumeet Kaur[1,2] and Arkaprava Das[3]; [1]Guru Nanak Dev University, India; [2]Global Group of Institutes,, India; [3]University of Tübingen, Germany

We investigate the origin of progressive spontaneous polarization enhancement at room temperature (RT) in $Ba_{1-x}Sm_xTi_{0.8}Fe_{0.2}O_3$ (BTO) solid solution (x = 0, 0.10, 0.15, 0.20) with increasing Sm doping. X-ray diffraction and Raman spectroscopic results confirm A (Sm_{Ba}) and B (Fe_{Ti}) site cationic substitution and increase in the tetragonality. The cooperative off-centering phenomena promote interpolar clustering via nucleation causing an enhancement in remnant polarization and coercive field with increasing Sm doping. Microscopic observation has indicated the presence of multivariant ferroelectric domain fringes along with more compact and larger grain distribution at the highest Sm concentration. The continuous reduction in oxygen vacancy density observed from X-ray photoelectron spectroscopy results in domain wall depinning and easier domain switching. The X-ray absorption spectra for Ti $L_{3,2}$ shows the increase of <!--[if gte msEquation 12]><m:oMath><m:f><m:fPr><m:ctrlPr></m:ctrlPr></m:fPr><m:num><m:sSub><m:sSubPr><m:ctrlPr></m:ctrlPr></m:sSubPr><m:e><i style='mso-bidi-font-style:normal'><m:r>t</m:r></m:e><m:sub><i style='mso-bidi-font-style:normal'><m:r>2</m:r><m:r>g</m:r></m:sub></m:sSub></m:num><m:den><m:sSub><m:sSubPr><m:ctrlPr></m:ctrlPr></m:sSubPr><m:e><i style='mso-bidi-font-style:normal'><m:r>e</m:r></m:e><m:sub><i style='mso-bidi-font-style:normal'><m:r>g</m:r></m:sub></m:sSub></m:den></m:f></m:oMath><![endif]--> ratio indicating enhanced Ti 3*d*<!--[if gte msEquation 12]><m:oMath><i style='mso-bidi-font-style:normal'><span style='font-family:"Cambria Math","serif";

Large Magnetic Proximity Effect in Manganite Oxide Heterostructures Suryakanta Mondal, Naveen Negi and Bhagwati Prasad; Indian Institute of Science Bangalore, India

The fabrication of spintronic devices necessitates the use of multi-layer structures made up of diverse magnetic materials. Such magnetic structures lead to a wide range of interface effects, prominent among which is the proximity effect. Manganite oxide thin film heterostructures are potential candidates for a comprehensive exploration of these proximity effects, primarily because manganites showcase emergent phenomena due to the dynamic interplay among charge, spin, orbital, and lattice degrees of freedom [1]. Some of their fascinating properties are colossal magnetoresistance and metal-insulator transitions. These properties arise from the intricate interactions among charge carriers, spin ordering, and lattice distortions, and they can be modulated by external stimuli like magnetic or electric fields. The physical attributes of manganites, such as Sm1-xSrxMnO3 (SSMO), undergo significant changes with alterations in the Sr doping percentage. Depending on the doping ratio, SSMO can exhibit ferromagnetic, antiferromagnetic, or even mixed magnetic phases [2]. The extensive variety of phenomena that can be tuned based on Sr concentration in SSMO highlights its scientific importance and makes it a compelling subject for the study of diverse properties [3, 4]. In this study, we investigated the magnetic proximity effect in SSMO bilayer and tri-layer heterostructures. Initially, we deposited a single layer of ferromagnetic metal (FMM) and an antiferromagnetic insulator (AFI) onto a SrTiO3 (STO) substrate using the pulsed laser deposition (PLD) technique. Their magnetic attributes were assessed with a SQUID magnetometer, and the results were consistent with earlier reports. Subsequently, we laid down a bi-layer stack of FMM/AFI and a tri-layer configuration of AFI/FMM/AFI on the STO substrate. We observed a marked increase in magnetic moment across these structures, indicating that the magnetic proximity effect in the heterostructures was the main contributor. In conclusion, manganite heterostructures present a promising avenue for further exploration of novel electronic and magnetic phenomena at their interfaces. References: 1. Y. Tokura, Reports Prog. Emergence of Dynamic Memory and Perturbation Effect in $Dy_{2-x}Fe_xTi_2O_7$ Pyrochlore Oxides Pramod Yadav and Pavan Nukala; Indian Institute of Science, India

Investigation of topological materials and their exotic properties, along with understanding crucial exponents, holds great interest for the advancement of next-generation devices. A particular focus lies in the study of out-of-equilibrium properties observed in $Dy_2Ti_2O_7$ spin ice, which presents unique opportunities to comprehend the intricate magnetic behavior found in disordered magnetic materials. Through our experimental analysis, we have discovered the magnetic field-induced anomalous thermomagnetic hysteresis, a phenomenon exclusively observed in temperature- and magnetic field-dependent AC susceptibility measurements. Notably, this observed memory effect exhibits a strong dependence on both thermal and non-thermal driving variables. We have identified that even a minor substitution of the Heisenberg Fe-spins within the Ising matrix, formed by Dy ions, significantly alters the memory effect. Our results clearly demonstrate that defects play a crucial role in the dynamic magnetic properties, which are particularly pronounced in the out-of-equilibrium state. This phenomenon is believed to arise from the combined influences of geometric frustration, disorder, and the cooperative nature of spin dynamics exhibited by these materials. The emergence and controllability of the memory effect with thermomagnetic variables and substitution present a promising foundation for future applications of quantum-based devices.

Polar Topological Defects in Ferroelectric Nanostructures: Novel Features and Phenomena Laurent Bellaiche; University of Arkansas, United States

About twenty years ago, electrical topological defects were predicted in ferroelectric nanostructures [1-3]. These fascinating objects are now forming one active and exciting research field, since they have the potential to revolutionize technologies but also yield striking phenomena (see, *e.g.*, Refs. [4-7] and references therein).

The aim of this Talk is to reveal and explain, via the use of first-principle-based atomistic effective Hamiltonians and state-of-the-art experimental growth and characterization techniques, the emergence of novel features, all associated with polar topological states. This includes:
Their activation by THz pulses and twisted light [8-10],
Their role in creating magnetism in nominal non-magnetic systems [11],
The systematic control of their motions across thin films [10,12,13],
The unusual lattice vibrations and soft modes responsible for their condensation [14,15],
The transitions between different topological states [16-20], and
The occurrence of novel phases and phenomena, such as polar solitons in low-dimensional multiferroics [21], quantum-induced dipolar liquid states and quantum criticality [22] and electrical hopfions [23].

The authors at Arkansas thank the Vannevar Bush Faculty Fellowship (VBFF) from the Department of Defense, the MonArk NSF Quantum Foundry supported by the National Science Foundation Q-AMASE-I Program under NSF Award No.DMR-1906383, the ARO Grants No. W911NF-21-1-011 and W911NF-21-2-0162 (ETHOS), the DARPA Grant No. HR0011727183-D18AP00010 (TEE Program), and the ONR Grant N00014-21-1-2086. Structural, Magnetic and Magnetocaloric Study of Rare-Earth and Cobalt Co-Doped $La_{0.8}RE_{0.2}Cr_{0.5}Co_{0.5}O_3$ (*x* = 0.2; RE = Nd and Gd) Chromite
Jolaikha Sultana[1], Surendra Dhungana[1], Santosh K. Chhetri[2], Jin Hu[2] and Sanjay R. Mishra[1]; [1]The University of Memphis, United States; [2]University of Arkansas, Fayetteville, United States

Heavy rare earth chromite's, specifically $RCrO_3$ (where R represents Ho, Er, Yb, Lu, and Y), are a class of advanced multifunctional materials that demonstrate multiferroicity, which combines ferroelectricity and canted antiferromagnetism. These materials have significant promise for utilization in magnetic refrigeration applications. This work presents structural, magnetic and magnetocaloric effect (MCE) observed in polycrystalline orthochromites $La_{0.8}RE_{0.2}Cr_{0.5}Co_{0.5}O_3$ that have been doped with rare-earth and cobalt elements. The materials were synthesized by the sol-gel auto combustion method. XRD pattern reveals that all the samples crystallize in the perovskite phase with an orthorhombic structure (space group Pbnm). The lattice parameter of the powder samples was calculated from the XRD pattern refinement, which showed a decrease in lattice parameter and volume upon rare-earth substitution. This systemic change in the lattice volume is the result of the lanthanide contraction of the ionic radii of rare earth elements. Magnetic measurement shows Paramagnetic (PM) to Canted Antiferromagnetic (CAFM) transition with Néel temperature (T_N) below 300K and paramagnetic Curie-Weiss temperature (θ) undergoing shift towards lower temperature upon RE and Co co-doping. An increase of considerable magnitude in magnetization has been observed in the doped compounds because of the development of ferromagnetic properties. All the doped compounds showed an enhancement in MCE performance compared to the pristine compound. The compound $LaCr_{0\text{-}5}Co_{0.5}O_3$ exhibited a maximum change in magnetic entropy of $0.07 Jkg^{-1}K^{-1}$ when subjected to an applied field of 5T. The Nd and Co co-doped $La_{0.8}Nd_{0.2}Cr_{0.5}Co_{0.5}O_3$ compound showed the highest magnetic entropy change of 6 $Jkg^{-1}K^{-1}$, whereas the Gd and Co co-doped $La_{0.8}Gd_{0.2}Cr_{0.5}Co_{0.5}O_3$ compound showed magnetic entropy change of 4 $Jkg^{-1}K^{-1}$,both under a 5T applied field. Due to the substantial rise in magnetic entropy change, these materials have potential for use in magnetic refrigeration applications at low temperatures.

5:20 PM *EL07.14.05
Tunneling in Ferroelectric Heterostructures: A Tale of Two Interfaces Nagarajan Valanoor; UNSW Sydney, Australia

The various demonstrations of robust ferroelectricity down to a few unit cells at room temperature has triggered the quantum era of ferroelectrics. Nearly two decades ago the concept of a ferroelectric tunnel junction (FTJ) was brought to the fore leading to a flurry of activity in the field of polarization control of tunneling current and related tunneling electro-resistance (TER) effects studies. In this presentation we cover two types of new ferroelectric devices based on the tunneling effect, both founded on the control of electrode/ferroelectric interface in an ll oxide heterostructure.
The first part of the talk discusses our recent demonstration of a ferroelectric resonant tunneling diode (RTD) , which exploits the switchable electric polarization state of the quantum-well (QW) barrier to tune the device resistance at room temperature. We show robust room-temperature ferroelectric-modulated resonant tunneling and negative differential resistance (NDR) behaviors in all-perovskite-oxide $BaTiO_3/SrRuO_3/BaTiO_3$ RTDs. The resonant current amplitude and voltage are tunable by the switchable ferroelectric polarization of the ultrathin $BaTiO_3$ layers with the NDR ratio modulated by ~3 orders of magnitude and an OFF/ON resistance ratio exceeding a factor of 20 000. An average tunnel lifetime of 0.47 fs on the resonant states is obtained, which is orders of magnitude smaller than those obtained in semiconductor QWs. This work appears in Ma et al , Adv. Mater. 2022, 34, 2205359.
In the second study we explore how electronic phases at the interfaces can be deterministically harnessed to modulate the TER. We find a large tunneling electroresistance (TER) of 6 orders of magnitude when inserting a 0.5 nm-thick $La_{0.8}Ca_{0.2}MnO_3$ layer between the $Pt/BaTiO_3$ interface in $Pt/BaTiO_3/Nb:SrTiO_3$ ferroelectric tunnel junctions (FTJs), benefitting from the double interface effect. That is, both the $BaTiO_3/Nb:SrTiO_3$ and $La_{0.8}Ca_{0.2}MnO_3/BTO$ interfaces are synchronously metal or insulator phases in response to the ferroelectric polarization switching, thus amplifying the difference in resistance between the high resistance state (OFF state) and low resistance state (ON state). It is found that a thicker $La_{0.8}Ca_{0.2}MnO_3$ layer leads to the decrease of the TER. This is attributed to the decreased barrier height/width at the $BaTiO_3/Nb:SrTiO_3$ interface as revealed by analysis of the electron transport mechanism. We show it occurs by Fowler–Nordheim (FN) tunneling. Our reports provide a pathway, namely interface control of the oxide heterostructure, to achieve high- performance ferroelectric tunneling devices for future oxide electronics at the nanoscale.
The speaker would like to acknowledge the support of an Australian Research Council (ARC) Discovery Project and Australian Research Council Centre of Excellence in Future Low-Energy Electronics Technologies (Project No. CE170100039) grant.

Integrating Surface-Enhanced Raman Spectroscopy and Electrokinetics for Bacterial Identification in Wastewater Yirui A. Zhang, Liam Herndon, Punnag Padhy, Babatunde Ogunlade, Alexandria Boehm and Jennifer A. Dionne; Stanford University, United States

Antibiotic-resistant bacterial infections claim over 1.2M lives annually and are projected to be the main cause of death in 30 years [1]. Elevated pathogen levels in wastewater are one of the first indicators of disease outbreaks, making wastewater a powerful tool for surveilling the infections present in a community [2]. However, bacterial WBE presents outstanding challenges; current culturing or fluorescence-based methods [3] to identify bacteria are slow and costly, and not suitable for high-throughput screening of diverse bacterial species. Further, the complex substances in wastewater can interfere with chemical probes or cause false negative results.
In this study, we develop a generalized enrichment with Raman-machine learning spectroscopy (GERMS), employing surface-enhanced Raman spectroscopy (SERS) [4] and integrating it with electric fields and machine learning models [5], to enable rapid and amplification-free bacteria identification in filtered wastewater, even at low concentrations down to 10^4 cells/mL. To achieve this, we first synthesize gold nanorods designed to electrostatically bind with bacteria, enabling SERS measurements from the cell surfaces. We perform SERS measurements on various bacteria, including Staphylococcus aureus, Staphylococcus epidermidis, and Escherichia coli, across a concentration range spanning from 10^9 down to 10^4 cells/mL. Spectral clustering analysis reveals that as the concentration decreases, bacterial signals become progressively more challenging to distinguish from the background wastewater. Furthermore, we incorporate electrokinetic effects into SERS by employing gold microelectrodes to apply external electric fields and leveraging dielectrophoresis [6] to rapidly displace and enrich bacteria within minutes. Microscopy directly visualizes the enrichment of bacteria with nanorods, leading to a remarkable increase in Raman signal intensities by up to tenfold under external electric fields for bacterial concentrations from 10^6 down to 10^4 cells/mL. This enhancement has the potential to extend the detection sensitivity to environmentally-relevant concentrations. In addition, through data science approaches, we identify biologically significant "fingerprint" Raman peaks that characterize proteins, nucleic acids, and lipids on bacterial surfaces. This discovery holds promise for the rapid identification of bacterial species for wastewater-based epidemiology.

Evaluating The Refractometric Sensing Performance of Plasmonic Titanium/Hafnium Nitride Nanohole Arrays Beyza N. Gunaydin[1,1], Meral Yuce[1] and Hasan Kurt[2,3]; [1]Sabanci University, Turkey; [2]Imperial College London, United Kingdom; [3]Istanbul Medipol University, Turkey

Noble metals, such as gold and silver, have conventionally been the preferred materials for plasmonic applications owing to their elevated electrical conductivity, surface plasmon frequencies within the visible spectrum, and chemical stability. However, they are increasingly expensive to utilize, incompatible with conventional CMOS process, difficulties in large-scale manufacturing, and have low melting temperatures at the nanoscale. In this perspective, refractory group IVB metal nitrides present a remarkable ability to modulate their plasmonic behavior within the visible to near-infrared range as alternatives to noble metals. These materials can exhibit exceptional resistance to high temperatures, mechanical robustness, compatibility with CMOS

technology, chemical inertness, and outstanding compatibility with prevailing electronic platforms. Thus, these properties render group IVB metal nitrides, especially titanium nitride (TiN) and hafnium nitride (HfN), highly promising candidates for diverse plasmonic applications.
In this study, we have investigated the optical properties of TiN and HfN thin films using variable angle spectroscopic ellipsometry, focusing on the $Ar:N_2$ ratio to improve the metallic properties of thin films. X-ray diffraction and Raman spectroscopy have been thoroughly carried out on thin TiN and HfN films to assess the stoichiometry and structure of thin films with different gas flow rates. In addition, periodic nanohole arrays of TiN and HfN (especially HfN is a hard material, called conductive ceramic) were successfully fabricated by electron beam lithography (EBL) and induced coupled plasma reactive ion etching (ICP-RIE) to evaluate the refractometric sensing of plasmonic assays. Finally, to explore the potential of plasmonic metal nitrides as alternatives to noble metals, the refractive index sensitivities of TiN and HfN nanohole arrays were investigated using a custom micro-spectrometry setup under different mediums. The refractive index sensitivities for TiN and HfN nanohole arrays achieved 180 and 631 nm/RIU, respectively. This study provides unique insights into the behaviors of TiN and HfN nanohole arrays in refractometric sensing applications, and the full potential of refractory metal nitrides in plasmonics is yet to be realized.

9:15 AM EL08.01.04
Temporal Vs Stable Plasmonic Anticounterfeit Tags for Structural Health Monitoring Studies Maha Ibrar, Megan Knobeloch, Zachery Mccurtain, David Crandall and Sara Skrabalak; Indiana University Bloomington, United States

Proliferation of counterfeit goods has resulted in exorbitant economic fallout, device reliability issues, and health and safety concerns. Hence, developing anticounterfeit platforms has become imperative for reliable and cost-effective authentication, tracking of products, and detection of potential tamper activity. Here, we report covert anticounterfeit platforms where plasmonic nanoparticles (NPs) were used to develop tags to authenticate goods. The two platforms developed are Unique images and Physical Unclonable Functions (PUFs). Fabrication of Unique images entails assembling plasmonic nanoparticles in arrays with the help of templates, whereas PUFs result from light scattering from randomly drop casted NPs. These techniques allow critical goods to be facilely tagged, and the resultant pattern from either a nanoparticle assembly or individual NPs is analyzed with darkfield optical microscopy imaging. Au and Ag NPs were prioritized due to their tailorable optical responses in the visible spectrum. The sensitivity of metal nanoparticles (particularly Ag) to the environment was also leveraged as a monitor of structural health and to show evidence of tampering. Functionalized Ag NP inks were used to create tags that serve as temporal sensors where changes in color response were tracked with variable exposure times to ambient environmental conditions. These temporal sensors are authenticated with machine learning protocols that keep track of the optical changes with time.

9:30 AM EL08.01.05
Scalable Manufacturing, Transfer and Integration of Metasurfaces for Biosensing Hao Wang, Ashish Pandey, Nanzhong Deng and Haogang Cai; New York University, United States

Building upon a long-established history of plasmonic and nanophotonic biosensors, the recent advancements in metasurfaces have brought to light exciting new possibilities, such as tailor-designed high-Q resonances, spectrometer-less and imaging-based sensing. However, there is still a major challenge towards the widespread implementation of metasurface technology, for either sensing or wavefront engineering: optical metasurface manufacturing largely relies on electron beam lithography (EBL), which provide high resolution at a price of low throughput. It is difficult for EBL to offer either high-volume production or large area metasurfaces. Moreover, EBL-compatible substrates are planar and bulky, usually orders of magnitude thicker than the metasurface itself. Conventional substrates not only nullify the reduced footprint advantage of metasurfaces, but also limit their application scenarios.
To address these challenges, we demonstrate scalable manufacturing of metasurfaces using the self-assembly approach known as nanosphere lithography, which is versatile in terms of material selection, nanopattern geometry and dimension tunablility. Through a process called “Marangoni convection”, polystyrene (PS) latex beads float at the air-water interface and eventually self-assemble into hexagonally close-packed pattern upon addition of surfactant. Nanosphere hexagonal arrays can be formed on a wider range of substrates, and then used as masks for metal deposition or etching to create complementary geometries of nanohole and nanodisc arrays, respectively. Oxygen plasma is used to etch the PS beads for fine tuning of the feature size in the nanoscale. After removing and cleaning of the PS beads layer, the metallic nanopatterns can be directly used as plasmonic metasurfaces for biosensing, or used as etching masks for pattern transfer into the underlying dielectric materials. Recently, dielectric metasurfaces are drawing increasing attention for sensing applications due to their advantages of negligible ohmic loss and high-Q resonances, compared to the plasmonic counterparts.
Taking gold nanohole arrays as an example, the metasurface geometric parameters are tuned by the following: the period is determined by the original PS bead size, the nanohole diameter is determined by the Oxygen plasma etching, while the thickness is determined by electron beam deposition. We started with 600 nm PS beads assembly on glass coverslips, and etched the diameter to 360 nm for gold deposition of 50 nm. For the optofluidic integration, a polydimethylsiloxane (PDMS) chamber was formed in a mold, and then bonded on top of the metasurface after Oxygen plasma treatment. Microfluidic tubes were inserted to the PDMS chamber, forming inlet and outlet channels. In the medium of DI water, a transmission resonance dip was found near 700 nm wavelength using a spectroscopy setup. By changing media with different refractive indexes (RI), the bulk RI sensitivity was measured as 550 nm/RIU, with a limit of detection down to = 2×10^{-4} RIU. The sensing performance matches well with finite-difference time-domain (FDTD) simulations, and approaches that of the state-of-the-art devices manufactured by EBL. The metasurface sensor was used to detect the specific binding between protein A/G and antibody, which can be further customized for various biosensing targets.
In summary, we demonstrated the scalable manufacturing and optofluidic integration of metasurface biosensors. They provide high sensing performance comparable to EBL, while the high through and low cost make them more suitable for point-of-care testing. The scalable manufacturing and our recently developed metasurface transfer technique largely expand the selection of substrates, which will enable promising applications such as the integration of flexible/wearable devices and lab-on-fiber technology for in vivo sensing and diagnostics.

Terahertz Monitoring of Gas-Matter Interactions: Exploring Interatomic and Interfacial Dynamics through Palladium Nano-Film Hybrid Metasurfaces Jinwoo Lee[1,2], Jongsu Lee[1], Geon Lee[1,3], Ryu Yong-Sang[2] and Minah Seo[1,2]; [1]Korea Institute of Science and Technology(KIST), Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

Terahertz (THz) technology is an attractive optical sensing platform that offers accurate approaches for the real-time investigation of intrinsic materials in non-invasive and non-contact manners. In addition, using metamaterials that have been extensively researched recently, diffraction-limit and absorption cross-section-limit can be overcome [1]. Here, we monitored molecular dynamics by gas-matter interactions including interatomic and interfacial reactions such as absorption, desorption, adsorption, and catalytic reaction. In-situ THz measurement using nano-patterned slot antennas is introduced to investigate Palladium (Pd) based interatomic and interfacial gas-matter interactions. Interatomic interaction which is atomic scale changes can be measured using our geometrically optimized nano-slot structure, which consists of a narrow gap of approximately 14 nm between a gold wall and a deposited Pd metal thin film. Furthermore, we manipulated nano-slot structures to maximize the sensitivity of THz signals in terms of water, formed by the Pd catalytic reactions, and their absorption. Our proposed experiment aims to analyze the dynamics of interatomic hydrogenation, interfacial oxygen adsorption, and water-forming reactions in a highly consistent and dependable manner, enabling real-time analysis [2].
The molecular dynamics are interpreted by THz transmittance measurement under the various gas concentrations including N_2, H_2, and O_2. The molecular

dynamics can be determined by inspecting resonance frequency shifts and transmittance changes in the transmitted resonance signals that were filtered by our nano-slot structures. The Pd hydrogenation process, the oxygen adsorptions, and the catalytic water formation reactions according to the various concentrations of H_2, O_2, and N_2 were dynamically measured by resonance frequency and transmittance response.
The atomic scale response, such as hydrogen absorption, desorption into the Pd lattice, and catalytic water formation response which is a relatively huge scale can be measured in a reliable manner using such a long wave-length light. In addition, by interpreting inclinations that are plotted on the map composed of the amount of resonance frequency and transmittance response, not only the three different dynamics can be classified, but also a complex hidden process of water-forming reactions can be tracked.

Passive and Active Metasurfaces for Wireless Telemetry Sensors Hanwei Wang, Xiaodong Ye, Yulei Shen, Yun-Sheng Chen and Yang Zhao; University of Illinois Urbana-Champaign, United States

In this talk, I will discuss both the theoretical design and experimental realization of metasurfaces aimed at enhancing the efficiency and operational range of wireless charging for surgically implanted biosensors. I will delve into several design concepts of metasurfaces including auto-reconfigurability, magnetic mode forming, and Parity-Time (PT) symmetric metasurfaces, which hold the potential for achieving unity efficiency. My discussion will extend to the inverse design principles and their impact on mode optimization. Further, I will explore the practical applications of these theoretical concepts by introducing the metasurface as a wearable device designed to sustainably power a surgically implanted bio-potential sensor, encompassing electromagnetic compatibility with both in vitro and in vivo demonstrations.

Designing Spoof Plasmonic Metasurfaces for Microwave Frequencies and Applications in Biological Processing Zachary Nichols and Chris D. Geddes; University of Maryland, Baltimore County, United States

Plasmonic metasurfaces are a growing subclass of metamaterials which are materials whose properties are based on their structure rather than their composition and can be tuned and designed for different applications as a result. Metasurfaces are the two-dimensional analogs of three-dimensional metamaterials and plasmonic metasurfaces are those that use electron oscillations in metals, termed plasmons, to achieve their desired properties. Most applications of plasmonic materials have been limited to the visible and UV frequency ranges of light since lower frequency photons have insufficient energy to excite plasmons in metals, however “spoof plasmons” which mimic normal plasmons, have been created in the terahertz and microwave frequency ranges by utilizing subwavelength metal structures in periodic arrays. Spoof plasmonic metasurfaces (SPMs) are metasurfaces that can mimic plasmonic metasurfaces at lower frequencies by utilizing properties of spoof plasmons. In this work, we have designed several SPMs for use in the microwave frequency range using a combination of computational modeling and physical testing. SPMs were designed *in-silico* using finite-difference time-domain (FDTD) methods and then fabricated for physical testing with microwave irradiation. Once designed, these SPMs were assessed for their utility as a sample processing platform for biological samples such as microbes, nucleic acids, and proteins in a variety of laboratory assays such as genomic sequencing or diagnostic polymerase chain reaction (PCR). While many applications of metasurfaces to biological problems have been focused on sensing biological signals and imaging, this work is focused on using their properties to process biological samples via light-matter interactions and their products. Thus far this work has shown promise in applying SPMs to a new area of biological processing as well as exploring existing metasurface design principles for alternative applications.

11:15 AM EL08.01.09
***In-Situ* Raman/SERS Photocatalysis mediated by Coupling $NaREF_4$ Upconversion Nanoparticles with Plasmonic Gold Nanoparticles to Reaction Conversion of 4-Aminothiophenol to 4,4′-Dimercaptoazobenzene** Gesiane Pinha Sousa[1], Anerise De Barros[1], Flavio Makoto Shimizu[2,1], Fernando Aparecido Sigoli[1] and Italo O. Mazali[1]; [1]Universidade Estadual de Campinas, Brazil; [2]Centro Nacional de Pesquisa em Energia e Materiais, Brazil

Lanthanide-doped upconversion nanoparticles (UCNPs) absorb low-energy photons, in the near-infrared region (NIR), and emit high-energy photons, in the visible or ultraviolet region (UV/Vis). This property of radiation emissions can be used to promote plasmonic photocatalytic reactions by coupling UCNPs with plasmonic nanoparticles. For this, the highly crystalline β-$NaYF_4$:Yb_{3+}, Er^{3+}@$NaYF_4$:Nd^{3+}@$NaYF_4$ UCNPs capped with an amino-modified nanosized silica shell were coupled with gold nanospheres (13 ± 2 nm). The plasmonic-driven dimerization of 4-aminothiophenol (4-ATP) to 4,4′-dimercaptoazobenzene (DMAB) was carried out solely by using the UCNP visible emissions to excite the gold nanoparticle localized surface plasmon resonance band. The reaction was monitored in situ through surface-enhanced Raman spectroscopy (SERS) and optimal conditions were achieved in order to eliminate secondary influences during spectra acquisition. The SERS substrates containing either UCNPs@SiO_2-NH_2/Au or SiO_2-NH_2/Au nanoparticles were prepared by the drop-cast method in silicon substrates. In the studied reaction conditions, plasmonic photocatalytic activity was observed only in the substrates containing UCNPs and Au nanoparticles. The plasmonicdriven reaction was achieved by UCNPs excitation with a 980 nm laser (25.7 mW), aligned in a Raman spectrometer, only after 5 s of exposition. Interactive document mapping (IDMAP), which is an unsupervised pattern recognition method, was applied to analyze the numerous SERS spectra acquired during the plasmonic photocatalytic measurements. The high values found for the silhouette coefficient (0.88 for the Si_SiO_2-NH_2/Au and 0.76 for the Si_NYF@SiO_2-NH/Au substrate) indicate that strong discrimination among the Raman spectra was achieved. Thus, through IDMAP, it was observed that the SERS spectra obtained for the substrates containing either UCNPs@SiO_2-NH_2/Au or SiO_2-NH_2/Au corresponded to spectral features, respectively, from the DMAB product and the 4-ATP reagent, evidencing that, in the optimized reaction conditions, the dimerization occurred only through the interaction of the UCNPs with the Au nanospheres.

Fluorophore Induced Plasmonic Current (FIPC) for The Detection of Biological Species for The Purposes of Assay Development and Onsite Detection Dan Pierce; University of Maryland, United States

The recent COVID-19 pandemic has made it abundantly clear that there is a growing need for the capacity to have analytically precise detection of pathogens be performed as quickly as possible for the best public health outcome. Fluorophore Induced Plasmonic Current (FIPC) is a newly developed

testing modality that is based upon the principles of modern fluorescence detection, but differs in its implementation and applicability. Where a traditional fluorescence-based assay would require a laboratory environment and an expensive fluorimeter, an FIPC only requires a current detection device and an excitation source to achieve similar results. Based on the properties of FIPC wherein a fluorophore that is excited close to the surface of a plasmonically active metal nanoparticle film is able to transfer a portion of its excitation energy to the film, these proposed assays revolve around this property for the detection of various fluorescent tags and probes for the analytical detection of DNA and proteins. The goal of this presentation is to demonstrate the advances made in the assay development side of FIPC research, and to highlight its strengths and identify its shortcomings when compared to traditional fluorescence detection.

11:45 AM EL08.01.11
Low-Loss Plasmonics with Nanostructured Potassium and Sodium-Potassium Liquid Alloys Ankun Yang; Oakland University, United States

Alkali metals have low optical losses in the visible to near-infrared (NIR) compared to noble metals. However, their high reactivity prohibits the exploration of their optical properties. Recently sodium (Na) has been experimentally demonstrated as a low-loss plasmonic material. Here we report on a thermo-assisted nanoscale embossing (TANE) technique for fabricating plasmonic nanostructures from pure potassium (K) and NaK liquid alloys. We show high-quality-factor resonances from K as narrow as 15 nm in the NIR, which we attribute to the high material quality and low optical loss. We further demonstrate liquid NaK plasmonics by exploiting the Na-K eutectic phase diagram. Our study expands the material library for alkali metal plasmonics and liquid plasmonics, potentially enabling a range of new material platforms for active metamaterials and photonic devices.

Meta-Optics for Image and Spectral Classification Jason G. Valentine; Vanderbilt University, United States

Here, we demonstrate how meta-optics can be designed, and realized, to work in concert with a digital back-end for a range of tasks including image and spectral classification. In the case of image classification, the meta-optic serves to off-load computationally expensive tasks into an optical front-end, speeding computational speed while lowering energy consumption. For spectral classification, meta-optics serve as complex filters which are used in conjunction with a digital neural network to achieve a compact flow cytometer capable of classifying up to four unique fluorophores, and their combinations.

Printable, Emissivity-Adaptive and Albedo-Optimized Radiative Covering for Dynamic Radiative Thermal Management Jiachen Li[1,2,1], Kaichen Dong[1,3], Ruihan Guo[1], Tiancheng Zhang[1] and Junqiao Wu[1,2,1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Tsinghua University, China

Radiative cooling technology utilizes thermal emission to cool buildings and uses outer space as a natural heat sink. Traditional radiative cooling materials focus on static, cooling-optimized material properties to maximize the cooling power, but the constant strong cooling causes overcooling in cold climates, which increases energy budget in the HVAC system. Recently, advances in temperature-adaptive structures have been made to solve the overcooling issue. However, great challenges remain in their fabrication feasibility, and their unoptimized solar heating that may override the radiative cooling benefit.
In this work, we develop a printable, emissivity-adaptive and albedo-optimized covering (PEAC) based on recyclable materials with roll-to-roll fabrication. With a metastructure embedded with the phase change material vanadium dioxide, PEAC automatically switches its sky-window emissivity from 0.25 to 0.85 when the surface temperature exceeds a preset transition temperature, whereas delivering an albedo that is optimized for maximal year-round energy saving or thermal comfort in a given climate. Numerical simulations and outdoor experiments show that PEAC outperforms radiative cool roofs in terms of annual energy saving in most climates, especially those with substantial seasonal variations. PEAC can also be applied to objects in addition to building roofs and walls, such as space objects, tents, and vehicles.

Low-Dimensional Phonon-Polariton Materials for Higher-Order Hyperbolic Dispersion and Efficient Thermal Transport Guanyu Lu[1], Zhiliang Pan[1], Christopher R. Gubbin[2], Ryan A. Kowalski[1], Xun Li[3], James R. McBride[1], Rinkle Juneja[3], Mackey Long[1], Lucas Lindsay[3], Simone De Liberato[2], Deyu Li[1] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]University of Southampton, United Kingdom; [3]Oak Ridge National Laboratory, United States

Phonon polaritons are stimulated by coupling infrared photons with the polar lattice vibrations. Such quasi-particles offer low-loss, highly confined electromagnetic energy propagation at subwavelength scales. Here, we discuss the launching and manipulation of higher-order hyperbolic phonon polaritons (HPhPs) in low-dimensional materials.[1] Additionally, we discuss how non-equilibrium phonon polaritons in these materials can further enhance thermal transport as additional energy carriers.[2]

HPhPs in low-symmetry polar crystals offer ray-like light propagation with out-of-plane or in-plane hyperbolic wavefronts at deep-subwavelength scales. While hyperbolic dispersion in HPhPs implies multiple propagating modes at a given frequency, experimentally launching and probing the higher-order modes, especially for in-plane HPhPs, remains challenging. We report the experimental observation of higher-order in-plane HPhP modes, stimulated on the 3C-SiC nanowire (NW)/α-MoO_3 heterostructures. This demonstrates the advantage of leveraging both the low-dimensionality and low-loss nature of polar NWs to launch higher-order HPhP modes within two-dimensional α-MoO_3 crystals.

One-dimensional polar NWs not only bridge the wavevector mismatch between free-space light and the higher-order, high-momenta HPhPs but could also significantly impact thermal transport. While optic phonons typically contribute minimally to thermal conductivity, their hybridization with photons as phonon polaritons could facilitate conductive heat transfer in nanostructures. Although some signs of progress in phonon-polariton-mediated heat conduction have been made, experimental efforts so far suggest only very limited contribution from such modes. Here, by combining nanoscale real-space

mapping of phonon polaritons within 3C-SiC NWs with direct thermal transport measurements of these NWs (coated with gold as an efficient polariton launcher), we unambiguously demonstrate phonon-polariton-mediated heat conduction, resulting in orders of magnitude enhancement compared to equilibrium predictions.

An Abnormal Single Molecule Detection by Plasmonic InGaN Quantum Dots Thi Anh Nguyet Nguyen and Kun-Yu Lai; National Central University, Taiwan

Detecting single molecules is a formidable challenge. Surface-enhanced Raman spectroscopy (SERS) is one of the few techniques that can achieve the goal. To verify the presence of single molecules with SERS, the bianalyte proof is the most adopted approach since it is a statistical result from thousands of spectra, rather than the conclusion based on the blinking signals at few selected spots. However, the bianalyte method relies on an undesirable nature of SERS, i.e., the hot spot (SERS-active regions) is too small (< 10 nm) to cover two or more molecules. Since it is extremely difficult to control the size of a hot spot in a scalable manner, only a very limited portion (< 1%) of the diluted molecules can yield detectable Raman signals.

In this work, we demonstrate an abnormal single-molecule signal by SERS, covering 89.6% of the scanned spots. The result was achieved by making the hot spot big enough to simultaneously boost the signals from two or more single molecules. The hot-spot expansion was accomplished by coupling the localized surface plasmons at every Au nanoparticle with electrons confined by the subsurface InGaN quantum dots (QDs). This SERS configuration allows all of the dense Au nanoparticles to become the intensity-boost centers. Thus, any single molecule adsorbed on the SERS substrate can be easily captured by the Au-QD complexes, making single-molecule detection a prevailing event, instead of a rare instance.

With the greatly expanded SERS-active region, the single molecules can deliver stable signals by staying within the “hot surface” before and after the thermal diffusion upon laser excitation. This is not achievable with the conventional hot spots, where blinking signals are often observed by the SERS detection of diluted analytes. Our approach not only changes the bianalyte principle, but also allows researchers to analyze the molecular dynamics with reliable data.

SESSION EL08.03: Thermal Emission with Nanostructure and Nonreciprocal System

Harnessing The Infrared: Materials and Structures for Breaking Reciprocity and Control of Thermal Radiation Harry A. Atwater; California Institute of Technology, United States

In this talk I will discuss materials and photonic design concepts that allow us to experimentally observe breaking of optical reciprocity for thermal radiation, as well as metastructures that allow for considerable control of the thermal emission angular distribution. Thermal emission—the process through which all objects with a finite temperature radiate electromagnetic energy—has generally been thought to obey reciprocity, where the absorbed and emitted radiation from a body are equal for a given wavelength and angular channel. This equality, formalized by Gustav Kirchhoff in 1860, is known as Kirchhoff’s law of thermal radiation and has long guided designs to control the emitted radiation. There is considerable interest and numerous theoretical proposals for design of nonreciprocal absorbers that violate the Kirchhoff thermal radiation law. Until recently however, there were no experiments demonstrating this concept. I will discuss direct observation of the inequality between the spectral directional emissivity and absorptivity for an InAs photonic metastructure arising from the non-diagonal permittivity tensor of InAs at the epsilon-near-zero condition under an externally applied magnetic field. The magneto-optic response of magnetic Weyl semimetals is characterized by non-diagonal permittivity governed by the nontrivial Berry curvature that exists between recombinant Weyl nodes. I will also discuss reciprocity breaking in the magnetic Weyl semimetal $Co_3Sn_2S_2$, confirmed via observation of a net reflectance modulation that is nearly an order of magnitude higher than that of the typical transverse magneto-optical Kerr effect in ferromagnets, without the concurrent application of any external magnetic field, and discuss implications of these findings.

4:00 PM EL08.03.02
Thermal Imaging through Hot Emissive Windows Ciril Samuel Prasad[1], Henry O. Everitt[2] and Guru V. Naik[1]; [1]Rice University, United States; [2]DEVCOM Army Research Laboratory - South, United States

The challenging problem of enhancing thermal emission in some directions while suppressing it in others is exacerbated for hot windows because they must remain transparent in the same spectral window. This complex problem has prevented applications such as infrared imaging through hot windows, whose own thermal emission is strong enough to blind the camera [1]. Here, we demonstrate a solution to this long-standing challenge by replacing the hot emissive window with one coated with an asymmetrically emitting thermal metasurface. By engineering the imaginary index of refraction to produce an asymmetric spatial distribution of absorption losses in its constituent nanoscale resonators, the metasurface suppresses thermal emission towards the camera while being sufficiently transparent for thermal imaging.
We create the constituent resonators of the asymmetric loss metasurface by coupling nanoscale Si discs with distinct losses [2, 3, 4]. These silicon nano-discs separated by SiO_2 spacer support a quasi-bound state in the continuum (q-BIC) mode. These photonic modes couple to each other under normally incident input excitation with coupling strength that can be tuned by varying the spacer thickness. We identify that, when the resonators are weakly coupled, the eigenmodes of the system are distributed asymmetrically across the resonators with a large fraction of photon energy confined in the lossless resonator and hence causes strong asymmetry in the far-field thermal radiation from the metasurface [4].
The asymmetry in energy confinement also causes the resonance dip in the transmission spectra to be narrow and as a result, enhances the overall transmission in the spectral bandwidth of the thermal camera. Thus our metasurface design, inspired by non-Hermitian optics, balances the need for good transmittance and emissivity asymmetry required to achieve thermal imaging through an emissive hot window. Our metasurface window, operating at 873 K, enhanced the thermal imaging contrast by nearly 2 times when compared to a conventional window at the same temperature. This demonstration

illustrates the power of using the imaginary index as a design parameter for nanophotonic thermal devices, thereby enabling novel functionalities for energy, imaging, and sensing applications.

Far- and Near-Field Heat Transfer in Transdimensional Plasmonic Film Systems Svend-Age Biehs[1] and Igor Bondarev[2]; [1]University of Oldenburg, Germany; [2]North Carolina Central University, United States

Radiative heat transfer in transdimensional plasmonic film systems is analyzed using the confinement-induced nonlocal electromagnetic response model built on the Keldysh-Rytova electron interaction potential [1]. Results are compared to the local Drude model routinely used in plasmonics. The former predicts greater Woltersdorff length in the far-field and larger film thickness at which heat transfer is dominated by surface plasmons in the near-field, than the latter. Analysis performed suggests that the theoretical treatment and experimental data interpretation for thin and ultrathin metallic film systems must incorporate the confinement-induced nonlocal effect to provide reliable results in radiative heat transfer studies. The fact that the enhanced far- and near-field radiative heat transfer occurs for much thicker films than the standard Drude model predicts is crucial for thermal management applications and in general for the development of new quantum photonics materials based on ultrathin metallic films and metasurfaces of controlled thickness. The latest experiments to confirm this fact will also be reported [2].

Path Towards Large Space Bandwidth Product Spatial Light Modulator Arka Majumdar; University of Washington, Seattle, United States

Shaping an optical wavefront with sub-wavelength spatial resolution is important for various applications with far-reaching scientific and technological impacts (e.g., in adaptive optics and imaging through turbid, disordered media) and commercial interest (e.g., LIDAR for autonomous transportation and pixelated holography). The primary enabling technology for such capability is a compact optical phase shifter, which can change the phase of the incident light by a full 360 degree with low energy and high frequency (~MHz). Existing tunable optical technologies cannot provide this functionality; mechanically tunable modulators can reach a speed of only a few kHz, while liquid-crystal based modulators operate at 100's of Hz. The pixel size of the spatial light modulator is also on the order of tens of wavelengths, which increases the energy consumption per pixel.
In this talk, I will discuss our effort to tune meta-optics using non-volatile phase-change materials. Additionally, I will talk about varifocal meta-lens using micro-mechanical actuators. Apart from physical tuning, we can also implement varifocal functionality using computational techniques. Finally, I will discuss the issues of scalability of meta-optics based spatial-light modulation, and how we can use static meta-optics to effectively scale the number of tunable pixels in a spatial light modulator.

11:00 AM EL08.04.02
Enhanced Quantum Properties of Single Photon Emitters in Hexagonal Boron Nitride Flakes Using Plasmonic Nanocavities Abdelghani Laraoui[1],

Mohammadjavad Dowran[1], Ufuk Kilic[1], Suvechhya Lamichhane[1], Adam Erickson[1], Sy-Hwang Liou[1] and Christos Argyropoulos[2]; [1]University of Nebraska-Lincoln, United States; [2]The Pennsylvania State University, United States

Recently, single-photon emitters (SPEs) in solid-state materials have drawn a huge interest for different usages in quantum sensing and quantum nanophotonics [1]. Significant developments led to the finding of a variety of atom-like SPEs in low-dimensional and two-dimensional (2D) materials, such as hexagonal boron nitride (hBN), which exhibit favorable quantum properties at room temperature, making them highly desirable element for integrated quantum photonic circuits [2]. One major challenge of using these SPE host 2D materials in such applications is their low quantum efficiency with a fluorescence emission rate way below 0.5 Mc s^{-1}.
In this work, we use composite nanophotonic structures based on gap plasmonic modes, integrated with hBN multilayered flakes, to achieve a speedup and enhancement in the quantum interaction processes at room temperature. We first created a high density (> 0.5 SPE/1 μm^2) of stable SPE in thin (thickness ≤ 35 nm) hBN flakes deposited on a Si/SiO_2 substrate by using a high-temperature (1100 °C) annealing method under O_2 flow. We then transferred the annealed hBN flakes with SPEs to epitaxial gold (Au) film (thickness ~ 100 nm), grown on Si substrate, and characterized their quantum properties using a home-built confocal fluorescence microscope [3]. We demonstrated a plasmonic enhancement of SPE properties from the nanograins (size 50- 65 nm), found in the Au film, manifested by a decrease of quantum emitter lifetime by one order of magnitude and an increase of the emitter fluorescence by ~ 392% [4].
To enhance further the quantum properties of SPEs on a selected thin hBN flake we spin coated commercial silver nanocubes (SNCs) with size of 100 nm on the annealed Au/Si substrate. We optimized the spin coating parameters to increase the chance of getting the SNCs coupled spatially with the SPEs [3]. We observed plasmon nanocavity enhancement of SPE properties near the SNCs on top of the hBN flake manifested by a decrease of emitter lifetime by 100%, and a fluorescence enhancement of 200% [4]. The overall saturation counts is > 2 Mc/s for some of the SPEs in the plasmonic (metallic) Au/hBN/SNC nanocavities in comparison to ~ 0.25 Mc/s for SPEs in just hBN flakes deposited on SiO_2/Si substrates. The presented two order of magnitude enhancement of SPE quantum properties at room temperature is further investigated by using COMSOL numerical simulations. The hBN flakes are integrated into the fabricated nanophotonic cavities that are characterized by an optical frequency resonance response where light-matter interaction is particularly enhanced [4]. Zero Diffraction: A Novel Approach for High-Contrast Switching of Light Patrick Goerrn, Andreas Henkel, Sven O. Schumacher, Christopher Knoth and Maximilian Buchmueller; University of Wuppertal, Germany

The ultrafast electro-optic Pockels effect is widely used for modulating light in terms of its intensity, phase, and polarization, because controlling these parameters is the basis of modern information and communication technology. However, other applications, including displays, scanners, or solar concentrators, also require the control of geometric parameters of light, such as its pathway in space. Until today, the efficient spatial control of light remains challenging.

The common approach for achieving spatial control involves modifying optical components. These modifications often rely on the mechanical movement of lenses, mirrors or gratings, which is much slower compared to modulations based on the Pockels effect. Recent reports propose novel approaches based on interference. [1] In these cases, the optical components remain mostly unchanged, but their interaction with light strongly depends on the light's properties like phase or momentum leading to a limited set of operation parameters.

Here, we propose a novel approach for controlling the diffraction of light at a leaky waveguide grating using the ultra-fast Pockels effect. The leaky waveguide grating is illuminated by two symmetrical incident plane waves. By tuning the relative phase between the two waves, the diffraction can be entirely suppressed, termed *zero diffraction*. [2] Therefore, this phenomenon enables to control the diffraction of light with infinite contrast. Remarkably, it not only occurs at singular spectral positions but on continuous curves in the energy–momentum space.

In analogy to our recent report, we first investigate a standalone grating and a symmetric waveguide grating under symmetric dual-plane wave incidence. Simulations using rigorous coupled wave analysis (RCWA) show that the diffraction efficiency can be controlled with an average contrast below 100. Zero diffraction cannot be found in either of these cases.

In the next step, we introduce leakiness and find zero diffraction for plane waves. We demonstrate the experimental feasibility of these theoretical findings using real laser beams instead of plane waves. For that purpose, a symmetric waveguide grating is placed between two lithium tantalate ($LiTaO_3$) wafers of opposite crystal direction. The high refractive index of the $LiTaO_3$ introduces leakiness, while the opposite crystal direction maximizes the relative phase shift when applying an electric field across the entire waveguide stack. After creating symmetrically propagating beams, we measure the optical power diffracted at the waveguide grating as a function the applied field strength and find a maximum contrast of 1236.

This way, we also show how zero diffraction can be applied in a nonlinear waveguide in order to control trapping and detrapping of light. The position where a directed laser beam is detrapped from the surface can be selected with an electric field without any mechanics. Laser displays based on zero diffraction would be more efficient than liquid crystal displays as are not based on absorption. Instead, they extract the light only where it is needed. At the same time, such laser displays could be completely transparent and promise immense possibilities in terms of color rendering due to the narrow spectrum of the laser.

Metamaterial-Controlled Parity-Time Symmetry in Non-Hermitian Wireless Power Transfer Systems Hanwei Wang, Xiaodong Ye and Yang Zhao; University of Illinois at Urbana-Champaign, United States

Wireless power transfer (WPT) technologies contain two main categories, radiative and non-radiative. Non-radiative WPT utilizes the magnetic near-field to carry energy and is more commonly used due to its advantages of high-power volume and safety. The receiving (Rx) resonator couples with the transmitting (Tx) resonator through magnetic mutual induction. Inductive WPT systems can be described as non-Hermitian systems through coupled-mode theory. Power transfer in such systems is efficient when forming PT-symmetric states, which could be guaranteed by the physical symmetry in a strong

coupling regime. However, spontaneous symmetry breaking happens in the weak coupling regime as the increasing of the Tx-Rx separation, where the resonant states become anti-PT-symmetric.

Relay resonators can be used to increase the overall coupling and, therefore, increase the maximum Tx-Rx separation for the PT-symmetric state. The PT-symmetric states in such systems are also known as the topological edge state for magneto-inductive waves, which have been used for mid-range WPT and frequency-robust WPT. However, one drawback of the relay resonators is the potential involvement of higher order resonant states of the system; many of the states are anti-PT symmetric. To avoid these states, spatial arrangement of the relay resonators needs to be symmetric and the geometry of the Tx and Rx resonators need to be identical. Such requirements are impractical in many applications, such as free-positioning WPT.

Metamaterials, demonstrating excellent ability in manipulating electromagnetic and acoustic fields and waves, show great potential in solving this challenge. Researchers have developed metamaterials to control the PT-symmetry for above-unity transmission and reflection, nanoscale sensing, and coherent perfect absorption. However, such an approach remains challenging for WPT systems due to the lack of accurate control in the metamaterial's resonance mode. In our previous works, we have demonstrated a quasi-Hermitian metamaterial that can achieve on-demand field-shaping for magnetic resonance imaging and WPT. In this conference presentation, we will extend the theory by showing metamaterial-controlled PT-symmetry in a non-Hermitian WPT system.

We derive the states of the system and show that a PT-symmetric state can be achieved with certain metamaterial's configuration. The sizes of the Tx and Rx do not need to be identical, and their physical positions are not limited as long as operating in the strong coupling regime. We prove that the state is stable when the system operates in a strong coupling regime. We theoretically and experimentally demonstrate the transition between anti-PT-symmetric and PT-symmetric states controlled by the metamaterial's configuration. We further show that the PT-symmetric state can be achieved with different spatial arrangements of the Rx resonator. This technique largely increases physical freedom of Tx and Rx and provides a paradigm for designing many-body WPT systems.

Ultrafast Collapse of Molecular Polaritons to Pure Molecular Transition in Plasmonic Photoswitch-Nanoantennas Joel Kuttruff[1], Marco Romanelli[2], Esteban Pedrueza-Villalmanzo[3], Jonas Allerbeck[4], Jacopo Fregoni[5], Valeria Saavedra-Becerril[6], Joakim Andréasson[6], Daniele Brida[7], Alexandre Dmitriev[3], Stefano Corni[2] and Nicolò Maccaferri[8,7]; [1]Universität Konstanz, Germany; [2]Università degli Studi di Padova, Italy; [3]University of Gothenburg, Sweden; [4]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [5]Universidad Autonoma de Madrid, Spain; [6]Chalmers University of Technology, Sweden; [7]University of Luxembourg, Luxembourg; [8]Umeå University, Sweden

Molecular polaritons are hybrid light-matter states that emerge when a molecular transition strongly interacts with photons in a resonator. At optical frequencies, this interaction unlocks a way to explore and control new chemical phenomena at the nanoscale. Achieving such control at ultrafast timescales, however, is an outstanding challenge, as it requires a deep understanding of the dynamics of the collectively coupled molecular excitation and the light modes. Here, we investigate the dynamics of collective polariton states, realized by coupling molecular photoswitches to optically anisotropic plasmonic nanoantennas. Pump-probe experiments reveal an ultrafast collapse of polaritons to pure molecular transition triggered by femtosecond-pulse excitation. Through a synergistic combination of experiments and quantum mechanical modelling, we show that the response of the system is governed by intramolecular dynamics, occurring one order of magnitude faster with respect to the uncoupled excited molecule relaxation to the ground state. Our results provide exciting foundation for the further exploration of the synthesis and characterization of strongly coupled photoswitch systems, towards a full control of ultrafast chemical processes at the nanoscale.

Active Excitonic 2D Metasurfaces Using Exciton Polaritons in Monolayer TMDs Thomas Bauer and Jorik Van de Groep; University of Amsterdam, Netherlands

Monolayer transition metal dichalcogenides (TMDs) like WS_2 exhibit strong exciton resonances in the visible spectral range that govern their optical response. The excitonic light-matter interaction in these 2D quantum materials is inherently strong and highly tunable, which can be leveraged to realize mutable flat optical elements as well as novel spin-valley coupled information carriers. To unleash the full potential of exciton-enhanced wavefront shaping and active optical switching in atomically thin metasurfaces, it is essential to gain a detailed understanding of the exciton's quantum mechanical properties and its coupling to hybrid light-matter quasiparticles known as exciton polaritons.

Recently, it was shown theoretically that exciton polaritons can exist as excitations from the continuum of three-dimensional electromagnetic modes even for atomically thin layers of materials. Coupling to such 2D exciton polaritons (2DEPs) was subsequently demonstrated experimentally in a free-standing monolayer membrane via photoluminescence excitation and outcoupling through a photonic crystal. Realizing such a strongly coupled light-matter state in on-chip photonic environments promises new opportunities for tunable wavefront shaping, photonic sensing, as well as probing of fundamental quantum-mechanical properties of light scattering by excitons.
However, direct integration of coherently coupled 2DEP functionality into nanopatterned monolayers on substrates has so far remained elusive due to the stringent requirements on the dielectric environment as well as monolayer quality to support 2DEPs.

Here, we experimentally demonstrate active control of coherent coupling to 2DEPs in a monolayer of WS_2 on a quartz substrate, allowing for enhanced photonic functionality given directly by the geometry of the monolayer itself. We accomplish guiding along the monolayer by managing the refractive index contrast between the top and bottom side via a 230nm thick capping layer of PMMA. Using guided mode resonances in sub-wavelength gratings structured in mm-sized continuous WS_2 monolayers, we realize polarization-selective dynamic phase control of light scattered coherently off the hybrid light-matter state. The sub-wavelength nature of the grating together with the high quality and homogeneity of the initial monolayer leads to an electrically and/or thermally tunable phase modulation of the reflected light when exciting close to the 2DEP guided mode resonance.

Further utilization of photonic metasurface concepts allows for active amplitude switching of higher diffraction orders via binary blazed gratings, leading to

expected modulation depths exceeding 80% stemming from an atomically thin optical element. This opens a path to full active control over the complex optical response in tailored atomically thin metasurfaces via exciton resonance tuning.

1:45 PM EL08.05.02
Asymmetric Propagation of Hyperbolic Polaritons in MoO_3 and β-Ga_2O_3 Heterostructures Saurabh Dixit[1], Maximilian Obst[2], José Á. Cuervo[3], Giulia Carini[4], Ryan Kowalski[1], Aitana T. Martín-Luengo[3], Gonzalo Alvarez Perez[3], Katja Diaz-Granados Santos[1], Aditha Senarath[1], Niclas Müller[4], J. Michael Klopf[5], Lukas Eng[2], Susanne Kehr[2], Thomas G. Folland[6], Pablo Alonso Gonzalez[3], Alex Paarmann[4] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]Technische Universität Dresden, Germany; [3]University of Oviedo, Spain; [4]Max Planck Society, Germany; [5]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [6]The University of Iowa, United States

Opposite signs of the dielectric permittivity along different principal directions of optical materials (hyperbolic anisotropy) allow for exotic quasiparticles to be formed due to the hybridization of photons and phonons (phonon polariton) in the mid-infrared spectral region. Phonon-polaritons in such hyperbolic materials enable the confinement of electromagnetic waves at the nanoscale, which offers mechanisms to induce large enhancements of the optical response and reduce the footprint of photonic devices such as molecule sensors, polarizers, waveplates, optical modulators, IR sources and detectors, and many others. To design nanophotonic devices, it is necessary to engineer the characteristic features of phonon polaritons, like propagation direction and distances. It has been demonstrated that characteristic features of hyperbolic phonon polaritons can be engineered via the choice of crystal symmetry. Hyperbolic polaritons in crystals with varying symmetries from hexagonal, such as boron nitride (h-BN), exhibit isotropic propagation in plane, whereas reducing to orthorhombic structures like MoO_3 and V_2O_5, results in directional propagation. Monoclinic systems, such as β-Ga_2O_3 or $CdWO_4$, with further reduced symmetry exhibit exotic phenomena in the form of shear, whereby the polariton wavelength and direction of propagation disperse with changing frequency. This provides an additional degree of freedom to manipulate polariton propagation. By employing twisted low symmetry structures, such as twisted slabs of MoO_3, highly directional propagation with minimal divergence can be observed (canalization) at specific 'magic' angles. Yet, it remains unclear if such canalization can be observed in twisted structures of different Bravais lattices. Here, we investigate heterostructures of MoO_3 orthorhombic) and Ga_2O_3 (monoclinic) to determine the role of twisting with non-degenerate polariton resonances, as well as the potential influence of shear. By investigating a series of MoO_3 slabs twisted with respect to the a-axis of β-Ga_2O_3 we observed the change in the direction of propagation along with asymmetric dispersion via a scattering-type SNOM coupled to a free-electron laser. It is determined that the high asymmetry in the propagation in the twisted structure is driven principally by the twist angle, rather than the inherent shear in the underlying β-Ga_2O_3, indicating that the propagation direction can be dictated via twist angle, making such heterostructure platforms designable for future nanophotonic devices such as sensors, chiral sources, IR imaging components, and many others.

2:00 PM EL08.05.03
Polariton Design and Modulation via Van der Waals / Doped Semiconductor Heterostructures Mingze He[1], Joseph R. Matson[1], Mingyu Yu[2], Angela Cleri[2], Sai Sunku[3], Eli Janzen[4], Stefan Mastel[5], Thomas G. Folland[6], James Edgar[4], D. Basov[3], Jon-Paul Maria[2], Stephanie Law[2] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]The Pennsylvania State University, United States; [3]Columbia University, United States; [4]Kansas State University, United States; [5]Autocube, Germany; [6]The University of Iowa, United States

Due to the long free-space wavelength of mid- to far-infrared (IR) light, the realization of deeply subdiffractional photon confinement via the stimulation of polaritons is critical for IR nanophotonic applications, such as miniaturized optical components, on-chip photonics, polariton waveguides, and nanolasers. Specifically, hyperbolic polaritons supported in extremely anisotropic media, i.e., those featuring permittivity tensor components with opposite signs along different optical axes, can offer significant promise for many nanophotonic applications where stronger confinement and improved control over propagation are beneficial. Applications of these properties include hyperlensing, metasurface-based optical components, quantum optics, and probes of nanoscale defects. While hyperbolicity was first demonstrated with artificial dielectric/metal stacks, it was later discovered that a list of natural materials, including hexagonal boron nitride (hBN), MoO_3, V_2O_5, support hyperbolic phonon polaritons (HPhPs). Such HPhPs in natural crystals feature exceptionally low optical losses, as the polaritons are derived from optic phonons instead of scattering from free carriers.
Compared to surface polaritons, HPhPs offer further confinement of long-wavelength light to deeply subdiffractional scales. Furthermore, the evanescent field of volume propagation could interact with the local environment, e.g., substrate, allowing for tuning of wavevectors without modifying the hyperbolic media itself. Therefore, it is possible to realize polaritonic resonators and near-field polariton propagation without deleterious etching of hyperbolic materials. While it is promising to utilize the substrate-induced effect in engineering polaritonic devices, conventionally used noble metal and dielectric substrates restrict the tunability of this approach, leaving most of the wavevectors in the dispersion inaccessible.
Here, we present our recent work on exploiting substrate induced HPhP tuning. We demonstrate that using doped semiconductors, e.g., InAs and CdO, can enable near-continuous tuning and access to both the maximum and minimum wavevectors (~8.3 times experimentally demonstrated). We further elucidate HPhP tuning with the plasma frequency of an InAs substrate, which features a significant wavevector discontinuity and modal order transition when the substrate permittivity crosses -1 in the Reststrahlen band. Around the transition point, the HPhP system is sensitive to perturbations, e.g., the working frequency, InAs plasma frequency and superstrate, thus it is suitable for sensing and modulation applications. Although the loss of HPhPs peaks around the transition point, where the largest tunability is observed, we highlight that the increased loss can be neglected in some proposed applications/devices. We also illustrate that the hBN/InAs platform allows for active modulation at picosecond timescales by photo-injecting carriers into the InAs substrate, demonstrating a dynamic wavevector change of ~20%. Overall, the demonstrated hBN/doped semiconductor platform offers significant improvements towards manipulating HPhPs, and enormous potential for engineered and modulated polaritonic systems for applications in on-chip photonics and planar metasurface optics.

Strong Field Enhancement Based on Manipuation of Anapole State in Dielectric Metasurface Wen-Hui (Sophia) Cheng and Meng-Hsueh Tsai; National Cheng Kung University, Taiwan

Resonant metamaterials and metasurfaces cause by light-matter interaction in sub wavelength structures have been a hot research topic recently due to its potential in progressing the conventional devices. Anapole, a new hybrid mode is formed by overlapping toroidal dipole (TD) and electric dipole (ED) mode. Since the far field radiations of TD and ED are antiphase, destructive interference between them will turn this hybrid mode into a dark mode with strong near field. In addition, the electric field can be further enhanced by incorporating the slot effect, which happens to fulfill the continuity of electric displacement field at interfaces of low-refractive-index and high-refractive-index material. In this work, we propose a dielectric metasurface which can support anapole mode and introduce slot effect to manipulate field enhancement. The structure is composed of a concentric circle and ring, with a middle bar connecting them. We find the middle bar and gap are critical and give rise to the tunability. From the multipole decomposition, a combination of TD and ED with same amplitude can be corresponded to the anapole mode. It shows that the middle bar creates a path for displacement current passing through it, supporting the nonradiative mode with high quality factor. The strong near field enhancement and high Q demonstrated is believed to be useful for many applications including PL control and nonlinear effect.
Keywords: Anapole, Slot effect, Metasurface, Dielectric, Field enhancement

2:45 PM EL08.05.05
Weak Coupling of WSe_2 to Plasmonic Surface Lattice Resonance Stanislav Tsoi, Marc Christophersen, Joseph A. Christodoulides, Hsun Jen J. Chuang, Paul D. Cunningham, Adam D. Dunkelberger, Kathleen M. McCreary, Nicholas Proscia and Igor Vurgaftman; U.S. Naval Research Laboratory, United States

Weak coupling of light emitters to optical cavities facilitates efficient photon extraction by directing their emission into cavity modes instead of random directions in free space. Monolayer transition metal dichalcogenides (TMDs) are 2D semiconductors with the direct band gap attractive for future nanoscale optoelectronics. The present experimental work investigates weak coupling of monolayer WSe_2 to a metasurface cavity, consisting of a lattice of plasmonic nanodisks and supporting surface lattice resonances (SLRs) propagating in its plane. The nanodisks were fabricated from aluminum and WSe_2 mechanically transferred on top of the cavity. Angle-resolved photoluminescence (PL) measurements show efficient light emission by WSe_2 into the SLRs. The most efficient emission appears to take place into spectrally narrow modes resulting from interference of two counter-propagating SLRs, a previously unreported behavior in metasurface cavities. The obtained results suggest the opportunity to control the interference modes via geometrical factors of the lattice and thus tune the strength of its coupling to emitters, including the possibility of strong coupling.

3:30 PM EL08.06.01
Plasmon Enhanced Light Emission in Metal Halide Perovskite Nanowires Tintu Kuriakose[1], Qingyu Wang[1], Hao Sha[2], Shengfu Yang[2] and Robert A Taylor[1]; [1]University of Oxford, United Kingdom; [2]University of Leicester, United Kingdom

Photonic nanowires based on semiconductor materials have potential applications in light generation, propagation, detection, and amplification at the nanoscale and play a key role in the development of integrated photonic/electronic devices. To achieve the best optical performance for these applications it is crucial to enhance the photon conversion efficiency of the nanowires. A promising way to enhance light emission from nanowires is to combine semiconductors with noble metals. The strong confinement of electromagnetic field resulting from plasmonic structures can effectively transfer surface plasmon resonance energy to semiconductors via excited electrons and thus effectively enhance the photoluminescence (PL) yield. However, the synthesis of hybrid metal-semiconductor nanowires having desirable optical properties has proven challenging due to the non-wetting between the two types of materials.

Here we report plasmon-enhanced light emission from a hybrid nanowire consisting of noble metal and semiconductor materials. The demonstration is performed in a cesium lead halide perovskite-based four-layer structure (CsPbBr3/PMMA/Ag/Si) designed to limit plasmonic losses in the metal while exhibiting efficient surface plasmon-photon coupling at moderate power. We used solution processing to make the nanowires, which were then spin-coated onto a Si substrate coated with Ag nanoparticles. These were produced by using quantized vortices in superfluid helium, which circumvents the non-wetting between the two types of materials. We employ temperature-dependent micro-photoluminescence spectroscopy (from 4 K to 300 K), to study the optical properties of the nanowires. We excite the individual nanowires by considering several configurations with Ag nanoparticle diameters ranging from 7 to 10 nm and PMMA layer thicknesses ranging from 5 to 25 nm to better understand the optical performance. The study, conducted with 100 fs laser pulses at a repetition rate of 76 MHz and at an excitation wavelength of 400 nm reveals that a 5 nm thick PMMA layer and 7.5 nm sized Ag nanoparticles enhanced the PL intensity by approx. 40% compared to pure semiconductor structures at 4 K. In addition, we investigate the emission dynamics of carriers and excitons in the nanowires using time-resolved photoluminescence spectroscopy techniques. Observation shows enhanced carrier recombination dynamics due to plasmonic interactions with the perovskite. These results show a potential way to excite hybrid nanowires at sufficiently low photon density so that single photon excitation/emission could be possible from these structures. Moreover, this fundamental demonstration confirms a proof-of-concept for further work involving plasmon-enhanced light emission from core-shell metal/semiconductor nanowires and opens the door for realizing lead halide perovskite-based micro and nanolasers in the visible range and more broadly for developing on-chip nanophotonic devices.

Functional Materials for Next Generation Photonic Chips Volker J. Sorger, Nicola Peserico, Russell Schwartz, Hao Wang, Chandraman Patil and Hamed Dalir; University of Florida, United States

Emerging and functional materials are critical for next-generation optoelectronic device performance, energy efficiency, and application capabilities. In this presentation we share recent developments on efficient, fast, and compact electro-optic modulators, as well as sensitive photodetectors with high gain bandwidth products, as part of advanced integrated photonic circuits. The second part of the presentation then shows how these emerging device-level technologies enable performance gains for photonic-electronic heterogeneous integrated AI chiplets to accelerate machine learning applications such as matrix-matrix multiplications and convolution operations.

4:15 PM EL08.06.03
Disordered Meta-Doublets for Unidirectional and Synergistic Imaging in The Mid–Infrared Romil Audhkhasi, Maksym Zhelyeznyakov, Anna Wirth-Singh and Arka Majumdar; University of Washington, United States

Recent advances in metamaterials have enabled the realization of complex optical functionalities within a compact form factor. The vast number of design degrees of freedom in such systems provides the ability to manipulate optical waves in the spatial and spectral domain, thereby enabling the development of photonic devices for a broad range of applications. Here, we propose an all-silicon metamaterial platform for advanced imaging applications in the mid-infrared wavelength range. Specifically, we design large aperture, all-silicon meta-optic doublets for unidirectional and synergistic imaging at a wavelength of 4 μm. The large design space afforded by metamaterials often makes it challenging to optimize such devices for a desired functionality using a conventional forward design approach. Here we develop a differentiable model that maps the structure of our meta-atoms to their optical response. Our algorithm uses this model iteratively to modify the structural parameters of our devices and optimize a figure of merit that mathematically describes the desired optical response. The phase profiles of our optimized devices possess a large degree of disorder that is tailored to realize the required imaging functionality. When illuminated by a plane wave in the forward mode, our unidirectional imager generates an intense spot on its optic axis at a predefined

focal length. In the reverse mode, the imaging performance is significantly reduced, accompanied by a dramatic reduction in light intensity on the focal plane. On the other hand, our synergistic imager is optimized to enable imaging only when the constituent meta-optics are used in conjunction with each other. We envision our devices to provide new avenues for the development of metamaterial imaging platforms for applications in defense and data security.

4:30 PM *EL08.06.04
Electrolyte-Gating for Metasurfaces and Large-Area Fabrication Vivian Ferry; University of Minnesota, United States

Alternative materials for metasurfaces enable new properties and lay the foundation for advantage applications. This talk will discuss two strategies for new, tunable metasurfaces. The first part of the talk will discuss the use of electrolyte gating to control the optical properties of materials, focusing on $La_{1-x}Sr_xCoO_{3-d}$ (LSCO) as an exemplary case. We fabricate electric double layer transistors using LSCO and an ion gel, and under application of positive gate voltage gating facilitates the formation and migration of oxygen vacancies, and a transition from a perovskite phase to an oxygen-vacancy-ordered brownmillerite phase. This is accompanied by substantial change in optical properties, as measured with spectroscopic ellipsometry. The talk will discuss how LSCO can be incorporated with metasurfaces to produce tunable optical response. The second part of the talk will discuss a new strategy for fabricating large-area metasurfaces, using roll-to-roll compatible additive manufacturing methods. This method, which uses solution-based inks to create the metasurfaces, can pattern a variety of materials, including metals, dielectrics, and semiconductor nanocrystals, and also create multilayer structures.

5:00 PM EL08.07.01
Polarization-Multiplexed Metalens for Far-Field Super-Resolution Imaging Yaxi Liu, Bohan Zhang, Qiushuang Lian, Shuai Wang and Yuanmu Yang; Tsinghua University, China

Recent decades have seen an increasing interest in developing super-resolution imaging methods that allow overcoming the diffraction limit. Near-field imaging methods achieve super-resolution by collecting evanescent waves with high spatial frequency components, often having subwavelength working distances or requiring the sample to be placed near a specially structured hyperlens. On the other hand, far-field super-resolution microscopy imaging with fluorescent substances often requires staining the sample. For non-invasive far-field super-resolution imaging systems based on a super-oscillatory lens, the field-of-view is limited by the unwanted sidelobes and sidebands. The throughput efficiency of the super-oscillatory lens dramatically decreases with the reduced size of the main focal spot. Here, we propose a far-field non-invasive super-resolution imaging method based on polarization-multiplexed metalens. By designing and optimizing the polarization-multiplexed, multi-channel point spread functions of the metalens, the system can obtain multi-channel optical information in a single shot. As a result, we obtain a digitally synthesized point spread function with a center hot spot with a small full width at half maximum as well as suppressed sidelobes and sidebands. Such a compact, single-shot super-resolution imaging system could enable new applications in diverse areas ranging from remote sensing to microscopy over a wide field-of-view.

5:00 PM EL08.07.02
Hotspot at Dimer, Small Aggregate and 2D Nanoassembly by Near-Field Scanning Optical Spectroscopy Mohammad Kamal Hossain; King Fahd University of Petroleum & Minerals, Saudi Arabia

Nanoassembly of noble metal nanoparticles facilitates surface plasmon confinements, and such localizations can coalesce and percolate due to a small variation in local nanogeometry. However, realizing such confinement by conventional microscopic and spectroscopic techniques has been challenging until now. We report near-field optical confinement observed by an aperture near-field scanning optical microscopy (a-NSOM). Three typical constructs of gold nanoparticles, viz., archetype dimer, nanoassembly of a few nanoparticles, and long-range two-dimensional (2D) nanoassembly, were investigated. Surface-sensitive techniques such as near-field surface-enhanced Raman scattering (SERS) and near-field surface-enhanced two-photon-induced photoluminescence (TPI-PL) have been recorded using a-NSOM. Well-correlated optometrology was confirmed amongst the SERS, TPI-PL, and shear-force topographies of the abovementioned constructs tapping simultaneously at the very same spot of interest.
Distinctive aggregates and 2D nanoassemblies of gold nanoparticles (~100 nm diameter) were fabricated by the “sandwich technique”, wherein the droplet on a silane-treated treated cover-slip was sandwiched by another glass slide. Monomers, dimers and nano-assemblies of various sizes were confirmed by a field-emission scanning electron microscope. The specimens were spin-coated with Raman active dyes, Rhodamine 6G. A fs-Ti: sapphire laser (λ= 800nm, <100fs, 80MHz) and He-Ne laser (λ=632.8nm) were coupled to the a-NSOM to carry out TPI-PL and SERS measurements. Au-coated tapered optical fiber was used to carry the excitations and act as an apertured probe (aperture ~ 50–100 nm) to scan the specimen. The emitted signals were collected by an objective lens and transferred to an avalanche photodiode (for single-channel detection) and/or to a polychromator-CCD (for multichannel detection).
As expected, optical signals from SERS and TPI-PL were found to be confined and localized at the interstitials of dimers, whereas coalescence and hybridization of such nearby confinements for nanoassemblies were observed. For long-range 2D nano-assembly, optical confinements were more complex and homogenously distributed apart from the edge effect in this context. Finite-difference time-domain (FDTD) simulations were carried out to validate the results obtained in this investigation. FDTD models were designed so that the geometries and parameters closely represent the constructs under investigation and the a-NSOM setup. Such a direct observation with high spatial resolution is required to comprehend the origin of the localized electromagnetic (EM) field at the "hotspot" and the EM amplification factor in surface-sensitive optical processes.
The author acknowledges the Interdisciplinary Research Center for Sustainable Energy Systems (IRC-SES), Research Institute, King Fahd University of Petroleum and Minerals (KFUPM), Dhahran 31261, Saudi Arabia (Grant # INRE2318).

5:00 PM EL08.07.03
Arrays of Split-Ring Resonator embedded in a Free-Standing Gold Membrane for Surface-Enhanced Infrared Absorption Biosensing Platform
Chieh-Chun Chang[1,2] and Yun-Chorng Chang[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

In this study, free standing gold (Au) membranes with embedded arrays of split-ring resonator (SRR) were fabricated using modified nanospherical-lens lithography. The diameter of the polystyrene nanosphere used is 2 mm. The SRR-shaped photoresist (PR) patterns were achieved by exposing ultraviolet light at a tilt angle while rotating the sample and subsequent PR development. A thin Au layer was evaporated onto the rotating sample at an oblique angle and the evaporated Au only covered the surface area, resulting the Au membranes with embedded SRR arrays. The Au membrane was released from the

substrate by dipping into the solvent and was recovered onto a stainless-steel plate with micron-sized holes. The Au membrane suspended within the micron-sized hole is the free-standing gold Au membrane with embedded SRR arrays. Surface plasmon resonance (SPR) of the fabricated SRR is in the mid-infrared, which was confirmed by the theoretical simulation. The structural parameters of the SRR were tuned so the SPR is within the molecular infrared signature region between 400 to 4000 cm^{-1}. 4-aminothiophenol (4-ATP) molecules were applied to the Au membrane and their absorption signal around 1490 and 1600 cm^{-1}, which are correspondent to the vibrational modes of C=C bond and NH_2 scissoring, are greatly enhanced. Therefore, the proposed gold membrane with embedded SRR array can be ideal platform for surface enhanced infrared absorption spectroscopy.

Infrared Magnetic Hyperbolic Metamaterials Swati Parmar, Yayoi Takamura and J. Sebastian Gomez-Diaz; University of California, Davis, United States

Magneto-optic (MO) materials represent a fascinating realm where the manipulation of magnetic spins is intricately entwined with the control of light propagation.[1,2] Our research delves into harnessing the potential of established MO effects— Faraday, Voigt, and Kerr effects—to steer, sense, manipulate, and process infrared light through ferromagnetic hyperbolic metamaterials (HMTM). The core of our innovation lies in the integration of ferromagnetic oxides with gold nanorods, creating broadband HMTM that exhibit epsilon-near-zero (ENZ) properties. Additionally, we leverage infrared surface plasmons supported at the interface between the HMTM and air to amplify MO effects, forging a synergistic relationship between magnetics and plasmonics. This magneto-plasmonic synergy not only opens avenues for developing compact nonreciprocal devices but also facilitates the creation of magnetic field-sensitive hyperbolic composite materials, enabling the precise manipulation of electromagnetic waves at the nanoscale. Our objective is to contribute to technologies at the intersection of magneto-optics and plasmonics.

In our fabrication process, nanocomposite films consist of vertically aligned gold (Au) nanopillars within ferromagnetic $(La,Sr)MnO_3$ (LSMO) oxide matrices, achieved through pulsed laser deposition. X-ray diffraction confirms the highly epitaxial nature of the (001)-oriented ferromagnetic LSMO film along, while X-ray reflectivity attests to the uniformity of electron density and high-quality surfaces and interfaces with a film thickness of approximately 30 nm. Detailed analysis through atomic force microscopy and scanning electron microscopy reveals the formation of Au nanopillars with diameter of around 45 nm within the LSMO matrix. X-ray photoelectron spectroscopy of the Au 4f and Mn 2p core levels highlights that the electronic structure of the nanocomposite displays a correlation between Fermi energy and electrical conductivity.

Notably, Fourier transform infrared (FTIR) microscopy uncovers a highly reflective band observed between approximately 12.2 µm and 8 µm optical phonon wavelengths. Ellipsometry microscopy further demonstrates the presence of double negative materials in our engineered nanocomposite. Further, we employed scanning near-field optical microscopy nano-FTIR, providing high-resolution insights with 10 nm spatial resolution. This technique not only enables chemical analysis but also characterizes local electromagnetic fields, offering a comprehensive understanding of the intricacies within our magneto-plasmonic nanocomposite.

Laser-Based Facile Fabrication of Plasmonic Gold Nanostructures and Their Sensory Applications Do-Hyun Kang, Nguyen H. Minh, Ga-Eun Han, Jae Sung Yoon, Kwanoh Kim and Yeong-Eun Yoo; Korea Institute of Machinery and Materials, Korea (the Republic of)

Plasmonic nanostructures presenting localized surface plasmon response (LSPR) have attracted great attention in diverse sensory applications. Susceptible change of LSPR peak wavelength to the environmental stimulus, such as molecular binding, has been exploited to detect rare biomolecules at extremely low concentrations. In addition to such biomolecule sensing, the LSPR peak change to the distance variation between individual plasmonic nanostructures has been used to equipment-free colorimetric sensing of mechanical strain. Various nanolithography techniques have been employed to craft plasmonic metal nanostructures to realize the above-mentioned sensor applications; however, there is still a need for a low-cost, simple, fast, and scalable fabrication method to achieve reliable and reproducible LSPR sensors. Herein, we introduce a laser scribing-based technique for rapid formation and patterning of plasmonic gold nanostructures. In our process, a high-power laser beam melts a thin gold film on glass or quartz substrates, and subsequent dewetting of the melted gold results in nano-island structures consisting of surface-bound gold nanoparticles with an average diameter of 42 nm. We have been successfully applied the plasmonic structures to the highly-sensitive and selective immunoassay of the SARS-CoV-2 nucleocapsid protein, enabling the diagnosis of recently prevalent infectious disease, COVID-19. On the other hand, we have also developed a technique to transfer the gold nanostructures from the hard quartz substrate to the soft and flexible elastomer tape, aiming to create convenient colorimetric strain sensors capable of detecting mechanical motions of human bodies or mechanical behaviors of building structures.

5:00 PM EL08.07.07
Molecular Reporter-Immobilized Ag-Au Shell-Satellite Nanoassemblies for a SERS-Based Galactose Sensor Eun Hae Heo and Hyejin Chang; Kangwon National University, Korea (the Republic of)

Galactosemia is a genetic metabolic disorder caused by a deficiency of galactose-degrading enzymes, leading to the accumulation of galactose and its metabolites in the body. The early diagnosis of galactosemia is crucial, as it can lead to death if left untreated. In this study, we present a surface-enhanced Raman spectroscopy (SERS) sensor based on a capillary tube for the convenient and sensitive detection of galactose. To enhance the SERS signal, we introduced gold nanoparticles (Au NPs) onto the surface of silver nanoshells (Ag NSs) to create an Ag-Au shell-satellite nanoassemblies on the inner wall of a capillary. We then fabricated a Ag-Au shell-satellite structured SERS sensor using 4-mercaptophenylboronic acid (4-MPBA) as a Raman reporter molecule. The galactose detection method relied on the conversion of 4-MPBA to 4-mercaptophenol (4-MPhOH) due to the production of hydrogen peroxide (H_2O_2) resulting from the oxidation of galactose by enzyme (galactose oxidase, GOx). A new SERS band was observed, which can be attributed to the H_2O_2 produced during the reaction between galactose and GOx. Additionally, we observed an increase in the band intensity ratio between 418 cm^{-1} and 390 cm^{-1} (I_{390}/I_{418}) as a function of galactose concentration. This strategy for galactose SERS detection based on a capillary tube-based SERS biosensor demonstrates its potential as an early galactosemia diagnosis platform.

5:00 PM EL08.07.08
Enhanced Room-Temperature NIR Plasmonic Photodetection and Photoelectron Spectroscopy Eslam N. Abubakr[1,2,3], Masaaki Oshita[1], Shiro Saito[3] and Tetsuo Kan[1]; [1]The University of Electro-Communications, Japan; [2]Aswan University, Egypt; [3]IMRA Japan Co., LTD., Japan

The development of plasmonic photodetectors, especially in the near-infrared (NIR) region, has gained significant attention due to their non-destructive nature. It is essential to provide absorption of longer wavelengths in the most accurate, reliable, and repeatable manner; however, fabricating NIR detectors can be challenging due to their inherently low energy. Prior studies have laid a solid foundation for NIR detection and spectroscopy. However, responsivity was limited to a few tens of μA/W, and spectroscopy of the longer wavelength range of NIR beyond 1400 nm is not yet clearly demonstrated. In this work, we achieved remarkable detection over a wide range of wavelengths up to 2300nm with distinguished responsivity. Our emphasis lies in the extension of the spectral range for reconstructive spectroscopy into longer NIR wavelengths, fostering enhanced understanding and application possibilities.
Gold is widely used in semiconductor manufacturing processes; however, it forms unstable contacts with Si, leading to potential device reliability issues. The introduction of an interlayer not only enhances device adhesion but also modifies charge carrier generation and transport processes. A low Schottky-barrier photodetector with a plasmonic assist that receives Near-infrared (NIR) light at room temperature was demonstrated. A comparative study of Schottky plasmonic photodetectors employing titanium (Ti) as a Schottky interlayer metal, a diffusion barrier, an adhesion promoter, and to suppress the formation of intermetallic compounds or plasmonic resonance shifts with enhanced absorption led to a tenfold increase in device responsivity compared to previous studies. The study meticulously engineered a grating structure with a pitch of 1.4 μm. Grating design is determined by extensive experimental and modeling, ensuring a wavelength-specific plasmonic photodetection and a near one-to-one correspondence between incident angles and wavelengths within the NIR region.
It exhibited an exceptional photocurrent response at room temperature and zero biasing conditions, characterized by high linearity and sensitivity. In addition, it exhibited high sensitivity to low light intensities (less than 25 μW at 1900 nm). The device exhibited the capability to demonstrate clear SPR peaks for NIR even with parallel exposure to visible light and maintained high stability with neither hysteresis nor deterioration in photocurrent measurements over a time span of 240 days so far. The sharp and selective SPR peaks facilitated expanding the spectral range for reconstructive spectroscopy to longer wavelengths. Since the degree of surface sensitivity can be controlled by collecting photoelectrons emitted at different emission angles to the surface plane by changing the incident photon energy, the reconstruction of multiple parallel incident wavelengths could be successfully demonstrated. Making it a very powerful technique for investigating the electronic and chemical structures of various nanolayers and devices for green chemistry. This research represents a significant leap in NIR photodetection and spectroscopy, with far-reaching implications across applications such as gas sensing.
Light acquisition for 1.2–2.3 μm-long NIR wavelengths became possible through a single device and applicable in gas sensing, particularly within the vibrational absorption bands of alkane groups. This research builds upon a comprehensive array of experimental results, encompassing devices with diverse geometries and multiple interlayers, including Au, Ti, Mo, and Cr. These findings provide valuable design guidelines for optimizing device structures and insights into their application for various scenarios.

5:00 PM EL08.07.09
Nano-Metamaterial Design and Fabrication, Hybridized with Various Nanostructures for Gigantic THz Electromagnetic Wave Modulation and Their Biochemical Applications Minah Seo[1,2], Geon Lee[1] and Jinwoo Lee[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea Univeresity, Korea (the Republic of)

Large-scaled metamaterial design and fabrication, hybridized with various nanostructures for gigantic terahertz (THz) electromagnetic wave modulation and their applications. Their potential applications as highly sensitive target molecule-specific sensors, amplifying interactions between light and materials, are particularly noteworthy [1-2]. On the one hand, the terahertz (THz) waves offer non-destructive interactions with molecular modes for the sensing purpose, and reasonable process capabilities in terms of fabrication size. Metamaterials operating at this range, with similar-sized structures (micrometer scale), can be manufactured using photolithography methods on a wafer-to-chip basis. Notably, a large-area nanoscale process was successfully developed by selectively combining different techniques based on their intended purpose. This structure takes the form of a slot-shaped antenna, with a width of hundreds of nanometers and a high aspect ratio, extending tens of micrometers in the transverse direction. To enhance sensitivity and minimize noise levels, over 1,000 antennas per sensor chip were designed and arranged in an array configuration. The design of the metamaterial was thoughtfully engineered to enable the tuning of its resonant frequency by adjusting the antenna's length. Furthermore, the additional nanostructures including nanowires, self-assembled nanoparticles, 2D materials such as MXene, graphene, and catalytic materials as well were integrated to get further functionality. This innovative feature allows excellent detection of trace amounts of biomaterials, leading to several groundbreaking research outcomes at the forefront of the field.
In conclusion, we successfully produced nanoscale THz metamaterials using various process equipment, enabling high field enhancement, thus improving sensing and imaging ability. These THz metamaterial sensing chips demonstrated the ability to detect even DNA nucleotides, COVID viruses, micro-plastics, and trace biochemical substances with greatly improved sensitivity compared to existing light sources [3-4]. Its unique and powerful capabilities offer significant advancements in sensing and control applications, promising to revolutionize electro-optics and open up new possibilities across various industries.

Silver Nanowire Transparent Radiative Shield for Personal Heating Textiles Genesis M. Higueros[1,2] and Po-Chun Hsu[2]; [1]Duke University, United States; [2]The University of Chicago, United States

Heating requirements for residential and commercial dwellings result in significant financial costs and deleterious environmental effects. Personal thermal management textiles (PTMTs) regulate the wearer’s body temperature by controlling the material’s intrinsic optical properties. Passive heating materials suppress radiative heat losses and therefore eliminate energy usage for building heating requirements. Guided by a numerical theoretical approach, a transparent radiative shield (TRS) is designed capable of human body heat suppression and simultaneous visible light transmittance anticipated from commercial textiles. Simulations for visible transmission and mid-infrared reflectance of silver nanowire (AgNW) network are based on Mie scattering and a wire-mesh equivalent sheet impedance model, respectively. TRS achieves high infrared light reflectance (low emissivity of 35%) and visible light transparency values of 75% (400-800 nm). Fabrication of TRS is a simple, scalable process consisting of a AgNW network and thermoplastic elastomer protective layers granting notable stretching capabilities and mechanical robustness. TRS may conform to any body shape or object. The novel theoretical approach permits a scalable pathway towards low emissivity and visibly transparent textiles for personal thermal comfort.

5:00 PM EL08.07.11
Enhancing CsFAMA Perovskite Solar Cells with Plasmonic TiN Nanoparticles: Structural, Morphological and Optical Effects Oleksii Omelianovych, Liudmila Larina and Ho-Suk Choi; Chungnam National University, Korea (the Republic of)

Perovskite solar cells have undergone significant advancements in recent years, with a strong focus on optimizing perovskite crystallization and surface passivation. One promising avenue for improving the light absorption and electrical properties of perovskite layers is the incorporation of plasmonic nanoparticles. In this study, we investigate the effects of TiN nanoparticles on the structural, morphological, electrical, and optical properties of $Cs_{0.05}(FAPbI_3)_{0.83}(MAPbBr_3)_{0.12}$ (referred to as CsFAMA) perovskite.
Prior to conducting experimental measurements, we performed optical finite-difference time-domain (FDTD) simulations to assess the anticipated impact of embedding TiN nanoparticles into CsFAMA on the optical absorptance spectra. Our simulations revealed moderate increases in absorptance within the visible range, accompanied by notable enhancements in the near-infrared region. Subsequent real UV-Vis-NIR measurements closely aligned with the simulation results, with one exception: the overall reflectance of TiN-containing perovskite films exhibited a decrease. We attribute this phenomenon to the higher crystallinity and larger size of CsFAMA grains, as confirmed through X-ray diffraction (XRD) and scanning electron microscopy (SEM), respectively.
To gain further insights into the structural and morphological changes resulting from the presence of TiN nanoparticles, we conducted an aging study on as-deposited, unannealed CsFAMA films for a duration of 3 hours, followed by XRD measurements on the aged films. Our observations and XRD results indicate that as the content of TiN nanoparticles increases, the re-dissolution of CsFAMA becomes more pronounced, suggesting a larger quantity of trapped solvents within the perovskite film. Consequently, the apparent increase in grain size can be attributed to the ability of TiN nanoparticles to adsorb trace amounts of dimethyl sulfoxide (DMSO), leading to a less rigid perovskite film that crystallizes at a slower rate, thus facilitating the growth of larger crystals. These findings are in line with TGA and DSC measurements results.
X-ray photoelectron spectroscopy (XPS) analysis revealed the absence of TiN on the perovskite surface, indicating that the TiN nanoparticles are situated either at the TiO_2/CsFAMA interface or within the CsFAMA structure. Finally, we constructed perovskite solar cells incorporating TiN nanoparticles, resulting in increased efficiency related to an improvement of all electrical properties of solar cell (Jsc, Voc and FF). Our measurements of the incident photon-to-electron conversion efficiency (IPCE) demonstrated enhanced performance arising from both the larger size of perovskite grains and electron transfer from plasmonic nanoparticles at resonance wavelengths. Larger size of grains led to reduction in the recombination, as evident from PL results. As a result the incorporation of TiN led to increase in PCE from 19.5% to 21%.
In summary, the presence of TiN nanoparticles significantly influences the structural, morphological, electrical, and optical properties of CsFAMA perovskite. The incorporation of TiN nanoparticles leads to improved absorptance, enhanced crystallinity, larger grain sizes, and increased efficiency of perovskite solar cells. These findings contribute to the ongoing efforts to advance the development of high-performance perovskite-based photovoltaic devices.

5:00 PM EL08.07.12
Photothermal Enhancement Effects of Plasmonic Nanoparticles on Diels-Alder Reactions towards The Development of Solar Light Enhanced Recyclable Epoxy Arnob Dipta Saha, Madeline Finale, Julio Cubillas, Youngmin Lee, John McCoy and Sanchari Chowdhury; New Mexico Tech, United States

Thermosets are suitable candidates for vast range of applications such as in adhesives, electronics, automotives, aerospace, and household devices due to their superior mechanical properties, high chemical resistance, and thermal stability. However, irreversible crosslinking of thermosets poses problems for their recycling. We have developed light mediated recyclable epoxy incorporating thermo-reversible covalent adaptable network (Diels–Alder (DA) reactions) into it and mixing that with refractory plasmonic titanium nitride (TiN) nanomaterials. Plasmonic TiN nanomaterials can absorb broad spectrum visible light to generate localized heat to drive Diels-Alders reactions enabling reversible polymerization and depolymerization. Nanoparticles loading and their dispersion in the polymer matrix is optimized to maximize their photothermal efficiency. It was found that these nanoparticles can absorb visible light to drive the Diels–Alder (DA) reactions efficiently to reversibly liquefy the epoxy for reprocessing. We used in situ FTIR to study the kinetics of Diels Alder reactions driven by photothermal effects and compared that with conventional heat driven reaction kinetics. One of our key findings is that the kinetics of Diels-Alder reactions are significantly different with light induced photothermal heat generation in comparison to conventional heating even though the bulk temperature of the sample is similar. This indicates the local heat generation around the nanoparticles and the interaction of reactants with nanoparticles may affect the Diels-Alder reactions differently than the bulk heating. Further studies are being done to understand the exact mechanisms behind the photothermally induced Diels-Alder reactions.

Far Field excitation of Polaritons in Photonic Hypercrystals of Van der Waals Materials Nihar R. Sahoo and Anshuman Kumar; Indian Institute of Technology Bombay, India

This study delves into the realm of in-plane Hyperbolic Phonon polaritons (HPhPs), intriguing quasiparticles arising from the strong interaction between photons and optical phonons in hyperbolic materials. While these hold immense promise in various domains such as sensing, thermal emission, and high-resolution imaging, their technological application has been hampered by a substantial momentum mismatch between photons and in-plane HPhPs. Previous experimental demonstrations have primarily relied on intricate and costly near-field detection schemes.

In this work, we present a pioneering approach, exemplified by $\alpha-MoO_3$, showcasing the potential of constructing photonic hypercrystals. This innovative concept not only enables the far-field excitation of in-plane HPhPs but also offers the ability to fine-tune the far-field response by introducing controlled twists in the hypercrystal lattice relative to the lattice of $\alpha-MoO_3$. These findings represent a significant stride forward, promising the development of practical in-plane HPhP devices while also providing access to novel fundamental physics of such materials via conventional and well-established far-field measurement techniques.

The study systematically explores biaxial van der Waals (vdW) crystals, focusing on α-MoO_3, wherein HPhPs exhibit pronounced sensitivity to the crystal's basal plane direction. The isofrequency contours in these cases take on a hyperbolic geometry, a stark departure from the circular contours observed in uniaxial vdW materials like h-BN. This biaxial hyperbolicity in vdW crystals opens up unprecedented opportunities for manipulating and tailoring infrared light waves and energy flow at the nanoscale, offering intriguing optical phenomena such as negative refraction, topological transitions, light canalization, and twist photonics.

The research confronts the longstanding challenge of momentum mismatch for far-field excitation of phonon polaritons. Previous studies have proposed patterning the vdW crystal with various materials to surmount this limitation. This work, however, introduces the concept of a photonic hypercrystal, involving periodic structural modulations in a hyperbolic material. By employing α-MoO_3 as a model system, we demonstrate the feasibility of far-field excitation of in-plane HPhPs, showcasing a new dimension of control over light-matter interactions.

In essence, this study represents a transformative advancement in the understanding and utilization of in-plane hyperbolic vdW crystals. The results not only deepen our comprehension of the intricate interplay between light and these hypercrystals but also lay the foundation for the practical realization of phonon polariton-based devices. These findings hold broad implications, extending from the realm of nanophotonics to the burgeoning field of twist photonics, opening up a new chapter in the exploration of advanced photonic technologies.

SESSION EL08.08: Nonlinear Optics and Extreme Light-Matter Interaction with Metasurfaces and Plasmonics
Session Chairs: Ho Wai (Howard) Lee and Pin Chieh Wu
Wednesday Morning, April 24, 2024
Room 340/341, Level 3, Summit

8:00 AM EL08.08.01
Moiré Photonic Crystal enabled Optical Vortex Generation through Bound States in The Continuum Tiancheng Zhang[1], Kaichen Dong[1,2], Jiachen Li[1,3], Fanhao Meng[1,3], Jingang Li[1], Sai Munagavalasa[1], Costas Grigoropoulos[1], Junqiao Wu[1,3] and Jie Yao[1,3]; [1]University of California, Berkeley, United States; [2]Tsinghua Shenzhen International Graduate School, China; [3]Lawrence Berkeley National Laboratory, United States

The twisted stacking of van der Waals crystals has led to the emerging moiré physics as well as intriguing chiral phenomena such as chiral phonon and photon generation. Along with the surge of research into moiré physics of two-dimensional materials, moiré patterns in photonic systems have also drawn broad attention. In this work, we identified and theoretically formulated a non-trivial twist-enabled coupling mechanism in twisted bilayer photonic crystal (TBPC), which connects the bound state in the continuum (BIC) mode to the free space through a twist-enabled “moiré channel”. Moreover, the radiation from TBPC hosts an optical vortex in the far-field radiation with both odd and even topological orders. We quantitatively analyzed the twist-enabled coupling between the BIC mode and other non-local modes in the photonic crystals, giving rise to radiation carrying orbital angular momentum. The optical vortex generation is robust against geometric disturbance, making TBPC a promising platform for stable vortex generation. Furthermore, the incorporation of TBPC and micro/nanoelectromechanical systems (MEMS/NEMS) could lead to the creation of tunable vortex beams with adjustable topological orders, beam center positions, divergence angles, etc. As a result, TBPCs not only provide a new approach to manipulating the angular momentum of photons, but may also enable novel applications for integrated optical information processing and optical tweezers. Due to the intrinsic similarities between photonic systems and condensed matter systems, this work may also guide the exploration of orbital angular momentum and spin-orbit coupling in moiré van der Waals structures. Our work broadens the field of moiré photonics and paves the way toward the practical application of moiré physics.

8:15 AM *EL08.08.02
A Materials’ Screening Paradigm for Thermophotovoltaic Optical Emitters Declan S. Kopper[1], Margaret A. Duncan[1], Tao Gong[1], mariama dias[2], stuart S. ness[1], Scott J. McCormack[1], Jeremy N. Munday[1] and Marina S. Leite[1]; [1]University of California, Davis, United States; [2]University of Richmond, United States

Thermophotovoltaics (TPV) represent a promising route for converting heat into usable electricity via a clean energy paradigm. Yet, the material options used to date for the optical emitters substantially restrict the power conversion efficiency of this process. Here, we provide a survey of material options, based on a dual-layer emitter stack (coating + substrate) that could be scaled up. We screened the optical behavior of >2,800 material combinations with melting point >2,000 oC, comprising refractory silicides, borides, carbides, nitrides, etc. [1]. The mismatch in permittivity allowed for emission control, key for the successful employment of high performing TPV. We identified optical emitters for TPV with theoretical efficiency >50% for GaSb solar cells, while considering both optical properties and thermochemical stability. We analyzed the promising SiC/AlN option, where we found this material combination to be stable up to 1,200 oC in air and 1,500 oC in inert environments [2], using in situ high-temperature optical measurements [3]. Further, we quantitatively assessed the maximum power conversion efficiency using this emitter for TPV systems comprised of InGaAsSb, InGaAs, Ge, GaSb, and Si photovoltaics. The material screening approach implemented here could be expanded to additional high-temperature photonic devices, such as thermal regulation ones, and barrier coatings for extreme environmental conditions.

8:45 AM EL08.08.03
Unfolding The Origin of Titanium Nitride’s Ultrafast Optical Nonlinearity Silvia Rotta Loria[1], Beatrice Roberta Bricchi[1], Andrea Schirato[1,2], Luca Mascaretti[3], Andrea Li Bassi[1,4], Bruno Palpant[5], Margherita Zavelani-Rossi[1,6] and Giuseppe Della Valle[1,6]; [1]Politecnico di Milano, Italy; [2]Italian Institute of Technology, Italy; [3]Palacký University Olomouc, Czechia; [4]Center for Nano Science and Technology - IIT@PoliMi, Italy; [5]Université Paris-Saclay, CNRS, ENS Paris-Saclay, CentraleSupélec, LuMIn, France; [6]IFN-CNR, Italy

In the last decade, Titanium Nitride (TiN) has been brought into the spotlight as a promising alternative plasmonic material to noble metals, such as gold and silver [1]. Indeed, it boasts a refractory character, CMOS- and bio-compatibility, tunable permittivity at the synthesis stage, and epsilon-near-zero properties at optical wavelengths. On top of that, TiN shows an extremely rapid hot-electron relaxation time (< 100 fs), one order of magnitude lower than noble metals such as, e.g., gold [2]. This property is extremely appealing to exploit TiN as a novel material in devices for all-optical-modulation. Nevertheless, in order to perform device design, the bare knowledge of the hot-carriers cooling time is not sufficient. A comprehensive model, able to predict how the broadband dielectric properties of the material are modulated, upon ultra-rapid photoexcitation, is essential.
In this work, we develop an original numerical model, able to disclose the origin of TiN’s giant optical nonlinearity. Starting from a rate-equation model, we evaluate the increments in carrier and lattice temperatures following photoexcitation. Then, we manage to disentangle the interband and intraband contributions to the permittivity modulation, on a broad spectral domain, pointing out the key role of interband transitions in the first instants (< 150 fs) of TiN optical dynamics. The calculations are validated on ultrafast pump-probe spectroscopy experiments, starting from the simplest TiN structure: a 200 nm-TiN film on glass. The sample is excited with an ultrashort pump at ~ 500 nm, and probed with a broadband pulse, having a temporal resolution of ~ 100 fs [3]. The model is then implemented to study the ultrafast optical nonlinearity in TiN nanostructures. Specifically, we focus on a lattice of TiN nanodisks in air and on a colloidal solution of TiN nanospheres in water. For both systems, the comparison with ultrafast pump-probe measurements [4],[5] shows accurate results. As a further step, we aim at studying the hot-carriers induced optical nonlinearity on a even more complex structure, namely a TiN-based metasurface.

Our work provides a powerful tool: indeed, starting from the actual experimental conditions, such as the pump fluence or the nanostructure geometry, we are able to predict the ultrafast optical properties of virtually any TiN-based sample over a broad spectral range. This paves the way to the design and demonstration of new TiN-based devices for ultrafast plasmonics applications.

Nonlinear Optical Colloidal Three-Dimensional Metacrystals Ye Zhang and Chad A. Mirkin; Northwestern University, United States

Atomic and molecular structure inversion symmetry breaking in naturally occurring crystals dictate their physical properties including nonlinear optical effects, piezo-/ferroelectricity, and nonreciprocal charge transport behavior. With metamaterials composed of nanoscale building blocks (*i.e.*, meta-atoms), the spatial inversion symmetry violation on planar surfaces leads to spin-controlled photonics as well as nonlinear optical metasurfaces. While low-symmetry three dimensional (3D) metacrystals can be synthesized, limitations in long-range order and control over resulting symmetries inhibits the investigation of the symmetry-property relationships in these systems. Here we present a DNA-mediated gold nanoparticle assembly approach to create 3D colloidal crystals which can be designed to deliberately access high- or low-symmetry phases. By manipulating particle shape, size, and DNA design, we effectively tune the crystal symmetries of the superlattices in a controllable manner. Access to these different symmetries and facile transitions among them enable us to explore the symmetry-dictated functionalities of these colloidal crystals. Further, we investigate how the resulting crystal symmetry relates to their nonlinear optical interactions and identify that the non-centrosymmetric crystal functions as an effective nonlinear optical metacrystal, where second harmonic generation (SHG) arises from the asymmetrical distribution of the local electric field around the close-packed plasmonic nanoparticles. Moreover, this non-centrosymmetric colloidal metacrystal represents the first 3D nonlinear optical metamaterial developed through a bottom-up approach and exhibits a high maximum SHG conversion efficiency, notably surpassing the efficiencies observed in the majority of plasmonic 2D metasurfaces by two orders of magnitude.

9:15 AM *EL08.08.05
Modeling The Nonlinear Optical Response of ENZ Films Adam Ball[1], Ray Secondo[2,3], Yaqub Mukhtar[1], Samprity Saha[1], Jingwei Wu[1], Dhruv Fomra[4,1], Jacob Khurgin[5] and Nathaniel Kinsey[1]; [1]Virginia Commonwealth University, United States; [2]Azimuth Corporation, United States; [3]Air Force Research Laboratory, United States; [4]NIST, United States; [5]Johns Hopkins University, United States

The epsilon-near-zero (ENZ) regime of optical materials represents the transition point between metallic (negative permittivity) and dielectric (positive permittivity) response, similarly characterized by strong alterations in reflection, transmission, and absorption. This intriguing region of optical response has given rise to range of unique effects in both the linear and nonlinear optics fields, including wavelength expansion, slow light, and field confinement. In particular, the ability of the ENZ regime to enhance various nonlinear optical effects has garnered significant attention in recent years. Among them, a key is the ability to modulate the refractive index of the ENZ film on the order of unity on a picosecond timescale via nonlinear optical exciation. This has given rise to a significant interest in utilizing ENZ films for a number of optical devices including saturable absorbers, nonlinear activation functions, optical switches, and more. However, key to designing these devices is understanding the nonlinearity and modeling the change in complex index (permittivity) that will be experienced for a given excitation. In this talk we will highlight our recent efforts to model the intensity dependent index of Drude-based ENZ thin films, highlighting the Nonlinear Epsilon Near Zero (NLENZ) Calculator application available online via nanohub.org. We will introduce the basic theory of the non-parabolic conduction band and how it gives rise to nonlinear response of ENZ materials. We will then provide a high level outline of the models for interband and intraband nonlinearities, culminating in the use of the NLENZ app to predict the nonlinear properties of the material, using only experimental parameters and the material band structure, which can then be extracted and used in combination with other FEM or FDTD solvers for complex device design. We expcet this tutorial style talk to be of interest to researchers and materials scientists who are interested in working with ENZ materials in new devices or developing new materials with an ENZ response, and hope to support the further development and study of these unique effects by furthering the ability of the community to simulate mateiral and device responses incorprating ENZ.

Analysis of Near-Field Patterns generated by Propagating Polaritons Minsoo Jang, Sergey Menabde, Jacob Heiden and Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Polaritons are quasi-particles that are excited by the coupling of light and charges within a material. They are closely related to the motion of charges in matter, which gives them a deep connection to material properties. Additionally, in specific low-dimensional materials, they exhibit a high level of light-matter interaction and confinement. Polaritons hold significant value in the field of nanophotonics, and current research is underway in areas such as light absorption, thermal emission, biosensing, and beam deflection. However, directly measuring the complex propagation of polaritons remains a challenging aspect of research due to the difficulty of near-field measurements.
Scattering type scanning near-field optical microscopy (s-SNOM) enables the simultaneous measurement of the amplitude and phase of the near field by utilizing a metallic atomic force microscopy (AFM) tip as a near-field antenna and the interferometric coupling of this signal with the base signal. Typically, s-SNOM excites complex propagating polaritons through the tip and material edges and images them. In the past, Fourier transform (FT) was used on the image profile to extract real momentum, but the damping term was determined through direct fitting or by directly fitting complex momentum from the beginning. This method poses challenges in mixed signal analysis and background removal. Additionally, for edge-launched polaritons, the polariton momentum can shift depending on the edge angle, but this shift has not been considered in recent high-effective-index materials like hBN or MoO_3.
In this study, we first present a standardized method for analyzing the complex momentum of propagating polaritons. To analyze polariton momentum, we fit the FT signal of propagating polaritons with a function obtained by FT of the analysis model. We confirmed a perfect fit and also revealed the relationship between the full-width half-maximum (FWHM) of the FT signal and the damping of propagating polaritons, confirming a specific ratio of . This method using FT makes it easier to analyze comprehensive signals compared to the traditional direct fitting method and offers an advancement in analyzing the loss of polaritons based on the existing Fourier transform approach.
Secondly, we established an analytical model for tip and edge polaritons and experimentally demonstrated edge-oriented momentum shifts that occur during measuring process in edge mode. We measured polaritons on hBN transferred onto crystalline gold. Polaritons launched from the clear atomic gold

edge generate modes known as hyperbolic phonon-polaritons (HPP) and hyperbolic image polaritons (HIP) that propagate on both the glass substrate and crystalline gold. We measured the polariton by rotating gold edge at 45-degree angles and confirmed that the degree of shift matched the theoretical model. Furthermore, for HPP, it was observed that HPP exhibited a maximum momentum shift of approximately 8% even at a high effective index of 12.54.

Plasmonics Platforms for Strong Coupling Matthew T. Sheldon; University of California, Irvine, United States

Nanophotonic and plasmonic architectures present a compelling platform for investigating strong coupling phenomena. These nanofabricated optical structures enable precise tailoring of electromagnetic modes on sub-wavelength scales, leading to significant coupling interactions within near-field "hot spots". Recent advancements from our laboratory have showcased ultrastrong coupling to vibrational modes using innovative plasmonic cavity designs. The sub-wavelength localization of these platforms facilitates strong coupling to fewer molecules compared to traditional Fabry–Pérot (FP) cavities, potentially limiting contributions from "dark states" in polariton chemistry.

A notable feature of plasmonic-based cavities is their compatibility with established surface science techniques, such as confocal molecular Raman spectroscopy. With these tools, our recent studies have uncovered unique temperature-dependent dehydration behavior of transition metal salt films on plasmonic substrates, suggesting resonant thermal energy transfer when vibrational strong coupling is present. This discovery hints at the potential of pronounced thermal gradients within the near-field of plasmonic substrates.

Furthermore, our research delves into the design of cavities that support sub-radiant modes that exhibit higher q-factors, leading to stronger coupling interactions with molecular samples. Preliminary results indicate that these sub-radiant cavity modes with quadripolar field symmetry achieve very strong coupling with molecular samples, while offering a modification of the usual optical selection rules for bright and dark (N-1) polariton states.

11:00 AM EL08.08.08
Visualizing Chiral Plexcitons at Room Temperature Using Tip-Enhanced Photoluminescence Thomas P. Darlington[1], Kevin W. Kwock[1], Matthew Strasbourg[2], William Hayes[1], Nicholas Borys[2] and P. James Schuck[1]; [1]Columbia University, United States; [2]Montana State University, United States

Chirality is a fundamental property of nature, arising naturally in many systems, ranging from the structure of molecules to the spiral arms of galaxies. Structural chirality leads to circular dichroism, where photons of right or left handedness experience contrasting refractive indices for a particular molecular enantiomer. This phenomenon plays a crucial role in the chemical identification of molecules in the food and drug sciences. In the field of quantum optics, chiral single photon sources have gain increased interest due to their inherent non-repriciprocity[1], allowing for realization of novel optical devices such as single photon isolators and circulators[2]. A requirement in many quantum optical applications is the realization of polariton states through strong coupling of a cavity optical field with a material dipole excitation. In this regime, substantial recent work has focused on plexcitons, strongly coupled excitons with nanocavity plasmon-polaritons, due their ultra-confined cavity volumes ($<10\ nm^3$). These small volumes allow for strong coupling to be readily achieved at elevated temperatures, with Rabi splittings of 50 – 400 meV in a wide array of excitonic systems ranging from quantum dots[3,4], monolayer transition metal dichalcogenides[5], to molecular J-aggregates[6]. However, despite the explosion of the scientific efforts on the topic, chirality in plexcitonic systems has yet to receive significant experimental attention.
In this presentation I will show our recent experimental efforts on imaging chiral plexcitonic states formed with commercial CdSe/ZnS quantum dots with a gap-mode plasmonic cavity. Using tip-enhance photoluminescence (TEPL), we are able to map out the nanocavity-quantum dot response, revealing a naturally asymmetric spatial profile for nanocavities formed with commercially available silver nano-optical probes and gold substrates, a common cavity geometry. Our nano-optical measurements further show positional control of the quantum dot emission energy, with an upper and lower polariton branches forming in the TEPL spectrum depending on the probe-dot separation and orientation, demonstrating the plexciton nature of the emission. Using a novel nano-optical imaging method that integrates TEPL with single photon avalanche photodiodes (SPADs) and time correlated single photon counting hardware, we map out the degree of circular polarization as a function of probe-dot position, showing polarization ratios as large as 80%, that is controllable by varying the x,y,z position of the nano-optical probe. Our results demonstrate the ability to imprint chiral behavior on quantum-emitter-based polaritons using plasmonic nanocavities, and provide important insight into development of chiral quantum optical devices.

Perspectives of Design, Materials, Manufacturing and Applications for Optical Metasurfaces Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

In this talk, I will represent AI-designed metasurfaces, new materials and three low-cost manufacturing: 1) nanoimprinting with high-refractive-index dielectric particle embedding resin (PER), 2) bandgap engineering of hydrogenated amorphous silicon (a-Si:H), and 3) atomic-layer coating on imprinted resin. a-Si, TiO_2, and ZrO_2 PERs are used for metasurfaces at infrared (940 nm), visible (532 nm), and ultraviolet (325 and 248 nm), respectively; measured efficiencies reach 47% (940 nm), 91% (532 nm), 72% (325 nm), and 49% (248 nm). PER metasurfaces with an inverse design provide 3D, full-color holography at visible. The bandgap of a-Si:H is engineered to suppress optical losses, realizing metasurface efficiencies of 42% (450 nm), 65% (532 nm), and 75% (635 nm). We deposit an atomic layer on resin for 12-inch metasurfaces, achieving measured efficiencies of 61% (450 nm), 78% (532 nm), and 65% (635 nm). Finally, the recent development of mass production and manufacturing of metausrfaces and nanophotonic structures, and future direction with a bigger vision will be discussed.

Metasurfaces for Future Sensing, Imaging and Display Technologies Mark L. Brongersma; Stanford University, United States

Metamaterials are a new, emerging class of high-performance materials that derive their unique, physical properties from the way they are structured. In this presentation, I will focus on the creation of 2-dimensional metamaterials (i.e. metasurfaces) by nanopatterning glass, semiconductor and metal films. I will argue that these metasurfaces are ideal building blocks for the next generation of optical elements and optoelectronic devices.

I will highlight how metasurface functionalities can start to impact a variety of optical sensing, imaging and display technologies. For example, I will show how one can create transparent optical sensors on glass substrates that can extract valuable information from an optical scene. I will also discuss the use of integrated metasurfaces for new imaging modalities. The proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to many commercial applications.

2:00 PM EL08.09.02
Highly Collimated and Polarized Light Emitting Metasurface for AR displays JP Berenguer[1], Fenghao Xu[2], Qitong Li[1], Jung-Hwan Song[1] and Mark L. Brongersma[1]; [1]Stanford Univeristy, United States; [2]Stanford University, United States

Major technical challenges must be overcome in order for augmented reality (AR) technologies to fulfill its revolutionizing promises. Current solutions for AR displays suffer from very low efficiencies and large form factors, mostly due to the use of grating-based waveguides and polarizing optical elements. Therefore, there is a growing need for nanophotonics designs that can focus light emission at desirable in-coupling locations for maximum throughput and with a high degree of polarization to avoid the use of bulk polarizers.
Here, we present and characterize a directional and polarized light-emitting metasurface based on a generic GaN LED. We engineered arrays of Mie nanoresonators that preferentially couple to one linear polarization and make use of quasi-guided modes to achieve focused emission. We will discuss the underlying theory for optimal metasurface design and emitter placement as well as present photo and electroluminescence angle-resolved data to confirm a major enhancement in directionality, polarization, and overall efficiency as compared to a commercial LED. This work provides a feasible metasurface design tailored to improve μ-LEDs for next-generation display technologies and represents a significant advancement in the field of light emission control.

2:15 PM EL08.09.03
Compact Structured Light Generation and Depth Perception from Integration of Metasurface and PCSEL Yao-Wei Huang[1], Wen-Cheng Hsu[1,2], Chia-Hsun Chang[1], Yu-Heng Hong[2] and Hao-Chung Kuo[1,2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Hon Hai Research Institute, Taiwan

We demonstrate a novel depth sensing system that utilizes metasurfaces and photonic crystal surface-emitting lasers (PCSELs), realizing structured light generation and facial recognition in monocular depth sensing. Our single-shot system projects approximately 45,700 infrared spots from an about 300^2 μm^2 metasurface area, which is 233 times smaller than the commercial diffractive optical element (DOE) based dot projector used in the Face ID on iPhone. The system is lens-free and power consumption due to the utilization of PCSEL, reducing 5-10 times of power compared to dot projectors based on vertical-cavity surface-emitting laser (VCSEL) array. Our proposed system addresses the limitations of traditional structured light depth sensing technology, offering significant advantages in terms of size, power consumption, and potential for integration into wearable devices.

3:30 PM EL08.10.01
Single-Gate Active Beam Steering Graphene Metasurface Sangjun Han, Jinseok Kong and Min Seok Jang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Optical beam steering is a next-generation technology with applications in optical communications, laser patterning, three-dimensional laser point clouds and LiDAR systems. Conventional beam steering devices based on mirrors rotated by motors have a 360° horizontal field-of-view, but suffered from its bulky size and high heat generation. MEMS-based LiDAR, which combines an actuator and a micro-scanner, and flash LiDAR, based on diffractive elements, were adopted to address those issues. However, they still suffered from low durability and significant power consumption. Metasurface-based beam steering device offers several breakthroughs, including miniaturization, reduced power consumption, reduced heat generation and higher frame rates. Active metasurface beam steering device can be implemented utilizing liquid crystals, phase change materials, or carrier injection into Transition metal dichalcogenide monolayers or conductive oxides. However, previous studies have faced challenges such as a small field-of-view within a few degrees, poor diffraction efficiency or directivity. In conventional electrically tunable beam steering devices, they generally require a complex circuit driver inside to individually control each metaatom. Those system may also involve dielectric breakdown problems between adjacent metaatom. To scale up to practical beam steering technologies in the future, it is necessary to simplify the driving mechanism and improve performance.
In this study we developed a beam steering technique using only single-gate voltage. The limitations in design freedom imposed by removing a complex circuit driver can be overcome by carefully determining the structural parameters of the metasurface. In conventional forward design, a local periodic approximation is commonly adopted to understand overall performance of metasurface in metaatom level. However, this approximation is not appropriate when there are significant interferences between neighboring metaatoms, resulting in unwanted sidelobes and poor directivity. Recently, inverse design, which determines structural parameters based on its performance, has been introduced to address these shortcomings. We used a genetic algorithm to efficiently deal with large design hyperspace and find a device structure with high directivity and field-of-view without a complex circuit configuration. The metasurface consists of a gold grating and a graphene ribbon array with different widths and gaps. The height, width, gap and operating wavelength of the metasurface were optimized as design parameters. The designed metasurface is placed on a gold back reflector and a 200 nm low-stress silicon nitride dielectric spacer.
We measured modulation in diffraction efficiency and directivity at the 0th and -1st diffraction angles by varying a gate voltage applied to the device. When the gate voltage of 10 V is applied, the directivity at the 0th diffraction angle (45°) is approximately 0.675. This value decreases as the gate voltage is gradually decreased, reaching 0.325 at a gate voltage of -70 V. Meanwhile, the diffraction efficiency reaches 16%, gradually decreases to 8.5% when the

gate voltage decreases. This confirms that the reflected wavefronts can be actively switched with a field-of-view of 68° with single-gate voltage.

3:45 PM *EL08.10.02
Design and Fabrication of Large-Scale Meta-Optic Devices Xingjie Ni; The Pennsylvania State University, United States

Metasurfaces, artificially engineered ultrathin subwavelength nanostructures with exceptional light control capabilities, have the potential to revolutionize conventional optics. However, the traditional methods for creating these metasurfaces are slow, expensive, and lack scalability. To address this, we have developed a cost-effective and scalable design and fabrication method for large-scale meta-optic devices that work in both the visible and infrared regimes. We showcase several examples, including a single-lens telescope using a wafer-scale metalens, inch-scale meta-optic correctors, and a metasurface-enabled real-time hyperspectro-polarizmetry camera. Our technology facilitates versatile light control in scalable, compact, multifunctional flat optics devices with significant potential for real-world applications.

Machine Learning-Enabled Photonic Metamaterials Jonathan A. Fan; Stanford University, United States

In this talk, I will discuss advances in photonic engineering in which machine learning approaches to device implementation unlock new functional capabilities. First, I will discuss new concepts in nanostructure geometric parameterization, inspired from the computer graphics community, which enable freeform layouts to be specified in a manner that can be differentiated and maintain hard constraints. Second, I will show how deep generative networks can be used to perform population-based global optimization, producing best in class devices. Third, I will show how physics-augmented deep networks can serve as accurate surrogate electromagnetic solvers and how innovations in network architecture can enable these solvers to generalize to arbitrary sized domains and grayscale dielectric media. We anticipate that the ability for deep learning models to dramatically accelerate and even automate the simulation and design of photonic systems will push the innovation cycle in all domains of photonics research.

4:45 PM EL08.10.04
Modulating Color Response in Polymeric Photonic Crystals through Refractive Index Tuning with Gold Nanoparticles Chen Chen and Yadong Yin; University of California, Riverside, United States

Responsive photonic crystals with high brightness, straightforward fabrication, and excellent tunability are in high demand for a wide range of potential applications, including sensors, printing, and display units. In this study, we present an innovative design of highly-ordered photonic crystals with tunable color response through gold (Au) deposition using a space-confined seeded growth method.

The pivotal aspect of modulating color response is controlling the deposition of Au nanoparticles (NPs) within the hollow polymeric shells. Benefiting from the strong interaction between AuNPs and resorcinol-formaldehyde (RF) polymer, even the addition of tiny Au NPs leads to an unexpected decrease in the effective refractive index of the core-shell NPs. Compared to other plasmonic materials, Au exhibits a unique ability to significantly reduce the effective refractive index.

Leveraging the continuous decrease in refractive index during AuNPs growth, we fabricate a series of composite films displaying blue-shifted colors. The structural color can be easily modulated over a broad spectral range by simply adjusting the hollow shells, resulting in more abundant colors with rich saturation. Moreover, the blue-shift effect can be eliminated through Au removal, allowing for reversible color changes. Simple fabrication, flexible adjustment, and outstanding optical properties of our composite film make it a promising choice for the development of functional colorimetric sensors in the future.

SESSION EL08.11: Poster Session II
Session Chairs: Yao-Wei Huang and Min Seok Jang
Wednesday Afternoon, April 24, 2024
Flex Hall C, Level 2, Summit

5:00 PM EL08.11.01
Tunning Nonlinear Optical Properties of Titanium Nitride Nanocrystals Carla Berrospe-Rodríguez[1], Ariana Sabzeghabae[2], Guillermo Aguilar[1] and Lorenzo Mangolini[2]; [1]Texas A&M University, United States; [2]University of California, Riverside, United States

Titanium Nitride (TiN) nanomaterials have become a research interest since their present interesting photothermal and absorption/scattering properties. This novel material has a localized surface plasmon resonance response (LSPR) in the NIR window, in addition to having a higher thermal stability-resistivity compared to the commonly used plasmonic Gold (Au) or Silver (Ag) nanoparticles. Furthermore, several studies have confirmed the biocompatibility and low cost of fabrication of TiN nanoparticles with the intention of replacing Au for biomedical applications. [1] Currently, TiN nanoparticles are studied for implant coatings, photothermal therapy and bio-sensing, among other.

The search of plasmonic nanomaterials with tunable nonlinear optical properties has become crucial for laser-based applications in integrated electronics, biomedical and imaging, to mention a few [2]. Particularly, saturable absorption and self-focusing effect, are desirable third order non linearities for the design of non-reciprocal light propagation optoelectronic devices, high resolution spectroscopy, thermal lenses, and optical switches. Previous studies demonstrated non-linear absorption coefficients for TiN higher than Au, under the same laser radiation conditions. [3] Furthermore, the agglomeration of these nanoparticles can be utilized to enhance scattering properties, making these colloidal solutions ideal for tunable absorption. Therefore, it is of high value to investigate non-linear optical properties of TiN nanoparticles and TiN clusters in the NIR regime for the above-mentioned applications, particularly in the biomedical field.

In this work, the optical nonlinearities of TiN as a function of nanoparticle concentration in DI water solutions were investigated. Additionally, the effect of nanoparticle clustering, fabricated by 1 µm size clusters of 50 nm TiN nanoparticles, on nonlinearities was studied. It was found that the nonlinear absorption coefficient increases linearly with concentration for both models, however clusters required higher concentrations to exhibit similar values in absorption. Similarly, the optical threshold of reverse saturable absorption for cluster solutions was higher compared to the freestanding nanoparticles due to the collective scattering phenomenon. Finally, the self-focusing effect on TiN nanoparticles was explored on the continuous regime. Kerr lens with focal length as a function of solution concentration were obtained. The refractive index changes, due to photothermal effects and diffusive heat transfer,

produced changes in the beam diameter and consequently on the laser fluence. This work provides a comprehensive study of the tunability of nonlinear properties by the parameters of concentration and agglomeration.

Leveraging Correlations between The Statistics and Spectral Properties of Random Metasurfaces for Multi-Wavelength Cryptography Romil Audhkhasi, Maksym Zhelyeznyakov, Steven Brunton and Arka Majumdar; University of Washington, United States

Randomness and disorder are abundant in nature and help in sustaining the environment around us. In particular, random optical media encountered in various varieties of insects, birds and marine organisms are naturally optimized to offer survival advantage in their respective habitats. Historically, photonics researchers have focused their attention on periodic and ordered systems, and randomness has often been viewed as undesirable. In recent years, the broad range of functionalities exhibited by random optical media have prompted researchers to explore materials with tailored disorder for various applications. As opposed to their periodic counterparts, the vast design space afforded by disordered photonic devices provides greater flexibility in achieving tailored optical responses. However, the expanded design space makes it challenging to map the structural degrees of freedom of random photonic devices to their optical properties. This necessitates the identification of a tractable set of parameters that can be used to characterize random optical media. Here, we investigate correlations between the configuration statistics of random metasurfaces and their spectral response. Our metasurfaces consist of a two-dimensional array of silicon nanopillars with random widths on a silica substrate. We explore the effect of tuning the probability distribution characterizing the nanopillar widths on the wavelength-dependent transmissivity of the random metasurface in the 400 – 800 nm wavelength range. Furthermore, we exploit the correlations between the configuration statistics of the random metasurfaces and their spectral properties to design a photonic device encoding spectrally encrypted image data in the visible wavelength range. Our findings offer new insight into the optical properties of random media and provide avenues for developing such systems for a broad range of applications.

5:00 PM EL08.11.03
Engineering The Properties of Metal Nanoparticle Arrays for Optoelectronic Applications Gavin Farmer, Chris Littler, Athanasios Syllaios and Usha Philipose; University of North Texas, United States

This work focuses on a technique for the fabrication of ordered metal nanoparticle arrays with tunable particle diameter and inter-particle distance. The nanoparticle arrays were formed by a sequential solid state de-wetting process, using evaporated gold to fill the dimples of an anodized alumina membrane. The results show a direct correlation between the particle size and interparticle distance, factors that are determined by both the geometry of the dimples in the membrane as well as the volume of the evaporated gold. An experimental threshold for the evaporated gold film was determined, such that beyond a certain limit the existing nanoparticles were unable to preserve their ordering and spacing. This technique allows for fabricating ordered nanoparticle arrays with diameters ranging from 55 nm to about 85 nm, with inter-particle spacing's ranging from 10 nm to about 40 nm. This work is significant because ordered arrays of metal nanoparticles exhibit localized surface plasmon resonance, a phenomenon that can be taken advantage of in sensing applications

5:00 PM EL08.11.04
Aqueous Synthesis of Silver Nanocubes and Their Sensing Capabilities Annabella Talbott[1], Anika Guo[1,2], Nigel Ng[1] and Ying Bao[1]; [1]Western Washington University, United States; [2]University of Oregon, United States

Metallic nanoparticles are of great interest because they have shown promise in many fields like biomedicine, imaging, and sensing because of their chemical and physical properties. A focus has been put on controlling the morphology of metallic nanoparticles since specific characteristics (size, shape, composition, and structure) can impact the nanoparticles' properties and applications. Amidst these structures, sharp tips are of interest for enhancing related applications, as they allow for "hot spots" on the nanoparticles. Specifically, silver nanocubes (AgNCs) are desirable for sensing due to the "hot spots" located at their sharp corners, as well as the heightened plasmonic properties of silver. Typically, AgNCs are synthesized through a polyol process, but other methods are being explored due to the polyol process having been found to be toxic to the environment. In this work, an aqueous method of synthesizing the AgNCs was employed, and the effects of specific components of the synthesis and their resulting impact on the AgNCs were studied. This was done using UV-Vis spectroscopy and scanning transmission electron microscopy (STEM) to characterize the size and morphology of synthesized AgNCs. The refractive index sensitivity of varied sized AgNCs has been evaluated which shows a larger cube size has higher refractive index sensitivity. Furthermore, the synthesized AgNCs also were used for sensing iodide with the assistance of copper. In the future, the sensitivity of detecting iodide using various-sized AgNCs will be studied. The sensing of iodide using coated AgNCs will also be studied.

5:00 PM EL08.11.05
Iridescent Structural Color from Ultra-Low Refractive Index Aerogel as Fabry-Perot Cavity Dielectric Jennie Paik[1], Wei-Jie Feng[1], Sean Clark[2] and L. Jay Guo[1]; [1]University of Michigan–Ann Arbor, United States; [2]University of Florida, United States

Iridescent color-shift pigments are widely used across industries, from automotive and architectural coatings to cosmetics and packaging. To achieve a vibrant, iridescent, and lasting color, thin-film interference is used to generate structural color. By tuning the refractive index, thickness, and geometry of the component films, a wide range of vivid and iridescent colors can be produced. One strategy to produce iridescent films is to layer a thin, high refractive index (RI) film atop a thicker, low refractive index dielectric, thus allowing large optical path length variation within the dielectric. Artificial structural engineering of the low-RI layer by using a dielectric aerogel can reduce the RI of the low-RI layer, thereby imparting iridescence.
Commercial iridescent color-shift pigments layer materials of large refractive index differences, such as TiO_2 (RI = 2.2) and SiO_2 (RI = 1.46). However, the lowest refractive index of a naturally occurring solid dielectric is close to 1.37 (i.e. MgF_2), which is still not significantly lower than SiO_2. To address this, we developed a structure using SiO_2 aerogel as the low-RI dielectric, whose ultralow refractive index arises from artificial structural engineering towards high porosity, and demonstrated its performance in a TiO_2/SiO_2/Si system. The ultra-low refractive index of aerogel is close to that of air (n~1.06), thus the color can travel a very long trajectory on the CIE diagram upon angle variation.
To our knowledge, this work is the first to employ an ultra-low RI aerogel dielectric as a resonator in a FP cavity. To achieve high reflection and angle-dependent color, we utilize silicon dioxide (SiO_2) aerogel, which is an extremely porous network of SiO_2 and has a RI close to that of air (~1.06). Using titanium dioxide (TiO_2, RI ~1.8-2) as a high RI layer, we can achieve the highly iridescent structural color capable of traveling near completely around the CIE diagram upon angle variation. **By tuning the refractive index, thickness, and geometry of the aerogel layer, we control the reflection dip's shape, therefore producing a wide range of vivid and iridescent colors.**

5:00 PM EL08.11.06
Effect of pH on The Self Assembly of Janus Particles Maria Iftesum[1], Mohan K. Dey[1], Alisha Prasad[2], Jin G. Lee[3], Shirin Parvin[4], Meng Lu[4], Ram Devireddy[1], Bhuvnesh Bharti[1] and Manas R. Gartia[1]; [1]Louisiana State University, United States; [2]Catalent Pharma, United States; [3]University of Colorado Boulder, United States; [4]Iowa State University of Science and Technology, United States

The use of pH-adjusted self-assembly in Janus particles is a promising approach for controlling Raman scattering. These Janus particles, known for their asymmetry in composition and properties, provide distinct benefits for crafting precise nanostructures in surface-enhanced Raman scattering (SERS) applications. The study investigates using pH-controlled self-assembly of Janus particles to observe the changes in their Surface-Enhanced Raman Scattering (SERS) and Raman signals. Characterization methods such as scanning electron microscopy (SEM) and focused ion beam (FIB) technology were implemented for detailed information regarding the shape, size variation, and inner structure of Janus particles. Various analytical techniques, including TEM, EDAX, and elemental mapping, were employed to assess the assembled Janus particles by examining their elemental composition and how it is distributed. By adjusting the pH of the solution, electrostatic interactions between the Janus particles were manipulated, leading to controlled aggregation and spatial arrangement. As the pH value rises, the gap between the particles widens. At specific pH levels, self-assembly of Janus particles occurs, forming ordered nanostructures that concentrate analyte molecules. This spatial confinement caused significant changes in electromagnetic field intensity and Raman signals. Optimal pH selection enables control over interparticle spacing, plasmonic coupling, and electromagnetic field distribution, leading to remarkable modulation of Raman signals. This research also focused on analyzing electromagnetic fields, uncovering how electric and magnetic fields are distributed between Janus particles when exposed to excitation light. A decrease in Raman Intensity with the increasing number of Janus particles were observed at the Raman wavenumber. Using Finite-Domain-Time-Difference (FDTD) simulations, a decrease in electromagnetic field intensity with the number of particles were also observed, which validates our experimental finding. Analyzing the structure and optical and electromagnetic properties of Janus particles will further help us understand their behavior and potential applications. pH-tuned Janus particle self-assembly shows promise in creating sensitive and selective Raman sensing platforms. This research advances our understanding of Janus particle assembly for SERS-based sensing, with broad applications in areas like chemical analysis, bioassays, and environmental monitoring.

Visible Light Mediated Deposition of Pt Nanocatalyst on Refractory Plasmonic Titanium Nitride Nanoparticles Hirithya Sharad Jeyashangararaj, Sanchari Chowdhury and Naomi Helsel; New Mexico Institute of Mining and Technology, United States

Plasmonic photocatalyst can efficiently absorb light to generate photoexcited electrons to drive energy extensive catalytic reactions including CO2 reduction, water splitting and solar energy conversion. We have successfully synthesized composite plasmonic catalysts by visible-light-induced deposition of transition metal nanocatalysts such as Pt on refractory plasmonic titanium nitride (TiN) nanoparticles. Titanium nitride nanoparticles can absorb broad spectrum solar light to generate photoexcited electrons which reduce transition metal precursor salts to deposit the metal atoms on the surface. We could deposit different size of Pt nanocatalyts on titanium nitride by varying the photodeposition process conditions such as light intensities and duration of light illumination. We are studying the effect of light intensity, irradiation time and wavelength dependence of Pt precursor reduction rate to understand the reaction mechanism of Pt nanocatalyts deposition. The findings of this study can be used to develop a visible light mediated synthesis of single atom plasmonic catalysts under mild conditions, which has been a bottleneck for their widespread applications.

5:00 PM EL08.11.08
Large-Grain Thin Films of Biaxial Hyperbolic α-MoO_3 Using Alkali Metal Compound-Assisted Vapor Transport Deposition Ryan Spangler[1], Joshua D. Caldwell[2], Patrick E. Hopkins[3] and Jon-Paul Maria[1]; [1]The Pennsylvania State University, United States; [2]Vanderbilt University, United States; [3]University of Virginia, United States

As the application space of mid-IR technologies continues to expand, materials with new and advanced properties become of interest. α-MoO_3 is a transparent, layered semiconductor that can exhibit biaxial hyperbolicity of the dielectric function, where the optical properties can be switched from out-of-plane hyperbolic to in-plane hyperbolic by varying the mid-IR wavelength. This opens up opportunities for planar emitters, non-reciprocal plasmon waveguides, and directional collimation of energy within nanomaterials via long-lifetime hyperbolic phonon polaritons. However, research on these properties has been predominantly performed on samples of exfoliated flakes of α-MoO_3, with thin film fabrication techniques being relatively undeveloped. This is in part due to the difficulty of producing the large grains necessary for many polaritonic experiments of in-plane anisotropic crystals. Therefore, the experimental flexibility of α-MoO_3 studies has been historically limited and it is of great interest to repeatably produce large single crystals in thin film form. In this work, a physical vapor transport technique is developed which uses alkali metal compounds to promote grains possessing lateral dimensions of hundreds of μm to few mm. We observed that this technique overcomes the poor film texturing and morphology that is observed in α-MoO_3 grown on most substrates. Data will be presented on the film morphology and crystallinity as functions of different growth parameters including substrate composition and preparation, growth temperature, and presence of alkali metal compounds. Additionally, the applicability of this synthesis technique to the nanophotonics community will be demonstrated by characterizing the optical and hyperbolic phonon polariton properties of the synthesized films. This synthesis technique opens up new capabilities for controllable fabrication of large-area α-MoO_3 crystals for nanophotonics and polaritonics research.

SESSION EL08.12: Light Field Detection and Sensing

Monocular Metasurface Camera for Multidimensional Light Field Sensing Yuanmu Yang; Tsinghua University, United States

Conventional camera systems can only detect light intensity while losing important information about the target scene, including depth, polarization, and spectrum. In order to further obtain the multi-dimensional light-field information of the target object, it is often required to use bulky and expensive instruments. Metasurface is composed of an array of optical antennas that can manipulate the amplitude, phase, polarization, and spectrum of light at the subwavelength scale. By replacing conventional diffractive of refractive elements with metasurfaces in imaging systems, one may be able to build optical sensors for high-performance multidimensional light sensing with low size, weight, power, and cost. Here, I will present our group's recent effort to replace conventional camera lenses with metalenses. By leveraging the unique capability of metasurface to tailor the vectorial field of light, in combination with an advanced image retrieval algorithm, we aim to build compact camera systems that can capture multi-dimensional light field information of a target scene in a single shot under ambient illumination conditions. Specifically, I will show how we use a polarization-multiplexed metalens for imaging through turbid

water (Laser & Photonics Reviews 15, 2100097 (2021)). Recently, we further extended such a concept to build a monocular camera that can capture a 4D image, including 2D all-in-focus intensity, depth, and polarization of a target scene in a single shot (Nature Communications 14, 1035 (2023)). I would also like to present our effort to commercialize flat-optics-based passive monocular 3D cameras, which drastically differ from existing 3D imaging hardware, including LiDAR and binocular cameras. The miniaturized 3D camera module may be seamlessly integrated with smartphones, AR/VR headsets, and robots for a variety of applications, including face and gesture recognition, spatial localization and mapping, and collision avoidance.

9:15 AM EL08.12.03
Direct Measurement of Radiation Pressure Forces on Membrane Lightsails Lior Michaeli, Ramon Gao, Michael Kelzenberg, Claudio Hail, John Sader and Harry A. Atwater; California Institute of Technology, United States

We report direct measurement of radiation pressure forces exerted on a 100-nm-thick silicon nitride lightsail membrane. Our sensitive measurements rely on three key components: a noise-robust common-path interferometer with picometer resolution, rational design of the tethered lightsail for enhanced mechanical susceptibility, and an off-resonant driving scheme for quasi-static, linear dynamics. Ultrathin lightsails, propelled to relativistic speeds by laser radiation pressure, are being actively explored as a new generation of interstellar spacecraft probes, spearheaded by the Breakthrough Starshot Initiative [1,2]. Realizing laser-driven lightsails necessitates precise characterization of the optical forces on a material platform capable of exhibiting mechanical, beam-riding, and thermal stability. For a laser power density of 200 W/cm^2 at 514 nm, we measure displacements of ~10 pm, resulting from optical forces of ~30 fN. Contrary to optical trapping of microscopic objects, motion is induced by a collimated laser beam filling substantial part of the lightsail, mimicking the initial acceleration stage of interstellar lightsails. Furthermore, to predict the tilt-dependent dynamics of subwavelength thick lightsails, we characterize the non-intuitive trend of the optical force versus incidence angle in the range of ±20° for TE and TM polarization. Our study represents a critical milestone in realizing an experimental testbed for lightsail characterization, thus advancing the development of laser-driven spacecraft, and opening the door for manipulation of macroscopic objects through optical forces.

9:30 AM *EL08.12.04
Let's Twist Again: High-Quality-Factor Metasurfaces to Enhance Spin In Molecules and Monolayer Materials Jennifer A. Dionne; Stanford University, United States

Many inversion-asymmetric materials, including chiral molecules and certain van der Waals materials, exhibit a differential absorption of left and right circularly polarized light that is nearly five orders of magnitude less than their absorption of unpolarized light. Such weak differential absorption challenges applications such as single molecule circular dichroism spectroscopy, all-optical enantio-specific synthesis, and efficient valleytronic data encoding for quantum information. Here, I describe approaches to enhance helicity-dependent optical absorption, emission, and carrier relaxation in molecules and monolayered materials. We rely on high-quality-factor (high-Q) metasurfaces, which, when placed in the near-field of a molecular or monolayer sample, precisely control the amplitude, phase, and polarization of light. Each metasurface enables substantial and uniform-sign enhancements of both the electric and magnetic fields of light, with local photon spin fields that can be enhanced by several orders of magnitude.

First, we show how high-Q metasurfaces enable circular dichroism from a molecular monolayer. We fabricate silicon metasurfaces and functionalize them with short, ~10-mer DNA oligonucleotides. We measure their circular dichroism in a home-built table-top polarization sensitive spectrometer, and also show how this technique is sensitive to changes in the CD handedness through double- stranded to single-stranded DNA denaturing. Next, we show metasurface designs that can enable high-yield enantioselective photochemistry at visible and ultraviolet wavelengths. By overlapping the metasurface optical resonances with the chiral molecular resonance, we project a 2000-fold improvement in the yield of a photoionization reaction. Finally, we extend this platform for valleytronic applications with two-dimensional transition metal dichalcogenides (TMDCs). We integrate TMDC monolayers with high-Q metasurfaces to improve and control valley-specific absorption and emission, to realize solid-state, optically addressable spin qubits. Through the coupling to the metasurface modes, the degree of polarization of exciton and trion emission from each valley can be enhanced, even up to 190K. Combining Si-compatible photonic design with molecular and 2D materials integration, our work makes an important step toward all-optical enantioselective sensing and separation as well as on-chip quantum optical information systems approaching room-temperature operation.

SESSION EL08.13: Dielectric Metasurfaces
Session Chairs: Jennifer Dionne and Ho Wai (Howard) Lee
Thursday Morning, April 25, 2024
Room 340/341, Level 3, Summit

10:30 AM *EL08.13.01
Novel Dielectric Metasurfaces for DUV Photonics Bo Ray Lee, Ting An Shu, Pei Ying Ho, Mao Feng Jiang, Yu Chieh Peng, Kuan-Heng Chen, Jia Hua Lee, Yu Chia Chung, Yu Jie Wang, Der-Hsien Lien, Tzu-En Lin, Chao-Hsin Chien, Ray Hua Horng and Ming Lun Tseng; National Yang Ming Chiao Tung University, Taiwan

Deep ultraviolet (DUV) light covers wavelengths from 200 nm to 300 nm and has diverse applications including imaging, sensing, and medical treatments. Developing efficient and robust metasurfaces is crucial for improving the relevant DUV technologies. Here, we present innovative DUV dielectric metasurfaces providing field enhancement and several unique properties. By employing the photon doping effect and including a quasi-bound state in the continuum in the design, we realize a Si metasurface capable of showing a DUV plasmonic resonance. The field enhancement and the durability of biochemistry-related solvents of the sample enable its applications for DUV sensing applications. In addition, to generate strong field enhancement, we use low-loss HfO2 to create a dielectric metasurface. Combining HfO2's optical properties with novel designs results in multiple high-quality factor resonances and significant field enhancement. These results will advance the development of ultrasensitive biosensing chips within this crucial wavelength range.

11:00 AM EL08.13.02
Extremely Confined THz Phonon Polaritons in HfS_2 and $HfSe_2$ Ryan Kowalski[1], Gonzalo Alvarez Perez[2], Maximilian Obst[3], Katja Diaz-Granados Santos[1], Giulia Carini[4], Aditha Senarath[1], Saurabh Dixit[1], Niclas Müller[4], J. Michael Klopf[5], Thomas G. Folland[6], Lukas Eng[3], Susanne Kehr[3], Pablo Alonso Gonzalez[2], Alex Paarmann[4], Richard Haglund[1] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]University of Oviedo, Spain; [3]Technische Universität Dresden, Germany; [4]Fritz-Haber Institute, Germany; [5]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [6]The University of Iowa, United States

Plasmonics and polaritonics have enabled the field of nanophotonics to reduce the wavelength of light to length scales far below the diffraction limit, leading to optoelectronic devices miniaturization and enhanced light-matter interactions. Traditionally, complex heterostructures were necessary to achieve the desired confinement capabilities. Coherently coupled vibrations in polar dielectrics, or phonon polaritons, are an attractive alternative to realize these goals as they use a different mechanism intrinsic to the material, to compress light. Quality phonon polaritonic materials possess a large splitting between the transverse optic (TO) and longitudinal optic (LO) phonons, which results from a strong internal electric dipole. Within the TO-LO splitting, or Reststrahlen band, the dielectric permittivity becomes negative, opening the door for phonon polaritons. Traditionally, the dominant spectral range for phonon polaritons has been the mid-infrared (mid-IR), despite a rich potential for nanophotonic materials at far-infrared (far-IR) and terahertz (THz) frequencies where molecular vibrations and rotations are observed. The transition of plasmonics and polaritonics into the far-IR and THz has been stunted due to a lack of materials that can host phonon polaritons.

Transition metal dichalcogenides (TMDs) are commonly studied in the near-infrared (near-IR) and visible wavelengths, specifically for the excitonic properties in MoS_2, $MoSe_2$, WS_2, and WSe_2. However, the phonon resonances of these TMDs are not strong and do not possess large TO-LO splitting, making them a poor candidate for infrared nanophotonics. Conversely, Group-IVB TMDs such as HfS_2 and $HfSe_2$ have exceptionally large Reststrahlen bands (> 100 cm^{-1}), a priority for phonon polaritonics. They are also two-dimensional (2D) van der Waals crystals, making them even more attractive for nanoscale optics. Furthermore, due to the crystals' anisotropy, the dielectric permittivity between the in-plane (ε_{xy}) and out-of-plane (ε_z) directions differs with respect to the incident wavelength, which separates the Reststrahlen band into two dispersion bands, elliptic ($\varepsilon_{xy}*\varepsilon_z > 0$) and hyperbolic ($\varepsilon_{xy}*\varepsilon_z < 0$). In the hyperbolic regions, the isofrequency contour becomes an open hyperbola with extraordinary waves that do not have a momentum (k) limit, facilitating extreme compression of the free-space wavelength ($k = 2\pi/\lambda$).

In this study, we use polarized Fourier transform infrared (FTIR) spectroscopy to extract the anisotropic IR permittivity of $HfS(e)_2$ and reveal the exceptional TO-LO splitting in the mid- to far-IR. Within these broad bands, we image the near-field optical signal of phonon polaritons and measure confinement of the free-space wavelength by a factor of more than 100. Finally, by varying the substrate permittivity, we demonstrate tunable control of the coupling strengths between the hyperbolic phonon polaritons and epsilon-near-zero polaritons in $HfSe_2$. By examining an underexplored class of materials, this work directs the search for quality nanophotonic materials, in particular those that facilitate access to far-IR/THz wavelengths, a spectral range that suffers from limited optical materials.

11:15 AM *EL08.13.03
Metasurfaces for Light Detection and Ranging Patrice Genevet; Colorado School of Mines, United States

Metasurfaces are versatile optical components that can distribute optical power in desired regions of space, thus holding great potential for on-chip integration of miniaturized optoelectronic and imaging systems[1]. Using metasurfaces, we reported advanced LiDAR technology that leverages from ultrafast low FoV deflectors cascaded with large area metasurfaces to achieve large FoV (150°) and high framerate (kHz)[2].
Additionally, achieving wide-angle 3D imaging is becoming essential nowadays for autonomous robotic systems, yet most of the available solutions fail to simultaneously measure back-scattered from multiple directions. Inspired by arthropods eyes, we conceive a metasurface can overcome the limitation of curved optics, achieving panoramic vision. On-chip vertical integration of directional metalenses on the top of a planar array of detectors enables a powerful insect-inspired LiDAR vision that is capable of 3D imaging over a wide field of view[3].
The use of our disruptive LiDAR technology with advanced learning algorithms offers perspectives to improve perception and decision-making process of ADAS and robotic systems.

11:45 AM EL08.13.04
Silicon Nanophotonics for Multi-Omic Marine Detection Halleh Balch[1], Sahil Dagli[1], Varun Dolia[1], Kai Chang[1], Greg Doucette[2], William Ussler[3], Chris Scholin[3] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]NOAA/National Center for Coastal Ocean Science, United States; [3]Monterey Bay Aquarium Research Institute, United States

The oceans are host to diverse marine microorganisms that are capable of cycling nearly all chemical elements and are responsible for over half of the oxygen on earth, forming a key part of our carbon cycle. Yet, studying the marine microbiome remains an outstanding challenge. Very few marine microbes have been successfully cultured under laboratory conditions and culture-independent methods like metagenomics and mass spectroscopy are incompatible with the real-time and in situ measurements necessary to study how physico-chemical drivers impact microbial nutrient cycling.

Here, we present our approach based on high quality factor silicon nanophotonics to simultaneously and rapidly measure multiple 'omic' signatures from marine ecosystems. Our metasurfaces are composed of sub-wavelength silicon nanobars on sapphire substrates. First, by introducing small biperiodic perturbations to the lateral block dimension, free space radiation can be coupled into guided mode resonances to produce high-Q resonances with Q factors exceeding 10^3 in aquatic environments. We demonstrate in simulation and experiment that by varying the biperiodic perturbation from 10 nm to 50 nm, the quality factor can be modulated from 10^2-10^4 and that the local electric field can be driven to the silicon surface, increasing the overlap between the field and the binding surface by nearly four-fold. We experimentally demonstrate that by introducing tapered photonic mirrors, the resonator cavity length can be reduced by 10X while retaining Q-factors exceeding 3000, and that the long resonance lifetimes together with the increased field penetration at the binding surface results in strong spectral shifts of the resonance mode due to small perturbations to the local dielectric environment. We fabricate our metasurfaces by e-beam lithography and demonstrate that the optical responses of individual resonators can be spatially resolved as individually addressable finite 'pixels' and simultaneously read out on a 2D InGaAs CCD array in a cross-polarized reflection configuration.

Using this platform, we demonstrate quantitative and amplification-free detection of DNA and the harmful algae bloom toxin, microcystin, which poses a threat to drinking and agricultural water supplies. We selectively target nucleotides and the toxin microcystin on the same multiplexed platform using tailored surface functionalization of self-assembled monolayers (SAM) and a competitive antibody binding assay. We observe in both calculations and experiments that consecutive molecular layers generate 0.5 nm - 4 nm shifts to the resonant wavelengths as sequential layers bind to the resonator surface. Finally, I will discuss the integration of our high-Q metasurfaces with flow-through microfluidics and an autonomous robotic water sampler developed at the Monterey Bay Aquarium Research Institute (MBARI), that offers a pathway for in situ phycotoxin detection, processing, and analysis.

SESSION EL08.14: Active Control Metasurfaces and Metamaterials

2:00 PM EL08.14.02
Acoustically Modulated Gap Plasmons Skyler P. Selvin, Majid Esfandyarpour, Mohammad Taghinejad and Mark L. Brongersma; Stanford University, United States

Among all techniques used to modulate light, mechanical modulation techniques hold high promise due to their ability to alter the optical permittivity to a greater extent than any other modulation technique. However, typical mechanical techniques employing acoustic waves and the photo-elastic effect, such as Acousto-Optic Modulators (AOMs), struggle to efficiently modulate light due to the weak refractive index modulation that acoustic waves impose on optical materials. Micro-Electromechanical Systems (MEMS) can be more efficient, but are limited in speed and spatial resolution. The ideal mechanical system would thus combine the advantages of both AOMs and optical MEMS. Here, we present and characterize a Nano-Electromechanical System (NEMS) acousto-optic resonator, which comprises a gap plasmon resonator with a deformable gap filler. The plasmonic gaps confine light to nanometer-sized regions, enabling small nanometer-scale movements to significantly and efficiently modulate the optical scattering spectra. Surface acoustic waves (SAWs) are emitted and shaped under an array of these gap plasmon resonators, facilitating spatially tunable optical scattering. We show time-resolved optical spectra and demonstrate high-frequency continuous optical beam steering by sweeping the input SAW frequency. This work represents a significant advancement in the field of acousto-optic modulation, and provides a new platform to investigate soft materials at the nanometer and nanosecond scale.

2:15 PM EL08.14.03
Tunable Metal-CP-Metal Metasurface with Intrinsically Reflective IR-Electrochromic Conducting Polymer (CP) Ting-Hsuan Chen[1,2] and Po-Chun Hsu[2]; [1]Duke University, United States; [2]The University of Chicago, United States

Electrochromic conducting polymers (CPs) have made significant contributions on actively tunable applications from visible light to infrared (IR), including metasurfaces, plasmonics, and personal thermoregulation. By varying their charge concentration and localization, the interaction between CPs and electromagnetic waves is therefore modulated. Until recently, most CP-based IR-electrochromic studies focused on thin-films toggling between transmissive and absorptive state, due to the trade-off between electrical conductivity and ionic diffusion kinetics. Compared with the transmission modulation strategies, electrochromism based on intrinsic reflectance opens the opportunities to create substrate-agnostic devices.

In this presentation, we propose a tunable metal-CP-metal tunable metasurface by incorporating lossy metals with CP to achieve large tunability of absorption and emission in mid-to-long IR spectrum. The device utilizes the CP as the active material to modulate between reflective and absorptive states. Our study shows the active material, chemically synthesized camphor sulfonic acid doped polyaniline (PANI-CSA), can simultaneously achieve intrinsic reflectance and large mid-IR electrochromic contrast. The IR-spectroscopic ellipsometry and electrochemical characterization explains the correlation between the electrochemical kinetics and the charge localization during the modulation process. Finally, we will discuss and compare the several materials and design properties that affect the overall performance and efficiency in IR electrochromic metasurfaces.

2:30 PM ^EL08.14.04
Gap-Plasmon-Enhanced NbN Superconducting Photon Detectors at Single-Photon Level Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Single-photon detectors have been widely studied for decades because of their unique capability to resolve photon numbers, enabling many applications in quantum information technologies. Compared to other types of single-photon detectors, niobium nitride (NbN) superconducting nanowire single-photon detectors are promising candidates and are commercially available today. However, the absorption coefficient of superconducting NbN in the visible range is typically low, resulting in low quantum efficiency and low signal-to-noise ratios. In the present work, we use a novel approach to enhance the visible-light photoresponse in NbN superconducting microwire photon detectors (SMPDs) by integrating them with gap plasmon resonators (GPRs). This talk describes how we observe the plasmonic NbN SMPDs can achieve a 233-fold enhancement in the phonon-electron interaction factor (γ) compared to pristine NbN SMPDs under resonant conditions with illumination at 532 nm. The nonlinear photoresponse in the visible region is attributed to the gap-plasmon-induced heating that breaks the superconducting state to normal. In addition, an impressive detection efficiency of 98% was achieved using these plasmonic SMPDs. Our results open new opportunities for designing sensitive quantum detectors for quantum information processing, quantum optics, imaging, and sensing at visible wavelengths. The detailed mechanisms and possible applications will be discussed.

2:45 PM BREAK

3:15 PM *EL08.14.05
High-Efficiency Electrically Tunable Active Metasurfaces at Telecommunication Wavelengths Ruzan Sokhoyan, Martin Thomaschewski and Harry A. Atwater; California Institute of Technology, United States

We theoretically discuss different design pathways towards achieving high-efficiency active metasurfaces. We demonstrate electrically tunable active metasurfaces, which can dynamically manipulate the wavefront of the reflected light in the near-infrared wavelength range while exhibiting optical efficiencies > 80%. Our active reflective metasurfaces consist of a gold (Au) back reflector, followed by a silica spacer (SiO_2) on top of each we place an array of amorphous silicon (a-Si) pillars [1]. The quality factors of the designed metasurfaces can adopt values ranging from a few 100s up to 60,000. We achieve a dynamically tunable optical response by integrating an electro-optically tunable lithium niobate layer (LNO) layer into the resonant metasurface structure and introducing indium tin oxide (ITO) interconnects. By applying electrical bias, we achieve a dynamically tunable phase shift of 236º when the refractive index of the LNO layer varies between 2.212 and 2.208. The optical efficiency of the designed metasurface is > 80 % for all the considered values of the applied bias, and the Q-factor of the considered resonance is 40,000. In alternative implementations, we use ITO or tungsten disulfide (WS_2) as dynamically tunable materials and present realistic active metasurface designs adapted to the choice of the active material. Finally, we analyze the beam steering performance of the designed metasurfaces considering the cases of both two-dimensional and one-dimensional beam steering.

The designed high-efficiency metasurfaces could be useful for a number of applications such as free-space optical communications, light detection and ranging (LiDAR), and laser-based additive manufacturing.

[1] Ruzan Sokhoyan, Claudio U. Hail, Morgan Foley, Meir Y. Grajower, and Harry A. Atwater, "All-dielectric high-Q dynamically tunable transmissive metasurfaces", arXiv:2309.08031v1.

3:45 PM *EL08.14.06
Electrochemically Active Metasurfaces Po-Chun Hsu; The University of Chicago, United States

Electrochemistry is a powerful tuning knob for inducing drastic material property change. By applying an electrical bias while using counterions to maintain charge neutrality, electrochemistry can vary the carrier density or even trigger a phase transformation in an electrically addressable manner. Electrochemistry is an ideal tool in many applications where tunable range, scalability, or non-volatility is crucial. However, electrochemically active metasurfaces are still largely underexplored, probably due to the lack of a property database to perform metasurface design and optimization. More co-development is needed among fundamental materials science, metasurface design, and electrochemical device engineering. In this talk, I will present two examples of electrochemically active metasurfaces. (i) Conducting polymer near-perfect dynamic thermal emitter. We conducted infrared ellipsometry to measure the potential-dependent optical property and designed a tunable MIM near-perfect absorber for wearable variable emittance (WeaVE) devices for personal thermoregulation. (ii) Reversible metal electrodeposition for active beam steering metasurface. Because reversible electrodeposition can create and dissolve metals on demand, active metasurface can be achieved by creating and dissolving the meta-atoms or affecting the periodicity. As a proof of concept, we will demonstrate a reflection-type beam steering metasurface based on this principle and discuss the outlook and future challenges and opportunities.

4:15 PM EL08.14.07
Stop Coloring Inside The Lines- Meniscus-Guided Printing of Nanoparticle Films John R. Crockett, Kyung Sun Park, Yen-Chi Chen, Ying Diao and Qian Chen; University of Illinois at Urbana-Champaign, United States

Meniscus-guided printing has become a well-known technique for the application of polymer films. The ability to control orientation and thickness along with the ease of scaling have made it a low cost and effective process that is even used in manufacturing OLED displays. This research investigates the use of meniscus-guided printing for the simultaneous self-assembly and deposition of anisotropic gold nanorods. Through varying the speed, concentration of nanorods, energy of surface interactions, and size of substrate we have achieved deposition of several patterns with features from the millimeter to the nanoscale. This method can alleviate the necessity of costly and time-consuming templating or lithography steps, instead by controlling the confinement of the solution, and its interaction with the substrate, nanoparticle films can be templated and printed simultaneously.

Realizing Full-Spectral Image Encryption in The Infrared Using an Electrically Tunable Metasurface and a Matched Detector Romil Audhkhasi[1] and Michelle Povinelli[2]; [1]University of Washington, United States; [2]University of Southern California, United States

The ability of metasurfaces to manipulate optical waves in the spatial and spectral domain has provided new avenues for the development of compact and secure data storage platforms. Here we present an encryption system consisting of an electrically tunable metasurface and a matched detector for secure encryption of grayscale images in the 8 – 12 μm wavelength range. In the proposed scheme, the encrypted image corresponds to the spatially varying thermal intensity of the metasurface as captured by its matched detector. In contrast to previous metasurface-based encryption schemes, the current approach leverages the full spectral response of the associated photonic devices to achieve secure encryption while circumventing the need for an increased device size. Using examples of single and multi-image encryption, we show that the optical properties of either the metasurface or matched detector alone do not reveal any meaningful information about the encrypted image, thereby validating the security of the proposed scheme. The electrical tunability of the metasurface provides additional security as the image can only be retrieved by operating it at a predefined voltage level. We believe that our results provide intriguing possibilities for the development of compact and secure object tagging and anti-counterfeiting applications in the infrared.

5:00 PM EL08.15.02
Manipulating Confined Infrared Light via Polaritonic Design of Sub-Diffractional α-MoO_3 Wedges Ethan Ray[1,2], Mingze He[2], John Buchner[2], Saurabh Dixit[2] and Joshua D. Caldwell[2]; [1]Georgia Institute of Technology, United States; [2]Vanderbilt University, United States

The Mid-infrared (mid-IR) spectrum of light is crucial for various applications, including thermal imaging, molecular sensing, and free-space communication. However, the application of long free-space wavelengths of mid-IR light is limited in chip-scale devices due to the diffraction limit. This problem can be circumvented by using hyperbolic materials where the dielectric permittivities along the principal crystal directions exhibit opposite signs in the mid-IR spectral region. It has been well-demonstrated that hyperbolic materials (e.g. h-BN, α-MoO_3, α-V_2O_5) can confine high-momentum (short wavelength) electromagnetic waves in the form of hyperbolic phonon polaritons (HPhPs)- quasi-particles made from the hybridization of charged dipoles (phonons) and photons (an external light source). The propagation behavior of these HPhPs can be tuned and confined in deep sub-diffraction volumes using sub-wavelength structures, which offer distinct opportunities in the form of chip-scale nano-photonics devices for integrated optics and photonics applications.

In this work, we investigate sub-wavelength wedges of a hyperbolic material (α-MoO_3) to demonstrate in-plane focusing of electromagnetic waves beyond the diffraction limit and a transition of polaritonic propagation in the forbidden direction of the α-MoO_3 crystal. We design our wedges by optimizing lateral dimensions and wedge thickness using 3D numerical simulations via COMSOL Multiphysics. Numerically, we observed transitions from adiabatic compression to standing wave in polaritonic modes through changing wedge vertex angles (θ_v). For $10° < \theta_v < 30°$, we observe a compression factor (i.e. ratio of wavelength in standing wave region to the adiabatically compressed region in the wedge) of 2.89 (at 700 cm-1) and 1.42 (at 900 cm-1) that converge to 1 upon increasing vertex angle. Further, we investigate the effect of geometrical confinement at vertex angles $120° < \theta_v < 150°$ on propagation direction and found that a high vertex angle of wedge enables the propagation of HPhPs in the forbidden direction. After establishing these theoretical foundations, we

fabricated such wedges and characterized them with scattering-type Scanning Near-field Optical Microscopy (s-SNOM). Through s-SNOM, we found the presence of adiabatically compressed waves confined at the tip of the wedge at lower vertex angles and node formation along the forbidden propagation direction at high vertex angles. This work offers a novel tunable parameter for manipulating mid-IR light propagation in α-MoO_3 sub-wavelength structures. Further, these findings open avenues for chip-scale mid-IR nanophotonic devices and optical components with the ease of van der Waals integration for integrated optics and photonics applications.

New Design Principle of Chemically Tunable Bulk Hyperbolic Metamaterials Hyungseok Lee[1,1], Jong-Young Kim[2] and In Chung[1,1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Conventional hyperbolic metamaterials are fabricated to form artificial nanoscale structures that are designed to interact with light uniquely. In addition to the difficulty in theoretical prediction of the structures to induce desired properties, their structures had to be realized by technically challenging nanofabrication techniques. Herein, we present a new facile design principle to realize bulk metamaterials with a hyperbolic dispersion tunability. Using two exfoliated inherent hyperbolic materials as a building block, hexagonal boron nitride (h-BN) and graphite/graphene, we developed the facile synthesis method to obtain their heterostructured nanohybrid powders via self-assembly between two functionalized building blocks. Afterwards, the resulting powders were consolidated into dense bulk pellet using spark plasma sintering. The final bulk products comprise the alternating nanoscale layers of h-BN and graphite/graphene. Depending on the mixing ratio and thickness of the constituent building blocks their microstructures were delicately altered, consequently serving as a fine tool to control the hyperbolic responses. Remarkably, embedding a trace of rhombohedral boron nitride (r-BN) also anisotropically changes both type-I and type-II hyperbolic resonance modes and negative permittivities, thus indicating that r-BN acts as a ‘dopant’ in h-BN/graphite metamaterial system. For the first time, our work demonstrates the real bulk metamaterials with finely tunable hyperbolic dispersions by modulating chemical compositions. Negative permittivites are observed for the incident infrared light along both the in-plane and out-of-plane directions. Our achievement can serve a potential platform to rationally design and conveniently realize scalable bulk metamaterials without need of complicated fabrications.

Terahertz Time Domain Transmission Spectroscopy of Magnetic Nanoparticles for Frequency Selective Surface Application Kousik Pradhan[1], Sumit Saxena[1], Shobha Shukla[1], Siddhartha Duttagupta[1] and Sriganesh Prabhu[2]; [1]Indian Institute of Technology Bombay, India; [2]Tata Institute of Fundamental Research, India

Terahertz time-domain spectroscopy (THz-TDS), is an effective method for characterizing materials and monitoring processes. Metals, electronics, 2D materials, and even superconductors have all been tested with this technique, which does not require physical touch to obtain accurate results. Terahertz (THz) spectroscopy has developed as a method for investigating dielectric and transient photoconductive characteristics of materials over the past few decades. Since it can measure electrical resistance without touching the sample and has a temporal precision of a few picoseconds. Due to the low energy of THz radiation and the narrow pulse width, THz-TDS technology is non-destructive when used for extracting visual data from materials (picosecond range). This paper reveals optical parameters extraction methods by using THz transmission spectroscopy technology. In summation, materials with a low absorption of terahertz radiation can benefit from the adaptability of transmission methods, while materials with a high absorption capacity can take advantage of the advantages of reflection methods. To measure the magnetic material's optical properties like refractive index and absorption coefficient, we employ a transmission-type terahertz time domain spectroscopic instrument. The observations and analysis are performed in both the time domain and frequency domain, and we examine the transmission of terahertz radiation through a polymer based magnetic nanoparticle substance at frequencies from 0.1 to 3 terahertz (THz). In the past few years, magnetic materials based on frequency selective surfaces (FSS) have become indispensable in the design of gigahertz (GHz) and terahertz (THz) millimeter-wave filters, polarizers, absorbers, EMI shielding, antenna reflectors, and radar applications. In this research, ferrite was used to produce a microstructured FSS on a quartz substrate. Frequency Domain (FD) solvers included in the CST MWS commercial software package, which is based on the Finite Integration Technique (FIT), are used to evaluate the FSS's efficiency. Here, we demonstrate a terahertz filter made from arrays of circular holes in a quartz substrate, which acts as a frequency selective surface (FSS). We shall show the properties of FSS terahertz-wave transmission using a finite difference time-domain approach. Researchers looked examined the suggested design over a range of frequencies from 0.2 THz to 3 THz. The proposed structure's complementary behaviour is also statistically analysed. We evaluate the proposed layouts by investigating their most elemental characteristics, such as their transmittance and polarisation. The response of the proposed structure to a broad variety of incidence angles is also investigated. Additionally, at the frequency selective surface of the magnetic material, polarisation insensitivity is achieved for the TE and TM stimulated mode. This research presents the detailed layout and analyses of the evaluated parameters for the proposed terahertz wave filter. The suggested terahertz wave filter's parameters are then fine-tuned. The filter we describe has the potential to be widely used in future terahertz wave systems due to its low manufacturing costs and simple design.

Dynamic Tuning between a Reflecting Mirror and a Transmitting Window by Nano Sphere Lithography and Electrochemistry TsungYu Huang and Cheng-Yuan Xiao; Ming Chi University of Technology, Taiwan

In the ever-evolving landscape of technology, electronic devices such as displays, solar panels, and touchscreens have become indispensable to our daily lives. These devices rely on a critical component known as transparent conductive electrodes. In the past, indium tin oxide (ITO) was the common material for these electrodes. However, ITO has certain drawbacks. Its inherent oxide nature makes it brittle and susceptible to damage, and indium is a precious metal, with high cost. To overcome these challenges, researchers have explored novel nanostructures that serve as alternatives to traditional ITO electrodes. Yet, most of these nanostructures come with a drawback, i.e., they tend to possess fixed conductivity and transmittance values after production, lacking the ability for dynamic modulation.
To address this limitation, in this work, we combines nanosphere lithography, indium tin oxide deposition, and the electrodeposition of silver to design and fabricate a dynamic tuning between a reflecting mirror and a transmitting window. To fabricate such a device, first of all, we spin-coated polystyrene nanopheres for a uniform mask. The corresponding spacing among nanospheres was further modified by reactive ion etching. Next, ITO was deposited to form a countinous hollow hole array. Then, the electroplating of silver was carried out. By contronling parameters of electrochemical reaction, we could fint tune the corresponding thickness of silver and the open of the hole array for actively manipulation of transmittance of the proposed devices. The electroplating behavior of th device and the transmittance for different thickness and morphology of the device were further predicted by two simulations. The first simulation focused on the transmittance of the proposed device by tuning the periodicity and the opening of the devices and the thicknesses of both ITO and silver. The second simulation involves the electrochemistry reaction. The potential variables included material parameters of electrodes and electrolytes, applied current, electrodeposition area, and thickness to anticipate the experimental outcomes.

5:00 PM EL08.15.07
Configurationally Tunable Mie, Plasmonic and Diffractive Structural Colors in a Single Design Youngji Kim[1,2], Joshua D. Caldwell[1] and Jerome Hyun[2]; [1]Vanderbilt University, United States; [2]Ewha Womans University, Korea (the Republic of)

We have developed a structural color design capable of displaying Mie resonant, plasmonic, and diffractive colors within a single design, depending on the configuration of imaging setup. Previous research achieved two distinct colors arising from the same resonance mechanism by introducing anisotropy into the structural parameters of a 2D array and selectively displaying each color based on the polarization. In this study, however, we store and display multiple colors within a single design by employing a 1D metallodielectric grating composed of TiO_x nanowires sandwiched between two Ag layers. Choice of polarization allows for either an electric dipole Mie resonance or a localized surface plasmon resonance to occur independently, generating striking differences in color. Furthermore, the selection of numerical aperture (NA) can further extend the color modulation, as collected diffracted light wavelength is determined by the NA. We also demonstrate the color modes from the 1st order diffraction. All resonance mechanisms and imaging configurations depend solely on the two spatial parameters and their combination: the period and the width of the nanowire. Finally, we demonstrate four levels of encoded images produced from a single set of the gratings under different imaging setups. These findings open up new possibilities for applications, such as image encryption and data storage, and so on.

5:00 PM EL08.15.08
Coupling Surface Plasmon Polaritons to Surface Acoustic Waves Felix Kimeu, Derricka Jones, Renny Fernandez and Doyle Temple; Norfolk State University, United States

The interaction of surface acoustic waves (SAWs) with incident beams to excite surface plasmon polaritons (SPPs) represents an exciting and promising area of exploration in photonics, biotechnology, and nanoscience. This combination of acoustic and optical effects offers fresh opportunities for investigating and controlling surface-related phenomena and devices. The incorporation of SAWs and SPPs provides a unique platform with diverse applications, such as sensing, imaging, and signal processing, capitalizing on their combined strengths in propagation, high sensitivity, adjustable spectral properties, and precision. Our hypothesis suggests that through meticulous selection of the metal for the sensing area, precise control of the metal film's thickness, and accurate adjustment of the SAW frequencies, we can attain exact resonance. Using computational software, Mathcad in the design phase, we carry out simulations to determine the SAW frequencies necessary for achieving optimal coupling with incident beams of varying wavelengths. The research investigates the choice of the metal film at the sensing region and its thickness influences alterations in reflectivity at specific thicknesses of the metal film, and how these alterations affect the sensor's overall performance. The objective is to establish a robust theoretical foundation for the sensor's operation while considering the influence of different metals on its sensitivity and selectivity. The fabrication of the actual sensor prototype is outlined as a crucial aspect of future work, leveraging the insights gained from the simulations of different metals and variation of the thickness to build a functional and efficient SAW-SPP sensor. Additional future steps include calibrating and fine-tuning the sensitivity of the prototype to enhance its performance, as well as ascertaining its selectivity using different analytes.

Cost-Effective Wide-Angle High-Performance Mid-Wavelength Infrared Polymeric Polarizers by Sulfur-Rich Polymers Gyeongyeon Bae, Woongbi Cho and Jeong Jae Wie; Hanyang University, United States

Mid-wave infrared (MWIR) detectors have a wide range of applications in various fields, including non-invasive medical diagnosis, gas detection, and night vision. The IR polarization can significantly improve the resolution of IR images by selectively transmitting transverse magnetic fields (TM). However, state-of-the-art MWIR polarizers mainly use ceramic materials such as ZnS, ZnSe, and Ge. Although these materials offer excellent IR transmission and polarization properties, the material costs are expensive, and their crystalline structures require specialized etching equipment for processing. Toward cost-effective fabrication of MWIR 1D polarizers, we recently reported high-fidelity thermal imprinting of sulfur-rich polymer (SRP) by inverse vulcanization of elemental sulfur with diisopropenylbenzene (DIB). The SRPs are mainly composed of elemental sulfur, which is a byproduct of the petroleum refining process. However, 1D polarizers lack the ability to precisely manipulate the incoming light because they cannot accurately classify incoming light from various directions. In addition, the glass transition temperature (T_g) of DIB-based SRP is close to room temperature, suffering from dimensional stability to maintain the shape of the polarizer in practical applications. In this presentation, we discuss strategy to enhance T_g of SRP for thermal nanoimprinting of 2D nanostructured polarizer. We systematically fine-tuned various thermal nanoimprinting conditions for high-fidelity imprinting of the 2D patterns. This innovative 2D nanostructured polarizer, based on SRP, presents a cost-effective solution for MWIR applications, enhancing image quality and expanding its practical utility.

10:30 AM EL08.16.01
Probing The Impact of Interfaces on Thin-Film Lithium Niobate Electro-Optic Device Performance Matthew Yeh[1], David R. Barton[1,2], Gavin Smith[1], Evelyn L. Hu[1] and Marko Loncar[1]; [1]Harvard University, United States; [2]Northwestern University, United States

Thin-film lithium niobate on insulator (TFLN) has emerged as a strong candidate platform for integrated classical and quantum photonics due to its large linear electro-optic (EO) effect and wafer-scale availability. Driven by breakthroughs in nanofabrication, the EO interaction strength has greatly improved over the bulk, unlocking a new class of devices such as high-bandwidth and energy-efficient modulators, ultrafast pulse generators, and microwave-to-

optical transducers. Despite rapid advances in device functionality, however, material understanding has fallen behind. In particular, it is generally recognized that the reliability of TFLN modulators is subject to unstable EO response at dc and low frequencies. This instability is especially disruptive to the advancement of large-scale photonic circuits and cryogenic applications such as quantum photonics, which require precise index reconfigurability and low-power operation. Post-processing techniques such as thermal annealing have been developed to reduce these deleterious effects, but the microscopic origins of instability remain unclear.

Here, we combine measurements of the material structure, electronic properties, and EO device performance to identify a mechanistic insight for low-frequency instability in TFLN. All devices are fabricated on 600 nm thick x-cut lithium niobate on insulator wafers, and we explore modifications to the fabrication process that affect both bulk and interface properties. First, we correlate electronic transport measurements with improvements in the EO response magnitude to show that annealing reduces charge leakage pathways in TFLN. However, SIMS measurements of the elemental composition show that simultaneously additional dielectric relaxation pathways are introduced; annealing in the presence of a cladding oxide creates an interface by which lithium can diffuse out of the TFLN.

Next, we show through XPS that the etch chemistry and acid cleans used in our thin-film processing dramatically affect the surface chemistry of TFLN. Dry etching with an Ar plasma reduces Nb and creates a damaged amorphous surface layer, whereas employing a C_3F_8-based chemistry creates a prominent F peak stemming from the formation of LiF_x salts or fluoropolymers. The surface Li:Nb ratio can be restored both by specific chemical cleans that remove the damaged layer or thermal annealing. Surprisingly, forming metal contacts to LN surfaces that have been cleaned or annealed actually reduces the EO response magnitude and degrades the stability. Together, these measurements indicate that the metal-TFLN interface also plays a key role in determining EO device performance.

10:45 AM EL08.16.02
A Battery-Free Stretchable Strain Sensor Using Plasmon-Based Structural Color Naoji Matsuhisa[1,2], Riku Nakagawa[1,2], Keinosuke Soda[2], Yushi Suzuki[2], Hiroki Kajita[2] and Toshiharu Saiki[2]; [1]University of Tokyo, Japan; [2]Keio University, Japan

Soft and stretchable sensors offer superior skin conformability, enabling the capture of high-quality biometric signals. Among these, color-based sensors can be operated without batteries and read using devices like smartphone cameras, making them easy to use. While there have been advancements in strain sensors using structural colors, such as photonic crystals [1,2], their applications are limited due to challenges in tuning device softness.

Here, we introduce a battery-free, soft, and stretchable strain sensor using structural color that combines plasmon resonance and interference effects. The device structure comprises 4 stacked layers: a high-refractive-index (n=1.55) polymer, a low-refractive-index (n=1.33) polymer, gold nanoparticles, and a black silicone substrate. Structural coloration emerges from the interference of reflected light from gold nanoparticles, where plasmon resonance takes place, with the reflected light at the interface of the top high and low-refractive-index layers. Applied strain changes the thickness of a low-refractive-index polymer layer to induce different structural colors. This color can be adjusted by modifying the thickness of the low-refractive-index polymer layer and the gold nanoparticle size. Given our structural color layer is ultra-thin, under 1 μm, its flexibility is easily adjustable with additional PDMS layers. A particular device displayed a reflection peak of 730 nm (red) at 0% strain and 665 nm (green) at 60% strain. Moreover, our sensor adapted to finger joints and exhibited a distinct color shift during finger bending.

11:00 AM EL08.16.03
Investigation of The Nanoparticle – Support Interaction Effects of Plasmonic Gold Nanoparticles Deposited on Steel and Aluminum Rosemary L. Calabro[1,2], John Burpo[1], Stephen F. Bartolucci[2] and Joshua A. Maurer[2]; [1]United States Military Academy, United States; [2]U.S. Army DEVCOM Armaments Center, United States

Plasmonic nanoparticle (NP) based sensors have been developed to detect a wide range of analytes based on the principles of localized surface plasmon resonance (LSPR). With LSPR, the peak wavelength of absorption and scattering can shift, broaden, narrow, or be amplified or suppressed based on an interaction with the analyte of interest, allowing an optical readout. However, factors such a near-field coupling, size effects, and surface environment of the NPs can also influence the LSPR properties. Practical implementation of LSPR based sensors requires deposition of the NPs on a substrate, however most studies thus far have focused on very crystalline or pristine materials. We investigated the NP-substrate interaction effects of gold nanoparticles (AuNPs) on two industrially relevant substrates: steel and aluminum. AuNPs were drop cast on the substrates and the change in reflectivity was measured. The spectral properties were also compared to AuNPs in solution. Near field-coupling of the AuNPs was observed when the samples were transferred from water to isopropyl alcohol due to partial nanoparticle agglomeration, however this coupling effect was not observed when the particles were deposited from the isopropyl alcohol to the substrates, despite being aggregated together on the substrate. This suggests that the AuNP coupling effect to the substrate is much stronger than any NP interactions with each other. Shifts in the peak wavelengths were observed when depositing the AuNPs on the substrates, with AuNPs deposited on steel typically exhibiting a redder shift compared to AuNPs on aluminum. Variable angle measurements showed that the AuNPs absorbed strongly at low angles of incidence, with decreasing absorption as the angle increased. Other factors such as the separation of specular and diffuse reflectance, AuNP shape and size, different capping agents, and the surface roughness of the substrates were also considered. The results from this study provide valuable insight into NP – substrate interactions and will help better design LSPR based sensors for a wide range of industrial applications.

Scalable Classical and Quantum Light Sources Boubacar Kante; University of California, United States

The scaling of lasers and in-particular of surface emitting lasers is a multi-decade long question that has been investigated since the invention of lasers in 1958. It is an important question with numerous applications. In this talk, I will propose and discuss an intriguing solution to this question that we named the Berkeley Surface Emitting Laser (BerkSEL) and it is the world's first scale-invariant laser. In the second part of the talk, I will discuss our demonstration of the first deterministic quantum light source in silicon that emits single photons in the telecom band. The work opens unique perspectives for scalable quantum networks.

11:45 AM EL08.16.05
Light-Controlled Disorder-Engineering of Optical Metasurfaces: Aspects of Design and Applications Maximilian Buchmueller, Sven O. Schumacher and Patrick Goerrn; University of Wuppertal, Germany

Metasurfaces have become one of the cornerstones of modern nanotechnology. In planar optics, they enable the precise control of phase, amplitude, and polarization of light at the nanoscale, which has led to advances in numerous application fields, including sensing, nonlinear optics, and optical modulators.

However, their implementation often requires surface nanostructuring, based on complex design and fabrication methods such as electron-beam lithography of focused ion-beam milling. In addition, exploiting narrow spectral features, e.g., for sensing, is accompanied by high demands in terms of precise post-process alignments with respect to probing light, which is challenging particularly in the scope of miniaturization and device integration.

Here, we demonstrate the fabrication of optical metasurfaces exploiting the plasmon-mediated growth of silver nanoparticles (AgNPs). The particle growth is based on the reduction of silver ions in an aqueous solution. Incident light interacts with the localized surface plasmon resonances (LSPRs) of the AgNPs, and thus enables to enhance the reduction kinetics of the silver ions and support the particle growth at intensity hotspots. The changing scattering properties of the growing ensemble of particles can further influence the distribution of intensity hotspots and thus influence the growth positions of other AgNPs. The resulting metasurface shows an optical response, which is highly sensitive to changes in the electromagnetic environment.
The morphology of the resulting metasurfaces shows different features of engineered disorder, including disordered hyperuniformity. These features can be linked to the electromagnetic waves involved in the fabrication process.[1,2] By varying the illumination properties during the growth using incident waves with individual wave-front profiles, penetration depths into the solution and different frequencies, we demonstrate the vast design freedom of the presented method. It is even possible to simultaneously incorporate multiple waves into the fabrication process and thus to increase the amount of structural information stored in the metasurfaces.
As a first application scenario, we show that the metasurfaces are directly applicable as self-optimized optical sensors. The sensors are both instantaneously tailored and intrinsically aligned to the probing light source, as the fabrication and probing environment can be identical. The inherent sensitivity of the optical response to any variations of the electromagnetic environment thus enables high-performance nanoplasmonic sensing without the need for any post-process alignments. We found a sensing performance in terms of a Figure of Merit* of 968. [1]
Furthermore, we show that our method also renders it possible to harness short-range surface plasmon polaritons (SR-SPPs) in smooth ultra-thin silver films using a Kretschmann-Raether geometry. [3] Typically, it is challenging to utilize SR-SPPs in planar stack geometries, because of their high effective mode index. Nanostructuring ultra-thin metal films (around 20nm thickness), or placing metallic nanostructures in close proximity to the planar film for coupling is technologically challenging and can strongly influence the SR-SPP properties. The new possibilities given by our method promise great potential for sensing single surface binding events and high resolution imaging applications due to their strong field enhancement and localization. First promising results also suggest the possible use of other noble metals instead of silver, such as gold, for biological and medical applications.

SESSION EL08.17: Nanostructure Design, Fabrication and Characterization
Session Chairs: Boubacar Kante and Ho Wai (Howard) Lee
Friday Afternoon, April 26, 2024
Room 340/341, Level 3, Summit

1:30 PM EL08.17.02
Electrically Gated Organic-Based Metadevice for THz Amplitude Modulation Federico Grandi[1,2], Cristiano Bortolotti[1,3], Francesco Modena[3], Lorenzo Gatto[2], Matteo Butti[3], Iain McCulloch[4], Caterina Vozzi[2], Mario Caironi[3], Giorgio Ernesto Bonacchini[3] and Eugenio Cinquanta[2]; [1]Politecnico di Milano, Italy; [2]CNR-IFN, Italy; [3]Istituto Italiano di Tecnologia, Italy; [4]University of Oxford, United Kingdom

In the last years, the interest in THz technologies has increased rapidly due to their applicability across several application scenarios like telecommunication and sensing, with recent developments overarching the fields of optics and electronics [1]. Despite their scientific and technological appeal, THz waves have a major drawback coming from the absence of optoelectronic techniques and devices that can manipulate such light waves. To solve this issue, one of the most promising approaches relies on the use of metasurfaces [2], engineered composites whose optical properties can be specifically tailored to interact with THz waves. Therefore, research is now focused on trying to design reconfigurable metamaterials, also known as metadevices, able to modulate the amplitude, phase, and frequency of THz pulses, to achieve the highest modulation depth and switch speed possible [3]. Among the plethora of proposed modulation strategies based on optical, electro-mechanical, or thermal stimuli, electrically-tuned THz metadevices represent a flourishing approach that directly benefits from the development of novel and unconventional transistor configurations.
In our work, we explore for the first time the functioning and the effectiveness of an organic semiconductor-driven metadevice based on a matrix of metal Split-Ring Resonators, which can modulate the amplitude of a THz pulse passing through them [4]. This approach has already been shown to work nicely in the microwave spectral region [5] but has not yet been applied in the THz range. The modulation capabilities come from the electrically driven change of charge carrier density in the organic semiconductor, which enables the metadevice to act as an optical transistor, varying THz transmission around a specific frequency (~0.7 THz) with modulation depths of approximately 65%. These performances, which are comparable with current state-of-the-art technologies but with a way lower driving voltage (<1 V) result from the unique 3-dimensional charge modulation properties of a new class of organic mixed ion-electron conductors based on conjugated polymers with glycolated sidechains, such as the emerging p(g2T-TT) semiconductor.
Also, another key aspect of our work is to show that it is then possible to shift towards mass-scalable and cost-effective manufacturing techniques exploiting high-throughput deposition methods for both the metamaterial matrix and the organic semiconductor, on either rigid or flexible plastic substrates, without losing modulation efficiency.
In conclusion, we hope that this work will lead to the further development of metadevice technologies based on organic semiconductors, with the future aim of improving the effectiveness of this modulating technique in the THz spectral region, especially in terms of modulating speed. Moreover, this device development comes together with an ongoing study on the THz properties of this emerging class of organic semiconductors, leading to fundamental scientific insights that could also find application in other areas, such as electronics and bioelectronics.

Emergent Opportunities with Magnesium for Green Photonics Peifen Lyu, Tao Gong and Marina S. Leite; University of California, Davis, United

States

Structural color generation exploiting nanophotonics or plasmonic behaviors has burgeoning applications in displays, lasers, sensors and other optical sources due to promising advantages such as durability, environmental friendliness, and compatible integration with monolithic fabrication compared to traditional pigments and dyes. While conventional metals (e.g., Au, Ag and Cu) and their alloys are the focus of current optical research, magnesium (Mg) as an earth-abundant material, with biodegradability and CMOS compatibility, has not been fully explored in photonic applications. In our present works [1, 2], we have already established a novel platform for transient color filters/superabsorbers based on Mg and other dielectric thin films with angle-insensitive response and capabilities for fast fading of single vivid hues when exposed to water. These results motivate us to now pursue the realization of sophisticated 3D nanostructures that will form the building blocks of degradable/biocompatible devices. Based on our preliminary optical simulations using Finite-Difference Time-Domain (FDTD) for selected nanostructure configurations [3], all of the structures exhibit pronounced blueshift of their scattering peak frequency with decreased sizes (i.e. due to the etching process of Mg in water). These resonance shifts beget a plethora of applications in photonic devices. For example, it can produce a smooth transition of hues in color display devices for dynamic color tuning. Besides, we perform near-field scattering measurements with Mg nanostructures *in situ* to experimentally demonstrate the transient behavior as the Mg dissolves in a controlled manner. This helps us to achieve our long-term goal of realizing Mg-based devices for next-generation CMOS-compatible and green photonic devices.

Solution-Processed *In-Situ* Grown Ag-TiO_2 Nano-Schottky Junction Thin Films for Hot-Electron based Photodetection and Energy Conversion
Bhola N. Pal; Indian Institute of Technology, India

It is not very easy to capture hot plasmonic electrons for photodetection or solar energy conversion. In this work, an in situ grown Ag-TiO_2 nano-Schottky junction thin film has been deposited by a solution process technique, that contains a highly dense silver (Ag) nanoparticle (NP) surrounded by TiO_2. This Ag-TiO_2 nano-Schottky junction has a low barrier height and a high interface area with the least interface state, which enables efficient hot-electron transfer to the conduction band of TiO_2, which is realized in the external quantum efficiency (EQE) data. This EQE data shows intense photocurrent formation in the region of plasmonic absorption of Ag NP, indicating the primary contribution of hot electrons on photocurrent production. As a consequence, a narrowband photodetector with full width at half-maximum (FWHM) of ~55 nm is fabricated by utilizing this Ag-TiO_2 nano-Schottky junction thin film. This photodetector is fabricated on a glass substrate in a photoconductor geometry that shows a peak detectivity of 3.19×10^{11} Jones at 420 nm with a response time of ~2 s. Besides, this Ag-TiO_2 thin film has been utilized as photoanode for highly enhanced electro-photocatalytic H_2 generation. Photoelectrochemical measurement of optimized Ag(NPs)-TiO_2 thin film photoanodes showed a high photocurrent generation at a density of 42 mA cm^{-2} in 1 M KOH solution, which is three orders of magnitude higher than that of pure TiO_2, and stability for more than 1.5 h. An intense photocurrent generation in the region of plasmonic absorption of Ag NPs has been observed that reveals direct evidence of plasmon-induced hot electrons for solar energy conversion.

Chemical Growth of Chiral Plasmonic Metamaterials Shuai Feng, Blake Povilus, Jaewoo Park and Sui Yang; Arizona State University, United States

Controlling the polarization states of light through chiral metamaterials offers unprecedented opportunities in realizing novel functions including optical switches, modulators, wave isolation and phase shifter. The realization of metamaterials can be made from top-down and bottom up, either from lithographic methods such as EBL or self-assembly for nanoparticle coupling. However, significant challenge exists in controlling symmetry functions directly by the growth. Here we show that the direct chemical growth of chiral plasmonic metamaterials. This work provides a new metamaterials fabrication platform for symmetry control leading to the properties and applications previously deemed unfeasible.

3:00 PM EL08.17.06
Synthesis and Photocatalytic Activity of Porous Bimetallic Plasmonic Nanoparticles Formed on Solid Substrates Harshitha Rajashekhar, Navneet Kumar, John Garcia, Damini Vrushabendrakumar and Karthik Shankar; Univ of Alberta, Canada

Plasmonic catalysis aims to extract useful work from the surface plasmon resonance phenomenon in order to assist or drive a chemical reaction. Nanoparticles (NPs) composed of plasmonic metals such as Au, Ag, Cu and Al resonantly interact with light through the excitation of localized surface plasmon resonance (LSPR) modes which subsequently decay to produce highly energetic "hot carriers". There are two major technical obstacles that prevent the efficient utilization of hot carriers to drive chemical reactions. The first limitation is that plasmonic NPs are frequently synthesized as colloidal suspensions while a number of heterogeneous catalytic reactions require the catalyst to be anchored to a solid-state support. The second limitation arises due to the relative chemical inertness of noble metals, particularly gold, which prevents the adsorption of most types of reactant molecules on the surface of the plasmonic NP catalyst. As a consequence of the second limitation, plasmonic metal NPs often demonstrate low catalytic activity for many chemical reactions. In recent years, there has been growing interest in bimetallic nanostructures that combine the optical characteristics of plasmonic metals with the catalytic properties of metals such as Pt and Pd. In this work, we attempted the precise fabrication of diverse bimetallic plasmonic photocatalysts with a porous structure to overcome both the aforementioned technical problems. Porous bimetallic plasmonic nanoparticles with large surface areas possess an enhanced capacity to adsorb reactant molecules (compared to their monometallic counterparts) increasing their overall catalytic efficiency. In this work, we present a dealloying technique to fabricate porous bimetallic nanostructures on solid substrates and investigate their activity for the vapor phase transformation of CO^2 and H_2O into hydrocarbons at close to room temperature. We also analyze the photocatalytic ability of the as-fabricated porous bimetallic nanostructures in the decolorization of methylene blue (MB) dye. Scavenger studies indicate photogenerated electrons to be the active species responsible for photocatalytic activity. In both CO_2 photoreduction and dye photodegradation, bimetallic porous AuPt NPs outperform monometallic

porous Au NPs by nearly 33%. These results have important implications for more energy efficient, sustainable heterogeneous catalysis under milder conditions of temperature and pressure. This work also presents the application potential for the use of porous bimetallic plasmonic catalysts in water remediation and the generation of solar fuels.

Engineering Chiral Plasmonic Nanocrystals via Controllable Photoetching of Silver Nanorods with Circularly Polarized Light Tian Qiao, Tsumugi Miyashita, Anne Ashworth and MingLee Tang; The University of Utah, United States

Chiral plasmonic nanostructures have shown great potential for photonics and sensing applications. Chiral molecules and micelles have been demonstrated to be effective sources of chirality, enabling the colloidal production of large-scale, homogeneous chiral plasmonic nanocrystals. Recent investigations have explored the use of circularly polarized light (CPL) as a chirality source to fabricate chiral Au/PbO_2 heterostructures or as an additional ingredient in chiral molecule-directed synthesis to enhance the optical dissymmetry of the nanocrystals further. However, the mechanism by which these chiral structures develop with CPL has remained largely unexplored. Our latest study has revealed that the wavelength of CPL is a critical factor in determining the shape of chiral Au/PbO_2 heterostructures and their resulting chiroptical properties. Here, we further demonstrate that the asymmetry of the initial plasmonic nanocrystals plays a crucial role in generating more chiral nanostructures. Specifically, we utilized silver nanorods with varying aspect ratios as the starting materials. Ag was oxidized at selective sites upon circularly polarized excitation to create chiral structures. Our results indicate that the optical activity of resulting chiral nanostructures increases with the aspect ratio of the starting nanocrystals. Besides, tuning the excitation wavelength with Ag nanorods of a larger aspect ratio can yield higher contrast of chiral morphologies due to the larger number of higher-order modes accessible in these nanocrystals. Our study underscores the importance of carefully selecting the starting material and excitation wavelength to maximize chiral plasmonic nanocrystals' shape and optical dissymmetry when using CPL as the chirality source. Besides, the non-toxic chiral Ag nanocrystals are more suitable for bio-compatible systems than chiral Au/PbO_2 nanostructures.

Flat Optics: Arbitrary Wavefront Control with Metasurfaces and Metalenses for High Volume Applications Federico Capasso; Harvard University, United States

We will discuss metasurfaces that enable light’s spin and orbital angular momentum to evolve along the propagation direction and nonlocal supercell designs that demonstrate multiple independent optical functions at arbitrary large deflection angles with high efficiency. 2D phase and polarization singularities (“structured dark”) have been realized, as well as 0D singularities. I will present active metasurfaces for high-speed optical modulation at telecom wavelengths based on electrooptic polymers and Si and give the state-of-the-art of commercial metalenses including their high-volume manufacturing for consumer electronics. Finally, we will discuss our recent work on metalenses for the EUV (50 nm wavelength) based on vacuum guiding.

8:30 AM EL08.18.02
Investigation of Exciton-Plasmon Interaction in 2D Hybrid Nanostructures Dmitry Murausky and Pavel Malakhovsky; Research Institute for Physical and Chemical Problems, Belarus

Two-dimensional hybrid nanostructures composed of plasmonic and excitonic nanoparticles attract great interest in the range of applications such as solar photovoltaics, photoelectrochemical catalysis and biosensing. We developed novel 2D hybrid structures via depositing close-packed monolayers of hydrophobic Zn-$CuInS_2$/ZnS quantum dots (CIS QDs) atop silver nanoplates (AgNPls) electrostatically deposited onto thin (~20 nm) optically and e-beam transparent polycationic film. To study exciton-plasmon interaction the optical properties of these hybrid structures were compared with CIS QDs films without AgNPls. Photoluminescence quenching for samples with CIS QDs monolayer atop AgNPls was revealed. According to the time-resolved photoluminescence measurments plasmon-excitonic interaction leads to a pronounced lifetime shortening. We analyzed polarization photoluminescence spectra of the samples to reveal the resonance energy transfer from CIS QDs to AgNPls. We found that the ratio of p- to s-polarized emission light intensity is about 2 times less for samples with AgNPls, due to contribution from indirectly excited AgNPls plasmon scattering. CIS QDs demonstrate intrinsic reversible photoinduced PL quenching and we utilized variations in the quenching kinetics to reveal the FRET effect. A 30% reduction in the PL intensity of CIS QDs monolayers was observed , while CIS QDs atop AgNPls showed no noticeable tendency to PL quenching due to competitive FRET channel. Such hybrid exciton-plasmon nanostructures are perspective for nanophotonic devices with modulating emission. This work was partially supported by BRFFR X22Turk-004 and CHEMREAGENTS 2.1.04.01 projects.

8:45 AM *EL08.18.03
Wide Field-Of-View Metasurface Optics Juejun Hu; Massachusetts Institute of Technology, United States

Field-of-view (FOV) is an important performance metric of optical systems. In traditional optics, expanding the FOV necessarily involve increasing the number of optical elements at the expense of system size and complexity. Metasurfaces offer a promising solution to overcome this limitation, enabling wide-FOV systems with reduced element count while suppressing optical aberrations. In this talk, I will discuss the basic theory guiding the design of wide-FOV imaging and projection optics, and demonstrate wafer-scale, industry-standard foundry manufacturing of wide-angle metasurface optics for applications spanning imaging, sensing and display.

9:15 AM EL08.18.04
SERS Substrate Using Ag@ZnO Composite Coated on Electrospun Cellulose Acetate Fibers by Sputtering Deposition under Limited Adatom Mobility Adrian Camacho-Berrios[1] and Oscar M. Suárez[2]; [1]University of Puerto Rico at Ponce, Puerto Rico; [2]University of Puerto Rico at Mayagüez, Puerto Rico

The present straightforward fabrication methodology of plasmonic substrates is based on Ag@ZnO nanocomposites deposited on cellulose acetate fibers. Magnetron sputtering combined with electrospinning allowed for different morphologies of ZnO and Ag at the nano and microscale. We examined the

morphology and structural properties of the substrates by electron microscopy, Raman spectroscopy, and FT-IR spectroscopy. The results show that ZnO nanocolumns on the cellulose acetate fibers and Ag nanoparticles with various sizes and shapes can form on the ZnO surface. Also, we demonstrated the potential of substrates for surface-enhanced Raman scattering (SERS) applications by using benzenethiol and rhodamine 6G as probe molecules. Our results showed that the experimental substrates exhibited good SERS performance and reproducibility. Our method is simple, versatile, and scalable and could be applied to other metal/oxide systems for plasmonic applications.

9:30 AM *EL08.18.05
Design and Applications of Chiral and Quasi-Bound-States-In-The-Continuum Metasurfaces Stefan A. Maier[1,2]; [1]Monash University, Australia; [2]Imperial College London, United Kingdom

My talk will discuss the design and applications of chiral and quasi-BIC metasuraces for a variety of applications, from energy conversion and light harvesting to interactions with two-dimensional semiconductors. Examples include suppression of exciton-exciton annihilation and controlled enhancement and suppression of light emission, as well as strong-coupling, amongst others. A focus will lie on metasurfaces that can be generated using straighforward nanofabrication techniques with a robustness to defects.

10:00 AM *EL08.18.06
Meta-Fibers: Merging Optical Fibers and Nanophotonics Through 3D Nanoprinting Markus Schmidt; Leibniz Institute of Photonic Technology, Germany

Synopsis: Here, we will demonstrate how the combination of optical fibers and nanostructures creates a new category of fiber-integrated devices – meta-fibers, achieved by leveraging 3D nanoprinting. Essential results are high-NA holographic meta-lenses for optical trapping, multifocus generation via single-point phase-engineering, achromatic metasurface-based lenses, and dielectric ring-like gratings for boosting incoupling efficiencies.

Introduction: The development of nanostructures on fiber end faces offers a promising approach for unlocking new functionalities across various fields, such as biophotonics, quantum technologies, and optical sensing. Conventional top-down fabrication methods usually fail as the fiber geometry is complementary to that of planar substrates (e.g., wafers). In this presentation, we show on several examples that 3D nanoprinting using direct laser writing circumvents this bottleneck, allowing to implement intricate nanostructures on the end face of optical fibers.

Optical trapping with single fiber: Effective light focussing is crucial for numerous applications, while optical fibers have limitations due to the divergence of the emitted light. Here, we used 3D nanoprinting to integrate ultra-high NA holographic meta-lenses onto functionalized single-mode fibers, achieving record-high NA of up to 0.9 with diffraction-limited spots. This breakthrough allowed us to optically trap microspheres and bacteria with individual single-mode fibers, overcoming a significant limitation of fiber optic.

Achromatic light focusing: An open issue in the field of telecommunication is achromatic light focusing, for which no satisfactory solution exists so far. By integrating a nano-printed metasurface-based lens onto a fiber, we have been able to achromatically and efficiently focus the output light of a SMF-28 over the entire telecommunications range. Key is the use of nanopillars of different heights, representing a unique degree-of-freedom provided by the nanoprinting process that is crucial to wavelength independent light focussing.

Boosting in-coupling efficiency: Conventional commercial fibers suffer from low NS, restricting light incoupling to small angles. We have solved this problem by integrating axial-symmetric ring-type nanogratings onto the core of SMF-28, improving the incoupling efficiency at near-grazing incidence by more than four orders of magnitude. Additionally, incoupling at preselected angles and across large angular intervals by employing an optimization procedure was additionally shown. This approach overcomes the low NA limitation of commercial fibers and can lead to advancements in the field of fiber optics.

Summary: We have demonstrated that meta-fibers represent a new category of fiber-integrated devices that offer unprecedented applications for fiber optics. With the implementation of versatile application strategies, we anticipate broader use of meta-fibers in various fields, including quantum technology, bioanalytics, and nanophotonics.

10:30 AM EL08.18.08
A Nanostructured Microarray-Based SERS Sensor Targeted at Multiplex Mycotoxins Detection in Food and Feedstuff Using Handheld Apparatus Rohit K. Singh, Narsingh R. Nirala and Giorgi Shtenberg; ARO, Research Organization, Volcani Institute, Israel

Food and agricultural commodities contamination by various toxigenic molds is a seriously neglected problem, affecting ~25% of the world's crops with staggering economic losses. Regardless of decades of extensive research, mycotoxins continue to penetrate the food chain through food and feed crops and pose health risks to humans and livestock. Herein, we present a newly developed nanostructured microarray (5 by 5 sensing spots) based on silver-coated porous silicon used as a surface-enhanced Raman scattering (SERS) transducer. The unique microarray was facilitated without the need for any micro/nano-fabrication (clean-room) facilities. The inherent surface void and pore morphology (82±2% and ca. < 9 nm, respectively) were physically optimized to augment the SERS effect while achieving an enhancement factor of > 1.03×10^8. Under optimized conditions, three common mycotoxins (aflatoxin B1, fumonisin B1 and ochratoxin A) in feed ingredients and agricultural products were simultaneously assessed using a portable Raman device (1.5 µL sample analyzed in 30 min). The optical response was inversely proportional to the metabolite concentration upon selective interaction with anti-target mycotoxin aptamers modified sensing spots. The calculated limits of detection were 0.01, 0.6 and 0.9 ng/mL (part per billion, ppb) for aflatoxin B1, fumonisin B1 and ochratoxin A, respectively, within the dynamic range of 0.1-1000 ppb. Furthermore, the selectivity, regeneration and overall shelf-life were thoroughly evaluated while depicting satisfactory performances (no interferences with interfering mycotoxins, four regeneration cycles and five weeks of stability, respectively). Finally, the practicality of the developed SERS assay was elucidated in various matrices (*e.g.,* maize, rice and wheat), with recovery values of 95–103%. The successful validation of actual samples' analysis emphasizes the platform's reliability, robustness and suitability for practical use of multi-target analytes detection, including on-site operation.

10:45 AM EL08.18.09
Plasmonic and Plasmon-Free Nanostructured SERS Sensors Tania K. Naqvi, Prabhat K. Dwivedi and Manish M. Kulkarni; IIT Kanpur, India

Surface-enhanced Raman scattering (SERS) is employed for identification and detection of several types of analytes such as environment contaminants, explosives, pathogens, and biomarkers from body fluids for preventive healthcare. SERS outperforms the number of other analytical tools especially for detection of analytes at a trace level. In recent years, with advancements in small size Raman spectroscopy tools, portable, on-field, analysis of real-world complex compounds and point-of-care SERS devices is becoming a reality. However, to this end, there is a need to develop highly sensitive, label free and reproducible SERS sensors.

We demonstrate here fabrication of some plasmonic and plasmon-free SERS sensors and detection of analytes using portable Raman setup. The SERS sensors were developed using different nano/microfabrication techniques such as electrospinning, lithography and self-assembly. We compare the performance of plasmon free SERS sensors obtained via different polymeric carbon precursors and with plasmonic sensors for detection of standard analytes and selective explosives and biomarkers.

Material and Device Design for Multijunction Perovskite Solar Cells Rene A. Janssen[1,2]; [1]Eindhoven Univeristy of Technology, Netherlands; [2]Dutch Institute for Fundamental Energy Research, Netherlands

Metal halide perovskite solar cells have advanced into a viable option for future renewable energy. Record single and tandem junction all-perovskite solar cells already provide power efficiencies of over ~26% and ~29%, respectively. A next target in photovoltaic energy conversion can possibly be met by developing perovskite triple or even quadruple junction solar cells. While these hold a promise to afford higher efficiencies, they require developing stable perovskite sub cells with bandgaps in the range of 1.8 to 2.3 eV, i.e., a range that has not received much attention so far. These wide-bandgap perovskites often suffer from more pronounced voltage losses due to non-radiative bulk and interfacial charge recombination. In developing new perovskite sub cells, photocurrent spectroscopy and absolute photoluminescence spectroscopy are used in combination with bulk and interface passivation strategies to eliminate these losses. This has enabled to reduce the voltage deficit over a wide range of bandgap. Guided by optical modelling, monolithic multi-junction solar cells have been fabricated by stacking two and three different bandgap perovskite sub cells in series using recombination junctions designed to provide near-zero electrical and optical losses. Collectively, these strategies enable monolithic tandem and triple junction solar cells with a power-conversion efficiency of over 26%.

11:00 AM EN01.01.02
Towards Highly Efficient Upscaled Organic Solar Cells: Solvents, Fabrication and The Role of Charge Carrier Dynamics Eva Mazzolini[1,2], Richard A. Pacalaj[1], Bhushan Patil[3], Yuang Fu[4], Rahul Patidar[3], Xinhui Lu[4], Trystan Watson[3], Zhe Li[2], James Durrant[1] and Nicola Gasparini[1]; [1]Imperial College London, United Kingdom; [2]Queen Mary, University of London, United Kingdom; [3]Swansea University, United Kingdom; [4]The Chinese University of Hong Kong, Hong Kong

Organic solar cells (OSC) using non-fullerene acceptors in the Y6 family have now surpassed 19% efficiency. However, these lab-scale, state-of-the-art devices are usually processed using halogenated solvents, which are not suitable for up-scale. As the solvent used during deposition of the OSC's active layer has a significant impact on its microstructure, and therefore the device performance, one of the first steps towards industrialization is to start with materials that are already soluble in greener alternatives.

Moreover, there is still a large performance gap between spin-coated, hero cells and large-scale modules. This is due, among other factors, to the difficulties in maintaining an optimal active layer morphology when switching to industrial fabrication techniques. To bridge this gap, it is paramount to study the photophysics of devices made with scalable techniques, such as blade coating and slot-die coating.

In this work, we demonstrate highly efficient organic solar cells fabricated with spin-coating, blade coating, and slot-die coating techniques, using PM6 and Y12 in o-xylene as electron donor and electron acceptor materials, respectively.
We then investigate the differences and similarities between these techniques with a variety of optoelectronic techniques, including transient photovoltage, charge extraction, and GIWAXS, to determine charge carrier dynamics, morphology, photovoltaic performance, and stability.

Finally, this work demonstrates the application of green-solvent processed OSCs as semi-transparent devices with over 40% visible transmittance and a

fully solution-processed stack.

11:15 AM *EN01.01.03
Singlet Exciton Decay is The Main Competing Pathway to Free Charge Generation in Organic Solar Cells with Low Energetic Offset Dieter Neher; University of Potsdam, Germany

Since the advent of low bandgap non-fullerene acceptors (NFAs), the performance of organic solar cells (OSCs) has improved significantly. In combination with donor materials with complementary absorption, such NFA-based bulk heterojunction blends show efficient conversion of photons into electrons over a broad spectral range. Therefore, an important topic of current OSC research is to reduce the voltage loss by non-radiative recombination while maintaining the short-circuit current (Jsc) and the fill factor (FF) at a high level. The most popular approach to optimize the open circuit voltage of NFA-based blends is to reduce the HOMO-HOMO energy offset. Unfortunately, this is generally accompanied by a significant reduction of Jsc and FF - the reason for this being controversially discussed in the literature.[1–4]

Here we combine a wide range of methods, from spectroelectrochemistry to determine the blend energetics, to femtosecond transient absorption to study the early excitation dynamics, to bias-dependent photoluminescence spectroscopy in the steady state, to study the mechanisms and efficiency of free charge generation in relation to the HOMO-HOMO offset in selected Y-based blends. We find no evidence of the hybridisation of the interfacial charge transfer (CT) state with the local singlet exciton (LE), nor do we observe significant losses due to non-radiative CT recombination competing with charge separation. Instead, singlet exciton decay is identified as the main competing pathway for free charge generation in low energy offset OSCs. This interpretation is consistent with the observed strong decrease in Jsc when the HOMO-HOMO offset decreases from 0.32 eV to 0.17 eV. Our results show that the optimal range of the HOMO-HOMO offset for achieving optimal performance is quite narrow and lies at 0.3 eV - the exciton binding energy of Y6 aggregates.[5]

1:30 PM *EN01.02.01
Printed Solar – Green Energy for Industrial, Warehouse and Commercial (IWC) Buildings Paul Dastoor, Daniel Elkington, Warwick Belcher and Nathan Cooling; University of Newcastle, Australia

Printed solar modules based on organic photovoltaic materials offer significant promise as a next-generation solar energy technology manufactured using roll-to-roll printing. A relatively mature technology, printed solar weighs less than 300 g per square metre, is less than 0.3 mm thick and can be adhered to roofing and other structures using adhesives. Moreover, detailed economic modelling has demonstrated that by focussing on low-cost materials and manufacturing techniques, printed solar is commercially compelling even at relatively low device efficiencies and lifetimes [1].

A key application target for printed solar is the Industrial, Warehouse and Commercial (IWC) building sector. The size of the sector is significant with the area of IWC roofing conservatively estimated to be more that 100 million square metres in Australia [2] and over 4 billion square metres worldwide [3]. Over 70 % of IWC roofs are manufactured to the minimum specification and these “slender” roofs are low weight bearing and incapable of supporting the weight of conventional silicon solar panels which typically weigh around 20 kg per square metre.

In this paper we outline our work in developing large area printed solar for IWC applications in Australia, encompassing material synthesis, device development, demonstration installation, economic modelling and recycling. With modelled payback times of less than 2 years for a typical IWC roof, printed solar offers significant potential for sustainable energy generation in the sector.

Self-Promoted Vertical-Gradient Hole Transport Layers for Flexible Large-Area Perovskite Modules Wallace C. Choy; University of Hong Kong, China

While the power conversion efficiency (PCE) of single-junction perovskite solar cells (PSCs) has increased to over 26%, there are some challenges to achieving flexible large-area PSCs with good long-term stability for practical applications. In this work, we demonstrate a self-assembled gradient $Ti_3C_2T_x$ MXene incorporated PEDOT:PSS HTL for promoting flexible large-area PSCs by establishing half-caramelization-based glucose-induced MXene

redistribution. Through this process, the $Ti_3C_2T_x$ MXene nanosheets are spontaneously dispersed and redistributed at the top region of HTL to form the unique gradient distribution structure composed of MXene:Glucose:PEDOT:PSS (MG-PEDOT). Our results show that the MG-PEDOT HTL not only offers favorable energy level alignment and efficient charge extraction, but also improves the film quality of the perovskite layer featuring enlarged grain size, lower trap density, and longer carrier lifetime. Consequently, the power conversion efficiency (PCE) of the flexible device based on MG-PEDOT HTL is increased by 36% compared to that of pristine PEDOT:PSS HTL. Meanwhile, the flexible perovskite solar minimodule (15 cm^2 area) using MG-PEDOT HTL achieves a PCE of 17.06%. The encapsulated modules show remarkable long-term storage stability at 85degC in ambient air (~90% efficiency retention after 1200 hours) and enhanced operational lifetime (~90% efficiency retention after 200 hours) [1]. With the adoption of the flexible transparent electrodes [2] and the introduction of a new modification on the perovskite active layer, the power-per-weight of our flexible PSCs reaches about 8 W/g while the power-per-weight of PEN/ITO-based control about 1-1.5 W/g. The work contributes to the development of flexible PSCs for practical applications.

Natural Sunlight for Stability Testing of Perovskite Solar Cells Iris Visoly-Fisher; Ben-Gurion University of the Negev, Israel

A major challenge facing the development of perovskite- based solar cells is combining high efficiency with long-term stability. Outdoor stability testing under natural sunlight provides the most relevant test of performance dynamics under operational conditions. Understanding these cells' recovery properties under natural diurnal light-dark cycling can point to methods to extend its lifetime. Sunlight intensity/ concentration -dependent studies of perovskite-based devices elucidated the effect of bias applied to the solar cells on its lifetime and degradation mechanisms. Accelerated stability studies under different sunlight concentrations were examined to determine their relevance to degradation at operational conditions.

2:45 PM EN01.02.04
Fabrication of PEDOT Thin Films using Oxidative Chemical Vapor Deposition to Enhance The Stability of Perovskite Solar Cells Meysam Heydari Gharahcheshmeh; San Diego State University, United States

The practical applications of perovskite solar cells (PSCs) have been hindered by stability issues. One key factor contributing to this limitation is the inherent acidity of the commonly used hole transport layer, poly(3,4-ethylene dioxythiophene):polystyrene sulfonate (PEDOT:PSS), which can compromise the stability of PSC devices. To address this challenge, this study explores an innovative approach that leverages oxidative chemical vapor deposition (oCVD) with antimony pentachloride ($SbCl_5$) as a liquid oxidant. This method is employed to fabricate stable and ultrathin, highly conformal PEDOT films, offering a promising alternative as a hole transport layer in PSCs. The oCVD-grown PEDOT-Cl thin films, produced using liquid SbCl5 oxidant, exhibit outstanding optoelectronic properties, precise control over nanostructure, stability, and integration capabilities. These qualities make them a robust and efficient choice for use as a hole transport layer in PSCs. Incorporating oCVD PEDOT-Cl thin films as the hole transport layer in PSCs results in a remarkable PCE of 20.74%. This surpasses the PCE of 16.53% achieved by spin-coated PEDOT:PSS thin films treated with the dimethyl sulfoxide (DMSO) polar solvent. Moreover, PSCs incorporating oCVD PEDOT-Cl thin films demonstrate a notable 2.5× enhancement in stability compared to their PEDOT:PSS-DMSO counterparts. This technological advancement paves the way for the development of PSCs with not only high performance but also enhanced stability.

Attaining Long-Term Stability, Pure Phase and High Efficiency Beyond 23% in $FAPbI_3$ Perovskite Solar Cells via CsSCN Additives Ahmed Fouad Musa[1,2] and Tzu-Chien Wei[1]; [1]National Tsing Hua university, Taiwan; [2]Al-Azhar University, Egypt

Perovskite solar cells (PSCs) have garnered substantial attention due to their exceptional power conversion efficiency (PCE) and cost-effective fabrication. Among the semiconductors, the cubic α-phase of formamidinium lead triiodide ($FAPbI_3$) has emerged as the most promising choice for creating highly efficient and stable perovskite solar cells. Maximizing the performance of this material is of paramount importance to the perovskite research community. However, thin $FAPbI_3$ films tend to undergo a phase transition from the photoactive black α-phase to an inactive yellow δ-phase when the temperature drops below 150°C. In this study, we explored the impact of introducing cesium thiocyanate (CsSCN) into the perovskite precursor solution. This addition facilitated the creation of a stable perovskite film with a larger grain size, even at a lower temperature of 100°C. The role of SCN^- anions proved critical in promoting the formation and stabilization of α-$FAPbI_3$ below its thermodynamic phase transition temperature. Notably, the inclusion of the CsSCN additive resulted in a remarkable enhancement of the power conversion efficiency (PCE) of the devices, exceeding 23%. This performance improvement can be attributed to several factors, including the formation of a stable perovskite film with larger grains, a film that is more uniform and compact, reduced defects, and improved charge transport properties. Furthermore, X-ray diffraction analysis verified that the CsSCN additive facilitated the formation of pure α-phase perovskite crystals, eliminating undesirable secondary phases. These findings underscore the effectiveness of CsSCN as an additive in achieving stable and high-performance α-$FAPbI_3$ perovskite solar cells with a pure phase composition.

3:45 PM EN01.03.01
Perovskites in Space: Promising Results Aboard Two ISS Missions Samuel Erickson[1], William Delmas[2,1], Calista Lum[3,1], Jorge Arteaga[1], Kaitlyn VanSant[4], Joseph Luther[4], Timothy J. Peshek[5], Lyndsey McMillon-Brown[5] and Sayantani Ghosh[1]; [1]University of California, Merced, United States; [2]Sandia National Laboratories, United States; [3]University of California, Irvine, United States; [4]National Renewable Energy Laboratory, United States; [5]NASA Glenn Research Center, United States

The rapid commercialization of low Earth orbit (LEO) and NASA's return to the moon will require next-generation photovoltaic materials with high specific power and defect tolerance. Perovskite solar cells (PSCs) are an excellent candidate for such missions, having demonstrated their resilience against the unique stressors of space. These include rapid temperature cycling with each orbit, high-energy particle radiation, increased ultraviolet light in the AM0 spectrum, and exposure to atomic oxygen. This work discusses the effects of LEO on metal halide perovskite (MHP) samples from two recent Materials International Space Station Experiment (MISSE) missions. MISSE-15, launched in 2021, included eight PSCs of varying architecture and absorber composition to test several prototype devices. The cells were placed in open circuit at zenith orientation (facing normal away from the Earth) outside the ISS for 6 months before returning to Earth for characterization. MISSE-16 included five encapsulated methylammonium lead iodide (MAPI) thin films with different cover glass layers to test the effects of UV radiation. Upon return, all samples were investigated with high-resolution spectroscopy and microscopy. Photoluminescent (PL) emission and recombination lifetime data from the MISSE samples were compared with control devices to quantify how the former changed under LEO conditions.

Ultimately, all MHP samples showed strong PL emission intensity and little sign of chemical degradation. MISSE-16 films were encapsulated with long pass and band pass UV filters instead of standard top glass to expose each sample to specific UV wavelengths. This test was designed to study if and how MHPs would be affected by various UV bands in combination with the space stressors previously described. All five samples exceeded expectations, returning uniform, emissive, and energetically stable. Of the eight PSCs aboard MISSE-15, only the two $CsPbI_2Br$ cells experienced absorber failure. These cells returned nearly transparent due to $CsPbI_2Br$ photobleaching. The remaining six PSCs, including two each of MAPI, triple cation, and formamidinium-rich triple cation cells, returned with their absorber layers intact. Unfortunately, all cells experienced degradation to their top electrodes (Al or Ag depending on PSC), resulting in no electrical response in post-flight tests. This appears to be caused by ion migration, likely iodide, between the MHP and the metal. However, all MHP films were stable and emissive in regions without contacts and only slightly altered in areas behind the damaged contacts, further confirming the resilience of MHPs. Future MISSE missions will soon launch containing PSCs with indium tin oxide and Au contacts which are known to prevent ion transfer. Overall, the high stability and PL response of MHP films and cells demonstrates their ability to withstand the harsh environment of space.

Computational Exploration of Perovskite-Inspired ABX_3 Structures for Inorganic Solar Harvesting Materials Wonzee Jung[1,2], Suim Lim[1,2], Jiho Lee[3], Changho Hong[3], Yong Youn[1], Seungwu Han[3], Kihwan Kim[1], Joo Hyung Park[1] and Kanghoon Yim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Chungnam National Univerity, Korea (the Republic of); [3]Seoul National University, Korea (the Republic of)

In the last decade, hybrid organic-inorganic perovskites (HOIPs) have shown remarkable potential in enhancing the efficiency of solar cells. However, their practical application has been hindered by issues related to instability, primarily stemming from their inherent vulnerability to humidity and heat. To overcome the instability, which may originate from their organic components, the development of fully inorganic perovskites with comparable performance could be the solution for next-generation solar-cell materials. In our research, we explore all known ABX_3 inorganic compounds obtained from structure databases in search of novel materials for solar energy harvesting. Driving inspiration from the perovskite structure, which offers several advantages in photovoltaic properties, we systematically screen and classify materials featuring the connectivity information between octahedra composing the structures. Consequently, we have successfully classified the target structures in terms of dimensionality and porosity. To predict the photovoltaic performance of those perovskite-inspired structures, we conduct high-throughput screening, taking into account critical factors such as band gaps, optical absorbance, effective masses, synthesizability, and defect tolerance. As a result, we propose several new candidate materials for fully inorganic photovoltaic absorbers. Additionally, we analyze the overall trends in photovoltaic properties across the various structural types within our classification. We anticipate that this talk will offer valuable insights for discovering and designing new inorganic solar-cell absorbers from an expanded material pool.

4:15 PM EN01.03.03
HOMO Energy Level Modulation with Fluorinated Poly(aryl)amines for Wide-Bandgap Perovskite Solar Cells Tom Macdonald; University College London, United Kingdom

Fluorination stands out as an effective strategy to narrow the energy gap between HTMs, such as Poly(aryl)amines (PTAA), and perovskite materials. We demonstrate the synthesis of six novel fluorinated PTAA derivatives and present innovative methods for introducing trifluoromethyl (CF_3) groups into PTAA structures. Our investigation, incorporating electrochemical and optical spectroscopy analyses, highlights the significant influence of both the position and quantity of fluorine atoms on PTAA's energy levels. Additionally, we demonstrate that fluorine atoms and CF_3 groups impact orbital level structures differently, advancing our understanding of PTAA's role in PSCs. Importantly, we have fabricated wide-bandgap PSCs with fill factors exceeding 80%, short-circuit current densities surpassing 17 $mAcm^{-2}$, and power conversion efficiencies exceeding 17%. Notably, this was achieved without implementing surface passivation, underscoring the potential for optimizing high-performance HTMs in PSCs.

4:30 PM EN01.03.04
Efficient Indoor Light Harvesting with High Band Gap Perovskite and Sodium-Ion Battery Tsvetelina Merdzhanova[1], Li-Chung Kin[1,2], Zhifa Liu[1], Hans Kungl[2], Sergey Shcherbachenko[1], Thomas Kirchartz[1], Rüdiger-A. Eichel[2], Uwe Rau[1,3] and Oleksandr Astakhov[1]; [1]Forschungszentrum Jülich GmbH, Institut für Energie- und Klimaforschung (IEK-5-Photovoltaik), Germany; [2]Forschungszentrum Jülich GmbH, Institut für Energie- und Klimaforschung (IEK-9 Grundlagen der Elektrochemie), Germany; [3]Jülich Aachen Research Alliance (JARA-Energy) and Faculty of Electrical Engineering and Information Technology, RWTH Aachen University, Germany

Integrating storage technologies in renewable energy systems of the future is one of the most important problems of the moment. Recent development trends in small scale consumer electronics towards implementing "Internet of Things" and smart house/smart cities concepts make it imperative to have cheap, wireless power solutions for electronics that operate all day. The combination of photovoltaic (PV) devices with rechargeable batteries represents a viable strategy for powering such low power electronic devices. With the increasing use of indoor LED (light emitting diode) lighting worldwide, the matching spectrums of LED output and the absorption spectrum of lead halide perovskite solar cells (PSC) affords an opportunity to reuse emitted light with high efficiency to feed low power electronics. Recently, lead halide perovskite cells and modules have demonstrated efficiencies under artificial lighting of more than 30 % [1] with a record of 40.1 % achieved with an extra thick absorber layer [2]. The main reason is the very close overlap of the external quantum efficiency in lead halide perovskite solar cells with the emission spectrum of an LED lamp. However, there are not many publications showing a combination of perovskite-battery devices working efficiently under low light LED illumination intensities.
The aim of the work is to demonstrate a successful and highly efficient energy harvesting and storage under a wide range of light emitting diode (LED) illumination intensities by applying lead halide perovskite solar module directly coupled to a high-rate capable next generation sodium ion battery. Direct coupling of PV and batteries require fabrication of perovskite solar module with tailored current-voltage (IV) characteristic to match battery voltage under target irradiance conditions. A 3-cell perovskite module with $CH_3NH_3Pb(I_{0.8}Br_{0.2})_3$ absorber layer and fullerene electron transport layer were fabricated with a conversion efficiency of 17.8 %, with a fill factor of 81.3 %, short-circuit current density of 5.91 $mAcm^{-2}$ and open-circuit voltage of 3.71 V under

AM.1.5 illumination. To test the PSC modules for indoor battery charging under LED lighting a sodium ion battery with metallic sodium anode and cathode made from sodium titanium phosphate ($NaTi_2(PO_4)_2$) coated onto sheets of carbon nano-felt (NTP@CNF) was chosen due to its high charge rate capability, low charge-discharge overpotential and distinct charge and discharge voltage plateau. LED illumination intensity was attenuated by using neutral density filters.
High efficiency indoor charging of advanced sodium ion battery based on sodium titanium phosphate ($NaTi_2(PO_4)_2$) coated onto sheets of carbon nano-felt coupled with a perovskite solar module with $CH_3NH_3Pb(I_{0.8}Br_{0.2})_3$ absorber layer under LED illumination was demonstrated. We have directly coupled both devices without any power electronics and achieved overall PV-Battery efficiency of 24.3% at 300 lx LED lightning. Under target LED illuminance of 300 lx, the perovskite solar cell shows PCE of 29.4%, and coupling factor of 0.87, and roundtrip battery efficiency of 94.9 % [3].

Scaling of Perovskite Solar Cells with Carbon Nanomaterials Wei Wei; Wichita State University, United States

Perovskite solar cells (PSCs) that utilize carbon materials as the electrodes provide a great opportunity to enhance the stability and performance meanwhile reduce the cost. Carbon-based electrodes have been reported to be an alternative owing to material abundance, low cost, industrially mature preparation and excellent stability. In this talk, we will first introduce our recently designed chemical reaction for hydrogenated carbon preparation. Then its application for high performance perovskite solar cells will be presented. Last, the potential of using slot-die coating for large-area PSCs will be discussed.

Absorption Enhancement in Perovskite based Thin Film Solar Cells using Whispering Gallery Modes of Dielectric Spheres Ayusmin Panda; Indian Institute of Technology Madras, India

Organic and inorganic halide perovskite solar cells (PSC) are regarded as a promising candidate for next-generation photovoltaic technology owing to their low-fabrication methods and higher power conversion efficiency. PSC devices with adequate trapping of incident light, have been proposed in two different novel configurations. One with the inclusion of pristine TiO_2 microspheres and the other with $CsPbI_3$ coated TiO_2 microspheres, exhibiting resonating whispering gallery modes (WGM). The absorption in the $CsPbI_3$ active layer is enhanced due to the presence of WGM microspheres. The incoming electromagnetic wave couples with TiO_2 microsphere and forms confined resonating modes. Since, the in-coupling element is lossless, energy stored in microspheres is absorbed efficiently by the underlying active perovskite material. Thus, the devices show a higher current density in the range of **25 mA/cm^2**, which is almost **50%** more than a conventional PSCs device. The performance of the designed PSCs have been tested numerically using 3D full-field finite difference time-domain (FDTD) simulation tool. Further, different designs have been discussed for deciding the appropriate position of WGM spheres w.r.t thin-film PSCs featuring back-reflector and optimized anti-reflecting coating. We have also studied the influence of multi-sized array of spheres as well as perovskite coated dielectric spheres to propose an analytical model based on temporal coupled mode theory.

A Breakthrough in Indoor Light Energy Recycling: Dye-Sensitized Photorechargeable Batteries So Yeon Yoon, Myeong-Hee Lee and Tae-Hyuk Kwon; Ulsan National Institute of science and Technology, Korea (the Republic of)

Global energy consumption continues to escalate daily, accompanied by the rapid depletion of fossil fuel resources. The imperative for technological and economic progress has led to increased combustion of fossil fuels, resulting in diminishing reserves, environmental pollution, and extreme weather events. In response to the urgent challenges of energy depletion and environmental pollution, the exploration and development of renewable and recycling energy sources have become paramount. Among these sources, indoor light, constituting 10% of total energy consumption and widely available, has attracted significant attention. However, despite its advantages, indoor light recycling has proven challenging due to the absence of suitable technology.

Recently, a groundbreaking solution has emerged in the form of dye-sensitized photorechargeable batteries (DSPBs), designed to harvest and store energy under indoor light conditions. DSPBs represent a seamlessly integrated system comprising a dye-sensitized solar cell (DSSC) and a Li-ion battery. Their photocharging process is balanced by the spontaneous internal thermodynamic reaction between the redox materials in dye-sensitized solar cells and the redox Li-ion storage materials. Previous studies have showcased the remarkable efficiency of DSPBs, achieving a high light-to-storage efficiency of up to 13.2%. This efficiency translates into recycling 1% of total energy consumption, equivalent to the energy consumption of ammonia synthesis. However, a challenge remains in their energy density for operating devices.

In this study, we address this limitation by incorporating redox targeting materials inspired by the redox flow battery system into DSPBs. These materials facilitate energy harvesting by regenerating the redox material in DSPBs based on the Nernst equation. Consequently, the energy densities increased approximately threefold compared to previous conditions. This innovative approach not only provides a sustainable solution for indoor light energy recycling but also holds the potential to revolutionize the way we harness and utilize energy. Our research opens new avenues for enhancing energy efficiency, marking a significant step toward a more sustainable energy future.

5:00 PM EN01.04.04
Scalable, Low-Temperature Fabrication of High-Performance Perovskite Solar Modules and Their Application to Photo-Rechargeable Batteries Young Yun Kim, Sehee Kim, Jungdon Suk and Nam Joong Jeon; Korea Research Institute of Chemical Technology, Korea (the Republic of)

A fabrication of perovskite solar cells (PSCs) by scalable processes in large-area is prerequisite for the PSCs to fully utilize the inherent advantages of perovskite such as superior charge-transport properties, high absorption coefficient, flexible and light-weight form factors. Large-area perovskite solar

modules (PSMs) can be utilized in self-powered personal mobility and electronics, smart textiles, custom-shaped building-integrated photovoltaics, and so on.
Although several demonstrations of scalable production of PSCs have been reported, successful demonstration of fully scalable production of large-area PSMs is still lacking. The major obstacles are uniform wet-film formation via scalable process in large-area, and complete phase conversion of perovskite precursor to photoactive phase. Therefore, reliable scalable production methods should be established including wet-film formation and phase conversion steps.
In addition, the direct integration of energy generation and storage devices have attracted a lot of interest recently in order to correspond to the fluctuation of power input from the Sun and increasing demand for self-powered electronics. However, inherent mismatch of voltage and current range for charging and discharge from PSCs to Li-based batteries is a major obstacle to realize the direct integration between them. Additionally, power output from PSCs under continuous light illumination, and storage capacity from charging-discharging cycles from Li-ion batteries should be retained.
In this work, we successfully demonstrate high-performance PSMs and photo-rechargeable batteries by directly integrating PSMs and Li-ion batteries in a single substrate. All the layers constituting PSMs can be fabricated via solution shearing coating, with optimized rheological and interfacial properties, at a low temperature (<160 °C). An electron transporting layer (ETL) is designed to be uniform and compact in large-area, by systematically investigating the effect of leaving group in sol-gel precursor and applying an optimal tin precursor with organic crosslinkers. As a result, high-efficiency over 24% can be achieved, retaining over 90% relative efficiency compared to initial one after over 2000 h. Complete conversion of perovskite precursor to photoactive phase in a large area can be achieved via careful selection of proper antisolvent and bathing in it.
PSMs are carefully designed to have a proper area and structure to exactly match the charging voltage-current range of high-capacity Li-ion batteries. Consequently, over 20% efficiency of PSMs and over 14% of overall charging to storage efficiency can be achieved. The photo-charging can be repeatedly conducted over 50 cycles because of stable power output and storage of integrated PSMs and Li-ion batteries.

5:00 PM EN01.04.05
Passivate Leakage Current cia Active Layer and Electron Transport Layer Engineering for Enhanced Perovskite Optoelectronic Performance and Stability Junmin Lee, Woongsik Jang, Byung Gi Kim and Dong Hwan Wang; Chung-Ang University, Korea (the Republic of)

ABSTRACT BODY:
Perovskite optoelectronic devices have garnered immense attention in recent years due to their exceptional efficiency, low-cost fabrication, and potential to revolutionize the field of photovoltaics. However, enhancing their stability and performance remains a critical challenge [1,2]. This study delves into the systematic investigation of perovskite optoelectronics, focusing on the pivotal role played by the active layer and electron transport layer (ETL) in determining device efficiency and stability [3]. We investigate the role of the electron transport layer (ETL) in enhancing the charge carrier transport and extraction processes. PDI-derivatives, such as PDIN, PDINO, and PDINN which are well-known and used material in organic optoelectronic devices' electron transport layer, has high electron affinity, charge transport properties, and good chemical and thermal stability etc [4]. However, it was difficult to apply it on the perovskite layer because the alcohol-based solvent was used, so we solved this and applied it to the PSC device of the NIP structure It was confirmed that by applying PDINN on the PCBM layer, the defects of the PCBM layer were effectively passivated to reduce shunt leakage and at the same time suppress dark current. This process consequently suppresses the thermal degradation of the device and improves the stability of the device. Furthermore, we present a meticulous exploration of various active layer chemical physical process and their impact on the perovskite optoelectronic devices. Until now, it has been known that the grain size in the perovskite active layer is largely influenced by the time and temperature of the annealing process [5]. We note the relationship between the force and buoyancy acting on the active layer by the density of the washing solvent during the washing process, confirming that the lower density washing solvent receives lower buoyancy and consequently induces the formation of a larger grain size. It can be explained by the LaMer model, which represents the speed and time relationship between reaching the supersaturated state from the saturated state, confirming that the dark current is suppressed by reducing grain boundary concentration and passivate the leakage current through it [6]. This, in turn, leads to improved detection performance of the perovskite photodetector. Moreover, we have also conducted research to overcome the shortcomings of perovskite materials that are vulnerable to moisture [7]. A moisture trap capable of trapping water molecules is put into a perovskite solution to remove an infinitesimal amount of remaining moisture through over-night stirring, forming a well-oriented perovskite crystal, and preventing oxidation generated by internal moisture meeting the upper electrode when the device is driven, thereby improving device durability. In summary, our research offers valuable insights into the intricate interplay between the active layer composition, ETL properties, and the overall performance and stability of perovskite optoelectronic devices.

5:00 PM EN01.04.06
Investigating The Suitability of All-Perovskite Tandem Photovoltaics for Indoor Applications Jarla Thiesbrummel[1,2], Etienne Beier[2], Lucas Holte[2], Jonathan Warby[2], Fangyuan Ye[3,2], Henry J. Snaith[1] and Felix Lang[2]; [1]University of Oxford, United Kingdom; [2]University of Potsdam, Germany; [3]East China University of Science and Technology, China

To enable Internet of Things (IoT) applications powered by indoor photovoltaics, it is essential to attain high open circuit voltages. This eliminates the need for step-up transformers to supply the voltage required by the different IoT applications. Although so far, only single junction perovskite solar cells have been investigated for indoor use, all-perovskite tandems could be adapted such that their bandgaps are suitable for indoor illumination, with the advantage of providing a much higher open circuit voltage than single junctions. Here, for the first time, we present an all-perovskite tandem solar cell based on bandgaps that have been specifically tailored to indoor light sources. The performance of these tandems is evaluated for two different types of indoor illumination, and at different illumination strengths. Furthermore, a sub-cell-selective investigation of both sub-cells reveals their individual performance, and provides crucial insights into the factors limiting the tandem efficiency under different illumination conditions. Finally, the general suitability of all-perovskite tandem solar cells for indoor applications is discussed.

5:00 PM EN01.04.07
Indenofluorene-Based Polymer Donor containing The Structural Structure of Pyrolopyroledione Youngeup Jin[1], Suhee song[2], Jin Young kim[2] and Rajalingam Agneeswari[1]; [1]Pukyong National University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

We synthesized three new polymers, namely **P1–P3**, incorporating electron-donating 6,12-dihydro-6,6,12,12-tetraoctyl-indeno[1,2-b]fluorene (IF) and

structural isomers of weak and strong electron-accepting 2,5-dioctyl-4,6-di(thiophen-2-yl)pyrrolo[3,4-c]pyrrole-1,3(2H,5H)-dione (IFPPD) or 2,5-bis(2-ethylhexyl)-3,6-di(thiophen-2-yl)pyrrolo[3,4-c]pyrrole-1,4(2H,5H)-dione (LFPPD) or both the IFPPD and LFPPD units as an effort to study the performance of IF-based polymers on non-fullerene acceptor-based organic solar cells (NFA-OSCs). Polymer **P1** exhibited absorption from 300 nm to 450 nm with an optical bandgap (E_g) of 2.39 eV but polymers **P2** and **P3** showed extended absorption up to 700 nm with an E_g of 1.75 eV. The determined highest occupied molecular orbital/lowest occupied molecular orbital (HOMO/LUMO) levels for **P1–P3** were –5.44 eV/–3.05 eV, –5.26 eV/–3.51 eV, and –5.39 eV/–3.64 eV, respectively. The NFA-OSCs made by using each of **P1–P3** as an electron donor and Y6 as an electron acceptor gave a maximum power conversion efficiency (*PCE*) of 0.8%. We also utilized **P1–P3** as a co-adsorber and fabricated ternary NFA-OSCs using **P1–P3**:PM6:Y6 blends. It was noted that the performance of the ternary devices was lower than that of the binary devices made from PM6:Y6 blend

Photovoltaic Response and Mechanical Properties of Stretchable Solar Cells Antonio Facchetti[1,2]; [1]Georgia Institute of Technology, United States; [2]Northwestern University, United States

Recently, the power conversion efficiencies (PCEs) of rigid organic solar cells (OSCs) and all-polymer solar cells (all-PSCs) and have surpassed 19% and 18%, respectively, principally reflecting the introduction of (polymerized) small molecule acceptors. Here we report the synthesis of new acceptor semiconductors having fully conjugated and partially nonconjugated cores/backbones as well properly designed sidechains enabling both high efficiency ultra-high stretchability. Thus, all blend films were characterized by morphological, microstructural, and spectroscopic techniques and tensile experiments indicates that our blends can achieve ultimate strains surpassing 60%. Equally important, devices based on these blends achieve power conversion efficiencies > 16%, corroborating the molecular design of the new acceptors. Overall, these results convey important implications for developing future ductile and stretchable electronics.

9:15 AM EN01.07.02
Luminescent Solar Concentrator Greenhouses for Concurrent Energy Generation and Lettuce Production in The United States Kristine Q. Loh, Nathan J. Eylands, Uwe R. Kortshagen and Vivian Ferry; University of Minnesota, United States

Agrivoltaic systems promote dual land use by strategically combining photovoltaics (PV) and agriculture. One application space is in greenhouses, where PV glazing can offset or completely meet high energy demands from greenhouse operations. However, fully opaque PVs generate electricity at the expense of light transmission, thereby eliminating crop photosynthesis. Luminescent solar concentrators (LSCs) have received growing interest in the agrivoltaics community as their higher transparency can benefit crop yield while concentrating light onto small-area PV cells. Integrating LSCs into greenhouse roofs presents a promising opportunity to provide clean energy without significantly compromising crop yield; however, the LSC design considerations that balance transmission and electricity generation need to be better understood.

This work presents a modeling framework to evaluate the tradeoff between light used for energy generation and light used for crop growth in LSC greenhouses. Our model incorporates solar resources, heat and energy, power generation, lettuce (cv. Rex) crop yield, and economic models. Using data pulled from NASA and NREL, we determine the hourly power generation and energy demands for operating LSC greenhouses in Arizona (AZ), Florida (FL), Minnesota (MN), and Pennsylvania (PA). We compare two periodic LSC roof structures: a small-area 8 x 8 cm^2 LSC film surrounded by 2 cm-wide PV cells (36% PV coverage) and a large-area 24 x 24 cm^2 film surrounded by 2 cm-wide PV cells (15% PV coverage), as well as a conventional glass greenhouse. We also study three non-toxic luminophores previously evaluated as LSC roof materials: copper indium sulfide/zinc sulfide quantum dots (CIS/ZnS), silicon quantum dots (Si), and Lumogen Red 305 molecular dye (LR305).

First, we determine the influence of the luminophore spectrum and concentration in the LSC films on lettuce growth. CIS/ZnS and Si quantum dot roofs absorb blue light, while LR305 roofs absorb green light. We find that in all cases, the quantum dot roofs lead to higher lettuce yields than the dye roofs due to the reduction in blue light fraction.

Next, we study the impact of luminophore concentration on energy generation and the potential for net zero energy (NZE) greenhouses, where the total energy demand is met by the power produced by the PV cells. In AZ and FL, all small-area LSC greenhouses are NZE as the higher PV coverage allows for more energy generation. No LR305 large-area LSC greenhouses are NZE due to reabsorption losses and a lower PV coverage. All MN and PA LSC greenhouses have an energy deficit due to the high heating demands in these cold climates. However, for small-area LSC greenhouses in PA, the PV cells could meet roughly 1/3 of the energy demand.

Lastly, we calculate the net present value (NPV) to evaluate the tradeoff between crop yield and energy generation. We find that crop yield is the most significant determinant for the NPV, with higher yields leading to more profitable greenhouses. LSC greenhouses in AZ and FL can be more profitable than conventional greenhouses. In MN and PA, small-area LSC greenhouses are less profitable than conventional glass greenhouses. Still, large-area LSC greenhouses can be more profitable in PA due to improvements in crop yield and energy offset provided by the PV cells. The profit from AZ and FL LSC greenhouses can be further improved through net metering, where surplus energy is sold back to the grid. Overall, this study furthers understanding of the balance between power generation and light transmission in LSC-based greenhouses.

9:30 AM EN01.07.03
Constructing a Cascaded Type Perovskite/Perovskite Heterostructure with Transfer Printing Technique for Efficient Solar Cells Anjali Thakran[1,2], Mario Hofmann[1] and Chih Wei C. Chu[2]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

The perovskite/perovskite heterostructures, based on mixed-halide perovskites, manifest solution-processability, low-temperature, and competent efficiency like tandem solar cells. However, the current challenges of limited fabrication routes on solution-based materials, the interaction of the top layer with the underlying layer, solvent compatibility, and unmatched band alignment can cause poor performance and long-term stability issues. Herein, we have designed and demonstrated a sequential spin and transfer printing technique to fabricate a perovskite/perovskite device architecture (p-i-n type). We integrated Br-based perovskites (1.7 eV bandgap) as a bottom layer and Sn-based perovskites (1.2 eV bandgap) as a top layer with a thin interlayer. Due to

cascaded-type band alignment between the top and bottom layer, a smooth extraction and transfer of photo-carriers happened, which boosted power conversion efficiency compared to a single-junction counterpart. With further morphology investigation, we found that SEM and AFM analysis confirmed that the crafted perovskite film with a modified PDMS stamp provides a smooth surface, fewer pinholes, and better interface quality. The high crystalline nature with larger grain size, lesser grain boundaries, and defects across interfaces in heterostructure film helps to suppress recombination losses at the interfaces. The printed layer positively impacts morphology, improving the heterostructure's power conversion efficiencies (PCE). Apart from PCE, the well-distinguished top and bottom layer, as investigated with XPS analysis, greatly helps to maintain the stability of ~1000 hours. With our ongoing investigation, we are focusing on the variation of top and bottom layer composition with consideration of active bandgap of 1.7 eV/ 1.6 eV, 1.7 eV/ 1.5 eV, 1.7 eV/1.4 eV, and 1.7 eV/1.3 eV and investigate heterostructures potential to maintain stability and performance of perovskite-based solar cells. Our technique can be adopted for low-temperature processable layer printing, including HTLs, ETLs, or any interlayer, and promotes low-weight, portable, and flexible photovoltaic devices. Additionally, this strategy is advantageous for implementing traditional Si solar cells and multi-junction tandem structures.

Organic Photovoltaic Sails for Maritime Decarbonation and BIPV Applications Guillaume Wantz; University of Bordeaux, France

After briefly presenting the recent results obtained at lab scale in particular on water-processed OPV cells with record efficiencies, this presentation will mainly focuss on the use of OPV modules in specific novel applications. In the frame of the start-up company “HEOLE”, OPV-based sails have been manufactured incorporating OPV modules direclty into the flexible and lightweight fabrics. These sails have been tested in real life, on multiple actual sailboats sailing since May 2022. Results on the monitored solar electricity and energy yields will be discussed as a promissing direction for OPV deployment. Additionnally, OPV sails have been combined with green roofing for rooftop application. Green roofing is an efficient strategy to enhance thermal insulation of buildings. However, green roofing cannot be easily combined with traditionnal opaque cristalline silicon prohibiting the plants developpement. The semitransparency of OPVs enables this combination with plant growing underneeth the solar modules. The experimental roof is operationnal since April 2023 in southern Germany. Results of monitoring will be presented and discussed.

High Performance Energy Harvesting Cells for Powering Consumer Electronics and IOT Devices Kethinni Chittibabu, Bates Marshall, Sammaiah Thota, Debora Martino, Chris Turkstra and Joshua Wright; Ambient Photonics Inc, United States

Dye sensitized solar cells (DSSC) are very attractive for indoor light harvesting technology due to spectral tuning of DSSC to match ambient light spectrum. Ambient Photonics Inc has developed photovoltaic cells that perform well under a variety of indoor and diffused outdoor irradiating conditions. Ambient technology enables the development of battery free devices in consumer electronics and smart sensor applications.

Solid Transparent Photovoltaics for Invisible Energy Supplies on Human Interface Applications Joondong Kim; Incheon National University, Korea (the Republic of)

Humans have been widely using fossil fuels due to their ease of consumption for energy production with substantial concern. United Nations reported the World Commission on Environment and Development for “Our Common Future”. Sustainable development is defined as “meeting the needs of the present without compromising the ability of future generations to meet their own needs.” Renewable and sustainable energy resources are among the pivotal issues of sustainability, and photovoltaic power is a powerful shifter of the energy paradigm.

Photovoltaic energy production provides a great opportunity to support global energy demand. If we can transparently produce energy, we may apply invisible power generators to residential architectures to supply energy without losing visibility.
Transparent Photovoltaic (TPV) is the technology of solar cells to convert light to electric energy beyond the darkness. Different from the typically dark or opaque solar cells, TPV is transparent by passing the visible range lights due to the wide-energy bandgap of metal-oxides. And thus, human beings may not recognize the existence of TPV entities but the electric energy is generated through the invisible power generator. This kind of invisible TPV may open a new era for on-demand energy supplying system, by being applied in windows of cell phones, displays, vehicles, and buildings.

Beyond the energy issues, transparent power generation can interface to human for bioelectronics, communications and memory devices. One day, human will use the invisible energy and relevant devices without losing a vision. ‘There’s plenty of room at the bottom (Richard Feynman)’ to explore the future technologies with the energy ubiquity.

Strategies for Resilient Organic Photovoltaics Derya Baran; King Abdullah University of Science and Technology, Saudi Arabia

Organic solar cells (OSCs) offer a distinct set of advantages among next-generation photovoltaics, i.e. their flexibility, lightweight design, low-cost manufacturing, and semi-transparency. Substantial efforts have been invested in boosting device efficiency, and this potential is now underpinned by

impressive laboratory-scale efficiencies approaching 20%. As efficiency gradually approaches commercialization requirements, the stability of OSCs becomes increasingly paramount in academic research. Numerous factors can influence device stability, including delamination of the photo-active layer or interface triggered by oxygen and water, light-induced chemical alterations in materials, and thermally induced morphological changes. Therefore, it is imperative to comprehend the stability bottlenecks of high-efficiency systems at this stage towards real-world applications.
In this talk, I will elaborate on the stability of various non-fullerene acceptors (NFAs) and different polymer donors for OSC. We established a connection between the molecular structure of Y-series NFAs, specifically the endgroup and side-chain, and their photostability, ultimately affecting the device's lifetime. We also explored the significance of various polymer donors in determining device longevity and highlighted the side-chain-induced degradation pathway in polymer donors. We further provided theoretical tools for understanding the photostability of polymer donors. Photochemical degradation in both Y-NFAs and polymer donors, under illumination, leads to a significant increase in trap-assisted recombination, resulting in decreased device performance under outdoor conditions. We systematically compared the photostability, thermal stability, and outdoor stability of devices fabricated with state-of-the-art materials, aiming to gain a comprehensive understanding of how the photoactive layers influence long-term performance in the hot and sunny climate of Saudi Arabia. Furthermore, I will propose new strategies to simultaneously improve the photostability, thermal stability, and outdoor stability of devices for resilient organic photovoltaics. Overall, our findings offer valuable insights for the design and synthesis of photoactive materials, with the goal of achieving both high efficiency and long-term stability in OSCs for real-world applications.

Combined ML, DFT and Drift-Diffusion Model for Fabrication and Optimization of DSSCs and PSCs. Andrews Nirmala Grace; VIT University, India

The development of highly efficient third generation solar cells (Dye sensitized solar cells (DSSCs) and Perovskite solar cells (PSCs)) is greatly hindered by the lack of a reliable and understandable Machine Learning (ML) model. In this study, a ML model is developed by integrating machine learning and computational quantum chemistry, DFT and drift diffusion modelling. The model is accurate, robust, and capable of interpretation. Utilizing this model, virtual screening and synthetic accessibility evaluation are conducted to discover novel absorbers that are efficient and easily synthesized for use in DSSCs and PSCs. Ultimately, a rigorous selection process has identified a subset of organic dyes that exhibit both high power conversion efficiency and synthetic accessibility, from an initial pool of over 5000 possibilities. In the context of deducing plausible chemical rules for high-performance absorbers, the interpretability of the model is utilized. This utilization is anticipated to facilitate future advancements in the practical applications of DSSCs and PSCs.

Voltage-Matched Configurations for Monolithically Series-Connected All-Perovskite Double- and Triple-Tandem Solar Modules Yasuhiko Takeda, Ken-ichi Yamanaka and Naohiko Kato; Toyota Central R&D Labs Inc, Japan

We designed all-perovskite (PVK) double- and triple-tandem solar modules.[1] Monolithically series-interconnected structures were adopted, because these offer high scalability by exploiting the advantages of thin-film modules over wafer-based crystalline-silicon modules. We revealed the voltage-matched configurations and their variants improve the annually averaged conversion efficiencies outdoor with potentially higher durability and lower costs compared with those of the conventional current-matched configurations.
Although the combination of PVK top cells and crystalline-silicon bottom cells has been realized higher conversion efficiencies of double-tandem modules at present, all-PVK tandem modules have various advantages of scalability, lightweight, and suitability for mass production. Therefore, improvements in the efficiencies of all-PVK modules are extremely important. Thus, to find the suitable module configurations, we modeled the photovoltaic performance of single PVK cells with different bandgaps by reference to previous experimental data. Then, we optimized the cell widths and transparent-electrode thicknesses used for the monolithically series-interconnected modules, along with the PVK bandgaps. Finally, we evaluated the annually averaged conversion efficiencies under various meteorological conditions using a database.
The conventional current-matched two-terminal double-tandem (Double-2T) modules have an advantage of a simple structure. The current matching condition requires the use of a large-bandgap PVK top cell. However, the photovoltaic performance currently lowers with increasing bandgap. This lowers the module efficiency. By contrast, the efficiency of another conventional configuration: four-terminal double-tandem (Double-4T) modules is less sensitive to the PVK bandgaps. This allows us to use more efficient and durable PVK compositions. However, Double-4T complicates the power-conditioning system, and hence it is not suitable for practical use. The voltage-matched double-tandem (Double-VM) module consists of the parallel-connected top and bottom modules, in which plural top cells and bottom cells are connected in series, respectively, so that the voltages of the maximal-power points (V_{MPP}) of these modules are approximately the same as each other. We revealed that Double-VM combines the advantages of Double-2T and Double-4T, and mitigates their shortcomings.
The voltage-matched triple-tandem modules also offer similar advantages to those of Double-VM. However, the use of three substrates covered with transparent conductive oxide films increases the optical loss and ohmic loss, resulting in lower efficiencies than those of the triple-tandem 2T modules. To solve this issue, we proposed a new configuration of the triple-tandem series/parallel-connecting voltage-matched (Triple-SPVM) module, in which the middle-bottom module consisting of directly series-connected middle and bottom cells is connected to the top module in parallel. The use of only two substrates improves the efficiency and lowers the cost. The current mismatch between the series-connected middle and bottom cells is not a great issue, because of slight changes in the relative solar spectrum in the relevant near-infrared range. Thus, Triple-SPVM is the best suited for practical use.
An emerging application of solar modules is power supply to electrochemical reactors for CO_2 conversion to useful organic substances. Direct connection of these two devices is exactly an artificial-photosynthetic device, and stores time-varying solar energy. It is of great importance for efficient conversion of CO_2 that the device operates at V_{MPP} of the solar modules. Double-VM and Triple-SPVM are suitable for this application, because V_{MPP} of the module is tunable by changing the series-connected cell numbers in each submodule.[2,3]

Exploiting The Synergy between Perovskite and Organic Photovoltaics in Semi-Transparent Solar Cells and Modules Aldo Di Carlo[1,2]; [1]University of Rome Tor Vergata, Italy; [2]Consiglio Nazionale delle Ricerche, Italy

Metal halide perovskites, characterized by tunable bandgaps, cost-effectiveness, and excellent optoelectronic properties, find diverse applications from indoor photovoltaics to tandem integration with silicon. Notably, their tunable bandgap enables transparent photovoltaics, a transformative technology for building-integrated photovoltaics (BIPV). Photovoltaic windows represent a compelling application, where visible light transmission is crucial, allowing for effective conversion of near-infrared (NIR) and/or near-ultraviolet (NUV) light into electrical energy. This technology holds particular promise in urban settings with limited rooftop space for traditional photovoltaics. The ability to continuously adjust the bandgap of halide perovskite materials across a broad

spectrum facilitates the development of semi-transparent solar cells and modules with high visual transmittance. Through bandgap optimization, tandem configurations with NIR organic solar cells can be designed to enhance efficiency without compromising average visual transmittance (AVT). This coupling can be boosted by a specific light management optimization that allows to increase the current density and/or the AVT and consequently the light utilization efficiency (LUE) of the cell. Numerical simulations suggest that optimized tandem architectures, leveraging photonic crystals and materials, can achieve a 15% power conversion efficiency with a 50% AVT.[1] The EU CITYSOLAR consortium [2] addresses this challenge through tailored strategies, encompassing material optimization, light management, and innovative characterization approaches. This presentation highlights the consortium's progress in surpassing the state of the art, showcasing diverse fabrication techniques, from solution processes to physical deposition, for see-through photovoltaics. Beyond solar cells, module-level developments, including a low-temperature, full blade-coating method for depositing semi-transparent $FAPbBr_3$-based perovskite modules on 300 cm substrates [3] and innovative coupling between top perovskite module and bottom organic module [4] are discussed.

4:15 PM EN01.09.05
High-Performance Monolithic Perovskite/Organic Tandem Solar Cells Hin-Lap Yip; City University of Hong Kong, Hong Kong

The emergence of solution-processed organic and metal halide perovskite solar cells can transform the landscape of photovoltaic technology in delivering scalable and high-performance solar cells to provide sustainable green energy. While the power conversion efficiencies (PCEs) of both single-junction organic solar cells (OSCs) and perovskite solar cells (PSCs) are rapidly ascending to >19% and >25%, respectively, their maximum efficiency is limited to ~33% accordingly to the Shockley-Queisser model for single-junction devices. However, it is possible to significantly increase the efficiency of solar cells by constructing a tandem device that consists of multiple light absorbers with considerably different bandgaps to reduce the solar cells' overall transmission and thermalization losses.
In this talk, I will discuss our work on developing high performance monolithic perovskite/organic tandem solar cells comprising a wide bandgap perovskite (WBG) front cell and a narrow bandgap (NBG) organic rear cell connected through a recombination junction. The WBG (Eg: 1.7-1.85 eV) PSCs are chosen for the front cell due to their strong and broad absorption for visible light, smaller voltage loss, and higher photoresponse compared to their organic counterparts with approximate bandgap. While NBG (Eg: 1.1-1.25 eV) OSCs can offer better near-infrared absorption tunability and stability compared with the Sn-based NBG perovskites, making them favorable candidates for the rear cell.[1] Moreover, the advantage of the perovskite and organic light absorbing layers being processed from orthogonal solvents imposes fewer constraints on the choice of the materials for constructing the recombination junction and provides better flexibility on the device design of tandem solar cells.
To demonstrate state-of-the-art perovskite/organic tandem cells, an integrated strategy combining materials, interface, optical, and process engineering was adopted to optimize the two subcells and the interconnect junction simultaneously.[2-5] In addition, a comprehensive optoelectronic model is being developed to simulate the electrical and optical properties of the tandem solar cells and to provide guidelines to optimize their device performance. The successful development of perovskite/organic tandem cells will have far-reaching impacts on producing high efficiency, low cost and scalable PV cells for clean energy production.

Toward Long Term Organic Solar Cell Device Stability via Thermocleavable Donor and Acceptor Active Layer Haoyu Zhao[1], Jordan Shanahan[2], Soumya Kundu[1], Guorong Ma[1], Andrew Bates[1], Wei You[2] and Xiaodan Gu[1]; [1]University of Southern Mississippi, United States; [2]University of North Carolina at Chapel Hill, United States

The performance of organic solar cell (OSC) was surged during past decades, however, the insufficient efforts to improve stability set the barriers to realize the practical applications for OSC devices. The morphological stability of OSC bulk heterojunction layer (BHJ) is apparently affected by the molecular mobilities of donors/acceptors under operational conditions. The introduction of thermocleavable side chains provides an effective and efficient method to reduce the dynamics of conjugated polymers (CP) to improve the thermal stability as evidenced by the enhanced T_g after fully cleavage. Furthermore, the newly synthesized donor-acceptor conjugated polymers (DA CPs) with thermocleavable contents were expected to achieve both good performance and stability for long term usage. This work focused on the investigations of the morphological changes as well as phase separation behaviors for thermocleavable donor/acceptor BHJ blend film. The solar cell devices were also prepared to evaluate the performance under various conditions. Finally, our work revealed the good performance and stable morphology over long term at elevated temperatures after alkyl side chains were completely removed, which could provide a pathway to improve the stability of optoelectronic properties in future OSC devices.

The Benefits or Circular Recycling for Terawatt Photovoltaics Ian Marius Peters and Misha Sytnyk; Helmholtz Institute Erlangen Nürnberg, Germany

Solar energy and wind power stand as the twin cornerstones of the 21st-century energy revolution. Acknowledged by the Intergovernmental Panel on Climate Change (IPCC), the installation of solar panels and wind turbines emerges as the most potent and cost-effective means to decarbonize our energy systems. To attain the ambitious goal of limiting global temperature rise to 2 degrees Celsius, we must embark on the massive deployment of tens of billions of solar panels, necessitating the mobilization of several hundred million tons of raw materials. Encouragingly, the global industry is taking formidable strides to meet this challenge, projecting annual production capacity to exceed 1 terawatt peak (TW_P) before 2030, along with rapid expansion across the globe.
Yet, as we fast-forward a few decades, a pivotal decision looms on the horizon. As these solar panels reach the end of their operational life, we find ourselves at a crossroads – we can either discard these modules in landfills or we can opt for a more sustainable and forward-thinking approach. This approach involves integrating them into a circular system, fostering their reuse, repair, and eventual recycling.
Notably, we are not bound by resource constraints; although exceptions like silver exist, alternative materials are readily available. Thus, the option of dumping solar panels would not fundamentally hinder the realization of a renewable energy system operating at 100% capacity. However, opting for circular treatment offers an array of compelling benefits, rendering dumping the less favorable choice. Circular handling invariably encompasses the recovery and restoration of the materials and components involved, ensuring that these resources maintain their utility and minimize waste. The rate at which this recovery occurs must align with the pace of production, underscoring the imperative for our circular treatment capacity to match our production capacity.
Given the staggering scale of photovoltaic production, non-circular processes will become increasingly inviable. The photovoltaic market is poised to become a major consumer of reclaimed products, further incentivizing circular strategies. In this presentation, we will delve into the dynamics that will steer a terawatt photovoltaic market toward circular recycling. Furthermore, we will explore the potential of emerging photovoltaic technologies, which hold the promise of enabling more processes with unprecedented material recovery and reuse, cementing the path toward a sustainable and circular energy future.

11:00 AM EN01.10.02
Ultrathin a-Si:H/Oxide Transparent PV Devices Deposited onto Architectural-Compatible Glass and Ceramic Substrates Alex J. Lopez-Garcia[1], Gustavo A Alvarez[1], Eloi R. Costals[2], Pablo Ortega[2], Cristobal Voz[2], Joaquim Puigdollers[2] and Alejandro Perez-Rodriguez[1,3]; [1]Institut de Recerca en Energia de Catalunya, Spain; [2]Universitat Politècnica de Catalunya, Spain; [3]Universitat de Barcelona, Spain

Transparent Photovoltaics (TPV) is an emergent branch in the toolkit of PV that promises to extend the potential applications of PV and complement the most mature strategies that are limited in terms of on-site integration and applicability, especially into architectural components.[1] The most important feature of PV devices is power output (i.e. efficiency). However, this approach brings in another critical feature almost at the same level of importance, which is the transparency and aesthetics of the device, which have to meet certain standards that can differ depending on the specific application and/or integration. As such, it adds some degree of complexity when optimizing, as other properties become more important. For TPV to be implemented in real-world scenarios they do not need to compete with high efficiency devices, rather they must be tailored to maximize efficiency with special care on transparency and aesthetic characteristics. For cost competitiveness, existing and mature industrialized materials (earth-abundant and non-toxic) and processes are a good starting point for first implementations. Developing such devices can potentially allow for fast-developing integration in areas such as building-integrated PV (BIPV) in the form of façade windows and other glazing elements, or to be integrated ubiquitously into sensors and future IoT devices with low-power requirements, as well as in Agrivoltaics (APV). Recent work has effectively studied the use of a-Si :H/oxide structures on glass substrates for TPV, showing some limitations especially in terms of V_{oc}.[2,3]
In this work, we present inorganic-based TPV devices relying on ultrathin a-Si:H as absorber and different oxides as carrier selective contacts and transparent electrodes. In an innovative approach, we have inserted a high dipolar moment molecule (PAMAM-G3 dendrimer) at the ETL/absorber interface. This interface modification allows working with oxide charge transport layers (CTLs) that offer high transparency while eliminating surface energy barriers that decrease the resulting V_{oc} of the device, avoiding doping strategies (i.e. a-Si:H(p), a-Si:H(n)) and reducing costs due the low-temperature deposition processes. This new solution has allowed a record Light Utilization Efficiency (LUE) of 0.85%, by improving V_{oc} from 410 (reference) to 781 mV (PAMAM G3), still not reached by state-of-the-art devices with these materials, with negligible reduction in Average Photopic Transmittance or Color Rendering Index. The basic device structure is SLG/FTO/AZO/PAMAM-G3/ZnO/a-Si:H(30nm)/MoO_3/ITO. At the present time, spectrophotometry and J-V measurements under AM1.5G illumination (from the front and back sides) as well as Spectral Response measurements have been carried out. We report also on the bifaciality aspect of the architecture, showing almost unity bifacial factor, due to the ultrathin absorber coupled to wide-bandgap CTLs that make the device optically symmetric. Additionally, reference devices without dipoles have been also deposited onto ceramic substrates successfully and will be presented, confirming the potential of this approach to be integrated in different architectural environments such as glass and ceramics.
The work presented is of high relevance for the development of the field of inorganic thin film Transparent PV technologies, especially those working on ultrathin absorbers. It might also spark interest in thin film technologies in general that rely on advanced ETL/Active layer/HTL architectures.
This work has received funding from MCIN/AEI/10.13039/501100011033 under grant numbers PID2019-109215RB-C41 and TED2021-129758B-C32 and by the NextGeratiouEU/PRTR.

11:15 AM EN01.10.03
A Phenomenological Figure of Merit for Photovoltaic Materials Andrea Crovetto; Technical University of Denmark, Denmark

I propose a figure of merit Γ_{PV} to estimate the maximum efficiency attainable by a generic non-ideal PV absorber in a planar single-junction solar cell under the non-concentrated AM1.5G spectrum. This efficiency limit complements the more idealized limits derived from fundamental physics, such as the Shockley-Queisser limit and its subsequent generalizations. Specifically, the present figure-of-merit approach yields stricter efficiency limits applicable to realistic PV absorbers with various imperfections, including finite carrier mobilities and doping densities. Γ_{PV} is a function of eight properties of the absorber that are both measurable by experiment and computable by electronic structure methods. They are: band gap, non-radiative carrier lifetime, carrier mobility, doping density, static dielectric constant, effective mass, and two parameters describing the spectral average and dispersion of the light absorption

coefficient. Γ_{PV} has high predictive power (absolute efficiency error less than ±1.1%) and wide applicability range. The Shockley-Queisser limit and its generalizations are reproduced by Γ_{PV}. Simpler figures of merit proposed by others are also included as special cases of Γ_{PV}.

For a generic PV absorber at any stage of development, determination of its Γ_{PV} figure of merit helps understand whether imperfect PV performance is intrinsic to the material (inadequate bulk properties at the current stage of development), or if it "only" requires a different device structure, contact layers, or improved interface properties. I will show the outcome of this analysis for 25 PV absorbers with record PV efficiencies between 0% and 85% of their Shockley-Queisser limit. Using a local version of the Γ_{PV} figure of merit, a material-specific optimization strategy is laid out for any experimentally synthesized PV absorber, by specifying the bulk properties that should most urgently be improved to increase their PV efficiency.

11:30 AM EN01.10.04
Photochromic Dyes for Semi-Transparent Solar Cells and Solar Mini-Modules with Light-Adjustable Transmittance and High Colour Rendering Index Renaud Demadrille[1], Samuel Fauvel[1], Antonio J. Riquelme[1], Diego Mirani[1], Johan Liotier[1], Valid M. Mwalukuku[1] and Stéphanie Narbey[2]; [1]CEA, France; [2]Solaronix, Switzerland

Among the emerging photovoltaic technologies, dye-sensitised solar cells (DSSCs) have recently achieved power conversion efficiencies (PCE) above 15% and have demonstrated good stability, with lifetimes exceeding 12 years in real-world conditions. These devices can be coloured and semi-transparent, making them very attractive for both building-integrated photovoltaics (BIPV) and agrivoltaics (Agri-PV). However, to integrate these cells into windows for use in buildings or greenhouses, it is often necessary to find the right compromise between transparency and efficiency.
In this talk, we will present our recent work aimed at developing new photochromic dyes specifically designed for use in photovoltaic devices. [1] We will present the synthetic routes to these photochromic photosensitizers and detail their optoelectronic and photochromic properties. We will show that by modifying the substitution of dyes from the diphenylnaphthopyran family, it is possible to modulate their absorption range in the visible, to control their discoloration kinetics and to reduce the recombination processes in solar cells. [2] [3]
We will then show that these dyes can be used to fabricate a new generation of semi-transparent solar cells and solar modules capable of self-regulating their optical transparency and energy conversion efficiency as a function of light intensity.
Thanks to the molecular engineering of these photosensitizers and the development of novel formulations for the electrolytes, we will show that solar modules with a transmittance varying between 50 and 65% as a function of light exposure and a color rendering index above 95 can be obtained. [4]

Over 18% Efficiency Kesterite Solar Cell under Indoor Illumination Conditions Yuancai Gong[1], Alex Jimenez Arguijo[2,1], Axel Gon Medaille[1], Outman El Khouja[3], Romain Scaffidi[4], Guy Brammertz[4], Denis Flandre[5], Bart Vermang[4], Aurelian Catalin Galca[3], Alejandro Perez-Rodriguez[2], Sergio Giraldo[1], Edgardo Saucedo[1] and Zacharie Jehl Li-Kao[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Institut de Recerca Energética de Catalunya, Spain; [3]National Institute of Materials Physics, Romania; [4]IMEC, Belgium; [5]Université Catholique de Louvain, Belgium

Indoor photovoltaic (IPV) cells have the potential to power distributed and remote sensors, actuators, and communication devices, enabling the widespread implementation of the Internet of Things (IoT). Commercial (c-Si, CIGS, CdTe) and emerging (perovskite, organic solar cells) photovoltaic technologies face several challenges for indoor applications, including cost, toxicity, stability, and/or spectral mismatch. In contrast, kesterite materials are composed of earth-abundant, non-toxic elements and exhibit excellent stability, with a wide bandgap tunability between 1.0 eV up to 2.1 eV. This technology has recently achieved certified efficiencies of 14.9% under AM1.5G for the narrow band gap (Se-rich; 1.1 eV) compound and 11.4% for wider bandgap (S-pure; 1.5 eV), demonstrating its high efficiency potential.
In this work, we present the first complete theoretical and experimental study of the behavior of kesterite solar cells under indoor illumination conditions, with different high efficiency devices. First, we will show that the most relevant and mature photovoltaic technology, that is c-Si, expectedly drops the performance in indoor conditions due to its narrow band gap. Hence, the use of wide band gap materials is required for a good performance in indoor conditions. We will show that, under indoor conditions, the wide band gap (S-pure; 1.5 eV) can achieve efficiencies above 20%.
The experimental results demonstrate the excellent optoelectronic properties under low injection conditions, showing that the efficiency of narrow bandgap (12% efficiency in AM1.5G conditions) is practically unchanged with the AM1.5G light intensity down to 0.2 suns. To further support the high potential of kesterite materials for low injection applications we studied the narrow bandgap device performance under simulated indoor conditions by red shifting the typically used indoor spectra, corresponding to the blackbody emission at 2700K, 3000K, 4000K and 5000K. These spectra can be achieved using a calibrated LED based solar simulator. As predicted from the numerical simulation results, the devices demonstrate an outstanding efficiency over 18%. These results motivate the development of efficient kesterite solar cells with a wider bandgap, specifically tailored for IPV applications. The indoor performance of the wide bandgap kesterite material has been studied using the same experimental procedure, revealing a performance of above 12% under simulated indoor conditions, consistently with the numerical simulation. The charge carrier extraction is analysed with spectral response (External quantum efficiency, EQE) and the changes induced by indoor light are characterized by performing EQE under dark and indoor illumination conditions.
Furthermore, to prevent interface recombination and drastically improve the IPV performance two strategies will be presented: (i) Ge alloying to further widen the bandgap and minimize the spectral mismatch, and (ii) device engineering by using passivation interlayers (e.g. Al_2O_3), adjusting the thermal post deposition treatment conditions or employing other electron-selective contacts (e.g. ZnSnO).
Therefore, the pathway for achieving efficiencies over 20% for indoor kesterite solar cells will be presented. These original ideas will set the stage for affordable, bio-safe, and durable indoor solar cells. It will also provide a technical approach for the comprehensive design of other emerging PV technologies.

Exploring charge pair generation in single-component macromolecular materials for photovoltaic energy conversion Jenny Nelson, Flurin Eisner, Mohammed Azzouzi and Jolanda Simone Müller; Imperial College London, United Kingdom

The discovery of several new classes of electron-accepting molecule that work well as electron acceptors at molecular heterojunctions had led to a strong increase in the power-conversion efficiency in organic solar cells, from 11 to 19% in the last 5 years. The impressive performance of the new materials and the range of chemical structures has led to interest in whether alternatives to the traditional 'bulk heterojunction' architecture for an organic solar cell can be found.
One approach concerns structures where, through chemical design, electron-rich and electron-poor components of a single macromolecular material are constrained to have a particular geometry relative to each other, being electronically coupled either through space or through bond. In a second intriguing development, devices based on a single molecular material have been reported deliver relatively high charge-generation efficiency in the absence of a donor-acceptor interface. This latter example challenges the current understanding of how free charges are generated in organic semiconductors. Achieving efficient energy conversion with a single macromolecular component would be both interesting and practically useful.
In this work, we report on studies of the design, characterisation and modelling of both types of structure, including a variety of non-fullerene acceptors, and macromolecular compounds with tethered donor and acceptor type domains. By combining experimental characterisation under varying conditions (field, temperature, excitation) with molecular and device-level calculations, we endeavour to relate exciton and charge dissociation efficiency in single-component devices to molecular parameters.

9:00 AM *EN04.05/EN01.05.02
Homo- and Heteromolecular interactions and Their Relevance for Morphological and Mechanical Stability of Non-Fullerene Organic Solar Cells Harald Ade; North Carolina State University, United States

Organic solar cells (OSCs) are one of the most promising cost-effective options for utilizing solar energy in high energy-per-weight or semi-transparent applications. Recently, the OSC field has been revolutionized through synthesis and processing advances, primarily through the development of numerous novel non-fullerene small molecular acceptors (NFA) with efficiencies now reaching >19% when paired with suitable donor polymers. The device stability and mechanical durability of these non-fullerene OSCs is critical and developing devices with high performance, long-term morphological stability, and mechanical robustness remains challenging. Yet, morphological and mechanical stability is a prerequisite for OSC commercialization. Here, we discuss our current understanding of the phase behavior of OSC donor:acceptor mixtures and the relation of phase behavior and the underlying hetero- and homo-molecule interactions to performance, processing needs (e.g., kinetic quenches), and morphological and mechanical stability. Characterization methods range from SIMS and DSC measurements to delineate phase diagrams and miscibility to x-ray scattering to determine critical morphology parameters and molecule packing and dynamic mechanical analysis (DMA) to assess specifically the hetero-interactions. The results presented and its ongoing evolution are intended to uncover fundamental molecular structure-function relationships that would allow predictive guidance on how desired properties can be targeted by specific chemical design. Comparative studies show that the molecular hetero-interactions between the donor and NFA are not always the geometric mean of the homo-interactions. The presentation will focus on these heterointeractions and the results underscores the limited success often encountered when Hanson Solubility Parameters and surface energies are used to estimate molecular interactions [1]. Additional insights into the molecular interactions are also provided and the relevance discussed in rubber-toughening of OSCs with a SEBS additive [2].

9:30 AM EN04.05/EN01.05.03
Sustainability Considerations for High Performing Organic Solar Cells Julianna Panidi; Imperial College London, United Kingdom

Organic semiconductors are an emerging class of materials with various optoelectronic applications. The high commercialisation potential of this technology is evidenced by a few companies that have already launched their products into the market or are working towards this goal. Solution-processed organic electronics have a high potential to reduce the carbon footprint of the semiconductor industry if they are developed further and increase their market share.

In my talk, I will introduce sustainable routes to manufacture solution-processed organic electronics. Particular focus will be given to organic solar cells, which recently attracted immense attention due to the development of a new family of semiconductors that allows highly efficient light harvesting in indoor and outdoor conditions. One current limitation, though, is the use of not eco-friendly solvents and materials during the device development stages. Most organic electronic devices require halogenated and non-halogenated aromatic solvents during their fabrication. For large-scale production and further commercialisation, this is a key limitation. This arises from the fact that organic semiconductors are highly soluble in this category of solvents, which are often carcinogenic or toxic to the human reproductive systems and negatively impact the environment. Here, I will show high-performing organic solar cells fabricated from biomass-based solvents. In addition, recycling considerations are required for any product entering the market. Lastly, I will demonstrate a tool that enables quick solvent screening and the link between organic solar cells' performance in an effort to replace the use of toxic ones.

Overall, this work highlights the importance of replacing harmful chemicals and materials in the organic electronics fabrication stages, resulting in faster and wider commercialisation and new market opportunities.

9:45 AM EN04.05/EN01.05.04
Structure Control during *In Situ* Printing of Donor-Acceptor Blend Films for Organic Solar Cells Peter Muller-Buschbaum; Technical University of Munich, Germany

Among the next generation solar cells, in particular organic photovoltaics are gaining impact as a promising alternative to conventional silicon-based solar cells. However, despite big achievements in terms of power conversion efficiencies in the last years, it remains an unresolved challenge to fabricate large-area organic solar cells without sacrificing efficiencies. The reason behind is that basic understanding is still very limited due to the complexity of the systems. Moreover, presently a substantial number of researchers use spin-coating for film deposition, which is not compatible with the needs of a large scale production. Thus, using up-scalable deposition methods such as printing are of immanent interest. [1] Large-area printing such as slot-die coating involves complex hydrodynamic processes and simply transferring optimized parameters from spin-coating studies has only limited success. Thus, in the present work, we use advanced scattering methods such as grazing incidence small and wide angle X-ray scattering (GISAXS and GIWAXS) in situ during

printing of donor:acceptor blends to gain fundamental understanding about the underlying film formation processes. Different examples of polymer donors and small molecule acceptors are presented and the resulting morphologies are correlated with solar cell device performance. A special emphasis is put on the shift towards more environmentally friendly solvents, [2] which will be also a pre-requisite to promote a large-scale production of organic solar cells.

Semitransparent Organic Photovoltaics with High Average Visible Transmittance Thuc-Quyen Nguyen; University of California, Santa Barbara, United States

Organic Photovoltaics (OPVs) offer sustainable, solution-processable, and cost-effective energy harvesting solutions. While opaque devices underwent enormous progress in the past decade, it remains a challenge to meet the high transparency requirements for integrated semitransparent OPVs (ST-OPVs) for buildings, skylights, skyscrapers, or greenhouses. In this work, we investigate the charge generation-recombination dynamics in three semitransparent blend systems with varied donor concentrations to understand the performance limitations. We also study the effect of the optical expediency of Au, Ag, Al, and graphite as back electrode material on ST-OPVs and show that 'one size fits all' is not a valid approach for choosing the back electrode material. It is important to consider the active layer absorption, active layer thickness and application in selecting the back electrode material. We demonstrate that using the dilute donor approach with an appropriate back electrode can yield devices with 73 % average visible transmittance.

11:00 AM EN04.05/EN01.05.06
Exciton Delocalization Induced by Aggregation for Efficient Non-Fullerene Organic Photovoltaics Robert J. Westbrook[1], Kui Jiang[2], Cheng Zhong[3], Jianxun Lu[4], Francis R. Lin[2], Sei-Hum Jang[1], Jie Zhang[5], Yuqing Li[4], Zhanhua Wei[4], David S. Ginger[1] and Alex Jen[2,1]; [1]University of Washington, United Kingdom; [2]City University of Hong Kong, Hong Kong; [3]Wuhan University of Technology, China; [4]Huaqiao University, China; [5]Shenzhen Institute of Advanced Technology, China

Intimate π-stacking in organic semiconductors is known to form aggregates, which drive dissociation of photogenerated excitons through delocalization of exciton wavefunctions [1-3]. In particular, the onset of non-fullerene acceptors (NFAs) such as Y6 has seen a dramatic rise in discussion of exciton delocalization and its relation to (acceptor-donor) hole transfer [4-6]. Here, we explore the concept of exciton delocalization and show that such treatment is necessary to accurately describe charge separation in high performance OPV blends based on D18:Y6. Specifically, we evaluate how π-interactions in aggregates contribute to delocalization strength, revealing that the formation of delocalized excitons in strongly π-interacting materials opens a new pathway for free carrier generation. This pathway partially bypasses the formation of performance-limiting singlet and triplet charge-transfer states in OPV blends and improves the internal quantum efficiency in OPVs to realize power conversion efficiencies of >19%. We further show that the extent of delocalization can be tuned with precise structural modifications of organic donor and acceptor molecules. Ultimately, we provide an insight into overcoming the fundamental limit of OPVs associated with intrinsic material properties. Designing materials with more pronounced delocalization character should maximize the exciton dissociation efficiency and minimize the terminal back recombination, pushing OPVs forward closer to theoretical efficiency limits [7].

11:15 AM EN04.05/EN01.05.07
Bifacial Indoor OPVs: Investigating The Influence of Vertical Stratification on Performance Symmetry of Semi-Transparent OPVs Gulzada Beket[1,2], Anton Zubayer[1], Uli Wurfel[3], Thomas Österberg[2], Jonas Bergqvist[2] and Feng Gao[1]; [1]Linköping University, Sweden; [2]Epishine AB, Sweden; [3]Fraunhofer Institute for Solar Energy Systems ISE, Germany

The demand for sensors in building digitalization is growing rapidly due to the increased need for better monitoring. However, Internet-of-Things (IoT) sensors typically rely on batteries, leading to high maintenance costs and environmental concerns related to battery recycling. One of the innovative solutions is harvesting ambient light to power these sensors. Organic Photovoltaics (OPVs) offer a promising approach due to their semi-transparency and high power-per-weight ratio, making them suitable for integration with IoT devices like electronic shelf labels and asset tracking labels.The synthesis of organic semiconductor materials for OPV gives flexibility which allows to design material systems which surpass state-of-the-art inorganic PVs for indoor applications.
Recent advancements in solution-processable, flexible, and semi-transparent indoor OPVs made by roll-to-roll and lamination technologies have opened the door to large-scale industrialization of IOPVs[1], reducing manufacturing costs by eliminating vacuum processing and scarce materials. Nevertheless, semi-transparent IOPVs may exhibit performance asymmetry when illuminated from different sides (cathode/anode illumination), which is problematic for IoT sensors requiring bifacial use.
In our study, we investigate the link between performance asymmetry and vertical phase segregation in semi-transparent IOPVs featuring various photoactive layers, including fullerene and non-fullerene-based materials. Through a combination of optoelectronic characterizations and simulations, we identify that a filtering layer within the photoactive layer does not contribute to photocurrent extraction and is the source of observed cathode/anode performance asymmetry[2].
Our investigation delves into the vertical arrangement of the cathode and anode stack, utilizing techniques such as Neutron and X-Ray Reflectivity, Time-of-Flight Secondary Ion Mass Spectrometry, and Ellipsometry. We find that certain photoactive layers, while highly efficient for indoor use, tend to phase separate when deposited on the cathode electrode, creating a physical barrier and causing trap-assisted recombination when illuminated from the anode side. Furthermore, we found that some photoactive layers remain vertically homogeneous, regardless of the electrode used, presenting the potential for electrically symmetric semi-transparent IOPVs.

Through thorough screening, we identify a photoactive layer system that not only delivers high and air-stable indoor performance but also exhibits perfect symmetry when illuminated from either the anode or cathode side. These findings offer a comprehensive understanding of how photoactive layers affect electrical symmetry in semi-transparent IOPVs, especially for bifacial applications. Our research contributes valuable insights for designing photoactive layers to achieve air-stable, and electrically symmetric semi-transparent IOPVs for various applications in the field of IoT sensors.

11:30 AM *EN04.05/EN01.05.08
Photovoltaic Enabled Indoor Light Harvesting Paul Meredith; Swansea University, United Kingdom

By the mid-2020s it is predicted that billions of sensors and other IoT devices will be deployed worldwide monitoring every aspect of our environment. These devices require electrical power with batteries being the preferred choice when hard-wiring is impractical or too expensive. Other alternatives to batteries are being advanced and particularly for the indoor environment harvesting the 'free' artificial and / or externally transmitted light seems a tangible possibility.
It is becoming more appreciated that the design of an optimised and integrated PV system for indoor light harvesting is very different to conventional solar cells. Artificial lighting sources have bespoke spectral characteristics (consider warm and cool white LEDs) radically different to AM1.5G, and indoor lighting is low intensity (< 500 lux). The question thus arises – what type of PV is best suited to this emerging application? Answering this question involves thermodynamic considerations such as the optimal bandgap in the radiative limit, generation and transport losses under low photo-generated carrier concentrations, additional voltage losses due to shunt, etc. We must also consider architectural approaches such as doubly transparent contacts and cell interconnection to deliver appropriate voltages and currents.
In my talk I will expand upon these basic considerations for the specific case of organic and organohalide perovskite PV and compare and contrast with other systems including silicon and compound semiconductors. Specifically, I will discuss the optimum bandgap for typical indoor lighting sources and advance a new predictive model to assess the performance of various materials. This analysis allows for the specification of design rules for indoor light harvesting.

1:30 PM *EN04.06/EN01.06.01
Shedding Light on The Dark Side of Triplets: Exploring Their Potential Safa Shoaee[1,2]; [1]University of Potsdam, Germany; [2]Paul Drude Institute for Solid State Electronics, Germany

The top-performing organic solar cells (OSCs) currently achieve similar peak external quantum efficiencies and fill factors as traditional photovoltaic devices. Nevertheless, they experience significantly elevated voltage losses, primarily stemming from nonradiative recombination, imposing a significant constraint on their performance. To explore the potential influence of triplet states on this phenomenon, we investigate PM6:o-IDTBR system. While we suspect that the open-circuit voltage (VOC) is constrained by the energy of the triplet state, the measured non-radiative voltage loss is surprisingly minimal. By comparing as-prepared and thermally annealed blends, we demonstrate that triplet-triplet annihilation - under operating conditions - may potentially offset the detrimental effects of triplet-induced dark losses.

2:00 PM EN04.06/EN01.06.02
Potential and Limitations of High Performance and Scalable Evaporated Organic Solar Cells Richard A. Pacalaj[1,1], Yifan Dong[2], Roderick Mackenzie[3], Ivan Ramirez[4], Mehrdad Hosseini[4], Martin Pfeiffer[4], Eva Bittrich[5], Julian E. Heger[6], Peter Muller-Buschbaum[6,6], Pascal Kaienburg[7], Moritz Riede[7], Jiaying Wu[8] and James Durrant[1,1,9]; [1]Imperial College London, United Kingdom; [2]National Renewable Energy Laboratory, United States; [3]Durham University, United Kingdom; [4]Heliatek GmbH, Germany; [5]Leibniz Institute of Polymer Research, Germany; [6]Technische Universität München, Germany; [7]University of Oxford, United Kingdom; [8]The Hong Kong University of Science and Technology, China; [9]University of Swansea, United Kingdom

The bulk heterojunction (BHJ) active layer of organic photovoltaics (OPV) is typically deposited either via thermal evaporation (small molecule donors, fullerene acceptors) or by solution processing (polymer donors, non-fullerene acceptors). The commercial viability of thermal evaporation has been proven for organic light emitting diodes (OLED), including the deposition of complex multilayer stacks and co-evaporated BHJs. Evaporated blends in OLEDs and OPVs have been shown to be more stable than their solution processed counterparts. Furthermore, the solvent free deposition lowers the environmental impact compared to solution processed technologies. Looking at the power conversion efficiency (PCE), Heliatek GmbH achieved an OPV record PCE of 13.2 % with an evaporated tandem cell in 2016. Since then, novel solution processable polymers and non-fullerene acceptors paved the way for performance increases beyond 19 % that could not be matched by evaporated OPVs. As a result, the academic community is today largely focussed on lab scale performance increases and reproducible upscale of solution processed OPVs, leading to a lack of studies addressing the limitations of high performance, industrially relevant evaporated OPV materials.
A key bottleneck in evaporated OPVs is the trade-off between efficient charge collection and maximising absorption by increasing the active layer thickness. This is evident from the high losses in fill factor for active layer thicknesses beyond 50 nm while solution processed cells often perform best at thicknesses >100 nm. Studies on solution processed devices showed that active layer blends with efficient collection (high mobility vs. slow non-geminate recombination) exhibit a phase separated morphology. This is often achieved through post-deposition optimisation (e.g. thermal annealing, solvent vapour annealing). Similar studies on the connection between morphology, recombination kinetics and mobility in evaporated OPVs are key to identifying ways to increase their performance through improved deposition control and molecular design.
Here, I will present a study on a state-of-the-art evaporated small molecule donor paired with C_{60}. The acceptor-donor-acceptor type small molecule was synthesized by Heliatek. Devices with different active layer morphologies were studied. A wide range of optical (photoluminescence, ultrafast spectroscopy) and optoelectronic device measurements (transient photovoltage, charge extraction) demonstrate that the low and imbalanced charge carrier mobility is a key bottleneck even in the optimised blendz. An in-depth characterisation of the active layer morphology (RSoXS, GIWAXS) enables us to

identify the aspects of the morphology that should be addressed to further improve performance. I will contrast our findings about the collection efficiency with results from solution processed devices (PM6:Y6, BTR:PCBM) as well as giving an outlook for feasible performance improvements based on drift-diffusion simulations (OghmaNano).

2:15 PM EN04.06/EN01.06.03
Enhanced Solid-Liquid Phase Separation and Carrier Transfer for High-Performance Organic Solar Cells by Modulating The Mixing Gibbs Free Energy Wallace C. Choy; University of Hong Kong, China

The similar conjugated backbone of donor/acceptor material and fast film-formation kinetics have led to spinodal-decomposition-orientated phase separation that the film presents an intimately mixed morphology and random molecular orientation and thus critically hinders the carrier extraction for high-performance non-fullerene organic photovoltaics. To solve the issue, we enhance the mixing Gibbs free energy-triggered solid-liquid phase separation during the film formation process by solidifying one component and solvating the other based on a liquid additive. Following the liquid evaporation process, a favorable vertical distribution is obtained. Meanwhile, the prolonged solvation process enlarges the domain size and assists the molecules to diffuse and orient properly, enabling better exciton/charge dynamics during the power conversion processes. In detail, we alter the phase separation behavior from original liquid-liquid de-mixing to solid-liquid de-mixing during the film formation process to prolong the phase separation and assist the molecules to further orient. Finally, we achieve the donor/acceptor phase separation with the enlarged phase domains, favorable vertical distribution, and significantly ordered crystal orientation [1], which contributes to a high fill factor of >80%. The corresponding device power conversion efficiency (PCE) reaches 18.72% with a short-circuit current density (*J*sc) of 27.30 mA/cm^2 and open-circuit voltage (*V*oc) of 0.854 V. Importantly, the better light stability is also captured in the more phase-separated device. This work optimizes donor/acceptor vertical distribution and orientation by enhancing the solid-liquid phase separation via a predictable method for realizing high-performance and stable organic photovoltaics [2].

2:30 PM BREAK

3:30 PM *EN04.06/EN01.06.04
Efficient and Stable Organic Photovoltaics Thomas D. Anthopoulos; King Abdullah University of Science and Technology, Saudi Arabia

Organic photovoltaics (OPVs) show great potential as a complementary technology to traditional silicon-based photovoltaics due to their lightweight, flexible, and potentially low-cost properties. However, they face challenges such as poor operational stability and lower power conversion efficiency (PCE) compared to commercial solar cell technologies. In recent years, there have been significant advancements in materials and cell architectures to enhance the PCE of OPVs. This presentation will focus on practical new strategies to improve OPVs' efficiency and operational stability. Specifically, it will discuss the innovative use of charge-extracting interlayers, which help increase the efficiency of next-generation OPVs. The benefits of these interlayers include a higher open-circuit voltage, reduced recombination losses, and improved operational stability. Additionally, recent progress in utilizing molecular dopants to enhance the PCE of advanced OPVs will be presented, demonstrating their effectiveness in improving the cell's fill factor and short-circuit current density. Moreover, it will be shown that combining innovative charge-extracting interlayers with molecular dopants and advanced functional material formulations can lead to even more significant improvements in efficiency and device stability.

4:00 PM EN04.06/EN01.06.05
Origin of Temperature-Driven Morphology Changes in High-Performance Bulk Heterojunction Active Layer of Organic Solar Cell Device Haoyu Zhao, Nathaniel L. Prine, Guorong Ma, Soumya Kundu, Andrew Bates and Xiaodan Gu; University of Southern Mississippi, United States

The performance of conjugated polymer-based organic solar cell (OSC) device relies on the bulk heterojunction morphology of the electron donor and acceptor blend. The morphology including the average domain size, crystallinity, and phase purity of donor/acceptor blend determines the device performance. Although the power conversion efficiency (PCE) of OSC is above 19%, the origin of the instable performance over longer times remains poorly understood. In this work, we conducted multiple characterization techniques to explore the dynamic, temperature-dependent morphology of a state-of-the-art donor polymer (PM6) blended with a non-fullerene small-molecule acceptor (Y6). Particularly, we focused on the thermal analysis of the donor and acceptor using fast scanning calorimetry (Flash DSC) to understand the crystallization kinetics. Combined with the assistance of atomic-force microscopy paired with infrared microscopy (AFM-IR) and X-ray scattering, we concluded the origin of PCE loss can be attributed to the severe phase separation caused by acceptor diffusional crystallization. The pure Y6 showed growing crystallization as annealing temperature increased. And the isothermal crystallization growth of blend was further accelerated due to diffusions of Y6. As the blend is maintained at elevated temperatures, the formation of Y6 crystalline domains induced phase separation with donors, as evidenced by the domain purities via AFM-IR characterizations. The influences of small molecules crystallization were characterized by the performance changes for solar cell device. This study will contribute to the development of more reliable, efficient and commercially viable OSC in the future.

4:15 PM EN04.06/EN01.06.06
Radiation Hardness of Organic Solar Cells Yongxi Li[1,2] and Stephen R. Forrest[1,3,4]; [1]University of Michigan, United States; [2]Michigan Materials Research Institute, United States; [3]Departments of Physics, United States; [4]Departments of Material Science and Engineering, United States

Over the past few decades, space exploration has opened up new frontiers in both scientific knowledge and technological innovation. These endeavors have created new opportunities for addressing global challenges. As we set our sights on the forthcoming era of space exploration, the demand for substantial power looms large. Electric propulsion, driven by solar energy, emerges as a pivotal technology to support these capabilities.

Organic photovoltaic cells (OPVs), in particular, have exhibited great promise for solar power generation in space due to their incredibly high specific power, reaching up to 40 kW/kg[1], compared, for example to the ubiquitously employed Si cells of ~ 1 kW/kg[2]. Furthermore, OPVs have the ability to withstand tensile strains exceeding 300% when supported by elastomeric materials, making them far more flexible than their inorganic counterparts[3]. The continuous advancement of organic materials has enabled the power conversion efficiency (PCE) of OPVs to exceed 20%[4,5] and intrinsic operational lifetime over 30 years[6], making them competitive with other thin-film inorganic photovoltaic devices. The only pervasive myth associated with OPVs is that the materials are intrinsically vulnerable to degradation when exposed to high energy incident radiation.

In this work, we found that carefully selected and designed organic materials and device structure are capable of showing high radiation hardness. Previous studies have identified proton irradiation as a prominent source of radiation-induced damage to photovoltaic systems in space, generating vacancies, interstitials, or complex defects within semiconductor materials[7]. Through simulations of proton energy loss per unit depth using SRIM/TRIM, we found that proton energies exceeding 100 keV can traverse the organic active layer without inducing collisions, consequently yielding a low total vacancy count. This phenomenon is attributed to the relatively slim nature of the organic active layer within OPV cells, measuring only a hundred nanometers in thickness,

rendering them comparatively transparent to high-energy particles. To evaluate the proton tolerance of OPVs, we fabricated devices based on the two most reliable OPV configurations demonstrated by our lab. The results demonstrated that the PCE of the OPV device can be maintained even at energies as high as 1 MeV and fluences up to 10^{12} cm^{-2}, equivalent to 20 years of operation in low Earth orbit (LEO) missions. Remarkably, this performance surpasses that of crystalline silicon (c-Si) cells, which undergo around 40% degradation, and perovskite cells, which show nearly 10% degradation at the same fluence. This compelling evidence suggests the potential of OPVs to offer extraordinarily long operational lifespans in space environments.

The Determination of Referenced HOMO/LUMO Levels with Pulse Radiolysis Michele Myong, Mrinalni Iyer, Yaejin Kim, John Miller and Matthew Bird; Brookhaven National Laboratory, United States

With organic photovoltaic (OPV) power conversion efficiencies nearly at 20%, and their emerging applications in photocatalysis, knowledge of the driving force for electron transfer is vital for understanding how to further optimize these materials.

Pulse radiolysis (PR) enables the rapid generation of excess, free charges in any solvent without the need for electrolyte or electrodes. Relative one-electron redox potentials of pairs of solutes can be determined through charge transfer equilibria measurements with PR. This approach offers the tantalizing possibility of determining accurate, referenced one-electron redox potentials of conjugated polymer chains in nonpolar environments, something that has been desperately needed in the field of organic electronics since its inception.

The two leading approaches for estimating HOMO and LUMO levels in these highly conjugated materials come from onset potentials obtained by CV or UPS/IPES measurements on films. Both methods give important information but, even in the best case, we expect 50-100 mV accuracy which could correspond to orders of magnitude variation in electron transfer rates. Remarkably, one of the leading OPV blends of PM6 and Y6 has been reported to have a HOMO offset of 90 meV with CV but 700 meV with UPS. The PR method may help to understand these differences.We have developed a “redox ladder” in o-xylene to serve as a measuring stick to get internally referenced redox potentials in a nonpolar media. The ladder is constructed from numerous equilibrium constants for electron or hole transfer between pairs of small molecules. The choice of o-xylene gives nonpolar redox potentials and enables both reduction and oxidation processes to be studied. Newer “green” OPV materials are designed to be soluble in o-xylene.

We have performed these measurements to determine accurate one electron redox potentials for several common conjugated polymers and small molecules including PM6, Y6, P3HT, IDTBT, PFO, PCPDTBT, F8BT with respect to the Fc/Fc+ couple in o-xylene. We hope this method will provide a reliable measure of the inherent redox properties of single conjugated polymer chains and we plan to expand it to include aggregated polymers to determine how inter-molecular interactions affect redox potentials.

11:00 AM *EN02.01.02
Photoresponsive Piezoelectric Ceramics for Multisource Energy Harvesting and Sensing Yang Bai; University of Oulu, Finland

Among all kinetic energy harvesters, those made from piezoelectric materials are considered the most efficient when working at resonance of the electromechanical coupling process. High-performance piezoelectrics, such as piezoceramics and single crystals, are usually oxide perovskite ferroelectrics which also exhibit photovoltaic effect. This fact offers a unique opportunity to integrate light harvesters with the piezoelectric ones in a single material to achieve multi-source energy harvesting and/or sensing. Coupling multiple energy in one material promotes self-sufficiency and sustainability of energy harvesters and associated electronic systems. Strong piezoelectricity has been thought to inevitably lead to wide photonic band gaps, and vice versa, narrow band gaps eliminate piezoelectricity. This view, however, is being changed. This talk will walk through the achievements in recent years in terms of band gap engineering of piezoelectric materials with an emphasis on works carried out by the speaker's research group, including piezoelectric compositions based on the potassium niobate and lead titanate perovskite solid solutions.

11:30 AM EN02.01.03
Self-Powered Gas Sensing based on Triboelectric Effect via Metal-Organic Frameworks Alibek Kakim, Baktiyar Soltabayev, Amanzhol Turlybekuly and Gulnur Kalimuldina; Nazarbayev University, Kazakhstan

Triboelectric nanogenerators (TENG) have demonstrated potential for ambient energy harvesting and sensing applications in different fields in the last decade. In this work, we focus on unveiling the usage of TENG as a self-powered gas sensor. The conventional sensors for detecting environmental gas concentrations are powered by batteries, which limits their usage. We propose the development of a self-powered portable gas sensor based on the TENG incorporated with MOF particles with comparable accuracy to the conventional sensors. MOFs have charge-trapping properties resulting from the ionic interactions of the metallic ions. While MOFs are widely used for gas storage, their gas sensing capabilities, such as TENG, need further research. Specifically, MIL-125 and ZIF-8 MOFs have promising potential. ZIF-8 has garnered significant interest as a gas sensor due to its two distinct advantages compared to traditional zeolites. Firstly, ZIF-8 boasts larger pore dimensions (approximately 1.6 nanometers) and typically exhibits smaller crystal sizes, increasing surface area. Secondly, ZIF-8 demonstrates a notable hydrophobic characteristic. MIL-125 is a promising gas-sensing material due to its large surface area, adjustable pore size, and controllable surface properties.

11:45 AM EN02.01.04
On-Skin Breathable Triboelectric-And-Electromagnetic Liquid-Metal Nanogenerator for Extracting Biomechanical and Electromagnetic Energy and as Whole-Body Epidermal Self-Powered Sensors Ying-Chih Lai; National Chung Hsing University, Taiwan

On-skin electronics can be conformably deployed on body for health monitoring, assisted living, and human/computer interfaces. However, developing corresponding energy devices is a critical challenge. Herein, a permeable and stretchable multifunctional liquid-metal electronic skin that can generate electricity by recovering ambient electromagnetic pollution (from surrounding electrical appliances) and biomechanical energy (from body movements) is presented for epidermal energy and self-powered sensing applications. To the best of our knowledge, this is the first demonstration that a breathable on-skin device can convert ambient electromagnetic pollution into useful electricity. The device was constructed using two stretchable microfibrous films sandwiching self-organized mesh-like and wrinkled liquid metal that affords electricity via induced electrification (±9.3 V, ±1.7 μA; 60 Hz) and triboelectricity (205.6 V, ±2.3 μA; 4 Hz). Its applicability in powering electronic devices has been demonstrated. Moreover, it can serve as an epidermal self-powered sensor for continuously monitoring whole-body physiological signals and motions of the eyelids, face, throat, chest, and limbs, thus demonstrating its potential to remotely collect clinical and biomechanical information. Finally, it was used as an interface in diverse system-level applications. These results shed light on new directions in on-skin energy and sensing, enabling to usher electronics toward untethered and diversified applications.

Tuesday Afternoon, April 23, 2024
Room 332, Level 3, Summit

2:00 PM *EN02.02.02
Approaches Toward Efficient Piezoelectric based Energy Harvesting Chong Yun Kang; Korea Institute of Science and Technology, Korea (the Republic of)

Due to relatively low power generation capability and energy conversion efficiency, however, these harvesting technologies have been applied only to limited applications. In order to solve these issues, here, we address three type of piezoelectric energy harvesting. First, we design and demonstrate a piezoelectric/electromagnetic hybrid energy harvester that can generate significant amount of electricity at vibration environments. Oval-like configuration using two curved piezoelectric energy harvesters based on MFC (Macro-fiber composite) piezoelectric material induces large displacement of a permanent magnet installed at the end of the top surface which allows efficient power generation both piezoelectric and electromagnetic energy harvesters. Second, Second, we introduce a PVDF-based piezoelectric energy harvester applicable to roads. The PVDF-based piezoelectric energy harvesters provide a competitive power output at small vertical displacements with proper module design, making the tough piezoelectric materials suitable for efficient and durable roadway energy harvesting. Finally, we demonstrate an ultra-wide bandwidth piezoelectric energy harvesters through the automatic resonance tuning. Piezoelectric energy harvesters typically exhibit sharp peak in output power around resonance frequency. We expect that the automatic resonance tunable piezoelectric energy harvester can provide the much-needed breakthrough in the deployment of mechanical energy harvesters for naturally occurring vibrations.

Cooperative Contact Electrification enabled by Control Over Electron and Ion Transfer Directions Xiaoting Ma, Jiaming Zhou, Eunjong Kim, Jingyi Gao and Dong-Myeong Shin; University of Hong Kong, Hong Kong

Contact electrification (CE) is a phenomenon that occurs when two materials are broungth into contact and exchange charges. Although recent studies show that CE between two solids including metals, semiconductors and nonionic polymers is basically due to electron transfer, the mechanism for CE involving ionic materials remains controversial. In this paper, the CE process between single-ion conducting materials (SICM) and fluorinated ethylene propylene (FEP) is systematically investigated to elaborate the electrification mechanism when ions are participating in CE. In the study, electron thermionic emission method was also used to separate the contributions of ion transfer and electron transfer in the total static charges when varying the environmental humidity. Furthermore, molecular dynamics simulations were performed to reveal the molecular interactions and dynamics of the polymer surfaces, mobile ions and water molecules at the interface. The results show that ion transfer is an important mechanism in the CE of FEP/SICM pairs and that higher humidity leads to more free ions and higher contribution of ion transfer in the total transferred charges. Our research not only provides new insights into the mechanism of contact electrification that involves ion transfer but also introduces a uniqu category of triboelectric materials that are single-ion conducting.

3:30 PM EN02.02.04
Sustainable and High-Performance Triboelectric Nanogenerator Based on Sulfur-Rich Polymer/MXene Composites Woongbi Cho[1], Sungsu Kim[1], Hyeonhoo Lee[1], Nara Han[2,3], Hyunki Kim[2], Minbaek Lee[2], Tae Hee Han[1] and Jeong Jae Wie[1,3,4]; [1]Hanyang University, Korea (the Republic of); [2]Inha University, Korea (the Republic of); [3]State University of New York College of Environmental Science and Forestry, United States; [4]The Michael M. Szwarc Polymer Research Institute, United States

Sulfur-rich polymer (SRP) is a great candidate to construct a waste-based but high-performance triboelectric nanogenerator (TENG), as elemental sulfur is a huge waste from the petroleum refining process and possesses the highest level of electron affinity (−200 kJ mol^{-1}). In our previous reports, the SRP-based TENG outperformed polytetrafluoroethylene (PTFE), one of the state-of-the-art triboelectric materials, by directly fluorinating the surface of SRP and adapting a blend system with fluoropolymer. However, these strategies raised environmental concerns about using F_2 gas and per- and poly-fluoroalkyl substances (PFAS), which are toxic to humans. Herein, we introduce the SRP/MXene composites to circumvent environmental issues and to achieve a high-performance triboelectric nanogenerator (TENG). We achieved the maximized MXene distribution in SRP with minimized MXene content by introducing the segregated structure. This well-distributed MXene enhances triboelectrification through the enhanced dielectric constant via microscopic dipole interactions at the interface between SRP and MXene. As a result, SRP/MXene-based TENG demonstrated a record high peak voltage of 331.4 V and peak current of 19.6 μA, which are 2.9 times and 19.5 times higher than those reported in previous SRP-based TENGs. The used SRP/MXene film also can be recycled by regrinding and compressing due to its dynamic bond exchanging property, and the recycled SRP/MXene film maintains its modulus and triboelectric output performance. Finally, scaled-up 4-inch SRP/MXene film-based TENG demonstrated a record high peak power density of 3.89 W m^{-2} after applying corona discharging, surpassing the reported SRP-based TENG.

3:45 PM EN02.02.05
A Volume Effect based Triboelectric Nanogenerator for Omnidirectional Wave Energy Harvesting Jiaming Zhou, Xiaoting Ma, Eunjong Kim and Dong-Myeong Shin; University of Hong Kong, Hong Kong

The marvel of the liquid-solid triboelectric nanogenerator (LS-TENG) has been demonstrated in its efficient energy harvesting via the contact electrification effect between liquid and solid triboelectric materials. The insufficient contact problems and wear issues frequently encountered in solid-solid TENGs are avoided through this technology. Nevertheless, the droplet-based LS-TENG has been plagued by problems of continuous falling droplets, which limits its practical application. Herein, we present an innovative droplet-based omnidirectional triboelectric nanogenerator (DB-TENG) utilizing the volume effect of droplets for efficient harvesting of ocean wave energy. With a unique concentric circular electrode pair built on an oblate plate, the DB-TENG achieves a significant improvement in output performance compared to traditional liquid-solid TENGs, with a maximum output voltage of 160V, which is 16 times higher, and a maximum current of 4000 nA, which is 40 times higher. This volume effect DB-TENG can perform reliably under extreme conditions of high humidity or high concentrations of salt, acid, or alkali solutions, making it a flexible tool for all types of working environments with enhanced reliability and reduced maintenance costs. What's more, the DB-TENG's omnidirectional capabilities make it suitable for capturing energy from various directions of ocean waves. The TENG's performance in ocean wave energy harvesting is evaluated and compared with traditional TENGs, demonstrating superior results in terms of output voltage and current. The proposed design holds significant potential for practical applications in blue energy harvesting and can inspire the development of self-sufficient ocean sensors. Overall, this study highlights the importance of volume-effect in enhancing the output performance of TENGs and presents a promising approach for efficient and sustainable ocean wave energy harvesting.

SESSION EN02.03: Mechanism and Manufacturing for Energy Harvesting
Session Chairs: Yang Bai and Andris Sutka
Wednesday Morning, April 24, 2024
Room 332, Level 3, Summit

9:00 AM *EN02.03.01
Advances in Plasma-Enabled Nanomaterial Synthesis for Enhanced Energy Harvesting Devices Ana Borras, Javier Castillo-Seoane, Xabier Garcia-Casas, Juan Delgado, Fernando Nunez-Galvez, Melania Sanchez, Lidia Contreras-Bernal, Jorge Budagosky, Vanda Godinho, Victor Lopez-Flores, Carmen Lopez-Santos, Juan Sanchez-Valencia, Angel Barranco and Javier Castillo-Seoane; CSIC, Spain

In this communication, we will present our latest advances in the development of nanostructured thin films and supported core@multishell nanomaterials for energy harvesting. The foundation of the synthetic approach centers around the utilization of a one-reactor system,[1] where we integrate various industrially scalable vacuum and plasma deposition methods for tailored nanostructured thin film deposition and the fabrication of one-dimensional devices. The transition from conformal layers to core@multishell devices is driven by the application of single-crystalline organic nanowires as supported soft templates compatible with a wide array of substrates.[2,3] We demonstrate the integration of materials, spanning from plasma polymers to sculptural hybrid halide perovskites and metal oxide nanotrees, onto energy harvesting devices such as solar cells, piezoelectric, pyroelectric, triboelectric, and hybrid nanogenerators. Our presentation highlights the role of micro and nanostructures and interface control in optimizing these energy-harvesting solutions.[4-9]

9:30 AM EN02.03.02
Machine Learning Aided Exploration of Chalcohalide-Based Solid Solutions for Photovoltaic Applications Cibrán López Álvarez[1,2], Ivan Caño Prades[1,2], Jose M. Asensi López[3], Zacharie Jehl Li-Kao[1,2], Edgardo Saucedo[1,2] and Claudio Cazorla[1,2]; [1]Polytechnic University of Catalonia, Spain; [2]Barcelona Research Center in Multiscale Science and Egineering, Spain; [3]University of Barcelona, Spain

Ternary chalcohalides, of general formula ABC (A = {Bi, Sb}, B = {S, Se}, C = {I, Br}), conform a new family of promising photovoltaic solar cell absorbers [1], with band-gaps lying between 1.5-1.9 eV and high absorption coefficients ($\sim 10^5$ cm^{-1}).

Chalcohalide-based tandem solar cells have revolutioned the landscape of photovoltaic energy conversion in the past years as a promising alternative to single-junction silicon-based panels (e.g., tandem solar cells). Given the great stability of this novel family, solid solutions of chalcohalides [2], of general expression $Bi_xSb_{1-x}S_ySe_{1-y}I_zBr_{1-z}$, present extraordinary possibilities in terms of device tunability and efficiency, something that has not been explored so far to the best of our knowledge.

We present a comprehensive study of the energetic stability and optoelectronis properties of chalcohalide-based solid solutions covering all possible compositions that is based on a combination of first-principles calculations and novel deep learning techniques. Experimental validation is as well obtained from the synthesis and characterization of a solid-solution in the laboratory. Finally, a realistic BiSBr-BiSeI tandem device is optically simulated and optimized, showing a very competitive short-circuit current of 18.65 mA/cm^2.

9:45 AM EN02.03.03
Three-Dimensional Physical Modeling of The Wet Manufacturing Process of Solid-State Battery Electrodes Mohammed Alabdali[1], Franco M. Zanotto[1], Marc Duquesnoy[1], Anna-Katharina Hatz[2], Duancheng Ma[2], Jérémie Auvergniot[2], Virginie Viallet[1], Vincent Seznec[1] and Alejandro A. Franco[1]; [1]LRCS - Université de Picardie Jules Verne, France; [2]Umicore, Belgium

We present an innovative three-dimensional physics-based modeling workflow that addresses the issue of poor performance of Solid-State Battery (SSB) cells due to the challenging design and manufacturing of composite electrodes with appropriate ionic and electronic conductivities. While modeling approaches have been utilized in the literature to investigate the influence of stochastically-generated microstructures on their conductivities, computational simulations able to predict the influence of manufacturing parameters on the SSB electrode microstructures remain elusive [1]. We present a novel physics-based computational modeling framework able to numerically investigate the impact of wet manufacturing process parameters (*e.g.* formulation, drying rate, calendering degree) on the properties of SSB tape casted composite electrodes. In analogy to our previous work on the simulation of the manufacturing process of Lithium Ion Battery electrodes [2], the Coarse-Grained Molecular Dynamics (CGMD) is adapted and used here for the simulation of the manufacturing process of SSB composite electrode cathode based on the physical interactions among individual particles representing the materials constituting the slurry and the formed electrode (*i.e.* NMC622, Carbon-Binder Domain and Li_6PS_5Cl) involved in the wet manufacturing process. By encompassing the entire process of wet manufacturing of SSB electrodes, from the slurry to the calendering, the model is able to predict the correlations between manufacturing parameters and electronic and ionic conductivities of the electrodes. We show why and how this model constitutes an important tool to assist in the optimization of interfaces between the materials in the electrodes, leading to improved SSB performance and durability.

10:00 AM BREAK

10:30 AM *EN02.03.04
Harvesting Motion via Polymers: From Mechanisms to Electricity Peter C. Sherrell[1,2], Ronald Leon[2], Andris Sutka[3] and Amanda Ellis[2]; [1]RMIT University, Australia; [2]The University of Melbourne, Australia; [3]Riga Technical University, Latvia

For many centuries people have pondered (notably and dubiously Thales of Miletus)[1] why some materials become electrically charged when brought into contact with other, dissimilar, materials. We now know that this charging phenomena is governed either by piezoelectricity from deformation, for non-centrosymmetric unit cells, or contact electrification (also known as triboelectricity) from interfacial friction. While piezoelectricity (and ferroelectricity) is well understood, the mechanisms of contact electrification remain a subject of debate in the literature.[2] This debate on the driving force being electron-, ion-, or material-transfer,[2-3] coupled to poor measurement techniques leading to conflation of piezoelectric and contact electrification,[4-5] has limited the design of optimal polymer energy harvesters.

If we can develop improved understandings of how polymers charge from friction, we can design devices that can capture motion to harvest electricity,[6] drive chemical reactions,[7] or even enable wound healing.[8]

To address this lack of understanding, we have studied how polymers generate charge at a contact interface. This has linked the polarity of generated charge directly to polymer structure via cohesive energy density,[9] and surface topography.[10] These relatively simple understandings have enabled the production of layer-by-layer ‘laminate’ assemblies from arbitrary polymers.[11] These laminates, which function purely off contact electrification and

interfacial friction, generate internal dipole moments that mimic piezoelectric polymers – enabling exceptionally efficient vibrational energy harvesting. Finally, we demonstrate the use of recycled foamed/expanded polystyrene to fabricate such laminates, capable of harvesting over 12 µA and 200 V from just 16 N of force. Moving forwards, these laminates, as well as piezoelectric polymers,[12] are being studied tools to drive catalytic reactions ranging from fuel production through to small molecule synthesis.

This talk aims to provide a pathway to design highly efficient electromechanically active surfaces from polymers towards catalysis and sustainable chemistry.

Innovative ITO Nanocrystals for Sustainable Thin Film Fabrication in Optoelectronics and Clean Energy Printing Using Solution Processing Techniques Ivet Maqueira Albo[1,2], Luca Rebecchi[1,2], Andrea Rubino[1] and Ilka Kriegel[1]; [1]Italian Institute of Technology, Italy; [2]Università degli Studi di Genova, Italy

To address the growing global energy demand while mitigating environmental concerns, innovative technologies and materials for clean and sustainable energy generation are essential. Transparent Conducting Oxides (TCO), like Indium Tin Oxide (ITO), play a pivotal role due to their exceptional transparency in the visible spectrum and metal-like electron mobility. These materials not only show great promise in the field of optoelectronics but also significantly contribute to enhancing the capabilities and sustainability of cutting-edge printing technologies. Recent efforts have been directed toward implementing transparent conductive inks, which offer the potential for solution processing and the use of flexible substrates. This work primary focuses on the synthesis and characterization of ITO nanocrystals (NCs) and the subsequent fabrication of thin films using various solution-based deposition techniques. The synthesis of Indium Tin Oxide (ITO) nanocrystals employs a precise slow injection technique that provides meticulous control over dopant positioning within the crystal lattice. By fine-tuning the injection rate and duration, it becomes possible to precisely adjust dopant concentration and distribution, thereby ultimately affecting the thin film properties. This is related to the control of dopant segregation and activation. Characterization techniques such as spectroscopy, electron microscopy and electrical conductivity measurements can directly relate to the dopant placement in the nanocrystals. This comprehensive analysis greatly enhances the potential of TCO nanoparticles in solution-based thin film production, contributing to a more sustainable and energy-efficient future.

11:15 AM EN02.03.06
Unlocking The Pt Sintering Prevention Mechanism by Trace Amount of Atomic Layer Deposition Shyama C. Mandal[1,2], Gennaro Liccardo[1,2], Bang T. Nhan[1], Matteo Cargnello[1,2], Stacey F. Bent[1,2] and Frank Abild-Pedersen[2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The catalytic performance of Pt-based metals has long been recognized for its remarkable activity. Nevertheless, the sintering of Pt during the reactions diminishes its active sites, ultimately resulting in reduced reactivity. Therefore, it is imperative to inhibit the sintering of Pt during the reactions. In this context, we have conducted atomic layer deposition (ALD) of Al_2O_3 and ZrO_2 onto Pt nanoparticles and observed the prevention of sintering. For a comprehensive understanding of this phenomenon, we focused on the theoretical investigation on Pt(111) terrace sites and Pt(211) step sites. Step sites are particularly susceptible to detachment, which can lead to Ostwald ripening, ultimately resulting in the deposition on larger nanoparticles. During our investigation, we considered various ALD species that could form during the process and calculated their binding energies on terrace and step sites. Our calculations revealed that most of the species exhibited a preference for binding to step sites, suggesting their ability to stabilize the steps. Additionally, we proposed a possible ALD mechanism and calculated the reaction free energies for each elementary steps on both the ALD recipes. These calculations indicated that the most favorable intermediate on Pt(211) step sites would be $Al_2(OH)_6$ and $Zr(OH)_4$ for the Al_2O_3-based and ZrO_2-based ALD processes, respectively. The ALD sample exhibited lower catalytic activity compared to Pt supported on Al_2O_3 during combustion of propene. However, an increase in catalytic activity has been observed after aging the ALD sample. This could be attributed to the opening of the ALD layers during aging or the diffusion of Pt through defects in the ALD layer. Notably, our calculated binding energies showed that Pt has a stronger binding within the ALD layer, suggesting the possibility of Pt diffusion through the ALD layer and its subsequent participation in the catalytic reaction. In summary, our research demonstrates that even trace amounts of ALD can effectively stabilize supported Pt catalysts, mitigating sintering-related deactivation and significantly enhancing the efficiency of the catalyst.

A Comparative Study of Switched-Capacitor and Inductor-Based Boost Converters for Indoor Light Energy Harvesting Tharaka Kaushalya[1,2], Markus Littow[2], Eetu Virta[1], Tarmo Ruotsalainen[2], Jari Juuti[1] and Yang Bai[1]; [1]University of Oulu, Finland; [2]Nordic Semiconductor Finland Oy, Finland

With the development of sustainable and energy-efficient smart buildings and cities, scavenging indoor light energy to power the Internet of Things (IoT) has become an increasingly attractive solution. This solution helps to extend the lifespan of devices by reducing the frequency of battery replacement whilst resulting in less battery waste. However, the energy that can be harvested from an indoor light environment is limited compared to natural, outdoor sunlight, emphasizing the importance of efficiency of the entire energy harvesting system rather than that of individual harvesters. Power management circuitry plays a crucial role here but there has not been a system-level study for different power management schemes when connected to both harvesters and batteries whilst working under real lighting conditions. In this talk, performances of both a Switched-Capacitor (SC) and an Inductor-based (IN) boost converter will be evaluated with reference to their charging efficiencies when connected to photovoltaic cells and Li-ion batteries under indoor office light. Results suggest that, although the IN converter tends to be cumbersome, it provides unbeatably high and stable battery charging efficiency across a broad range of light intensities compared to the SC converter even though the latter is specifically designed for low-power applications competing with the IN counterpart.

11:45 AM EN02.03.08
Developing Triboelectric Materials for High-Performance Generators Andris Sutka[1], Kaspars Malnieks[1], Artis Linarts[1], Linards Lapčinskis[1] and Peter C. Sherrell[2,3]; [1]Riga Technical University, Latvia; [2]RMIT University, Australia; [3]The University of Melbourne, Australia

Triboelectric generators are the most promising mechanical to electrical energy converters at a small scale because they can extract energy from a huge range of mechanical sources: from motion, ambient vibrations, noise, and even from water droplets. However, their performance is limited due to low surface charge density and output power.
Herein, we will describe various approaches for increasing the triboelectric surface charge density. These will include MM ordering [1], functionalization [2], controlling interfacial strain [3], and exploiting volumetric dipoles [4,5]. We will show enhancement from controlled net surface charge polarity, intensified organo-ion transfer, and the complementary induction from triboelectric or piezoelectric dipoles in volume. We will look at the perspective of combining these approaches for providing generators with high performance up to 50 W/m^2.

SESSION EN02.04: Emerging Materials for Energy Harvesting
Session Chairs: Jinbo Bai and Chang Kyu Jeong
Wednesday Afternoon, April 24, 2024
Room 332, Level 3, Summit

1:30 PM *EN02.01.01
Self-Powered Flexible Piezo-Sensor and MicroLED: Toward Commercialization Keon Jae Lee; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

This seminar introduces two recent progresses of self-powered flexible devices; piezo-sensors and microLED. The first part will introduce flexible inorganic piezoelectric membrane that can detect the minute vibration of membrane for self-powered acoustic sensor and blood pressure monitor. Speaker recognition has received spotlight as personalized voice-controlled interface, smart home, biometric authentication. The conventional speaker recognition was realized by a condenser type microphone, which detects sound by measuring the capacitance value between two conducting layers. The condenser type microphone, however, has critical demerits such as low sensitivity, high power consumption, low recognition rate and an unstable circuit due to the large gain amplification. Herein, we reported a machine learning-based acoustic sensor by mimicking the basilar membrane of human cochlear. Highly sensitive self-powered flexible piezoelectric acoustic sensor with a multi-resonant frequency band was employed for voice recognition. Convolutional Neural Network (CNN) were utilized for speaker recognition, resulted in a 97.5% speaker recognition rate with the 75% reduction of error rate compared to that of the reference MEMS microphone. In addition, wearable piezoelectric blood-pressure sensors (WPBPS) were developed for continuous non-invasive arterial pressure monitoring. WPBPS achieves a high normalized sensitivity (0.062 kPa−1), and fast response time (23 ms). The transfer function of a linear regression model converts flexible piezoelectric sensor signals into blood pressure values. Clinical validation of WPBPS was performed on 35 subjects/175 measurements, that satisfies international standard of blood pressure measuring devices.
The second part will discuss the highly efficient flexible micro LED for displays and biomedical applications. Flexible displays can be easily affixed anywhere, such as on the surfaces of human skin, clothes, automobiles and buildings. III-V inorganic LEDs have superior characteristics, such as long-term stability, high efficiency, and strong brightness compared to OLED. However, due to the brittle property of inorganic materials, III-V LED limits its applications for flexible electronics. Here we introduce the flexible GaAs/GaN microLED using innovative micro-vacuum transfer technology. The superb properties of flexible inorganic LED enable not only full-color displays and wearable phototherapy patches like hair growth, melanogenesis inhibition and pancreas cancer. In addition, combining with optogenetic mouse models, flexible microLED stimulates the neurons of motor cortex for manipulating mouse body movements and synchronized electromyogram (EMG) signals.

2:00 PM *EN02.04.01
Piezoelectric Biomaterials and Devices for Energy Harvesting and Application in Cardiovascular Systems Xudong Wang; University of Wisconsin--Madison, United States

Nanogenerator (NG) is a promising solution to biomechanical energy harvesting inside human body. So far, many technology innovations have advanced the NG technology toward a broad range of biomedical applications. Among many potential directions, cardiovascular applications possess substantial significance given the wide spread of cardiovascular diseases and high demands of cardiovascular electronic devices. In this talk, I introduce our most recent development of piezoelectric materials and composites that are particularly designed for implantable NG applications for both hearts and blood vessels. First, new ferroelectric composites are presented as a new material used in 3D printing for directly manufacturing of piezoelectric architectures with tunable piezoelectric and mechanical properties. Artificial blood vessels and stents are developed using this new technique that enable in vivo monitoring of blood pressure and early detection of blockage. Materials and devices that enables effective energy harvesting from hearts will also be introduced, showing a promising solution for long-term in vivo operation for powering cardiovascular electronics. Toward the end, other relevant challenges, such as device safety, biocompatibility, and packaging issues will also be discussed, together with additional novel application potentials for NGs for cardiovascular systems.

3:30 PM *EN02.04.03
Discovering Giant Magnetoelastic Effect in Soft Systems for Bioelectronics Jun Chen; University of California, Los Angeles, United States

The magnetoelastic effect, also named as Villari effect and discovered in 1865 by Italian experimental physicist Emilio Villari, is the variation of the magnetic field of a material under mechanical stress. This effect is usually observed in rigid metal and metal alloys with an externally applied magnetic

field and has been ignored in the field of soft bioelectronics for the following three reasons: the magnetization variation in the biomechanical stress range is limited; the requirement of the external magnetic field induces structural complexity and bulky structure, and there exists a gigantic mismatch of mechanical modulus up to six orders of magnitude difference between the rigid magnetoelastic materials and the soft human tissues. In 2021, we discovered the giant magnetoelastic effect in a solid soft polymer system, later in a liquid permanent fluidic magnet, which paves a fundamentally new way to build up intrinsically waterproof and biocompatible soft bioelectronics for diagnostics, therapeutics, and energy applications. Our group at UCLA is currently pioneering this research effort of harnessing giant magnetoelastic effects in soft systems for healthcare and energy.

4:00 PM EN02.04.04
High-Performance PVDF/PMMA Porous Matrix-Based Triboelectric Nanogenerators Assem Mubarak, Gulnur Kalimuldina, Bayandy Sarsembayev and Zhanat Kappassov; Nazarbayev University, Kazakhstan

The increasing demand for flexible and wearable devices is driven by ongoing advancements in intelligent electronics technology, coupled with the growing importance of the Internet of Things (IoT) in biomedical applications. Modern electronics must exhibit specific characteristics, including a lightweight design, high conductivity, good dielectric permittivity, low dielectric loss, and exceptional breakdown strength. Polyvinylidene fluoride (PVDF), a polymer known for its high triboelectric charge density, is a common piezoelectric material used in nanogenerators like triboelectric nanogenerators (TENGs). However, obtaining PVDF with a high β-phase content using conventional methods, typically employed for membrane materials, poses a significant challenge due to its high resistance and the inherent difficulty in polarization.
Therefore, this research study employs a novel quenching method to prepare a PVDF/PMMA porous matrix with a predominant β-phase content of around 86%, offering a relatively simple and cost-effective approach. The fabricated TENG device exhibited an impressive output power output of approximately 750 mW per and demonstrated excellent mechanical robustness, enduring more than 30,000 cycles. This mechanical robustness is three times higher than that of previous PVDF-based TENGs. Overall, this study demonstrates the potential application of a PVDF/PMMA porous matrix TENG device, fabricated through a simple and cost-effective method, highlighting its versatility and efficiency for various practical purposes.

4:15 PM EN02.04.05
Metal-Organic Frameworks for Textile based Triboelectric Nanogenerators Gaurav Khandelwal, Charchit Kumar, Satyaranjan Bairagi and Daniel Mulvihill; James Watt School of Engineering, University of Glasgow, United Kingdom

Metal-organic frameworks (MOFs) are crystalline porous materials composed of metal ion coordinated with an organic ligand. MOFs has numerous advantages including high surface area, tunable size, ease of post synthetic modifications, high porosity. Further MOFs offers specific pore size which can be advantageous for highly selective self-powered sensors based on triboelectric effect. However, majority of MOFs based TENG uses powders attached on the conductive tape by applying high pressure and blowing off the unattached particles. This widely used approach is unsuitable due to poor device reproducibility, repeatability and stability. Further, TENGs active layers designed by above method cannot be used for self-powered physical or chemical sensors. In case of physical sensors like pressure sensor, high pressure can lead to the transfer of material on the opposite contact layer. While in case of chemical sensors addition of analyte can lead to removal of material, thus making device unreliable. This work discusses the advantages and the challenges of MOFs for TENGs. Then MOFs are introduced for TENG based self-powered sensor applications with ZIF-8 based tetracycline sensor and Cu-Asp based thioacetamide sensor as examples. Finally, the talk will discuss the growth of MOFs on the textile substrates for TENGs, their triboelectric behaviour and potential for self-powered applications.

SESSION EN02.05: Poster Session I
Session Chairs: Chang Kyu Jeong and Kwi-Il Park
Wednesday Afternoon, April 24, 2024
Flex Hall C, Level 2, Summit

5:00 PM EN02.05.01
Flexible and Wearable Thermo/Piezo-Electric Hybrid Energy Harvesters Cheolmin Kim, Hyeon Jun Park, Gwang Hyeon Kim, Bitna Bae, HakSu Jang and Kwi-Il Park; Kyungpook National University, Korea (the Republic of)

Thermoelectric and piezoelectric hybrid generators (TPHGs) are attractive candidates for powering wearable body sensor networks continuously and permanently owing to their excellent access to human-generated energy. First, to achieve the enhanced piezoelectricity of flexible piezoelectric composites-based films, we have demonstrated the flexoelectric-boosted electromechanical properties of piezoelectric nanoparticles using an induced built-in strain gradient in heterogeneous core-shell nanostructure for enhancing the intrinsic piezoelectricity of pure $BaTiO_3$ nanoparticles. We have also demonstrated the enhanced poling efficiency in nanocomposite made of P(VDF-TrFE) and porous $BaTiO_3$ nanofibers. Moreover, we have developed the high-temperature workable f-PEH comprising the high Tc KNN-based ceramics and a thermally stable polyimide (PI) matrix which can be a promising candidate for developing f-PEH and self-powered sensors working in high-temperature environments. Next, to realize the flexible thermoelectric energy harvesting technology, we have fabricated the tailorable f-TEHs based on thermoelectric films and papers made by dispersing the Bi_2Te_3 particles inside polymeric and cellulose matrices, respectively. Finally, the hybrid generator was assembled through simple drop-casting and gravitational settling effect, for the first time. The film layer sedimented with the conductive thermoelectric particles simultaneously served as an electrode and a bottom substrate for piezoelectric energy harvesting. The proposed design concept for f-TPHGs can aid in the development of high-performance multisource energy harvesting devices for wearable sensors.

5:00 PM EN02.05.02
Enhanced Triboelectric Performance of Surface-Modulated 2D MoS_2 via Pulsed Laser-Directed Thermolysis for Self-Powered Wearable Electronics Hee Yoon Jang[1], Chang Kyu Jeong[2] and Seoung-Ki Lee[1]; [1]Pusan National University, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

In recent times, two-dimensional (2D) transition metal dichalcogenide (TMDC) nanomaterials have emerged as leading contenders for advancing the realms of flexible, transparent, and wearable electronics. Yet, there exists a conspicuous dearth in the exploration of their inherent properties in the domain of triboelectric nanogenerators (TENGs), a foremost technology for mechanical energy harvesting. This study presents a novel, rapid, ambient, wafer-scale, and patternable methodology for the synthesis of 2D MoS_2 through pulsed laser-directed thermolysis. Our groundbreaking laser synthesis approach facilitates the imposition of internal stress on the MoS_2 crystal by modulating its morphological characteristics, resulting in a surface-modulated MoS_2 TENG device that exhibits power generation amplified by approximately 40% relative to its flat MoS_2 counterpart. Distinctly, in comparison to analogous

MoS_2-based TENG devices, our model achieves superior energy harvesting metrics (reaching peaks of ~25 V and ~1.2 μA) without the requirement of supplemental materials, even in scenarios where the opposing triboelectric surface exhibits a marginally varied triboelectric series. This augmentation in triboelectrification can be ascribed to both alterations in work function and the amplification of surface roughness. Conclusively, the directly synthesized MoS_2 patterns are adeptly employed to craft a self-sustaining flexible haptic sensor array. The methodology delineated herein aims to galvanize expansive research into the triboelectric potentials and diverse applications of 2D TMDC nanomaterials.

5:00 PM EN02.05.03
Anomalous Output Performance Enhancement of Triboelectric Nanogenerators by Manipulation of Surface Molecular Dipoles Ruey-Chi Wang and Hsiu-Cheng Chen; National University of Kaohsiung, Taiwan

Since the invention of triboelectric nanogenerators (TENGs), numerous strategies have been proposed to boost their performance by altering the triboelectric materials, typically centered on increasing work function disparities or effective contact areas. However, in this study, we introduce a novel approach that significantly enhances output performance through the manipulation of surface molecular dipoles, a departure from conventional methods. In our research, we demonstrate a significant improvement in TENG output performance by manipulating surface dipoles, achieved by bonding copper ions to the oxygen-containing functional groups on the surface of graphene oxides. This bonding causes a reversal in the orientations of surface molecular dipoles, resulting in the enhancement of TENG output. Remarkably, the variations in TENG output performance due to these surface modifications are contrary to what would be predicted based solely on differences in work functions, as determined by Kelvin probe force microscopy. This observation suggests that factors beyond work functions play a pivotal role in governing TENG performance. We propose a self-bias-enhancement model by surface dipoles and further testifies it by polling processes. This mechanism is expected to have universal applicability to other materials aimed at enhancing the performance of TENGs and self-powered devices.

5:00 PM EN02.05.04
Computational Investigation of Low-Dimensional Materials for Spacesuit Applications Simone Lang and Shiru Lin; Texas Woman's University, United States

Modern Space Suit materials maintain properties that shield astronauts from radiation, severe lunar temperature, and microparticles; while upholding lightweightness, flexibility and tensile strength on long space missions. Most spacesuit materials are made from nylon, synthetic fabrics and synthetic polymers. High density polyethylene (HDPE) is a popular polymer for space applications due to their resistance properties from secondary radiation exposure and their richness in hydrogen atoms. However, HDPE lacks tensile strength, therefore causing urgency to find a material that will absorb well and maintain excellent properties with HDPE. In this project, low-dimensional materials, including graphene, graphene oxide and boron oxide are explored for spacesuit material additives HDPE, because of their successful electrostatic, thermal and mechanical properties. Density Functional Theory (DFT) computations are used to investigate the adsorption interactions between low-dimensional materials with HDPE with the variable of angle dependence. Moreover, exploring their ability to maintain radiation resistance, thermal cycling and electrostatic properties.

5:00 PM EN02.05.05
Influence of Relaxor Piezoelectric Polymer Matrix on Piezoelectric Nanocomposites-Based Energy Harvesting Hyunseung Kim[1,1], Wook Jo[2], Seung-Hyun Kim[3] and Chang Kyu Jeong[1,1,1]; [1]Jeonbuk National University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Brown University, United States

Piezoelectric nanocomposites consisting of a polymer matrix and ceramic fillers are candidate components of flexible, wearable, and self-powered electronic devices. The physical discrepancy between ferroelectric polymers and ceramics in a piezoelectric interface makes it difficult to assemble efficient hybrid piezoelectric nanocomposites without polarization and extraneous artifacts. Here, we describe the effect of a relaxor ferroelectric terpolymer matrix on the piezoelectric output, which can enhance the energy harvesting or sensor performance of piezoelectric composite device of nanocomposite generators with filler nanoparticles of lead zirconium titanate. The dielectric property and reduced ferroelectric hindrance of the proposed terpolymer matrix provides more poling to align the polarization of piezoelectric ceramic fillers compared with a normal ferroelectric copolymer matrix. Therefore, relaxor ferroelectric polymers can be better than normal ferroelectric polymers as the matrix of hybrid polymer-ceramic piezoelectric nanocomposite. This research provides important physical information about the interface between a polymer matrix and ceramic fillers in flexible piezoelectric nanocomposite applications.

5:00 PM EN02.05.06
Dual Contribution of Charge Loss Reduction and Charge Generation Assisted by Electronegative Double-Layered Triboelectric Nanogenerator Arun Mondal, Mohd Faraz, Mamta Dahiya and Neeraj Khare; Indian Institute of Technology Delhi, India

Converting ambient mechanical vibrations into electricity is a promising approach to providing independent power sources for smart portable electronic devices[1]. Triboelectric nanogenerator (TENG) is one of the very promising choices in the research community for harvesting mechanical energy for their easily available resources and simple fabrications. The major problem of a TENG device is the loss of generated negative surface charges of the electronegative layer before it can be captured. In the present work, we have fabricated a double-layered structure for the electronegative part to engineer the dual contribution: reduction in the surface charge loss and the improvement in the surface charge generation during contact electrification. The double-layer structure of the electronegative layer is a stacking of two different composite polymers, in which the bottom part is the $NaNbO_3$ nanocubes incorporated PDMS layer, and the top part is the composite of PVDF and MXene $Ti_3C_2T_x$ flakes, which is named as 15MP/15NP (PVDF+15wt% MXene/PDMS+15wt% $NaNbO_3$). An enhancement of 2.5 times in open-circuit voltages (V_{OC}), 2.5 times in short-circuit currents (I_{SC}), and 2.2 times in the transferred charges (Q_{SC}) have been observed in 15MP/15NP-based TENG. It also exhibits a large 7-fold enhancement compared to the bare PVDF, where the bare PVDF-based TENG shows a power density of 19 μW/cm^2, whereas the 15MP/15NP-based TENG shows 134 μW/cm^2. The enhancement in the electrical outputs in 15MP/15NP is due to the improved surface charge retention of the electronegative layer. The KFPM study confirms that the surface potential in the 15MP/15NP has been reduced significantly compared to bare PVDF, resulting in an increased work function, which enhances the surface charge density during contact electrification and improves the electrical outputs. [2]. The incorporation of $NaNbO_3$ in the PDMS layer improved the dielectricity and internal polarization of the PDMS+$NaNbO_3$ composite, which reduced the surface charge loss that arises from the internal electric field generated between the negative surface electrons and positive induced charges on the back electrode. Additionally, the incorporation of MXene in the PVDF layer effectively improved the electronegativity of the friction layer because of their surface-terminated electronegative -F groups and microcapacitive structure[3].

5:00 PM EN02.05.07
Hybrid Biomechanical Energy Harvesting for Wearable Microgrids Jiseok Kim and Il-Kwon Oh; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

With increasing interest in battery-free electronic devices, researchers are exploring ways to convert biomechanical energy from the human body into electrical energy. However, the commercialization of energy harvesting devices poses significant challenges. Such challenges can be attributed to various factors as follows; 1) The low efficiency of energy conversion results in a lack of viable electronic components for real-world applications. Additionally, the use of biomechanical energy harvesting devices may increase metabolic energy and causes discomfort. To address these challenges, this study proposes an innovative air-pumping-based energy harvesting device that aims to enhance energy conversion efficiency while minimizing user inconvenience. The device compresses rubber bladders through repetitive ground impacts during walking. It releases compressed air to induce rotor rotation hence converting low-frequency reciprocating motion that arises from impacts into high-frequency rotary motion to increase efficiency in electricity generation with a low crest factor. Unlike conventional energy harvesting devices, which generate single-pulse and discontinuous energy harvesting signals from low-frequency movements, this approach enables continuous energy harvesting by converting rotational motion. Additionally, it can be made of lightweight materials for a simple air-pumping mechanism rather than heavy mechanical components. The rotary energy harvester employs a hybrid energy harvesting technology that utilizes both an electromagnetic and tribovoltaic generator. The latter exploits the friction at the metal-semiconductor Schottky interface to produce unidirectional direct current beyond the energy barrier. This hybrid energy harvester facilitates the continuous operation of healthcare monitoring sensors when seamlessly integrated into smart wearable systems. We conclude that this technology is ideal for ensuring uninterrupted healthcare monitoring. In conclusion, the hybrid biomechanical energy-harvesting device developed in this research presents a promising solution for enabling the continuous operation of smart wearable systems, especially healthcare monitoring sensors, by utilizing energy harvested during daily walking activities.

5:00 PM EN02.05.08
Enhanced Output Performance of Triboelectric Nanogenerator Based on Sulfur-Rich Polymer with Controlled Composition Gradient Minji Bak[1,2], Woongbi Cho[1], Sungsu Kim[1] and Jeong Jae Wie[1,3,2]; [1]Hanyang University, Korea (the Republic of); [2]The Michael M. Szwarc Polymer Research Institute with Composition Gradient, United States; [3]State University of New York College of Environmental Science and Forestry, United States

Elemental sulfur of seven million tonnes is annually generated as a by-product from petroleum refining processes. Hence, the upcycling of elemental sulfur has gained significant attention owing to its high economic feasibility and environmental-friendliness. In previous reports, the sulfur-rich polymer (SRP) is utilized for the high-performance negatively chargeable friction layer in a triboelectric nanogenerator (TENG). Because the SRP has the highest electron affinity of –200 kJ mol^{-1} in the periodic table except for halogenic elements and precious metals like Au, Pt. In this study, we introduce a structural approach with composition gradient for improving TENG performance. A thin dielectric layer is typically favorable for high performance due to increased charge induction, but excessive thinness reduces surface charge density due to charge recombination. To prevent the recombination, a charge trapping layer (CTL) is employed for enhancement of surface charge density. Increasing sulfur content in SRP leads to a higher dielectric constant, resulting in the generation of more charge through triboelectrification. At the same time, the benzene content decreases, which reduces charge capture ability. This is because aromatic polymers have non-uniform energy levels along their polymer chain, containing numerous charge trapping sites. We optimize TENG performance by creating a monolithic film with spatially controlled elemental sulfur and benzene content through dynamic covalent bonding by the thermal processing of two films with different sulfur contents.<gdiv></gdiv>

5:00 PM EN02.05.09
Big Data Analysis for Cell Efficiency Prediction with Multi Wafer Quality Data Sung Ho Hwang[1,2], Yoonmook Kang[1], Hae-seok Lee[1] and Dongchul Suh[3]; [1]Korea University, Korea (the Republic of); [2]Research Institute for Energy Technology, Korea (the Republic of); [3]Hoseo university, Korea (the Republic of)

In photovoltaic (PV) products, three key parameters, namely high power, low cost, and high energy yield, have been the primary focus of investigation within both academic and industrial contexts. From a cost reduction perspective, the wafer has traditionally been the most expensive material in module manufacturing. In 2021, crystalline wafers (mono and multi) dominated the market, holding approximately 95% of the share. Within this, multi wafers accounted for around 15%. More recently, larger wafers like M10 and M12 have been adopted in the PV industry, continuing this trend. Given this market situation, reducing the cost of wafers has become a highly effective endeavor. Wafer manufacturers have been striving to produce thinner wafers to maximize the quantity from ingots.
Simultaneously, cell manufacturers have been working on methods to identify and separate lower-quality wafers before the manufacturing process begins. These lower-quality wafers can result in cells with reduced efficiency, making them unsuitable for module production, as they fail to meet the required power specifications. This decrease in cell efficiency has imposed a significant burden on cell manufacturers, leading to losses in materials, gases, chemicals, and production. Consequently, the development of improved screening methods is a critical and necessary step for cell manufacturers.

In this study, various properties of multi wafers, such as lifetime, dark area, dark edge area, edge defect, defect, resistivity, total thickness variation (TTV), saw mark, wafer thickness, and grain defects, were monitored and evaluated alongside final data on cell efficiency, short-circuit current, and open-circuit voltage during mass production. This analysis was conducted on Passivated Emitter Rear Contact (PERC) multi cells, using several tens of thousands of wafers. The performance of all tools was also assessed to establish a connection with these wafer quality parameters.

Several parameters demonstrated a strong correlation with cell efficiency. This correlation allows for the cell efficiency prediction based on wafer quality without any additional processes. This predicted cell efficiency was compared with the mass production data, revealing a significant correlation.

As a result of this study, cell manufacturers can identify and eliminate low-quality wafers that pose a risk of resulting in low cell efficiency during mass production. This process can ultimately lead to cost reduction by saving on gas, chemicals, process time, and pastes. Consequently, this study has the potential to contribute to reducing the levelized cost of electricity (LCOE) in the PV industry.

5:00 PM EN02.05.10
Metallic Glass Thin Film Electrodes for Chemically and Mechanically Stable Interface for Flexible Electronics Jae Sang Cho[1], Woongsik Jang[1], Keum Hwan Park[2] and Dong Hwan Wang[1]; [1]Chung-Ang University, Korea (the Republic of); [2]Korea Electronics Technology Institute, Korea (the Republic of)

Metallic glasses (MGs) or amorphous alloys gained attentions for their attractive mechanical properties and chemical stabilities, which originate from the randomly oriented atomic arrangement in the MGs that results in their strong strain-resistance and chemical inertness. MGs are often characterized by the absence of grain boundaries, which are often responsible for initiating catastrophic mechanical failures and corrosion (and other chemical reactions). Recently, their applicability in thin film via physical vapor deposition method have motivated researchers to replace electrode materials to MG thin films. MG thin films exhibit varying electrical and mechanical characteristics depending on their atomic compositions, thus should be analyzed thoroughly before replacing conventional electrode materials for the electrodes. Here, we present intriguing cases of adopting MG thin films for electrodes of organic photovoltaic cells and sensors. Through detailed investigations on MG thin films, fabrication of thin film devices with enhanced stability and flexibility is achieved. In specific, amorphous metallic surface in contact with polymers circumvents oxidation reaction caused by ambient air, which prevents formation of insulating oxides and loss of electrical conductivity of the electrode itself. In addition, MG thin film exhibited high crack resilience in bendable and stretchable devices, which yielded flexible devices with high flexibility and reliability.

3D Printed Ni-Mo Catalysts for High Performance HER at a High Current Density Yanran Xun and Jun Ding; National University of Singapore, Singapore

Developing efficient water splitting at high current density (>500 mA cm^{-2}) is essential for its scalability. [1] Electrochemical water splitting is one of the most promising technological approaches for producing green hydrogen, and it plays a crucial role in achieving carbon neutrality. [2] In the meantime, additive manufacturing as a simple and facile method has attracted researchers' interest for the past decades, and a couple of outstanding works about using 3D printing to fabricate electrodes for water-splitting have been done. [3]–[5] Here, we reported a series of monolithic 3D-printed Ni-Mo alloy electrodes for highly efficient water splitting at high current density (1500 mA cm^{-2}) with excellent stability and bubble removal behavior, which provides a solution to scale up Ni-Mo catalysts for HER to industry use. All possible Ni-Mo metal/alloy phases were achieved by tuning the atomic composition and heat treatment procedure, and they were investigated through both experiment and simulation, and the optimal NiMo phase shows the best performance. Density functional theory (DFT) calculations elucidate that the NiMo phase has the lowest H_2O dissociation energy, which further explains the exceptional performance of NiMo. In addition, the microporosity was modulated via controlled thermal treatment, indicating that the 1100 °C sintered sample has excellent catalytic performance, which is attributed to the high electrochemical surface area (ECSA). Finally, the 4 different macrostructures were achieved by 3D printing, and they further improved the catalytic performance. The gyroid structure exhibits the best catalytic performance of driving 500 mA cm^{-2} at a low overpotential of 228 mV and 1500 mA cm^{-2} at 325 mV as it maximizes the efficient bubble removal from the electrode surface, which offers the great potential for high current density water splitting.

Hydrophobic-Barrier-Assisted Formation of Vertically Layered Metal Electrodes within a Single Sheet of Paper for a Foldable Radio Frequency Energy Harvesting System In Hyeok Oh, Eiyong Park, Sinil Kim, Sungjoon Lim and Suk Tai Chang; Chung-Ang University, Korea (the Republic of)

Radio frequency energy harvesting (RFEH) systems have emerged as a critical component for powering devices and replacing traditional batteries, with paper being one of the most promising substrates for use in flexible RFEH systems. However, previous paper-based electronics with optimized porosity, surface roughness, and hygroscopicity still face limitations in terms of the development of integrated foldable RFEH systems within a single sheet of paper. Here, we present a novel integrated foldable RF energy harvesting system based on vertically separated metal electrodes within a single sheet of paper by using a combination of hydrophobic wax printing and water-based solution process. Our fabrication approach provided stable horizontal conductive patterning with high conductivity, vertical separation of electrodes, and more importantly connection through a via-hole inside a paper substrate. The via-hole processing is a key factor that dramatically expands the design freedom of the harvesting system. When the via-hole cannot be implemented, the harvester should be positioned in the same plane or use the multilayer and additional connecting line. Thus, by applying our novel fabrication process, all-in-one type foldable RF energy harvesting system can be realized by integrating RF antenna, RF to DC rectifier, and supercapacitor within only a single sheet of paper. The proposed RFEH system exhibits an RF/DC conversion efficiency of 60% and an operating voltage of 2.1 V in 100 s at a distance of 50 mm and a transmitted power of 50 mW. The integrated RFEH system also demonstrates stable foldability, with RFEH performance maintained up to a folding angle of 150°. Our single-sheet paper-based RFEH system thus has the potential for use in practical applications associated with the remote powering of wearable and Internet-of-Things devices and in paper electronics.

High Efficiency Triboelectric Generator by Combining Acoustic Metamaterial Absorber and Isotropic Spring TsungYu Huang and Wei-Zhi Weng; Ming Chi University of Technology, Taiwan

Due to the current energy shortage and the growing environmental awareness, researchers around the world have been dedicating significant efforts to the development of green energy solutions. One area of particular interest is the exploration of eco-friendly and semi-permanent devices for power systems. Among these, the triboelectric nanogenerator has garnered significant attention due to its ability to efficiently convert weak mechanical energy into electrical energy. This simple, high energy density, and cost-effective device make triboelectric generator a prime candidate for alternative power sources, especially in the context of sustainable energy solutions. In addition to the energy crisis, urban areas are currently grappling with severe noise pollution, which has led to an increase in irritability and negatively impacts on their overall quality of life. In response to this challenge, researchers have developed innovative acoustic metamaterials capable of absorbing incident sound waves efficiently, even at sub-wavelength thicknesses. This technological advancement offers a promising opportunity to address both the energy shortage and noise pollution simultaneously. In this study, our goal is to integrate an acoustic metamaterial absorber, isotropic springs, and nanoscale triboelectric generators to convert the original noise pollution into electrical energy that can be used to power low-power devices. The first component of our integrated system is the acoustic metamaterial absorber, which we have designed as a quasi-Helmholtz resonator. This absorber is specifically engineered to achieve perfect absorption of incident sound waves at sub-wavelength thicknesses. It operates as an efficient noise-capturing device, thereby significantly reducing noise pollution in urban areas. The second essential element of our system is the isotropic spring, which we have incorporated within the acoustic metamaterial absorber. This spring is designed to capture and store the mechanical energy generated by sound waves. To optimize the energy conversion process, we must carefully consider the characteristics of the noise we aim to

capture. General traffic noise, for instance, typically has a frequency of around 2000 Hz and a decibel level of approximately 90 dB. These values serve as crucial parameters for our design and performance assessment. In our simulation, we have set the sound pressure of the incident sound wave to 1×106 to represent the real-world noise pollution scenario. By accurately modeling this scenario, we can better evaluate the effectiveness of our system in capturing and converting noise into electrical energy. The heart of our innovation lies in the positioning of two different materials for triboelectric generation. We have strategically placed these materials at a location with the maximum displacement between the components of the isotropic springs and the side walls of the acoustic metamaterial absorber. This placement is critical to ensuring the efficient conversion of mechanical energy into electrical energy. In our simulation, we have found that the relative displacement between the spring and absorber is approximately 1.8 mm, which is a promising result indicating the potential for effective energy conversion. In conclusion, our innovative approach to addressing both the energy shortage and noise pollution in urban areas offers a promising solution.

Keywords: Acoustic Metamaterials, Absorber, Isotropic Spring and Nanogenerator

Plasma Enhanced Attachment of Graphene Dispersed Conductive Polymer to 1D Nanofibers for Sensing and Nanogeneration Elmmer A. Vera Alvarado, Md. Abdur Rahman Bin Abdus Salam, Ali Ashraf and Karen Lozano; The University of Texas at Rio Grande Valley, United States

Nanogeneration, an emerging area where nanotechnology meets energy harvesting, has the potential to transform how we provide power to our increasingly miniaturized and portable electronic devices. the concept of nanogeneration, which involves the utilization of nanoscale materials and processes to generate electricity from surrounding sources. Nanogeneration encompasses various technologies like piezoelectric nanomaterials, thermoelectric generators, and triboelectric nanogenerators, which make it possible to transform mechanical movements, temperature variations, and even environmental vibrations into electrical power. Polyvinylidene fluoride (PVDF) is a semi-crystalline thermoplastic fluoropolymer known for its remarkable piezoelectric properties. PVDF is a commonly employed material for piezoelectric sensors, serving to measure pressure, force, acceleration, and vibration in various devices. These sensors are applied in industrial monitoring, medical equipment, and consumer electronics. In this study, the Forcespinning® (FS) method was utilized to fabricate PVDF nanofiber mats, which then were cut into small strips for nanogeneration and sensing tests. A conductive polymer ink, composed of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and graphene nanoflakes, was created and diluted in a 1:1 ratio with deionized water, which was later applied using a dip-coating process on the nanofibers. These nanofibers were initially subjected to a 3-minute plasma etching process to eliminate excessive beading. The specific time was decided after several trials at different times under the plasma treatment, the samples were characterized by Scanning Electron Microscopy (SEM) and it was observed that as the treatment time increased, the finer the fibers became, decreasing the fiber diameter by approximately 500 nm from the pristine nanofibers. The plasma process was done to enhance the adhesion of 2D material particles to the nanofibers, confirmed by SEM. The microscopic images of untreated PVDF nanofibers following the 3-minute plasma treatment displayed a noticeable decrease in the number and dimensions of bead-like structures, along with a substantial reduction of 500 nm in nanofiber diameter. Additionally, the images revealed a strong adhesion between the conductive polymer ink and the nanofibers. Moreover, the coated nanofibers presented an approximate electrical conductivity of 250 kΩ, as well as an average output voltage of 50 mV for single finger pressing, comparable to the work performed by Rahman et al., where a voltage of 75mV was obtained from graphene-coated nanofibers [1]. Further tests for sensing and conductivity of these samples are to be performed, showing a promising advancement for low-powered sensors and energy harvesting.

Towards 1-Watt Capable Rotary Triboelectric Nanogenerators for Power at Sea Griffin Trayner, Calum Kenny and Jim McNally; National Renewable Energy Laboratory, United States

Increasing at-sea power generation by Triboelectric Nanogenerator (TENG) energy harvesters in the order of 1-Watt will create significant opportunities to power ocean observation buoys and distributed sensor nodes by extending mission time and increasing sensor payload [1]. Of the many possible configurations of harvesting wave energy with TENGs, we document the rationale for choosing and developing a rotary TENG that operates by the freestanding mode. The rotary TENG prototype consists of two plates, a rotor and a stator, to take advantage of the various mechanisms of converting wave action into rotational motion. We have constructed a testing apparatus that allows us to vary several key parameters of the device: distance between rotor and stator, triboelectric material, rotational speed, number of electrodes and output load impedance. Preliminary results show that when driven at a constant 500 rpm, we can achieve a power density of 0.7 W/m3. A variable speed motor drives the rotor, which can be driven using a velocity profile informed by the equivalent to the output from a wave energy converter (WEC). This profile may be generated by the hydrodynamic simulation software WEC-Sim. The optimized rotational TENG can be stacked and driven by a single shaft, increasing the energy density of the device. The output of such a TENG could be used to power devices in the ocean at a low cost and high durability.

Moisture Activated Zinc Ion Battery for Leak Detection Signaling Dylan D. Edmundson and Anthony Dichiara; University of Washington, United States

Every year $6 billion worth of potable water is lost to undetected leaks in addition to $20 billion spent on property damage in the U.S alone [1-3]. While many leak detection systems exist that use acoustic, thermal, and video detection principles, they often suffer from low signal to noise ratios, poor sensitivity, and require technician operation [4]–[6]. To overcome these challenges researchers have begun investigating new and inventive bio-based solutions such as conductive paper resistive sensors [7], [8]. While these systems are quite effective, they are difficult to implement in residential homes due to the expense of installation and the need of continuous monitoring and power supply. To overcome these drawbacks, a fully autonomous leak detection system was envisioned, where a leak can produce power through mechanisms such as moisture enabled generators (MEGs) however, the extremely low power production of MEGs is insufficient for WIFI signaling. In this study a zinc ion battery inspired device is developed in pursuit of a fully autonomous detection system. Zinc microspheres are embedded in a carbon nanotube/cellulose composite using a scalable paper manufacturing method. Using this anode with a moisture wicking electrolyte doped separator and manganese oxide cathode, a water activated battery was produced capable of powering a WIFI device signaling the presence of a leak.

8:00 AM *EN02.06.01
Paper-Based Electrokinetic Power Generator Dylan D. Edmundson and Anthony B. Dichiara; University of Washington, United States

Wearable devices integrated with microprocessors and multifunctional sensors are gaining momentum in a variety of industries over the past decade. Such advancements significantly exceed the development pace of portable power sources. Most batteries, besides pausing serious sanitary and environmental concerns, are unfit for wearable devices, which require flexible, lightweight, reliable, and long-lasting systems with power densities of at least several tens W/kg. The autonomous scavenging of energy from the ambient environment offers a sustainable solution to power wearable sensors over long periods without the need to recharge. Nanogenerators (NG), such as triboelectric, piezoelectric, and thermoelectric generators, have been developed to harvest renewable energy from ambient sources that can be used to power portable electronics. Among them, moisture enabled generators or MEGs are a class of NG that generate electricity from moisture transport mechanisms, giving them a great advantage as water is inherently present in the air everywhere in the world. MEGs are typically made up of conductive materials that form an electric double layer when contacted by water. As water molecules move through a porous material, viscous shear forces create a charge gradient causing a potential difference and inducing current. Inspired by the Earth's hydrological cycle, transpiration driven electrokinetic power generators (TEPGs) take advantage of transpiration forces using asymmetric wetting mechanisms to increase fluid transport without the need for flowing bodies of liquid water. The present research leverages the biodegrable nature, flexibility, and light weight of lignocellulosic paper and combines them with the excellent properties of carbon nanotubes to prepare electrically-conductive capillary pumps. This innovative papertronics is cost-effective, recyclable, and can be manufactured using easily scalable papermaking processes. As-produced TEPG materials were thoroughly characterized and achieved a sustained open circuit voltage and short circuit current of 225 mV and 7 μA, respectively, from the transport of a 10 μL aqueous aluminum sulfate solution. The power output was improved further by using an optimized active electrode design, yielding OCV and SCC values over 1 V and 3 mA, respectively. A single device exhibited an impressive maximum power density of 50 W/kg, which when connected in series and parallel, could supply power for some common electronic systems.

8:30 AM EN02.06.02
Streamlining The Hydration of Micron-Sized Aluminum Particle Surface Towards Enhanced Power Generation Mahmuda Ishrat Malek and Michelle L. Pantoya; Texas Tech University, United States

Aluminum particles possess a core-shell configuration in which an aluminum core is covered by a passive alumina (Al_2O_3) shell. This Al_2O_3 shell acts as both a heat sink and a barrier for reactions which impedes the process of harnessing the substantial chemical energy potential of Al, which stands at 31MJ/Kg. Hydrating the Al surface has the potential to replace the Al_2O_3 shell with $Al(OH)_3$, a material with favorable properties for energy extraction. While nano-sized Al particle surfaces can be hydrated by controlling the pH, micron-sized particles require external heating and subsequent aging because of 90% decrease in surface energy. Applying temperature above 35C to Al- water solution can expedite the formation of AlOOH and prolonged aging can lead to excessive consumption of Al core, both of which have adverse effect on the potential energy of the sample. For small amount of Al powder (230mg) controlling the temperature at 35C for a minimum of 18 hrs, $Al(OH)_3$ shell formation in place of Al_2O_3 can be achieved with 96% Al core still unconsumed. To hydrate a larger amount of powder (2gm) in a short period of time, high temperature (100C) is necessary to produce $Al(OH)_3$. Heating Al powder for 25mins at this temperature can produce 5% $Al(OH)_3$ with most of the Al cores (95%) unconsumed. Moving up to 30mins the powders have a trace of 3% AlOOH. TEM images of 18hrs at 35C and 25mins at 100C both have similar fuzzy surfaces. Upscaling the hydration process for micron-sized Al powder can lead to a time-saving method for larger quantities of Al and aid in producing modified shell-core properties that can be exploited for enhancing power generation techniques.

8:45 AM EN02.06.03
Performance Enhancement of Moisture-Induced Power Generators under Ambient Conditions through Flashlight-Induced Graphitization of $FeCl_3$-Impregnated Cellulose Papers Daewoong Kim, Jakyung Eun, Hyunsoo Han and Sangmin Jeon; Pohang University of Science and Technology, Korea (the Republic of)

We introduce a novel approach for the fabrication and performance enhancement of moisture-induced power generators (MPGs) utilizing flashlight-induced graphitization (FIG). $FeCl_3$-impregnated cellulose papers (FCPs) were photothermally converted into graphitized cellulose papers (GCPs) with a hierarchically porous structure by flashlight irradiation under ambient conditions. During the photothermal conversion process, Fe^{3+} ions partially convert into iron oxide compounds with limited solubility, highlighting that $FeCl_3$ serves multiple roles such as catalyst for graphitization, moisture absorber, and charge carrier. When a bilayered cellulose paper (BCP), formed by stacking GCP on top of FCP, was exposed to moisture, a potential difference was generated between the collecting electrodes due to the concentration gradient of dissociated Fe^{3+} ions within the BCP, with higher concentration in FCP

and lower concentration in GCP. The resulting migration of Fe^{3+} ions from FCP to GCP caused electron movement along the external circuit. The BCP-based MPG exhibited continuous voltage and current outputs, with maximum values of 0.39 V for voltage and 28.6 μA/cm^2 for current density at 45% relative humidity, marking a significant breakthrough in MPG performance under ambient humidity conditions.

9:00 AM EN02.06.04
Multidimensional Analysis of Moisture-Induced Power Generator Using Quartz Crystal Microbalance Hyerim Baek, Jihun Choi, Hyewon Lee and Sangmin Jeon; Pohang University of Science and Technology, Korea (the Republic of)

A novel quartz crystal microresonator was developed as a moisture-induced power generator (MPG) through constructing an interdigitated electrodes-lateral field excited (IDEs-LFE) quartz resonator. This system enabled the simultaneous measurement of both the electrical output of the MPG and the resonant frequency shift of the quartz crystal (QC) in real time. The SCP film, composed of sodium alginate, carbon nanoparticles and polyvinyl alcohol was coated onto the IDEs which were deposited on the top surface of the QC. Following the coating process, a voltage of 1 V was applied across the IDEs to construct ion concentration gradient, resulting in the generation of electricity during the adsorption of water molecules. Two symmetrical electrodes which were deposited on the bottom surface of the QC were employed to monitor the adsorption of water molecules into the SCP film by measuring the change in resonant frequency during oscillation. By conducting simultaneous measurements of the resonant frequency shift and electrical output under varying humidity conditions, parametric plots were established that correlate the electrical output with the resonant frequency shift. This dynamic interplay between resonant frequency shifts and electrical output provided insights into the impact of moisture adsorption on MPG performance.

9:15 AM EN02.06.05
Electrochemical Kinetic Energy Harvesting Mediated by Ion Solvation Switching in Two-Immiscible Liquid Electrolyte Donghoon Lee[1], You-Yeob Song[2], Angyin Wu[1], Jia Li[3], Jeonghun Yun[1], Dong-Hwa Seo[2] and Seok Woo Lee[1,3]; [1]Nanyang Technological University, Singapore; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Rolls-Royce at NTU Corporate Lab, Singapore

Kinetic energy harvesting (KEH) is the process of converting mechanical energy, typically in the form of motion or vibrations, into electrical energy using specialized devices or systems.[1] KEH is of significance in the realm of renewable energy, as it enables the harnessing of otherwise wasted or underutilized kinetic energy sources, thereby contributing to the development of sustainable power generation and self-sustaining electronic devices.[2] Nonetheless, presently existing techniques, like those relying on friction and deformation, require high-frequency kinetic energy and call for materials possessing exceptional durability.[3] Also, those methods have extremely high impedance, leading to reduced current and power outputs, thus constraining their practical applications.[4]
Herein, we propose an electrochemical KEH system that employs a two-phase immiscible liquid electrolyte, specifically combining aqueous and ionic liquid components, with Prussian blue analogue (PBA) electrodes. This system is designed to capture and harness kinetic energy from gentle and low-frequency mechanical motions while reducing impedance of the system. Starting from the state of equilibrium, where both PBA electrodes are submerged in distinct phases of the immiscible electrolyte, the open-circuit potential difference between these electrodes experiences an increment. This increase in potential difference enables the conversion of kinetic energy, associated with the movement of the electrodes into their respective phases, into electrical energy. The system generated 6.4 μW cm^{-2} of peak electrical power, accompanied by 96 mV of peak voltage and 183 μA cm^{-2} of peak current density when connected to a load resistor of 300 Ω. The applied load is three orders of magnitude smaller than what is conventional KEH methods. Furthermore, the proposed method demonstrated a continuous current output of around 5 μA cm^{-2} over one hundred seconds, at the frequency of 0.005 Hz for 23 cycles without any degradation in performance. Through computational simulations, we have determined that voltage between PBA electrodes originates from the difference in solvation Gibbs free energy within each phase of the two-phase electrolyte. The elimination and subsequent reformation of solvation shells surrounding solvated cations serve as the driving force for both the generation of voltage and the flow of electrons within the system. Moreover, we have effectively demonstrated the capability of our system within a microfluidic device, thereby paving the way for diverse applications. The microfluidic kinetic energy harvester is composed of identical PBA thin-film electrodes and the two-phase electrolyte. By utilizing the conversion of kinetic energy to drive the two-phase electrolyte through the microfluidic channel, our system attained a peak power density of 200 nW cm^{-2}.
In conclusion, we recognized the possibility of harvesting kinetic energy from solvation Gibbs free energies in the two-phase electrolyte mediated by ion-hosting materials and furnished persuasive evidence of its viability as a power source for self-powered devices. The incorporation of our system into the microfluidic harvester endows it with advantages for powering wearable electronics and Internet of Things (IoT) applications.

Wearable Device Monitoring Cough with Piezoelectric Energy Harvester as a Simultaneous Sensor and Battery Life Extender Yang Bai, Jaakko Palosaari, Eetu Virta and Miika Miinala; University of Oulu, Finland

Cough is the most common symptom for which individuals seek medical advice. However, wireless and autonomous tools and standards for cough monitoring are lacking, possibly due to issues of measurement reliability and device lifespan. This work utilizes the piezoelectric energy harvesting concept to sense coughing signals. Different from conventional sensing techniques, the piezoelectric harvester here converts energy of muscle movement triggered by cough into electricity which then charges a capacitor, rather than being directly read by the microcontroller. The capacitor will accumulate energy for a certain period and then the capacitor voltage will be read by the microcontroller. This simple change of data collection mechanism magnificently reduces the duty cycle of the entire electronic system whilst maintaining high accuracy of recording the history of coughs. Proven in clinical trials, the battery life of the device has been significantly extended to longer than a week compared to approximately only overnight where conventional sensing techniques are implemented, even if using the same piezoelectric harvester (sensor). The newly developed system can then be used to autonomously monitor and analyze cough data of in-/outpatients for daily, research and clinical purposes and thus to improve prediction and management of severe respiratory diseases.

Designing Solid Polymer Electrolytes for Energy Storage and Harvesting Christopher Li, William R. Fullerton and Tongjie Zhang; Drexel University, United States

Solid polymer electrolytes (SPEs), with a unique combination of electrochemical and mechanical characteristics, are promising for a wide range of energy storage and harvesting applications. The molecular architecture and structure of SPEs provide a versatile platform for tailoring materials' properties to suit specific application needs. This presentation will focus on the morphology and network structure effects on ion transport, electrodeposition, and the formation of metal dendrites. We demonstrate that the tortuosity resulting from the morphology of SPEs can be employed to fine-tune ion transport and guide the growth of metal dendrites. On the other hand, mechanically modulating the internal SPE structure can provide an alternative approach to controlling dendrite growth. By tuning SPE's molecular structure and chemistry, we can adjust the electrochemical and mechanical properties for improved battery performance while elucidating how these affect the underlying transport mechanism and electrodeposition behavior.

10:45 AM *EN02.07.02
A Modular Solid-State Electrolyte Platform Based on a Charged Double Helical Polymer Louis A. Madsen; Virginia Tech, United States

Our group has been developing a class of rigid solid electrolytes based on a highly charged double helical polyanion self-assembled with ion-containing fluids. We term this class of materials *molecular ionic composites* (MICs). These materials are highly thermally stable, and can reach ~ 1 GPa tensile modulus and > 1 mS/cm ionic conductivity with only 10-20% polymer content, and even with a substantial loading of cations like Li^+ or Na^+. Although MICs are macroscopically solid, the nanoconfined and partially ordered ions inside move only modestly slower (ca. a factor of 3) than in the neat precursor fluid. We can modulate the mechanical, transport, and chemical/thermal stability properties of MICs over wide ranges by changing the content and molecular weight of the polymer, and the chemistry of the ions and other mobile components. I will discuss the state of understanding of MICs, from the dependence of multi-scale morphology and transport on composition and liquid crystallinity, to the influence of specific molecular interactions on properties. I will discuss progress toward practical alkali-metal batteries, as well as extensions beyond our original MIC materials that include (1) segregation of highly Li-conductive nanocrystalline phases, and (2) high modulus thermo-reversible hydrogels.

11:15 AM *EN02.07.03
Coarse-Grained Molecular Dynamics Simulations of Polymer-Grafted Nanoparticle Systems Lisa M. Hall; Ohio State University, United States

Grafting polymer chains to nanoparticle surfaces, creating polymer-grafted nanoparticles (PGNs), allows for nanocomposites with a uniform and controllable distribution of inorganic particles in an organic matrix. Such materials are of interest as membranes for separations and dielectric materials, among other applications. The nanoparticle size, graft length, and graft density together set the interparticle spacing, as well as the degree to which conformations of chains on nearby particles can overlap, which impacts the local and overall material properties. Specifically, at high enough graft densities, the polymer conformations are stretched (brushlike) near the surface, then approach random walk conformations further from the surface if the grafts are long enough. We use a simple, efficient coarse-grained model to study how key controllable parameters such as graft density impact the chain conformations and local and overall properties. In particular, from molecular dynamics simulations, we analyze the structure, segmental and chain dynamics, and mechanical properties for a variety of polymer-grafted nanoparticle systems, including dilute PGNs in solvent and PGN monolayer films. We find an intermediate graft density leads to a relatively precise interparticle spacing along with a significant amount of overlap of polymers on nearby nanoparticles, which provides increased toughness versus high graft density systems.

11:45 AM EN02.07.04
Developing High-Performance Piezoelectric ZnS:Mn^{2+} Nanoparticles for Enhanced Mechanoluminescence and Piezocatalysis Zhongxiang Wang and Yadong Yin; University of California, Riverside, United States

Piezoelectric materials, featured by their non-centrosymmetric structures and unique charge separation properties under mechanical stimulation, hold significant promise for applications spanning pressure sensing, optogenetics, and piezocatalysis. However, existing materials often exhibit large particle sizes, posing challenges in specific applications like optogenetics, where nanoscale dimensions are required for barrier-free circulation through blood vessels. Furthermore, reducing particle size to the nanoscale offers increased surface area and enhanced reactant adsorption, a pivotal factor in catalytic performance. Thus, developing a straightforward method to produce highly piezoelectric nanomaterials is of great significance.
Herein, we introduce a novel approach for synthesizing ZnS:Mn^{2+} nanoparticles, employing the self-assembly of ZnS:Mn^{2+} quantum dots, followed by high-temperature calcination. During calcination, the ZnS:Mn^{2+} quantum dot assemblies transform into individual nanoparticles, accompanied by a phase transition from sphalerite to wurtzite structure. This sintering process is spatially confined within a silica layer, preventing nanoparticle interconnection. Subsequent etching of the silica layer using NaOH results in ZnS:Mn^{2+} nanoparticles with an average size of approximately 150 nm. These ZnS:Mn^{2+} nanoparticles exhibit exceptional piezoelectricity, featuring a piezoelectric coefficient (d_{33}) of up to 25 pm/V as measured via Piezoresponse Force Microscopy (PFM). Notably, this d_{33} value is around eight times higher than the literature-reported d_{33} value of ZnS (3.2 pm/V). It is worth mentioning that the d_{33} value exhibits variations dependent on calcination temperature and duration. Furthermore, the ZnS:Mn^{2+} nanoparticles display robust mechanoluminescence, both when dispersed in a PDMS film and an aqueous solution under focused ultrasound excitation. This mechanoluminescent emission from the nanoparticles has potential applications in controlling neural stem cell activities..
Moreover, the piezoelectric ZnS:Mn^{2+} nanoparticles demonstrate excellent performances in piezocatalytic dye degradation, effectively decomposing organic dyes like rhodamine B and methylene blue. The degradation process is attributed to the generation of reactive oxygen species from the combination of charge carriers and OH^-/O_2 in the solution, a mechanism supported by Electron Spin Resonance (ESR) measurements. The introduction of h^+, hydroxyl radical, and superoxide radical scavengers into the reaction system significantly reduces the degradation rate, further substantiating the catalytic mechanism. Compared to undoped ZnS nanoparticles synthesized in a similar manner, ZnS:Mn^{2+} nanoparticles exhibit superior piezocatalytic performance due to defect-induced polarization. Intriguingly, both mechanoluminescence and piezocatalysis are contingent on the non-centrosymmetric wurtzite structure of ZnS and its associated defect-induced polarization, each showcasing different optimal dopant concentrations and operating under distinct ultrasound frequencies.

SESSION EN02.08: Thermal Energy Harvesting

Soft-Matter Engineering for Thermoelectric Wearables with Unprecedented Power Generation Youngshang Han and Mohammad H. Malakooti; University of Washington, United States

Stretchable thermoelectric generators (S-TEGs) have recently drawn attention since they can compliantly be attached to complex surfaces to induce temperature change or harvest electricity from waste heat. Unlike conventional thermoelectric modules that are rigid and brittle, flexible thermoelectric devices commonly comprise elastic polymers with encapsulated semiconductor pellets. This stretchable device architecture also provides conformal contact with curved surfaces such as the human body. We have designed multifunctional elastomer composites to enhance the heat management and deformability of these emerging TEGs. Our approach involves dispersing liquid metal droplets within elastomers to create liquid metal elastomer composites (LMECs). LMECs with microdroplets exhibit high thermal conductivity while remaining electrically insulating, serving as thermal interface materials in the devices. Additionally, we have embedded hollow thermoplastic microspheres in the base elastomer to synthesize soft matter with low thermal conductivity, which separates the top and bottom thermal interface layers and encapsulates the semiconductor pellets. The difference between the conductivity of the two elastomer composites facilitates a larger heat flux in thermoelectric semiconductors, leading to improved device performance.
In this talk, we will begin with a brief overview of TEGs that utilize liquid metals and bismuth telluride semiconductors. Following this introduction, we will present our new findings on the design rationale of S-TEG, focusing on the improvement of energy harvesting performance at low-temperature gradients, along with enhancing mechanical resilience and stretchability. In particular, we will highlight the essential role of device structure in thermoelectric energy conversion, utilizing both numerical simulations and experimental analyses to illustrate our findings. The resulting S-TEG design is optimized for efficient thermal management, resulting in a notable power harvesting performance increase, exceeding baseline levels by more than sixfold. The electromechanical and energy harvesting characterization of this engineered S-TEG will be presented to showcase its full potential for a range of emerging applications. To conclude, we will explore the practical applications of these thermoelectric generators across various use cases.

Nanocomposite Ceramics Materials for Energy Harvesting and Heat Management Zouhair Hanani[1], Brigita Rozic[1], Daoud Mezzane[2], Mimoun El Marssi[3], Anna Morozovska[4], Serhii Ivanchenko[4], Hana Uršič[1], Matjaz Spreitzer[1] and Zdravko Kutnjak[1]; [1]Jozef Stefan Institute, Slovenia; [2]University Cadi Ayyad, Morocco; [3]University of Picardie Jules Verne, France; [4]National Academy of Sciences of Ukraine, Ukraine

Today's quest for sustainable energy solutions through greener energy harvesting and heat-management technologies has recently developed a significant interest in new flexible and biocompatible nanocomposite ceramics with large electromechanical, triboelectric, and electrocaloric (EC) effects [1]. Therefore, an overview of experimental and theoretical investigations of the large EC, piezoelectric, and triboelectric response in flexible ceramic nanocomposites exploiting enhanced multiferroic properties of ferroelectric nanoparticles within the polymer matrix will be presented in this contribution. Specifically, the enhanced EC response in lead-free BCZT and BaTiO3-based nanoparticles will be reviewed, including flexible polymer composites' large energy harvesting potential [2]. The impact of filler's dielectric permittivity and aspect ratio in high-k polymer and the benefits of combining 1D and 3D nanofillers on enhanced properties of flexible nanocomposites will be discussed [3]. [1] Z. Kutnjak., B. Rozic, R. Pirc., Wiley Encyclopedia of Electrical and Electronics Engineering, 1-19 (2015). [2] Z. Hanani et al., Nano Energy 81, 105661 (2021). [3] Z. Hanani et al., Nanoscale Adv. 4, 4658 (2022).

2:00 PM EN02.08.03
Soft Caloric Materials for Green Cooling Technologies Dejvid Cresnar[1], Matic Morgan[1], Bostjan Zalar[1], Samo Kralj[2], Zdravko Kutnjak[1], Gregor Skacej[3] and Brigita Rozic[1]; [1]Jozef Stefan Institute, Slovenia; [2]FNM, University of Maribor, Slovenia; [3]FMF, University of Ljubljana, Slovenia

With increased environmental awareness, the search for an environmentally friendlier heat- management device has been the topic of many scientific studies. Materials with large caloric effects, such as the electrocaloric (EC) and elastocaloric (eC) effects, have the promise of realizing new solid-state refrigeration techniques. A review of recent direct measurements of the large EC effect in liquid crystals (LCs) and large eC effect in liquid crystal elastomers (LCEs) [1, 2] will be given in this contribution, including the application aspect. In particular, in smectic LCs and mixtures of LCs with functionalized nanoparticles, the EC effect exceeds 8 K and the eC in main-chain (MC) LCEs exceeds 2K with the eC responsivity about three orders of magnitude larger than the average eC responsivity found in the best shape memory alloys. However, both soft materials can play a significant role as active cooling elements and parts of thermal diodes or regeneration material in developing new cooling devices. [1] D. Črešnar et al, J. Phys. Energy 5: 045004, 2023. [2] A. Rešetič et al, Nat Comm 7: 13140, 2016.

2:15 PM EN02.08.04
Direct Thermal-To-Pneumatic Body Heat Harvesting to Power Soft Actuators Marquise D. Bell, Aman I. Eujayl, Sofia Urbina, Anoop Rajappan, Barclay Jumet, Te Faye Yap, Evan Noce, Megan Enriquez and Daniel J. Preston; Rice University, United States

Wearable assistive devices have emerged as a viable aid in performing activities of daily living for people with physical disabilities, a group representing up to 27% of the U.S. adult population [1]. In particular, soft wearable assistive devices—most of which are pneumatically actuated [2]—can help those with limited mobility and dexterity caused by physical disabilities. A common limitation of these pneumatic assistive devices, however, is that they typically require a tether to an external pressure source, limiting adoption. Researchers have attempted to address this limitation by investigating methods to use the human body itself as a power source through various energy harvesting techniques, including implementation of piezoelectric, triboelectric, and thermoelectric devices [3,4]. However, these electronic energy harvesting approaches require multiple energy conversion steps for operation of pneumatic assistive devices (i.e., a mechanical or thermal input is converted first to electrical energy and then finally to pneumatic energy).

To address these energy conversion limitations, mitigate portability concerns caused by tethers to external power sources, and appeal to a larger percentage of those with physical disabilities, we developed a wearable textile-based system that bypasses the intermediate electrical conversion step by directly converting heat harvested from the body to pneumatic energy using a low-boiling-point fluid (LBPF). Our system consists of two pouches—a “warm” and “cool” pouch, thermally insulated from one another—where heat emitted from the body vaporizes a LBPF in the warm pouch to drive pneumatic actuation. After actuation, the vapor phase of the LBPF is recovered via condensation in the cool pouch, which is exposed to the lower temperature of the ambient compared to that of the body. Following eventual depletion of the LPBF in the warm pouch after a number of actuation cycles, the device can be flipped, placing the now-fluid-filled cool pouch in contact with the user to continue to vaporize the LBPF in a repeatable manner.

We characterized the system performance by modeling the transient pressure response, power output, efficiency, and life cycle of the device and compared modeling results with experiments, as well as with comparable thermal-to-electronic energy harvesting devices used in wearables in prior work. Our model uses fundamental thermodynamic and heat transfer principles to show how the frequency of operation and geometry of the device affect the overall system

performance. We also demonstrated the practicality of this system with a user applying the device to pneumatically actuate an assistive actuator for grasping. This work enables the use of body heat as a viable power source for pneumatically actuated assistive devices that can be used to enhance mobility assistance.

SESSION EN02.09: Poster Session II
Session Chairs: Jinbo Bai and Andris Sutka
Thursday Afternoon, April 25, 2024
Flex Hall C, Level 2, Summit

5:00 PM EN02.09.01
Printed Triboelectric Nanogenerator Incorporating MXene-Enhanced PVBVA for Skin-Interactive Devices and Touch-Sensing Arrays Ajay Pratap[1], Isaac Little[1], Fereshteh Rajabi Kouchi[1], Hailey Burgoyne[1], Naqsh Mansoor[1], Tony Varghese[1], Zhangxian Deng[1,1] and David Estrada[1,1,2]; [1]Boise State University, United States; [2]Idaho National Laboratory, United States

The adoption of soft contact structure designs in triboelectric nanogenerators (TENGs) has been a favored approach to enhance their durability. However, this method often presents a significant challenge to achieving high output performance. TENGs are often limited by their reliance on specific tribo-materials, which can restrict their practicality and performance. To address these limitations, we use additive electronics manufacturing methods for TENG fabrication, which enables energy generation from various tribomaterials, including human skin [1-3]. Our innovation lies in the integration of a high-performance polymer, Poly (*vinyl butyral-co-vinyl alcohol-co-vinyl acetate*) (PVBVA), with Ti_3C_2 MXenes [4], two dimensional transition metal carbides etched from the Ti_3AlC_2 MAX phase ceramics. Inks from these materials are formulated for microdispense printing and printed onto aluminum substrates using a Hyrel extrusion printer. This combination significantly enhances the triboelectric properties of the manufactured TENG device.
Our findings show that the PVBVA layer alone yields a triboelectric output of approximately 110 V. However, with the introduction of MXene at a concentration of 2.75 mg/ml, the output escalates to 150 V, and further increases to 250 V at a concentration of 5.5 mg/ml, demonstrating a substantial enhancement in performance. Beyond energy harvesting, we leveraged this TENG technology in a water energy harvesting system, effectively extracting energy from sources such as raindrops. Additionally, we developed a 2 x 2 touch sensor array utilizing this technology. This sensor array can generate charge through the triboelectric effect and dynamically map the output voltage values in response to touch, showcasing its potential for human-machine interaction and touch-sensitive interfaces.
In summary, our research introduces a groundbreaking approach to TENG fabrication by combining 3D printing technology with a PVBVA-MXene composite. This leads to TENGs with markedly improved triboelectric performance. The versatility of these TENGs not only enables efficient energy harvesting from environmental sources like rain but also holds significant promise for applications in touch-sensitive devices. This makes them a valuable asset for developing self-powered devices and interactive interfaces in fields such as healthcare and robotics.

Solvo-Voltaic Energy Harvesting for Distributed Electronic Systems Jihpeng Sun, Jongbin Won and Albert T. Liu; University of Michigan–Ann Arbor, United States

Electricity is the central energy currency in artificial programmable systems, akin to the role ATP plays in biological systems. Next-generation off-the-grid electronic systems call for alternative modes of energy harvesting. With numerous engineering possibilities in areas like circulating medical diagnostic devices and remote sensors in previously inaccessible locations, the Achilles' heel for such an electronic system at an extremely small length-scale has by and large been the energy constraint. While there has been tremendous progress toward improving the energy and power densities for traditional energy storage devices such as microbatteries and supercapacitors, their disadvantageous volumetric scaling poses fundamental constraints on important energy metrics that limit the application space of these electricity-demanding on-board electronics. To bridge this energy gap, we explore different liquid-based energy harvesting methods more broadly known as the '*solvo-voltaic*' effect, a phenomenon whereby various local energy inputs are converted into electricity within a quantum-confined nanostructure (*e.g.*, single-walled carbon nanotube, or SWCNT) by virtue of interactions with the surrounding solvent molecules. This technique stands out as a promising candidate to complement existing energy generation schemes like the photovoltaics, whose utility is diminished where visible light is not present, such as in the body.

5:00 PM EN02.09.03
Suppressing Conduction Losses of Polymer Composites Dielectrics for High-Temperature Capacitive Energy Storage Minhao Yang, Yanlong Zhao and Zepeng Wang; North China Electric Power University, China

Electrostatic capacitor that capitalizes on the rapid electric field-induced polarization and depolarization effects in dielectric materials to store and release electrical energy is one of the most important passive components in modern electronic devices and electrical power systems. The energy storage performance of electrostatic capacitors is mainly determined by the dielectric inside. Compared with inorganic dielectrics, polymer dielectrics from synthetic resins exhibit stable dielectric performance over a wide range of frequencies, superior high voltage endurance, excellent flexibility and processing properties. High-temperature resistance ability of polymer dielectrics is extremely important for the harsh operating environment with high temperature requirements. Nevertheless, most polymer dielectrics are more vulnerable to high temperatures due to their low glass transition temperature (T_g). The capacitive performance of polymer dielectrics degrades rapidly at high temperatures and electric fields, which is mainly attributed to the exponential increase of conduction loss. The increased leakage current further leads to an undesirable temperature rise inside the polymer dielectrics and consequently accelerates the thermal runaway of capacitors. Therefore, inhibiting the conduction loss of polymer dielectrics is extremely important for high-temperature

capacitive performance.

The bulk-limited conduction and electrode-limited conduction are the two main mechanisms inside the polymer dielectrics. With increasing the electric field and temperature, more trapped charge carriers are thermally activated to overcome the potential barrier of traps, even though the carrier energy is lower than the maximum energy of the potential barrier, and participate in the electrical conduction. Therefore, the conduction loss inside polymer dielectrics displays an exponential growth with temperature under high electric field. Introducing more deep charge traps is beneficial to suppress the bulk-limited conduction. Incorporating a small amount of wide bandgap inorganic fillers or small organic molecules with strong electronegativity into the high-temperature resistant polymer dielectrics is an effective method to increase the density of deep traps and trap depth. These fillers can act as trap centers to immobilize the charge carriers and constrain their mobility inside polymer composites, accordingly leading to the reduction in conduction loss. As for the electrode-limited conduction loss, charge carriers from the electrode can gain sufficient energy provided by thermal activation to overcome the energy barrier at metal-dielectric interface and increase the conduction loss. increasing the barrier height at the electrode/polymer interface is helpful for the suppression of electrode-limited conduction loss. Inserting a charge-blocking layer such as highly insulated inorganic and organic layers between the electrode and polymer dielectric can significantly increase the barrier height for the charge injection from the electrode.

From this, we unify the bulk and electrode-limited conduction losses and simultaneously suppress these two types of conduction loss through the surface engineering of polymer composites dielectrics. The leakage current at high temperatures and electric fields is significantly inhibited and the breakdown strength is greatly improved compared with un-modified polymer dielectrics. Accordingly, the polymer composites dielectrics exhibit superior capacitive performance with high discharged energy density and discharge-charge efficiency at high temperatures.

Printed Piezoelectric Transducers for Highly Integrated Motion, Vibration and Magnetic Waves Harvesting: From Simulation-Guided Design to High-Throughput Fabrication Philipp Schäffner, Asier Alvarez Rueda, Oliver Werzer, Andreas Petritz, Jonas Groten and Barbara Stadlober; Joanneum Research Forschungsgesellschaft mbH, Austria

Many application fields for energy harvesting require compact devices featuring a high integration density that can be realized with low-cost, high-throughput fabrication methods. We present multiple types of energy harvesters (EH) based on compact printed piezoelectric transducers for energy harvesting of motions, vibrations and magnetic stray fields in home and industrial environments. The EH design is guided by FEM simulations to optimize both conversion efficiency and electrical output characteristics to meet the requirements of low-power IoT electronics.
For smart wearable and healthcare applications, we have previously demonstrated a 2.5 µm thin imperceptible energy harvesting device with integrated, ultraflexible organic diodes for rectification.[1] Most recently, we accomplished a few millimeter thin smart floor piezoelectric harvester that generates up to 6 µJ/step at only 1 mm vertical displacement.[2] For harvesting of machine vibrations under realistic conditions, we demonstrate an energy harvesting system tuned to the main vibration frequency (50 Hz) of an electric vacuum pump. It is capable of harvesting up to 138 mJ per day, which is sufficient to power a wireless sensor node for condition monitoring of the engine.[3] Finally, we will take a look at the simulation-driven design of weak magnetic stray field (~100 µT) harvesters with in-situ tunable resonance frequency and < 1 mm displacement amplitude.

Ultra-High Durability and Performance of a Proton Composite Membrane containing long-Chain Amino Sulfonated Poly(arylene ether) and Cerium Oxide-Titanium Carbide over 1000 Hours for Hydrogen Fuel Cells Ae R. Kim, Milan B. Poudel and Iyappan Arunkumar; Jeonbuk National University, Korea (the Republic of)

As a key component of proton exchange membrane fuel cells (PEMFCs), the durability of the proton exchange membranes (PEMs) directly determines the service life of the PEMFCs. In this study, poly(arylene ether) containing amino and trifluoromethyl units (AFPAE) was synthesized by nucleophilic aromatic polycondensation followed by nucleophilic substitution to obtain butyl sulfonated poly (arylene)(SAFPAE). CeO_2-TiC prepared by the hydrothermal process were incorporated into the SAFPAE matrix and the content of the CeO_2-TiC was optimized. The morphological, physicochemical, and electrochemical investigation of the prepared membranes demonstrated that the random dispersion of the CeO_2-TiC in the SAFPAE matrix improves the thermal and mechanical stability as well as water adsorption, ion exchange capacity and proton conductivity. Particularly, the optimized SAFPAE/CeO_2-TiC exhibited high current output and power output at 20% relative humidity and 60 °C outperforming commercial membranes. Most importantly, the SAFPAE/CeO_2-TiC composite membrane demonstrated MEA durability over 1100 h under low humidity 20% RH operating conditions and was about 4.4 times more stable than pristine SAFPAE. SAFPAE with a special structure of hydrophilic backbone containing trifluoromethyl group and long aliphatic sulfonic acid group to create nano-sized proton conduction channels whereas, TiC provides mechanical support and CeO_2 improves the durability of PEM by scavenging free radicals. Therefore, the SAFPAE/CeO_2-TiC composite membrane reported in this study is a potential candidate for high-performance and durable PEMFC, suggesting its applicability in future large-scale PEMFC.

5:00 PM EN02.09.06
Synthesis Characterization and Electrochemical Evaluation of Quaternized Poly(2,6-dimethyl-1,4-phenylene oxide)/Ionic Liquid Composite Membrane for Anion Exchange Membrane Fuel Cell Application Ramasamy Gokulapriyan, Beom Ho Kim, Hyo Bin Kwak and Dong J. Yoo; Jeonbuk National University, Korea (the Republic of)

Quaternized poly(2,6-dimethyl-1,4-phenylene oxide) (QPPO) serves as a polymer electrolyte membrane facilitating hydroxide ion conduction, whereas with limited hydroxide conductivity and certain physiochemical drawbacks. To address this, modifications are necessary to enhance its overall performance. Composite membranes of QPPO and an ionic liquid were fabricated using the solvent casting technique. The ionic liquid, which contains quaternized imidazole groups, enhances hydroxide transport pathways within the QPPO membrane. Varying weight % of the ionic liquid were incorporated into the QPPO membrane during fabrication. The role of the ionic liquid in the QPPO membrane is to increase the bound water content and develop a hydrogen bonding network with the hydroxide ion transport channels, thereby increasing the hydroxide ion conductivity. Remarkably, the optimized QIL-8% composite membrane exhibits superior hydroxide conductivity compared to the QPPO membrane, achieving 135 mS cm^{-1} at 90 °C, while the QPPO membrane reached 56 mS cm^{-1} at the same temperature. Additionally, the QPPO/ionic liquid composite membranes exhibit appreciable water uptake, swelling ratio, thermal, and mechanical properties. In single-cell tests, the QIL-8% composite membrane achieves a maximum power density of 328 mW cm^{-2} at 60 °C, under conditions of 70% humidity on the anode side, 100% humidity on the cathode side, and an H_2/O_2 flow rate of 100/200 mL min^{-1}. Overall, this study illustrates the enhancement of QPPO membrane performance through the incorporation of synthesized ionic liquids.

5:00 PM EN02.09.07
Efficient Hot Electron Transfer and Improved Lifetime of Charge Carriers at The 1P Hot State in Sb_2Se_3/CdSe p-n Heterojunction Arshdeep K. Sohal[1], Tanmay Goswami[1], K. Justice Babu[1] and Hirendra N. Ghosh[2]; [1]Institute of Nanoscience and Nanotechnology, India; [2]National Institute for Science Education and Research, India

Utilization of hot carriers is very crucial in improving the efficiency of solar energy devices. In this work, we have fabricated Sb_2Se_3/CdSe p-n heterojunction through cation exchange process for the very first time and explored their interfacial photophysical processes with help of ultrafast transient absorption spectroscopy. In the transient study, the heterosystem was consisted with both the signature of Sb_2Se_3 and CdSe. Interestingly, the 1P excitonic bleach was found to be more prominent in the heterosystem. This is itself a testimony for hot electron migration from Sb_2Se_3 to CdSe QDs. From the comparative dynamic profiles, we found that both the 1P and 1S bleach signals are slower in the heterosystem, which again substantiates the electron migration phenomena. In fact, the hetero-system slowed down the 1P signal more efficiently than that of the 1S one. This is an incredible observation, as hot electron migration influenced the separation of charge carriers in a hot excitonic state (1P), not in the usual lowest excitonic state (1S). Enhanced charge carrier lifetime of the hot state would be helpful in the extraction of those charge carriers in a device set up. Our detailed spectroscopic investigation in this p-n heterojunction would help in the fabrication of many new heterojunctions and uplift the field of condensed matter based opto-electronic devices.

5:00 PM EN02.09.08
Machine Alignment Methods for Precision Roll-Forming of A5052 Aluminum Sheets: Achieving Smooth Finishes and Microstructure Evaluation. Krishna S. Bhandari; Jeju National University, Korea (the Republic of)

The roll-forming process stands as a crucial technique in shaping metal sheets across diverse industries, ranging from jewelry and aerospace to the automobile sector. Ongoing research endeavors center on achieving precision in shaping and minimizing defects, with a particular focus on challenges like spring-back—the tendency of a metal sheet to revert to its original shape post-formation. This scientific investigation has a dedicated purpose: to enhance the alignment of roll-forming machines, thereby ensuring the production of precise and smooth profiles. The study places special emphasis on a5052 aluminum sheets, a material prevalent in various industrial applications. Delving into the specifics, the research scrutinizes the intricacies of roll-forming a5052 aluminum sheets, providing a comprehensive examination of the associated challenges and opportunities. Beyond this, the study explores the integration of cutting-edge technologies to optimize the alignment and formability of roll-forming machines. These technologies encompass laser alignment, real-time feedback sensors, CNC systems for precise control, machine learning algorithms for adaptive processes, and finite element analysis for comprehensive simulation. The overarching objective is clear: to optimize both the alignment and formability of the roll-forming process, which will be used in sensor-making technology to additive manufacturing and nanomaterials. Through this, the research aims to contribute to the advancement of manufacturing techniques, ensuring the production of high-quality and accurately shaped metal profiles and materials across various industrial applications.

5:00 PM EN02.09.10
A Skin-Wearable Triboelectric Nanogenerator for Self-Powered Motion Monitoring and Energy Harvesting Agha A. Jan, Seungbeom Kim, Junhyung Kim, Sangyeop Lee, Uhyeon Kim and Seok Kim; Pohang University of Science and Technology, Korea (the Republic of)

Self-powered and wearable pressure sensors based on triboelectric nanogenerators (TENGs) have gained attention as promising candidates for tactile sensing and energy harvesting because of their design compatibility and ability to operate at low frequencies. While much research has focused on enhancing tribo-negative materials for flexible TENGs, the limited choices for tribo-positive materials have been a limiting factor. A crucial challenge in the development of wearable sensors is achieving biocompatibility without compromising broad-range sensitivity and energy-harvesting capabilities. Here we report a TENG based skin-wearable and self-powered pressure sensor by a simple fabrication using layer by layer deposition method. The flexible layered triboelectric nanogenerator (L-TENG) features a dielectric-to-dielectric configuration, with polytetrafluoroethylene (PTFE) and polymethyl methacrylate (PMMA) films serving as negative and positive triboelectric layers, respectively. These layers are sandwiched within a flexible and biocompatible polydimethylsiloxane (PDMS) matrix. A nanostructured PDMS surface obtained by oxygen plasma served as the structural backbone for the bottom indium tin oxide-copper electrode and overlying tribo-positive PMMA layer. The self-powered L-TENG sensor exhibited a broad range dual pressure sensitivity of 7.287 mV/Pa for low pressure and 0.663 mV/Pa for higher pressure ranges. Additionally, the L-TENG sensor adeptly detected physiological motions such as wrist extension and flexion, and finger bending angles while efficiently harvesting wasted energy from routine physical activities like walking and jogging. Notably, the maximum peak-to-peak voltages of 18.3 V and 57.4 V were measured during these motions. The L-TENG holds vast potential in wearable technology, spanning applications in healthcare, human-machine interfaces, and the powering of microelectronics from physical activities.

Keywords: skin-wearable, self-powered, wearable pressure sensing, triboelectric nanogenerator (TENG), energy harvesting, human motion monitoring

5:00 PM EN02.09.11
Tribovoltaic Devices based on Sliding Contact TiO2 Films Andris Sutka[1], Kaspars Malnieks[1], Peter C. Sherrell[2] and Osvalds Verners[1]; [1]Riga Technical University, Latvia; [2]RMIT University, Australia

Tribovoltaic (TV) devices are motion-based energy harvesters with high local current densities that can be generated. Debate remains surrounding the fundamental charge generation mechanism of TV devices. Here, we study the charge generation mechanism for TV device fabricated from thin films of the world's most common oxides, TiO2. We compare the TV performance under contact with metals of varying work functions, contact areas, and applied pressure. The resultant current density shows little correlation with the work function of the contact metal and a strong correlation with the contact area. Considering other effects at the metal−semiconductor interface, the thermoelectric coefficients showed a clear correlation with the tribovoltaic current density. We put in front the need to consider a variety of mechanisms to understand the tribovoltaic effect and design future exemplary TV devices.

SESSION EN02.10: Energy Harvesting Devices and Applications

8:30 AM *EN02.10.01
Surface Charge Effects: An Advantage for Enhancing The Piezoelectric Conversion Efficiency in GaN NWs Noelle Gogneau[1], Pascal Chretien[2],

Amaury Chevillard[1], Tanbir Kaur Sodhi[1,2], Szu-wei Chen[1], Laurent Couraud[1], Laurent Travers[1], Jean-Christophe Harmand[1], François Julien[1], Maria Tchernycheva[1] and Frederic Houze[2]; [1]Center for Nanosciences and Nanotechnologies, France; [2]Group of Electrical Engineering of Paris, France

For powering micro-devices with strong dimension constraints (smaller than 1 cm^2 or 1 cm^3), it is crucial to develop ultra-compact piezoelectric nanogenerators characterized with a high conversion efficiency per surface/volume unit. To reach this objective, we must both improve the electromechanical conversion efficiency of the active material and optimize the generator design to maximize the piezoelectric system performances in response to the environmental mechanical and vibration inputs.
1D-nanostructures have emerged as system of interest for developing ultra-compact piezoelectric generators. This interest lies in their quasi-lattice perfection and large surface-to-volume ratio, which confer to NWs larger degree of elastic deformation without mechanical deterioration and higher sensitivity to applied forces in comparison with their 2D-film counterparts and conventional bulk piezoelectric materials. In addition, sub-100 nm-wide NWs present the particularity to exhibit specific properties that can lead to a strong modulation of their characteristics. Among these “new properties”, we can cite the exaltation of the piezoelectric coefficients, the formation of nano-contact at the NW/electrode interface allowing an enhanced energy harvesting, or the modulation of the free carrier concentration due to the surface charge (SC) effects. Regarding this last property, simulations have recently established that these SC effects can be advantageous for improving the piezoelectric response of the NWs, since they can limit, in given conditions, the screening by the free carriers of the piezoelectric charges.
Since the expression of the SC effects depends on the NW dimensions and on the NW environment (in other terms of the soft matrix embedding them into nanogenerator devices), the in-depth understanding of the relationship between the SC effects and the piezoelectric conversion capacities of the NWs is now a prerequisite for further improving the device performances and thus approaching a future technological transfer.
To investigate the SC effects in sub-100 nm-wide GaN NWs, we use a systematic multi-scale analysis going from the growth of the GaN NWs by plasma-assisted Molecular beam epitaxy and their possible post-treatment for modulating their surface trap density, to the fabrication and testing of piezoelectric nanogenerators, passing through the characterization of single NWs using nano-characterization tools based on atomic force microscope equipped with electrical modules.
We experimentally highlight that the electromechanical coupling coefficient of GaN NWs is strongly affected by the expression of the SC. By finely adjusting the NW dimensions, we demonstrate that the SC effects can be advantageous for strongly improving the electromechanical conversion efficiency of GaN NWs up to 43%. We also establish that the piezoelectric response of the GaN NWs is sensitive to their direct environment. We confirm experimentally that the SC are useful for improving the piezo-conversion, and evidence that by properly engineering the GaN NWs surfaces, the piezoelectric response of the GaN NW-based nanogenerators can be enhanced. Finally, by architecting the nanogenerator design with regard to the deformation mode (direct compression or vibration) and the targeted application, we demonstrate generated power density in the μW-mW/cm^3 range in response to mechanical inputs miming the environmental ones (equivalent forces of few Newton in the 1-200 Hz frequency range).

9:00 AM EN02.10.02
Versatile Thiol-Amine Chemistry for The Synthesis of Complex Chalcogenides and Chalcohalides: New Opportunities to Develop Earth-Abundant Materials for Energy Applications Ivan Caño Prades[1], David Rovira Ferrer[1], Maykel Jiménez Guerra[1], Jonathan Turnley[2], Marcel Placidi[1], Joaquim Puigdollers[1], Rakesh Agrawal[2] and Edgardo Saucedo[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Purdue University, United States

Earth-abundant chalcogenides and chalcohalides are garnering substantial attention as innovative semiconductors compatible with solar energy harvesting, thermoelectric, pyroelectric applications and other optoelectronic technologies.[1] Among them, van der Waals materials possess an anisotropic crystal structure resulting from covalently-bonded ribbons along one crystallographic direction, which leads to unique electrical properties (e.g. enhanced carrier transport) when the material is correctly oriented. Among recent successes $Sb_2(S,Se)_3$ solar cells have achieved efficiencies above 10%[2], and SbSX (X=I,Br) micro-scale devices have been synthesized for the first time showing excellent optoelectronic properties[3]. However, although the synthesis techniques used so far have enabled significant progress, it is necessary to explore manufacturing routes that are more cost-effective, scalable and versatile in terms of composition and chemical doping.

Molecular precursor ink deposition is an excellent approach for thin film synthesis, being a low-energy, low-cost and versatile method, allowing various compositional analysis by modifying the stoichiometry of the precursor solutions, its integration into distinctive scalable deposition methods (including roll-to-roll coating), and deposition on flexible and non-planar substrates. In particular, thiol-amine solvent systems have recently demonstrated great potential to synthesize chalcogenide compounds (typically poorly soluble in polar solvents), producing promising results for Cu_2ZnSnS_4 and $BaZrS_3$, but there is still little information regarding van der Waals materials with low-dimensionality.[4,5]

In this work, Sb_2Se_3, Sb_2S_3 and $Sb_2(S,Se)_3$ thin films have been synthesized by dissolving either the chalcogenide itself or the constituent elements into different mixtures of ethandithiol and amines/diamines, followed by spin-coating and a short hot-plate annealing at 300 C. Then, different post-deposition treatments have been explored using a tubular furnace under chalcogen atmosphere to coalesce crystallites and to selectively orient texture in the (00l) direction, improving the quality of devices. Additionally, different doping strategies have been investigated to tune the conductive type and carrier concentration. For n-type doping, Sb_2Se_3 samples have been prepared incorporating NH_4Cl and $SbCl_3$ to the precursor solution (Cl-doping).[6] On the other hand, p-type doping strategies have been investigated through Sn-doping and synthesis of Se-rich samples, resulting in an increase of the V_{oc} of photovoltaic devices. Structural, compositional and electronic characterization have been performed by X-ray diffraction, microscopy, X-ray and UV photoelectron spectroscopy (determination of valence band and Fermi level), Seebeck coefficient and JV measurements.

Additionally, the universality of the thiol-amine solvent for chalcogenides will be discussed, presenting its successful implementation for synthesis on other systems, including emerging chalcohalides (e.g. SbSI, SbSeI) and Ag-based anti-perovskites (Ag_3SI). The latter has a cubic structure analogous to standard perovskite (switching anions by cations and vice-versa), bandgap around 1 eV, and shows superionic behavior above room temperature. Overall, this work demonstrates the viability of thiol-amine solvents to synthesize a broad range of cutting-edge complex chalcogenide materials, allowing composition and doping control, and opening the door to explore new properties for energy harvesting applications.

Self-Assemblies of Piezoelectric Metabolites and Their Energy Harvesting Applications Rusen Yang; Xidian University, China

Piezoelectric metabolite materials have received increasing attention in recent years owing to their inherent biological nature and efficient energy conversion capability, and piezoelectric metabolite self-assemblies are considered as promising smart materials for energy, sensor, robotics, healthcare, and many other areas. Rational material design is important to enhance their piezoelectric and biological activity. Herein, recent advancements to piezoelectric biomaterials, such as amino acids and peptide-based micro/nanostructures, are provided. Synthetic methods, morphological features, and piezoelectric performance of piezoelectric biomaterials are presented. The effect of growth direction, phase and structure of piezoelectric biomaterials on their piezoelectric activity are discussed. The applications of piezoelectric biomaterials in the field of nanogenerators are provided at the end.

Materials for Triboelectric Energy Harvesting: Current Situation and Some Thoughts Alain Sylvestre[1], Simon-Emmanuel Haim[1] and Armine Karami[2]; [1]University Grenoble Alpes, CNRS, Grenoble INP, G2Elab, Grenoble, France; [2]CNRS, France

The triboelectric effect is as old as the hills, and the first reported effects of electrification date back to Thales of Millet in 600 BC . However, it was only in the 17th century that experimental evidence of triboelectricity was found, and in the next century that electrostatic generators began to appear, their benefits not being exploited until much later. Triboelectric generators for energy harvesting are a very recent development, not even 15 years old. The advent of these generators and their popularity stem from the work of Prof. Zhong Lin Wang and his team at the Georgia Institute of Technology. They develop triboelectric nanogenerators (TENGs). Paying attention with the 'nanogenerator' term, which should not be taken to mean a nanometer-sized generator, but a generator that generally includes nanomaterials within it. More generally today, TENG is the established term for triboelectric generators dedicated to energy harvesting, even if nanomaterials are not present. While the basic concept of triboelectricity is well established, with positive and negative charges separating when two materials rub or make contact, many questions remain. This separation of charges is not necessarily two-sided (i.e. negative charges on one material and positive charges on the other), and research has shown the co-presence of positive and negative charges on the same surface after contact. Generally, electron transfer is involved, but sometimes also ion transfer, as well as material transfer when surfaces come into contact: in some situations, it's a point of debate. Likewise, the development of nanocomposites raises another question regarding the ranking of these new materials in the classification of the triboelectric series. Some studies show that preconditioning of materials can promote or conversely reduce triboelectricity: is there a sound strategy for implementing this route? As far as the basic operating modes for developing TENGs are concerned, there are several approaches: vertical contact-separation, sliding, free-standing, single electrode… Should one mode be favored over another in terms of expected performance if application requirements do not dictate it? How is performance in terms of energy harvested or produced truly calculated or estimated, and how can performance be easily compared between TENGs?
Through an abundant panorama of works from the literature on TENGs and their applications, we will attempt to shed light on some of these questions, and to highlight the advantages, difficulties and cautions to be taken in the announced promises in the actual use of these generators for energy harvesting. We will also present our research work on TENGs through the development of a test bench dedicated to the precise characterization of these materials in sliding mode, as well as a consolidated theoretical study enabling us to evaluate performance on resistive or capacitive loads. This theoretical study also led to a proposal for optimal TENG operation, which we then validated experimentally.

10:45 AM EN02.10.05
Sustainable Energy Harvesting by Employing Biocompatible Ferroelectric Molecular Cu(II) Complexes Rajashi Haldar; Indian Institute of Technology Bombay, India

To address the escalating global energy consumption, resulting in swift depletion of non-renewable fossil fuels, it is imperative to explore alternative approaches. A smart way to tackel this problem is harnessing abundant, renewable but otherwise wasted environmental energies (vibrations, pressure, heat, solar, tidal) and converting them into useful electrical energy, with the help of the self-powered nanogenerators (SPNGs). Researchers have employed pure inorganic materials like bulk oxides (perovskites and ceramics), polymers, organic molecules, even peptides and organic-inorganic hybrid structures for this purpose. [1] Among these, the oxide systems show excellent piezo and ferroelectric as well as energy harvesting properties but they suffer from huge disadvantages like costly high temperature synthesis methods, almost zero mechanical flexibility, tunability of properties in the long-range and of course bio-incompatibility due to the presence of toxic heavy metals. In case of polymers or peptides, stabilizing the polar ferroelectric state which is required for the application purpose (for example β-state of PVDF) is an extremely daunting task. Alternatively, hybrid organic-inorganic perovskite systems offer low temperature and easy processing method, as well as great output performances but these systems also suffer from a number of problems, including the stability of reactive metal halide bonds under aerobic conditions and moisture and the presence of toxic heavy metal ions like lead (Pb). [2] By careful molecular engineering and controlled design strategy, we have overcome almost all of the above-mentioned caveats by employing bio-compatible discrete molecular complexes, which is an active area of research in the current scenario. They are light weight, mechanically flexible and easily polarizable in presence of an electric field, making them perfectly suitable to use in various energy harvesting nanogenerators. The Cu(II) metal based molecular complexes synthesized by us not only provide high values of piezoelectric co-efficients (d_{33}= 10-30 pm/V), comparable to the popular bulk materials like $LiNBO_3$, ZnO and polymers like PVDF, PVDF-TrFE etc., but also has appreciable spontaneous polarization values as well, leading to appreciable energy harvesting capabilities in both single-crystal and composite forms. We have shown to obtain a high value of output voltage of 8 V, power density of 0.85 $\mu W/cm^2$ and an output current of 5 μA, with a discrete molecular ferroelectric complex which is used in the form of a flexible composite film with a non-polar polymer matrix polyvinylalcohol (PVA), and . [3] Our efforts successfully afford an efficient route of energy harvesting which can be modified for futuristic applications. On the other hand, an open circuit output voltage of (7.4 V/cm^2) and an appreciable pyroelectric coefficient of 29 $\mu C/m^2K$ was obtained by a single-crystal based device made by us using another biocompatible molecular complex. In contrast to the single crystals of conventional bulk oxides, single crystals of the discrete molecular complexes are easier to synthesize and can be envisaged for various other applications such as anisotropic sensors, ultrasound transducers, and acoustic devices so as to avoid multidirectional mechanical and heat flux fluctuation aided artifacts. This opens up a lot of possibilities for molecular complexes in real-world applications.

Bilayers, Gradients and Funnels: Harvesting Excess Energy to Surpass The Shockley-Queisser Limit Constantin Tormann[1], Dorothea Scheunemann[1], Clemens Goehler[1], Tanvi Upreti[2] and Martijn Kemerink[1]; [1]University of Heidelberg, Germany; [2]Linköping University, Sweden

Compared to inorganic solar cells, the energy losses in organic photovoltaics (OPV) are still (too) large. Fortunately, a significant fraction of these losses results from a relatively slow relaxation of photogenerated charges in the disorder-broadened density of states. In previous work, we have already shown that the slowness of the mentioned thermalization leads to a 0.1-0.2 V higher open circuit voltage (Voc) in OPV devices than would be expected for instantaneous thermalization. Here, we will discuss strategies to harvest even larger parts of this excess energy, even beating the Shockley-Queisser limit for the constituent material.
Specifically, we experimentally and numerically show how inhomogeneous distributions of electron donating and accepting phases can be used to entropically drive positive and negative charge carriers towards the anode and cathode, respectively. First, we analyze simple step-like bilayer devices without any built-in voltage (Vbi) to single out the contribution of said mechanism to Voc. Next, we discuss how more suitably chosen gradient profiles can be used to improve actual devices that do have a finite Vbi. Combining these concepts, we demonstrate that in optimized, funnel-shaped morphologies the enhanced, non-equilibrium diffusivity of photogenerated charges can be rectified, allowing to surpass the Shockley-Queisser limit for the same material in absence of gradients and under near-equilibrium conditions. Finally, we use a cellular automaton model to show a realistic pathway to generate the proposed funnel-like morphologies in actual donor-acceptor blends.

Degradation Mechanisms in Highly Efficient Organic Solar Cells Based on Non-Fullerene Acceptors Klaus Meerholz; Univ of Cologne, Germany

During recent years, organic solar cells composed of different donor-acceptor-type polymers and non-fullerene acceptors (NFA) have approached and even exceeded the 20% hurdle. However, still questions remain regarding their long-term stability, i.e. the degradation processes involved.
Here, we present a comprehensive study on ca. 10 different NFAs and try to derive structure/property relations regarding their chemical stability / degradation mechanism, respectively. Experiments include the 1) analysis of the chemical stability of the NFAs themselves by mass spectrometry, 2) electrochemical stability tests of the radical anions (“electrons”), 3) solar cell devices based on PCE-12 and the NFAs, respectively, as prepared ones as well as aged by accelerated life-time testing, and 4) chemical analysis of the degradation products.

11:15 AM *EN04.08.02
Interface Engineering in Organic Solar Cells Huiqiong Zhou; National Center for Nanoscience and Technology, China

Solution-processed organic solar cells (OSCs) have attracted much attention due to their low cost, flexibility and high transparency. Recently, the power conversion efficiency (PCE) of OSCs is approaching 20%. However, the unsatisfied interface issues limit further improvement in PCEs and stability of OSCs, through affecting the physical processes such as exciton separation and/or charge transport/extraction/recombination in the device. Our recent study on interface engineering in OSCs has shown that the introduction of new electron transporting materials could enhance the PCE and suppress the photodegradation at the cathode interface, achieving over 10000 hours of storage and thermal stability in OSCs. An original strategy for selecting an optimal interfacial layer based on the surface energy has been proposed, to optimize the morphology of the active layers by regulating the surface energy and its microscopic distribution of the interface layer. At the end, we have constructed semi-transparent devices by utilizing optical microcavities, achieving high uniformity of device transmission and controllable adjustment of reflection color, which offers a viable design strategy for semi-transparent OSCs toward applications in next-generation smart photovoltaic windows.

SESSION EN04.02: Concepts and Designs of Efficient Organic Photovoltaics II

Organic Solar Cells: Concepts towards The Single Junction Limit and Beyond Christoph J. Brabec[1,2] and Larry Lüer[1]; [1]FAU Erlangen-Nuremberg, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Thanks to the development of novel electron acceptor materials, power conversion efficiencies (PCE) of organic photovoltaic (OPV) devices are now approaching 20%. Further improvement of PCE is complicated by the need for a driving force to split strongly bound excitons into free charges, causing voltage losses. This presentation discusses recent approaches to find efficient OPV systems with minimal driving force, combining near unity quantum efficiency (maximum short circuit currents) with optimal energy efficiency (maximum open circuit voltages). We discuss apparently contradicting results on the amount of exciton binding in recent literature, and approaches to harmonize the findings. We then present a comprehensive view on motifs providing a driving force for charge separation, namely hybridization at the donor:acceptor interface and, polarization effects in the bulk. Apart from controlling the energies of the involved states, these motifs also control the dynamics of recombination processes, essential to avoid voltage and fill factor losses. Importantly, all motifs are shown to depend on both molecular structure and process conditions. The resulting high dimensional search space advocates for high throughput (HT) workflows. The final part of the presentation presents recent concepts for architectures allowing to bypass the single junction limit for organic photovoltaics.

2:00 PM *EN04.02.02
Critically Assessing The Potential and Challenges of Machine Learning for Designing Organic Photovoltaic Devices Martin Seifrid; North Carolina State University, United States

Due to the complexity of designing organic semiconducting materials (OSCs) and devices, researchers have long used computational tools to screen candidate molecular structures and gain further insight into physical processes. Machine learning (ML) is emerging as a powerful tool for accelerating this even further. While processing conditions are known to play a significant role in determining PCE, ML has so far only been used to predict the power conversion efficiency (PCE) of organic photovoltaics (OPV) from molecular structure alone

In this talk, I will discuss how we can integrate device fabrication data into ML models, as well as best practices of ML for OPV. One of the key challenges of gathering such datasets is the difficulty of extracting data from the literature. We have created the first dataset containing both molecular structure and device processing conditions. We find sobering evidence of the low quality of such data, which is particularly important if we seek to use ML to accelerate the development of OPVs and OSCs. Many are aware of the widespread problem of the low quality of literature data, which affects numerous fields and is not discussed openly enough. The question for the future of ML and meta-analyses based on datasets derived from the literature becomes: what do we do going forward?

I will initiate a discussion with the community about what we can do to make generating large OPV and OSC datasets easier and more reliable, both in the short and long terms. In particular, I will outline a set of standards that could help make reporting and collecting data more robust.

2:30 PM EN04.02.04
Experimental and Theoretical Understanding of The Y6:Rubrene Upconverting Bilayer Jarvist M. Frost and Hanbo Yang; Imperial College London, United Kingdom

Photon upconversion via triplet-triplet annihilation (TTA) is a promising approach to overcome the detailed balance limit of single band-gap photovoltaics. However, low triplet densities in the bulk often limit TTA efficiency. Recently, Izawa et al. [1] demonstrated a new bilayer upconversion architecture comprising a non-fullerene acceptor (Y6) and rubrene. Photoexcitation of Y6 is believed to produce charge-separated states at the interface, which then recombine with normal spin statistics (avoiding the energetic cost of inter-system crossing), generating a high density of triplets in the rubrene which then fuse into higher-energy emissive singlets. Despite this promising 2021 result, details of the upconversion mechanism and dynamics in this system remain largely unexplored.

We study this system with complementary experimental and theoretical techniques.

Performing optical and electron paramagnetic resonance (EPR) spectroscopy helps us understand the nature of the photo excited states and how their population changes with time. EPR spectroscopy directly detects the spin of the photo excited species.
Interpretation of this data is greatly helped by simulation of the non-adiabatic dynamics. This multi scale modelling approach starts with molecular dynamics (to get a representative interface) and then quantum chemistry (to understand and parameterise the eigenstates) and then a path-integral approach to the non adiabatic dynamics (to simulate the reduced density matrix as a function of time). The path integral approach to non adiabatic dynamics offers a principled and consistent hierarchy of simulation methods from fully quantum to semi-classical, ensuring trust in the results.

Our motivation for developing such a detailed understanding of the Izawa and Hiramoto Y6:Rubrene bilayer system is to then be able to make suggestions for synthesis for materials that have a higher upconversion efficiency and therefore can be used to engineer high efficiency photovoltaic systems. These upconversion based system would use large band-gap solar cells, making use of earth abundant chalcogenide and oxide semiconductors, and non donor-acceptor organic photovoltaics.

3:30 PM *EN04.03.01
Delocalisation in Device-Scale Drift-Diffusion Models Ivan Kassal; University of Sydney, Australia

In organic semiconductors, even small amounts of delocalisation can considerably enhance charge and exciton transport as well as charge separation. We recently developed delocalised kinetic Monte Carlo (dKMC), the first computational method able to describe the motion of partially delocalised charges [1] and excitons [2] in organic semiconductors on mesoscopic time and length scales, while considering the critical influence of energetic disorder, quantum-mechanical couplings, and polaron formation. dKMC has revealed new, basic physics of transport in organic semiconductors and can explain why mobilities predicted by traditional kinetic Monte Carlo are usually too low, showing that delocalisation over just a few molecules can increase mobilities by orders of magnitude [1,2]. Similarly, applying dKMC to the two-body problem of charge separation reveals a decisive enhancement of internal quantum efficiency (IQE) from a small amount of delocalisation [3,4].

In this talk, I will show that the benefits of delocalisation—first identified on the mesoscopic scale—also improve performance on the macroscopic, device scale. To do so, we have parametrised drift-diffusion models using dKMC to arrive at the first delocalisation-aware device models.

Our parametrisation relies on several new computational approaches. The first is jumping kinetic Monte Carlo (jKMC), a model that approaches the accuracy of dKMC, but with a computational cost comparable to conventional KMC [5,6]. Rates entering jKMC are simple modifications of ordinary Marcus hopping and can be used to include delocalisation effects in any existing KMC code. The low computational cost of jKMC also allows us to carry out the first calculations of all remaining parameters necessary for drift-diffusion models, which could not be computed by fully quantum techniques. These include steady-state mobilities, generation rates, and carrier recombination rates, processes that we show are also significantly affected by even modest delocalisation.

Putting all the ingredients together, our delocalised drift-diffusion code [7] can compute JV curves while faithfully capturing charge and exciton delocalisation. The results confirm the importance of delocalisation in device performance and help explain recent high-performance blends that defy explanation using classical models.

Disorder-Effect on The Photophysics of Solution Processed Polymeric Photovoltaic Materials through Sequential QM/CMD Approach L. R. Franco[1], C. Marchiori[1], D. Valverde[2], Yoann Olivier[2], Ellen Moons[1] and Moyses Araujo[1]; [1]Karlstad University, Sweden; [2]University of Namur, Belgium

The development of new organic photovoltaic materials based on non-fullerene acceptors (NFAs) has led to a significant increase in the power conversion efficiency of organic photovoltaics (OPV) in the last years [1]. However, the fundamental understanding of the charge photogeneration mechanism at the molecular level is still lacking, a scientific challenge whose solution could be the watershed in the discovery of novel OPV materials. To contribute to this end, we have developed a multi-scale method that combines Quantum Mechanics (QM) calculations and Classical Molecular Dynamics (CMD) simulations within the scope of a sequential QM/CMD approach [2] to assess the photophysics of organic-polymeric photovoltaic materials. Despite being a well-established method to study small and medium-sized molecules in solution, it has not yet been applied to investigate polymer films cast from solution. Our methodology starts with the simulation of film formation through solvent molecules evaporation procedure using CMD simulations. Afterwards, additional CMD simulations are carried out on the obtained film to generate uncorrelated configurations to be subsequently used on the properties' calculations. The latter is assessed through an electronic embedding scheme where a pre-defined molecular region of the generated configuration is treated at the QM level, incorporating explicit effects of the environment. The quality of the force field parameters adopted in the CMD simulations has also been carefully analyzed. For the QM calculations, density functional theory (DFT) and its time-dependent version (TD-DFT) have been employed along with the wavefunction-based method ADC(2) [3]. The latter has been widely used as reference method to assess the accuracy of TD-DFT method on the description of vertical excitation energies and excited-state potential energy surfaces. We have focused the study on the PF5-Y5 polymer [4,5], which can be seen as a model system to study covalently bound donor-acceptor interfaces. First, we have analyzed the structure of the films, focusing, for instance, on the tendency to stabilize π-π stacking conformations. Then, the dynamics and molecular environment effects on the electronic transitions have been quantified with an improved description of the optical absorption. The recently developed double-hybrid functionals [6], which include a MP2-like perturbation in the correlation part, were found to be the best theory-level within TDDFT framework to describe the singlet-triplet energy gaps in this complex donor-acceptor polymer. The comparisons with experimental results confirm the suitability of the developed s-QM/CMD approach, highlighting the importance of properly describing the disorder, dynamics and molecular environment effects in the modeling of the electronic properties of OPV materials.

A Digital Twin to Overcome Long-Time Challenges in Photovoltaics Larry Lüer[1], Ian Marius Peters[2], Ana Suncana-Smith[3], Eva Dorschky[3], Björn M.

Eskofier[3], Frauke Liers[3], Jörg Franke[3], Martin Sjarov[3], Matthias Brossog[3], Dirk Guldi[3], Andreas Maier[3] and Christoph J. Brabec[1,2]; [1]i-MEET, Germany; [2]Forschungszentrum Jülich GmbH, Germany; [3]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The recent successes of emerging photovoltaics are largely driven by innovations in material science. However, closing the gap to commercialization still requires significant innovation to match contradicting requirements such as performance, longevity and recyclability. In this contribution, we suggest a layout of a Digital Twin for PV materials able to provide the necessary acceleration of innovation.
The rationale of the Digital Twin is to bridge the gap between first principles calculations, currently not able to predict the crucial solid state properties for emerging PV materials, and high throughput experimentation, currently not able to provide datasets of the necessary scale needed to train generative artificial intelligence (AI) models.
The crucial aspect of our layout is featurization, that is, identifying and retaining only the relevant and non-redundant information present in a dataset. This allows designing fast proxy experiments and surrogate models across all relevant scales. We will learn more from faster and simpler experiments, and the resulting massive (but cheaply acquired) dataset will allow building better approximate models for solid state structure from chemical structure, closing the gap for molecular inverse design, that is, from a set of desired properties all the way back to molecular structure.
Our proposed layout of the Digital Twin combines machine learning approaches, as performed in materials acceleration platforms (MAPs), with physical models and digital twin concepts used in engineering. This layout will allow using high-throughput (HT) experimentation in MAPs to improve the parametrization of quantum chemical and solid-state models. In turn, the improved and generalized models can be used to obtain the crucial structural parameters. HT experimentation will thus yield a detailed understanding of generally valid structure-property relationships. Most importantly, and different from black-box AI approaches, our physics-aware approach can benefit from human abstract thinking, increasing the chance for breakthrough innovation.
Building a Digital Twin in PV materials is agile. We show that some of the necessary building blocks are already available, doing useful work today. Finally, we identify promising approaches for the open challenges such as fast scale-bridging surrogate models and large scale optimization under uncertainty.

4:30 PM EN04.03.04
The Photocurrent in Organic Solar Cells does not Vanish at Open-Circuit Clemens Göhler, Mónica Dyreby, Alexander Flamm and Martijn Kemerink; Institute for Molecular Systems Engineering and Advanced Materials, Universität Heidelberg, Germany

Organic solar cells (OSCs) had been around for several decades while scoring considerably worse efficiencies than their inorganic counterparts. Recently discovered materials have closed the gap considerably and optimized OSCs can now reach close to 100% conversion yield between incident photons to extracted charge carriers. Still, they suffer from losses to the open-circuit voltage and fill factor, and conventional equilibrium charge carrier dynamics fail to exactly reproduce their current-voltage-characteristic. Instead, non-thermalized charge carrier distributions—due to incomplete relaxation in a disordered density of states—provide better agreement, yet with at times uncommon ramifications: here, we will show that a non-neglectable photogenerated current under open-circuit conditions is a general feature of OSCs.

In more detail, we have investigated the internal quantum efficiency of photogenerated charges in non-fullerene acceptor OSCs in the steady state. Therefore, we have first measured their external quantum efficiency spectrum under different experimental conditions, including a constant background illumination. Utilizing a small signal light source, modulated at low frequencies, and varying the working conditions from reverse (collection) to forward (injection regime) fields, allowed us to determine how efficient photogenerated charges can be extracted at any point on the current-voltage-curve. We find that while the yield decreases towards open-circuit, it does not vanish completely and some 10-20% of the short circuit yield remains; therefore, the resulting photocurrent has to be compensated by charge injection in order to reach zero net current. In a subsequent step, we were able to reproduce these experimental findings with kinetic Monte-Carlo device simulations involving non-equilibrium dynamics with decoupled photo- and injection currents.

How 'Hot' are The Charges in OPV? Priya M. Viji, Constantin Tormann, Clemens Goehler, Dorothea Scheunemann and Martijn Kemerink; Universität Heidelberg, Germany

The question of whether charge transport in operational organic solar cells (OSC) occurs far-from-equilibrium or not is of significant practical and fundamental importance. While the equilibrium picture of the OSC assumes that the photogenerated charge carriers quickly lose their energy and attain lattice temperature, kinetic Monte Carlo (kMC) simulations of OSC have consistently shown that photogenerated charge carriers are extracted before reaching thermal equilibrium energy: the population thermalizes, albeit to an effective temperature that exceeds that of the lattice [1].
Probing the distribution of photogenerated charges possessing this excess energy has proven to be notoriously hard. In this work, we use Johnson thermometry to measure the temperature of the photogenerated carriers carried out by cross-correlated current noise spectroscopy. Two representative material systems, P3HT:PCBM and PM6:Y6, are tested against their inorganic counterpart, silicon. The experiments univocally prove, in stark contrast to silicon photovoltaics, that charges in operational OSC are not thermalised and are almost twice as hot as the lattice. The experimental findings are confirmed by kMC simulations. The simulations show that the energetic disorder in organic semiconductors is not only the reason for slow thermalisation but also for the high effective temperature observed in the Johnson thermometry experiments.
Our results imply that OPVs are truly far from equilibrium systems, which opens realistic prospects to mitigate the thermalisation losses and eventually beat the near-equilibrium thermodynamic limit [2]. In fact, the results presented show that even regular OPVs are Hot-Carrier Solar Cells in the sense that excess energy contributes to output power.

Effects of Deposition Angle on The Thin Film Quality of Indium Tin Oxide Grown by Magnetron Sputtering Tabitha Amollo[1,2] and Qi H. Fan[1]; [1]Michigan State University, United States; [2]Egerton University, Kenya

Indium tin oxide (ITO) has been widely used as a transparent electrode in various applications including solar cells, liquid crystal displays, plasma displays, smart windows, and light emitting diodes (LEDs). Many of these applications require low-temperature deposition of ITO thin film. But it remains a challenge to achieve satisfactory electrical conductivity and optical transmittance at low deposition temperatures. This work proves that the sputtering deposition angle has significant effects on the ITO film microstructure and properties. The ITO thin films are grown by a unique single beam ion source enhanced magnetron sputtering. The sputtering and ion beam directions relative to the substrate surface are varied from 30 to 90 degrees and the film structure and properties are subsequently investigated. X-ray diffraction is used to determine the film microstructure. Atomic force microscopy (AFM) and scanning electron microscopy (SEM) are used to characterize the morphology of the thin films. The thin films' electrical conductivity and carrier mobility are determined from four-point probe and Hall effect measurements, respectively. Optical transmittance spectra are obtained using UV-Vis spectroscopy. This study contributes to the advancement of thin film growth mechanisms

5:00 PM EN04.04.02
Attaining a Remarkable Efficiency of 11.57% in a Polymer Solar Cell Submodule with a 55 cm^2 Active Area using 1D/2A Terpolymers and Nonhalogenated Solvents Hyeonwoo Jung[1], Sung-Ho Jin[2], Chang Eun Song[3] and Youngu Lee[1]; [1]DGIST, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of); [3]Advanced Energy Materials Research Center, Korea Research Institute of Chemical Technology, Korea (the Republic of)

Polymer solar cells (PSCs) employing a bulk heterojunction structure exhibit a significant potential as energy sources for advanced portable electronic devices due to their low weight, scalable roll-to-roll (R2R) processing, and cost-effectiveness. Recent advances in the design of high-performance photoactive materials and device structure optimization, have resulted in a remarkable increase in the power conversion efficiency (PCE) of PSCs, surpassing 19 %. Recently, the PM6 copolymer has been widely used in the photoactive layers of PSCs due to its high crystallinity, superior hole mobility, and strong pre-aggregation behavior. However, achieving high-performance PSCs based on the PM6 polymer normally requires the use of halogenated solvents such as chloroform and chlorobenzene. Unfortunately, the use of these halogenated solvents is limited in mass production because of environmental toxicity concerns. Furthermore, due to the strong temperature dependent aggregation property of the PM6 polymer, PM6-based large-area PSCs fabricated using large-scale coating methods exhibits a significant reduction in PCE. For example, PM6-based small-area (0.12 cm2) PSCs exhibits a PCE of 15.1 %. However, the PCE of PM6-based large-area (54.5 cm2) PSC submodules can be significantly reduced to 8.73 %. This decrease in performance of PM6-based large-area PSCs in nonhalogenated systems can be attributed to the oversized domains and nonuniformity in the photoactive layer, leading to an increased cell-to-module (CTM) loss. The undesirable morphology of the PM6-based photoactive layer can be controlled using a high-temperature (HT) process such as a hot solution and/or preheated substrates. However, such a complicated process is unsuitable for the production of cost effective and highly reproducible R2R PSC modules. Therefore, it is necessary to develop new p-type polymer for high-performance large-area PSC modules based on simple processes and minimize the CTM loss in nonhalogenated systems.
Terpolymers composed of three different monomers have recently attracted attention as promising p-type polymer. Terpolymers can accurately control physicochemical properties, such as frontier energy levels, light harvesting ability, pre-aggregation behavior, miscibility, and crystallinity, by introducing a third component directly into the donor-acceptor (D-A) copolymer backbone.
Herein, we synthesize a new series of 1D/2A terpolymers for developing room-temperature (RT) and nonhalogenated solvent processed high-performance PSCs submodules. The terpolymers are composed of three components: benzo[1,2-b:4,5-b']dithiophene (BDT-F), thieno[3,4-c]pyrrole-4,6(5H)-dione (TPD-TT), and benzo-[1,2-c:4,5-c']dithiophene-4,8-dione (BDD). Three PBTPttBD terpolymers (i.e. PBTPttBD-25, PBTPttBD-50, and PBTPttBD-75) are synthesized using different ratios TPD-TT to BDD composition ratios, corresponding to TPD-TT contents of 25 %, 50 %, and 75 %, respectively. The composition ratio of the TPD-TT and BDD components can be used to control the light harvesting ability, energy level, molecular ordering, and charge transport properties of the PBTPttBD polymers. A grazing incidence wide-angle X-ray scattering and contact angle analysis shows that the PBTPttBD-75:BTP-C11 blended film exhibits a predominant face-on orientation with good miscibility. The RT and nonhalogenated solvent processed PBTPttBD-75:BTP-eC11 PSC exhibit a high PCE of 15.55 %. Furthermore, PBTPttBD-75:BTP-eC11-based PSC submodules, processed with *o*-xylene under RT conditions, achieve a notable PCE of 11.57 % over a 55 cm2 active area. This PCE value is among the highest reported in single-junction PSC submodules processed with nonhalogenated solvent.

5:00 PM EN04.04.03
Green Solvent Enables Record Performance in Model PCDTBT:PCBM Through Reduced Recombination Acacia Patterson, Awwad N. Alotaibi, Obaid Alqahtani and Brian A. Collins; Washington State University, United States

Organic solar cells (OSCs) are promising as a printable and massively scalable solar energy source, with efficiencies approaching 20%. For OSC production, toxic, halogenated solvents are typically used, limiting processing options for efficiency gains as well as prospects for commercialization. Additionally, there are inadequate connections between the complex nanomorphology and charge dynamics that occur during device operation to fully exploit and enhance performance gains. Here, we show how a non-halogenated solvent CS_2 can not only reduce toxicity but also result in a record high efficiency (30% higher than previous records with traditional halogenated solvents) for a model system PCDTBT:PCBM. We apply time delayed collection field (TDCF) in a comprehensive charge loss analysis under device-relevant conditions to reveal significant suppression of bimolecular recombination that explains the performance difference. This ultimately enables enhanced absorption with thick active layers that are more relevant to industrial production. Furthermore, we apply advanced X-ray techniques to demonstrate that the enhanced device dynamics and performance originate from increased nanodomain purity and crystalline order due to altered interaction with the host solvent. Moving forward, this work reveals a new emphasis on green processing solvents for scaleup that may also enable new record OSC efficiencies.

5:00 PM EN04.04.04
Dimerized Small-Molecule Acceptors Enable High-Performance Organic Solar Cells with High Open-Circuit Voltage and Prolonged Life-Time Jinwoo Lee[1], Cheng Sun[2], Yun-Hi Kim[2] and Bumjoon Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Gyeongsang National University, Korea (the Republic of)

The power conversion efficiencies (PCEs) of small molecule acceptor (SMA)-based organic solar cells (OSCs) have remarkably increased in recent years, but their thermal and long-term stability are insufficient for commercialization. In addition, the low open-circuit voltage (V_{oc}) of OSCs, compared to those of other types of solar cells (*i.e.*, perovskite solar cells), should be addressed to further improve their PCEs. Here, we demonstrate that the dimerization of an SMA resolves the performance limitations of SMA-based OSCs, in terms of stability and V_{oc}. The dimerized SMA (DYBO) connected by a benzodithiophene (BDT) conjugated linker affords OSCs with excellent PCEs (> 18%), which outperform OSCs based on its monomer counterpart (MYBO, PCE ~ 17.1%). The electron-donating BDT linker in DYBO effectively upshifts the lowest unoccupied molecular orbital energy level and reduces the voltage loss, synergistically increasing the V_{oc} of DYBO-based OSCs. Importantly, DYBO-based OSCs exhibit excellent thermal and photo stability. For example, DYBO-based OSCs retain more than 80% of their initial PCE even after 6000 hr of thermal exposure at 100 °C, whereas the PCE of MYBO-

based OSCs sharply degrade to ~80% of their initial value in only 36 hr. The improved stability of DYBO-based OSCs is attributed to (1) the high glass transition temperature (T_g) of DYBO of 179 °C (the T_g of MYBO is 80 °C) due to its extended chain, which stabilizes the blend morphology under thermal stress, and (2) the improved miscibility of DYBO with the BDT-based polymer donor. Thus, we highlight the significance of the molecular design of dimerized SMAs in realizing OSCs with excellent PCEs and stabilities.

Design of Mechanically-Robust Naphthalenediimide-Based Polymer Additives for High-Performance, Intrinsically-Stretchable Organic Solar Cells Chulhee Lim[1], Sanghun Park[1], Dong Jun Kim[1], Sunjoo Kim[2], Taek-Soo Kim[1] and Bumjoon Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Chung-Ang University, Korea (the Republic of)

High-molecular-weight electro-active polymer acceptor (P_A) is effective in simultaneously increasing photovoltaic performance and mechanical integrity of organic solar cells (OSCs) based on a polymer donor (P_D) and a small molecule acceptor (SMA). In this work, we develop a new naphthalene diimide (NDI)-based P_A, named P(NDI2OD-TCVT), and employ it as a P_A additive in a P_D:SMA blend to fabricate high-performance and mechanically robust OSCs. Copolymerization of NDI, bithiophene, and cyano-vinylene units ensures the n-type characteristics of the P(NDI2OD-TCVT). Noticeably, the cyano-vinylene group alleviates the crystalline nature of the NDI and bithiophene units, providing inter-domain bridges by being a tie molecule. As we vary the weight-averaged molecular weight (M_w) of the polymer, we find that the backbone structure enables a significant reduction of the critical molecular weight that ensures mechanical robustness. High crack-onset strain (COS) of 30.1% is achieved in the P(NDI2OD-TCVT) film with a relatively low M_w of 109 kg mol^{-1}, which is a stark contrast to the COS value (1.8%) of the reference P(NDI2OD-T2) film with similar M_w of 126 kg mol^{-1}. In addition, we find that incorporation of P(NDI2OD-TCVT) enhances the photovoltaic performance of the P_D:SMA-based OSCs, achieving a high power conversion efficiency (PCE) of 16.8%. Benefitted from the significantly enhanced mechanical properties of P(NDI2OD-TCVT), we also demonstrate the highly efficient and intrinsically stretchable organic solar cells (IS-OSCs). The IS-OSCs with 10 wt% of P(NDI2OD-TCVT) featured a PCE of 12.6% and retained 85% of the initial PCE after 100 cycles of stretching at 20% strain and releasing, outperforming those of P(NDI2OD-T2)-based IS-OSCs.

5:00 PM EN04.04.07
Highly Stable Organic Solar Cells with Fullerenol as Interfacial Compatibilizer Guan-Lin Chen, Shih-Hao Wang, Kai-Wei Tseng, Ching-I Huang and Leeyih Wang; National Taiwan University, Taiwan

The emerging technology of organic solar cells faces challenges related to long-term durability due to the combined effects of moisture, thermal, and photo stresses. To address this issue, we introduced a novel interfacial stabilizer, fullerenol, $C_{60}(OH)_x$, which substantially improved the durability of organic solar cells to cope with environmental stress. This study utilized X-ray photoelectron spectroscopy and Fourier-transform infrared spectroscopy to confirm that $C_{60}(OH)_x$ forms hydrogen bonds with both the oxygen atoms of ZnO and the fluorine atoms of Y6. As a result, the compatibility and charge transport between the electron transport layer (ETL) and the organic photoactive film were significantly improved, thereby stabilizing the interface. By incorporating the ZnO/$C_{60}(OH)_x$ ETL, the power conversion efficiency of the ternary PM6:Y6:$PC_{71}BM$ solar cell was increased from 16.1% to 17.8%. More importantly, such ZnO/$C_{60}(OH)_x$ device maintained 80% of its original performance (T_{80} lifetime) after being annealed at 65 °C for more than 6,973 hours in N_2. The T_{80} lifetime at room temperature (25 °C) was estimated to exceed 34,635 hours. Detailed characterizations demonstrated that $C_{60}(OH)_x$ can passivate the surface with regard to defects and effectively facilitated free radical scavenging. Overall, the ZnO/$C_{60}(OH)_x$ device retained 91% of its initial PCE after continuous light soaking with a solar simulator at one-sun intensity for over 1,200 hours in N_2. For a relative humidity of 50% at 25 °C, the un-encapsulated ZnO/$C_{60}(OH)_x$ device exhibited a T_{80} exceeding 1,323 hours. The successful showcasing of this new interfacial stabilizer can spur additional research and momentum towards the advancement of future photovoltaic technologies.

5:00 PM EN04.04.08
Atomic Layer Deposition of Tin Oxide Electron Transport Layer for High-Performance Organic Solar Cells with Inverted Structure Lorenzo Di Mario, David Garcia Romero, Han Wang, Eelco K. Tekelenburg, Sander Meems, Teodor Zaharia, Giuseppe Portale and Maria Antonietta Loi; University of Groningen, Netherlands

OSCs with the inverted n-i-p structure are considered more suitable for commercialization compared to those with conventional p-i-n structure, due to the superior stability of the materials used. However, the highest efficiencies (close to 20%) are currently achieved exclusively using the conventional structure. In fact, efficiencies above 17% from OSCs with the inverted structure are scarcely reported, mainly due to the low values of fill factor (FF) which characterize devices in this configuration. Electron and hole transport layers play a crucial role in determining the performance of OSCs. Therefore, a proper selection of them is essential to achieve higher efficiency in OSCs with inverted structure and to close the gap with devices with conventional structure.
Transparent conductive oxides are usually employed as electron transport layers (ETLs) in OSCs with inverted structure. Among them, zinc oxide (ZnO) is the most studied and adopted, since it provides a good band alignment with the organic semiconductors and it can be easily deposited from solution. Tin oxide (SnO_2) represents a valid alternative to ZnO as ETL, offering superior transparency to the visible light and higher electron mobility. Moreover, unlike ZnO, SnO_2 is reported to have an excellent ambient stability and to not cause any photocatalytic degradation of the organic materials [1].
A broad use of SnO_2 as ETL in OSCs is currently hindered by the difficulty in fabricating films of the material with low defect density. SnO_2 films for OSCs are often obtained from solution processing, starting from nanoparticle colloidal dispersions, with the result of a high defect density, especially on the surface. Moreover, organic ligands, used to stabilize the nanoparticle dispersions, often leave residuals in the deposited film, which can compromise the interface with the active layer. As a result, the overall performance of OSCs with SnO_2 as ETL is often poor, with in particular low values of FF [2].
In this work, highly efficient OSCs with inverted structure are demonstrated by using as ETL SnO_2 deposited by atomic layer deposition (ALD). ALD is an industrial grade technique which can be applied at the wafer level and also in a roll-to-roll configuration. ALD allows obtaining compact layers of SnO_2 with exceptional quality and low defect density. SnO_2 fabricated by ALD already attracted attention in the research field of photovoltaic, for perovskite [3] and tandem solar cells [4]. Nonetheless, its use in OSCs is scarcely reported and its potential not yet fully exploited. By using ALD to deposit the SnO_2 ETL, we fabricated OSCs with PM6:L8-BO active layer, reaching a champion efficiency of 17.26% and a record FF of 79%. The devices fabricated outperform not only solar cells using SnO_2 nanoparticles casted from solution (PCE 16.03%, FF 74%) but also those utilizing the more common ZnO (PCE 16.84%, FF 77%). Furthermore, the OSCs with ALD SnO_2 show a higher stability under illumination in comparison with those utilizing ZnO. The outstanding results achieved are demonstrated to arise from a superior quality of the interface between the ALD SnO_2 film and the active layer and, thus, from a reduced charge carrier recombination [5].

5:00 PM EN04.04.09
Anisotropic Nature of Vibronic Coupling, Singlet Fission and Triplet Transport of Single Crystalline Acenes (n=4-6) Yi Rao; Department of Chemistry and Biochemistry, Utah State University, United States

The escalating global energy predicament implores for a revolutionary resolution—one that converts sunlight into electricity—holding the key to supreme conversion efficiency. We embark on the exploration of the principle of generating multiple excitons per absorbed photon, a captivating concept that possesses the potential to redefine the fundamental confines of conversion efficiency, albeit its application remains limited in photovoltaic devices. At the nucleus of this phenomenon are two principal processes: multiple exciton generation (MEG) within quantum-confined environments, and singlet fission (SF) inside molecular crystals. The process of SF, characterized by the cleavage of a single photogenerated singlet exciton into two triplet excitons, holds promise to potentially amplify photon-to-electron conversion efficiency twofold, thereby laying the groundwork to challenge the detailed balance limit of solar cell efficiency. Our discourse primarily dissects the complex nature of SF in crystalline organic semiconductors, laying special emphasis on the anisotropic behavior of SF and the diffusion of the subsequent triplet excitons in single-crystalline polyacene organic semiconductors. We initiate this journey of discovery by elucidating the principles of MEG and SF, tracing their historical genesis, and scrutinizing the anisotropy of SF and the impact of quantum decoherence within the purview of functional mode electron transfer theory. We present an overview of prominent techniques deployed in investigating anisotropic SF in organic semiconductors, including femtosecond transient absorption microscopy and imaging as well as stimulated Raman scattering microscopies, and highlight recent breakthroughs linked with the anisotropic dimensions of Davydov splitting, Herzberg-Teller effects, SF, and triplet transport operations in single-crystalline polyacenes. Through this comprehensive analysis, our objective is to interweave the fundamental principles of anisotropic SF and triplet transport with the current frontiers of scientific discovery, providing inspiration and facilitating future ventures to harness the anisotropic attributes of organic semiconductor crystals in the design of pioneering photovoltaic and photonic devices.

5:00 PM EN04.04.10
Probing Nanomorphology of Guest Component in Ternary OPVs Tanner M. Melody, Acacia Patterson and Brian A. Collins; Washington State University, United States

Recent advancements in organic photovoltaic (OPV) solar technology show that with the inclusion of a third guest component to the traditional binary devices, efficiencies can surpass 20% which are comparable or even above competing technologies. The addition of ternary components contribute to increasingly complex nanomorphologies that most characterization techniques cannot determine. Our objective is to identify these key nanostructures that maximize the ternary advantage. First, we characterize the thermodynamic mixing of donor and acceptor molecules in phase-separated equilibrium states via surface energy measurements combined with the blend demixing experiments we have previously demonstrated using spectral X-ray microscopy. We then determine the dominant paradigm ternary morphology that enhances performance using traditional GIWAXS in conjunction with chemical sensitive nanoprobes such as spectrally resolved RSoXS analysis and STXM directly on high performance active layers. Uncovering the morphological pathways that these ternary components provoke will allow us to inflect the fabrication process of these devices to maximize the ternary advantage for commercially viable, high-performance OPVs.

5:00 PM EN04.04.11
Solvent Effect on Doctor Blade Coating Process for Large-Area Organic Solar Cell Modules Soonil Hong[1], Byoungwook Park[1], Chandran Balamurugan[2], Jinho Lee[3] and Sooncheol Kwon[2]; [1]Korea Research Institute of Chemical Technology, Korea (the Republic of); [2]Dongguk University, Korea (the Republic of); [3]Incheon National University, Korea (the Republic of)

Efforts to commercialize organic solar cells (OSCs) through the development of roll-to-roll compatible modules have faced challenges in optimizing printing processes to achieve laboratory-level performance in fully printable OSC architectures. In this study, we present efficient OSC modules fabricated using only printing methods. The effect of processing solvents on the morphology of key layers applied with the doctor blade coating method, including the hole transport, photoactive, and electron transport layers, was systematically evaluated with a focus on processability. The results showed that bathocuproine (BCP) processed from volatile alcohols required a delicate balance between wettability and vaporization, which contrasts with the results for spin-coated films. The fully printed OSC modules with uniform and continuous BCP layer formation achieved a remarkable power conversion efficiency of 10.8% with a total area of 10.0 cm2 and a geometrical fill factor of 86.5%.

Charge Generation in Neat Non-Fullerene Acceptor Domains Kaila Yallum and Natalie Banerji; University of Bern, Switzerland

Non-fullerene acceptors (NFAs) are exciting molecules allowing high efficiency in organic photovoltaic (OPV) blends with conjugated polymers. Interestingly, charges can also be generated by neat NFA films without additional donor. To understand the origins of exciton dissociation in neat NFAs, we have looked at the impact of aggregation, external electric field end non-linear effects. We used solvatochromism in order to gain insight on charge redistribution after excitation in isolated NFAs. We found that unaggregated NFAs feature a more dipolar excited state, revealing intramolecular charge transfer (ICT) character. This ICT character, however, is not enough to generate separated charges. Aggregation is the key to exciton dissociation in neat NFAs, which we observe with TA of solutions and films of several different NFAs. To explore the impact of an electric field on exciton dissociation in neat NFA devices, we used bias-dependent external quantum efficiency (EQE) and transient absorption (TA) spectroscopy. Electromodulated differential absorption (EDA) measurements then allowed us to observe charge transport under bias. Excitation correlation spectroscopy and fluence-dependent TA finally revealed how non-linear effects can increase the charge yield. Lastly, we comment on whether the neat domain charge generation significantly affects the photophysics of blends or not.

9:00 AM *EN04.07.02
Understanding Processes Limiting Charge Collection in Organic Solar Cells Oskar Sandberg[1] and Ardalan Armin[2]; [1]Abo Akademi University, Finland; [2]Swansea University, United Kingdom

Organic solar cells have many advantageous properties including tailorable light absorption, low embodied energy manufacturing, structural conformality,

and low material toxicity. However, owing to their low charge carrier mobilities, the competition between extraction and recombination of photogenerated charge carriers is an important factor limiting the performance of organic solar cells. This competition is further complicated by the inevitable presence of contact-induced dark carriers in the device. In this work, we clarify the effect of contact-induced dark charge carriers on photovoltaic device performance through theoretical device simulations. We find that first-order recombination between photogenerated carriers and contact-induced dark carriers is the dominant bimolecular recombination channel limiting charge collection in state-of-the-art organic solar cells. Furthermore, analytical models for the current-voltage characteristics are established. This work provides intriguing insights into the fundamental limits set by charge transport in organic photovoltaic devices.

9:30 AM EN04.07.03
Singlet Exciton Fission Sensitization of Silicon Photovoltaics Narumi Wong[1], Collin F. Perkinson[1], Kangmin Lee[1], Aaron Li[1], Kwanyong Seo[2], William Tisdale[1], Moungi G. Bawendi[1] and Marc Baldo[1]; [1]Massachusetts Institute of Technology, United States; [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

The efficiencies of crystalline silicon solar cells, the current industry standard for photovoltaics, are approaching the Shockley-Queisser limit. One method of going beyond this limit is to sensitize the silicon (Si) by using organic molecules that can perform singlet exciton fission (SF), a carrier multiplication process that can create two triplet excitons (electron-hole pairs) from a single photon. Successful transfer of these two triplet excitons to silicon can result in increased photocurrent and improved efficiencies.

Previous work has shown coupling between Si and the archetype singlet exciton fission material tetracene in the presence of passivating interfacial layers of hafnium oxynitride through magnetic-field dependent photocurrent [1]. However, the electrical device performance did not show an enhancement from tetracene due to insufficient passivation and poor carrier extraction from the surface [1]. We have developed a new interfacial heterostructure that both provides surface passivation of defects and facilitates intermediate charge transfer states for triplet exciton transfer from tetracene to silicon. Additionally, using silicon photovoltaic device architectures with shallow junctions and high carrier extraction efficiency at the surface, we demonstrate enhancements in short circuit current from singlet exciton fission in tetracene for the first time.

9:45 AM EN04.07.04
Electroabsorption Spectroscopy to Probe Charge Transfer Character in Donor/Acceptor Materials for Organic Photovoltaics Urvashi Bothra[1], Robert J. Westbrook[1], Demi Liu[1], Jian Wang[1], Mark Ziffer[2] and David S. Ginger[1]; [1]University of Washington, United States; [2]Columbia University, United States

We perform electroabsorption (EA) spectroscopy to understand charge transfer in polymer donor/acceptor blend systems comprised of three different acceptors: (i) fullerene acceptor, (ii) non-fullerene acceptor (IT-series), and (iii) non-fullerene acceptor (Y-series). We observe that the EA spectrum of polymer/fullerene blends and the blend based on 3,9-bis(2-methylene-((3-(1,1-dicyanomethylene)-6,7-difluoro)-indanone))-5,5,11,11-tetrakis(4-hexylphenyl)-dithieno[2,3-d:2', 3'-d']-s-indaceno[1,2-b:5,6-b']dithiophene (IT-4F) exhibit features which primarily correspond to first derivative of absorbance at the first optical transition, suggesting localized exciton formation upon photoexcitation. In contrast, the EA spectrum from the blend based on 2,2'-((2Z,2'Z)-((12,13-bis(2-ethylhexyl)-3,9-diundecyl-12,13-dihydro-[1,2,5]thiadiazolo[3,4-e]thieno[2",3'':4',5']thieno [2',3':4,5]pyrrolo[3,2-g]thieno[2',3':4,5]thieno[3,2-b]indole-2,10-diyl)bis(methanylylidene))bis (5,6-difluoro-3-oxo-2,3-dihydro-1H-indene-2,1-diylidene))dimalononitrile (Y6) is dominated by second derivative of absorbance spectrum, indicating formation of excited state with charge transfer (CT) characteristics upon photoexcitation. We carried out EA of neat Y6 and observed that the signal in blend originates primarily from Y6. Among the studied polymer donors and acceptors, Y6 exhibits the highest dipole moment change of 7.5±2.5 Debye, consistent with a high degree of CT character, and a relatively large polarization volume of 361±70 $Å^3$, suggesting better electron delocalization than other NFA acceptors such as IT4F. Further, we have also developed a new method to resolve CT state in the donor/acceptor blend by observing an additional feature in the EA of blend film at low energy, which is not present in the neat materials. These results provide evidence of EA spectroscopy in resolving the CT state across multiple polymer/non-fullerene acceptor blends and understanding the uniqueness of the Y6 acceptor due its large dipole moment change upon photoexcitation.

10:30 AM EN04.07.05
Elucidating The Performance Impeding Role of Exciton Dissociation in Low Offset Nonfullerene Acceptor-Based Solar Cells Atul Shukla[1], Manasi Pranav[1], Bowen Sun[1], Rong Wang[2], Larry Lüer[2], Christoph J. Brabec[2], Safa Shoaee[1] and Dieter Neher[1]; [1]University of Potsdam, Germany; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The performance of organic solar cells has made large strides with power conversion efficiencies exceeding 19%, and the milestone of 20% well within sight[1]. The emergence of non-fullerene acceptors (NFAs) has played a vital role in these advancements[2]. Particularly, organic blends comprising of NFAs with polymeric donors (D) having low energetic offset between the ionization energies (ΔE_{IE}) of the two components have demonstrated excellent photovoltaic performance with superior charge generation yields in conjunction with reduced voltage losses[3,4]. However, the process of free charge generation and the origin of performance limiting loss pathways has been a subject of debate. More specifically, the critical role of low ΔE_{IE} on the voltage losses and charge-generation efficiencies ask for a more detailed analysis. In this work, we systematically explore the role of energetic offset through methodical assessment of free charge generation process in a sample set of Y-series acceptors (Y6 and Y5) with well know polymeric donor, PM6. Herein, the PM6:Y5 material system is found to have a relatively lower energetic offset as compared to high performing system PM6:Y6. Our sample set uses the NFAs Y5 and Y6 blended with different molecular weights of the polymer donor PM6, spanning a large PCE range from 15% to 1%. This poor photovoltaic performance is further accompanied with pronounced field-dependence of free charge generation as demonstrate *via* time delayed collection field (TDCF) measurements. Using transient absorption spectroscopy (TAS), we find that the poor performing PM6:Y5 material system suffers from inefficient charge transfer at the interface, ultimately limiting the overall photovoltaic performance of Y5 based blends. We highlight the significance of driving force through field-dependent TAS measurements by demonstrating concomitant increment in free charge generation and exciton dissociation yields under the application of external electric field. These results supported with bias-dependent steady-state and transient photoluminescence studies provides a holistic view of the overall process and propounds that poor exciton dissociation is one of the main performance limiting channel in materials systems with diminishing energetic offset.

Activationless Charge Transfer Governs Photocurrent Generation in Organic Photovoltaic Blends Yifan Dong[1], Deping Qian[2], Helen Bristow[3], Tack Ho Lee[4], Hyojung Cha[5] and James Durrant[1,6]; [1]Imperial College London, United Kingdom; [2]Fujian Normal University, China; [3]King Abdullah University of Science and Technology, Saudi Arabia; [4]Pusan National University, Korea (the Republic of); [5]Kyungpook National University, Korea (the Republic of); [6]Swansea University, United Kingdom

Organic photovoltaics (OPVs) have recently shown substantive progress in device efficiency, driven in particular by advances in non-fullerene acceptor design and suppression of energy offsets between exciton (S_1) and charge-transfer (CT) states. Ultrafast charge transfer (< 200 fs) from polymer donors to fullerene acceptors has often been observed and attributed to the origin of efficient photocurrent generation in polymer:fullerene blends. While efficient charge photogeneration has also been observed in polymer:non-fullerene OPVs, several studies have reported much slower CT rates on the order of tens of ps. As suggested in Marcus theory, higher activation energy barriers could be the origin of slower CT rates. However, it remains unclear whether the suppressed S_1-CT offset and/or the hybridisation/thermal equilibrium between $S_1$and CT states would lead to higher barriers for charge generation and hinder charge transfer in such small-offset OPV blend systems. Herein, utilizing temperature-dependent transient absorption spectroscopy for a range of polymer:non-fullerene and polymer:fullerene OPV blends, we elucidate that the activation energy for charge generation is below 15 meV, implying that activationless charge generation pathway governs photocurrent generation in archetypal polymer based OPVs including the highly efficient low-offset PM6:Y6 blend. Suppression of the energy offsets in non-fullerene based OPVs does not lead to any increase in activation energy barriers for charge separation. While charge transfer is activationless, bimolecular recombination of charges proceeds with a high activation barrier of several hundreds of meV. Efficient charge photogeneration is universal among the blends studied herein and is not a limiting factor for device performance, while the geminate and/or no-geminate recombination losses appear to be the limiting factors.

11:00 AM EN04.07.07
Origin of Electric Field Dependence of Charge Generation in Organic Photovoltaics with Planar and Bulk Heterojunctions Kyohei Nakano, Yumiko Kaji and Keisuke Tajima; RIKEN CEMS, Japan

Efficient, electric-field independent charge generation in the photo-electron conversion process in organic photovoltaics (OPVs) leads to high short-circuit current (J_{SC}) and fill factor (FF). However, the origin of the electric field-dependent charge generation in OPVs is still unclear.
In this study, we fabricated bulk- and planar-heterojunction (BHJ and PHJ) type OPVs with the same donor (PM6) and acceptor (Y6) materials and investigated their charge generation process. The state energies of the singlet excited (S_1) and charge transfer (CT) states were experimentally quantified. In addition, the molecular orientation was determined by variable angle spectroscopic ellipsometry (VASE).
The charge generation process in the BHJ is electric-field independent, while that in the PHJ is strongly electric-field dependent. The state energy offset between S_1 and CT states in the PHJ is 70 meV smaller than that in the BHJ, indicating that insufficient energy offset is one of the origins of the electric-field dependent charge generation in the PHJ[1]. We also fabricated the PHJ with acceptors exhibiting different molecular orientations to figure out the effect of the relative molecular orientation between the acceptor and the donor domain on the charge generation process. We observed that the acceptor with face-on orientation to the donor domain showed field-dependent generation, whereas that with end-on (the direction of the end edge of the molecular long axis) orientated one had field-independent generation. The results suggest that the energy difference between S_1 and CT states and the molecular orientation in the BHJ film must be considered to realize high-performance OPV devices.

Triplet Excitons in Organic Solar Cells Alexander Gillett; University Of Cambridge, United Kingdom

Driven by the development of non-fullerene electron acceptor materials, the performance of organic solar cells (OSCs) has recently shown a remarkable improvement, with power conversion efficiencies nearly doubling from 11% to 19% in less than 10 years. However, the efficiency of OSCs is still lower than inorganic technologies, where efficiencies of >20% are commonplace. This is primarily due to excessive non-radiative recombination in OSCs, which reduces the open circuit voltage from the radiative limit.

In our work, we have identified recombination via low energy triplet excitons as a key factor responsible for the large non-radiative losses in OSCs. In state-of-the-art systems, such as 'PM6:Y6', up to 90% of the charge carrier recombination proceeds via triplet exciton states; this reduces the open circuit voltage by up to 60 mV. To address this issue, we propose two viable strategies. First, through the identification of systems where recombination via triplet excitons is suppressed, we demonstrate that significant hybridisation of the molecular triplet exciton and triplet charge transfer state can disfavour terminal recombination into the former. Second, we show that triplet-triplet annihilation has the potential to mitigate against triplet exciton losses by recycling up to half of these states formed back into singlet excitons, providing an opportunity for radiative recombination to occur. Therefore, our findings provide a framework to alleviate non-radiative losses via triplet excitons in OSCs, which could push efficiences towards and beyond the 20% milestone.

11:45 AM EN04.07.09
Fluorescent Emission Enhanced Efficient Organic Photovoltaic Cells Guodan Wei; Tsinghua-Berkeley Shenzhen Institute, China

Compared with non-fullerene acceptor (NFA), which has the advantages of high crystallinity and exciton diffusion coefficient, the polymer donors are limited by large Stokes shift and energy disorder, showing a lower exciton diffusion distance and higher non-radiative energy loss which limit their application in organic solar cells (OSCs). Herein, we reported a simple reverse-sensitization strategy and an organic small molecule thermally activated delayed fluorescence (TADF) material (BPhA-QAO) was designed and synthesized, which as solid additives was introduced into the widely studied PM6:BTP-4F based OSCs to enable a significant efficiency increase from 16.3% to 18.2%. The champion solar cell has efficiency close to 19.0%. Ultrafast optic and spectroscopic studies reveal that BPhA-QAO can transfer its long-lifetime singlet excitons to the polymer donor through energy transfer to ensure adequate exciton lifetime to expand its diffusion distance, and achieve better exciton dissociation efficiency. Morphological studies show that BPhA-QAO promotes the formation of more J-type aggregation for PM6, while inhibiting the stacking behavior of BPT-4F, regulating the degree of phase separation, and forming smaller domain sizes. Conductive AFM (C-AFM) shows that more thorough mixing of donor/acceptor improves the efficiency of exciton dissociation and charge transfer. This work demonstrates that the introduction of small molecule TADF materials based on the reverse-sensitization strategy is an effective strategy to achieve highly efficient organic solar cells larger than 20%.

Aggregation Control of Organic Photovoltaic Molecules toward High Performance Tao Wang; Wuhan University of Technology, China

The emergence of new organic semiconductors has driven the continuous development of organic solar cells, with the power conversion efficiency of single-junction devices having passed 19%. The strong intermolecular interactions between organic semiconductors lead to the self-assembly of them into hierarchical aggregates, which exhibits vastly different optoelectronic properties compared to those of the single molecules. Revealing and controlling the complex aggregation structure of organic semiconductors, and establishing the key relationship between structure and the power conversion process, is vitally important toward high performance organic solar cells, but remains as a grand challenge.
We have developed a number of physical and chemical approaches to tune the hierarchical aggregates of organic photovoltaic molecules: We developed the heating-induced aggregation strategy to suppress the large-size aggregation of crystalline semiconductors, realizing the conversion from large-size aggregation to small aggregation, which broadens the light absorption range and enhances exciton splitting; we developed the solution-induced aggregation strategy, realizing the conversion from random aggregation to ordered aggregation, which increases the light absorption intensity and improves charge transport; we also developed the small-molecular fibrillization strategy, realizing the conversion from short-range aggregation to long-range aggregation, which resolves the serious charge recombination issue during charge hoping and achieves a device efficiency of over 19%. The correlation between aggregates and light absorption, exciton dissociation and charge transport processes is eventually established to direct the future development of organic solar cells.

Towards High-Performance Organic Solar Cells Deposited from Nanoparticle Dispersions Felix Manger, Philipp Marlow, Jonas Armleder, Karen Fischer, Holger Röhm, Christian Sprau and Alexander Colsmann; Karlsruhe Institute of Technology, Germany

Record power conversion efficiencies of organic solar cells are most often achieved upon deposition from toxic solvents such as chloroform. Yet, organic solar cells can reach their full potential only if high performance is coupled with eco-friendly processing of organic semiconductors instead. Recent reports have demonstrated that organic nanoparticle dispersions are a viable route to combine sustainable production with maintaining high power conversion efficiencies. As of today, omitting surfactants for the stabilization of the dispersions appears mandatory when targeting highest solar cells performance since surfactants would remain in the solar cell and affect the formation of the delicate bulk-heterojunction. When using electrostatic stabilization instead, so far, only selected donors can be combined with selected absorbers in selected dispersion media to produce stable nanoparticle dispersions. In this work, design criteria will be discussed how to select the components of the dispersion. The role of the ionization potential of donors, the miscibility of donors and acceptors as well as the properties of the dispersion medium are elucidated. Stabilization concepts of the dispersions are compared for their process viability.

Ester-Functionalized Poly(thiophene vinylene) with Controlled Molecular Weights for High-Performance Intrinsically-Stretchable Organic Solar Cells Tan Ngoc-Lan Phan, Jinwoo Lee and Bumjoon Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Poly(thiophene vinylene)s (PTVs) are a promising type of polymer donors (PDs) for organic solar cells (OSCs) owing to their advantages of simple chemical structures and straightforward synthesis. However, the structural rigidity of PTVs results in the formation of thin films with inadequate mechanical properties for application in intrinsically stretchable (IS)-OSCs. In this work, we prepare a new ester-functionalized PTV with controlled molecular weights (MWs) (PETTCVT-X, X = L, M, and H) and demonstrate efficient and mechanically durable IS-OSCs. The crystallinity of the PTVs increases gradually with increasing MW, yielding enhanced hole mobility and suppressed charge recombination of the OSCs. Moreover, both the mechanical stretchability and electrical properties of the PTVs are improved notably with increasing MW. Consequently, rigid-OSCs featuring a PTV with the highest MW (PETTCVT-H) exhibit the highest PCE (15.3%) and crack-onset strain (COS, 8.3%) among the series, compared to lower values for the low- (PETTCVT-L, PCE = 9.7% and COS = 1.2%) and medium-MW counterparts (PETTCVT-M, PCE = 12.5% and COS = 4.3%)-based OSCs. Accordingly, the IS-OSCs utilizing PETTCVT-H present the highest initial PCE (10.1%) and stretchability (strain at PCE80% (retaining 80% of the initial PCE) = 16%). This work leverages the use of PTV for high-performance IS-OSCs.

Unraveling The Impact of Polymer and Solvent Additives on Aggregated Y6 Thin Films using Electroabsorption Spectroscopy Sudhi Mahadevan[1], Shanchao Ouyang[1], Liu Taili[2] and Sai Wing Tsang[1]; [1]City University of Hong Kong, China; [2]Yunnan Normal University, China

Organic photovoltaic cells (OPVs) using Y6 non-fullerene acceptors (NFA) have recently achieved record-breaking efficiencies with negligible photovoltage loss. According to GIWAXS and theoretical calculation results, Y6 exhibits unique molecular packing, significantly contributing to the overall charge transfer (CT) properties. In this report, we will demonstrate the application of electroabsorption (EA) spectroscopy to examine the impact of different aggregates on the intermolecular CT characteristics of Y6 and also the directional molecular orientation in thin films. To probe the intermolecular interactions in Y6, we fabricated and tested solid-solvation thin films by dispersing Y6 molecules in various organic polymers. We also used solvent additives such as DIO and CN to study the aggregation effect and corresponding charge transfer characteristics of Y6 in the second harmonic EA spectrum. Interestingly, the added polymers and solvent additives lead to aggregation-induced spectral shifts and broadening of both optical absorption and electroabsorption spectra. The differences in aggregated and non-interacting molecular distribution due to solvent additives in Y6 have been quantitatively evaluated using Franck-Condon analysis. From EA fitting results, it is found that along with increased dipole moment, the change in polarizability during aggregation contributes to the strong CT character, which has been overlooked in previous works. An exciton recombination model is proposed to validate the CT property by considering the spatial overlap of the electron-hole wavefunctions. These findings give insight into the impact of different polymer and solvent additives on the morphology and CT characteristics of Y6 thin films. Also, this can be an important step towards upscaling highly efficient organic photovoltaics.

3:30 PM *EN04.08.05
Precise Control of Nanostrcutres in Organic Photovoltaics beyond Mixed Bulk Heterojunction Keisuke Tajima; RIKEN Center for Emergent Matter Science (CEMS), Japan

Current organic photovoltaics (OPVs) achieve high conversion efficiencies through donor/acceptor interpenetrated bulk heterojunction (BHJ) structures. In general, BHJ structures are created by simply mixing two materials, electron donor and acceptor, but there are challenges in building nanostructures that are optimal for charge generation and their stability. For example, prolonged heat treatment causes donor/acceptor phase separation, which reduces conversion efficiency. More precise control of the nanostructures in OPVs beyond the simple mixed BHJ is needed to improve the efficiency and robustness of the devices.
One strategy we have investigated is the use of photocrosslinkers. We have introduced singlet photocrosslinkers based on diazirine (2Dz) or azide (2Bx) into BHJ to stabilize the morphology of mixed BHJ films. The photocrosslinking reactions in BHJs have significant detrimental effects on the performance of OPVs. This is in striking contrast to previous reports on organic field-effect transistors, where these singlet crosslinkers can solidify the films without affecting the charge transport properties. Based on the OPV results with the layer-by-layer deposited films and the transferred films, we found that the crosslinking reactions had greater effects on the non-fullerene acceptor than on the donor polymer. The photoluminescence measurements suggested that the crosslinkers could react with the π-conjugated backbone of the non-fullerene acceptor to form trace amounts of by-products that cause strong exciton quenching. These results indicate that the use of the "universal" singlet photocrosslinkers in OPVs requires careful selection of the organic semiconducting materials and crosslinkers. In the talk, we will also discuss other strategies recently employed in our group to control nanostructures and molecular orientations in OPVs.

4:00 PM *EN04.08.06
High-Throughput Screening of Materials for Rainbow Multi-Junction Organic Solar Cells Mariano Campoy-Quiles; ICMAB-CSIC, Spain

Single-junction organic solar cells (OSC) nowadays have reached promising power conversion efficiencies around 19%. Besides new materials, going beyond the current efficiencies could, in principle, be achieved by multi-junction devices, which promise a reduction in thermalization losses [1]. For this promise to become a reality, two items should be addressed, namely, the multi-junction geometry and the screening of materials with very different gaps. In this talk, we will present a multi-junction in-plane spectral splitting geometry that we call Rainbow solar cells [2]. In this geometry, a series of sub-cells are placed next to each other laterally, and illuminated through an optical component that splits the incoming white beam into its spectral components, thus matching local spectrum and absorption for each sub-cell. The fabricated n-terminal devices are capable of extracting the maximum power of each sub-cell without the need for current matching nor processing challenges. We demonstrate the concept for PM6:IO-4Cl and PTB7-Th:COTIC-4F blends, as high and low band-gap sub-cells, respectively. In agreement with simulations, we show an efficiency increase of around 30% of the Rainbow geometry with respect to our best single junction device [2]. Finally, we use high throughput methods based on gradients on the parameters of interest [3] to screen tens of materials exhibiting either wide band gap or narrow bandgap, and thus pushing the efficiency of the Rainbow multi-junction further up.

4:30 PM EN04.08.07
Open Circuit Voltage Losses in Organic Planar and Bulk Heterojunction Solar Cells - The Role of Interfacial Energetics Richard A. Pacalaj[1], Yifan Dong[2], Tack Ho Lee[3], Yuang Fu[4], Yi-Chun Chin[1], Lucy Hart[1], Ji-Seon Kim[1] and James Durrant[1]; [1]Imperial College London, United Kingdom; [2]National Renewable Energy Laboratory, United States; [3]Pusan National University, Korea (the Republic of); [4]The Chinese University of Hong Kong, Hong Kong

The introduction of non-fullerene acceptors (NFAs) has led to a surge in the record power conversion efficiency (PCE) of bulk heterojunction (BHJ) organic photovoltaics (OPV) now exceeding 19%.[1] These achievements were made in part due to the greater flexibility in tuning their energetic levels. Narrow bandgap NFAs enable improved absorption extending into the near-infrared region. Particularly successful candidates like Y6 and IT-4F have also been shown to exhibit long exciton diffusion length exceeding 30 nm.[2] At the same time, the possibility to better match the energy levels with complementary absorption donor polymers helped to decrease the energy offset related voltage losses. Despite this reduction in interfacial energy offsets, OPVs still exhibit larger voltage losses relative to their effective bandgap than other inorganic photovoltaic technologies. A better understanding of the involved voltage losses and how to further reduce them constitutes the main challenge on the quest to breach the 20% PCE threshold.
Up until now, efficient OPVs consisted of a bulk heterojunction (~ 10nm domain sizes) to enable efficient exciton separation while also allowing for thick active layers (~ 100nm) to maximise absorption. However, the large area of the donor/acceptor interface contributes to the observed voltage losses through the increased recombination rate.[3] Given the high exciton diffusion length of NFAs like IT-4F and Y6, this raises the question of whether a planar heterojunction (PHJ) architecture could yield reduced voltage losses at the limited well-defined interface while also enabling high photocurrents through tuning the acceptor layer to the exciton diffusion length.
Here, we study the charge generation and voltage loss characteristics of a series of well-defined PHJs (including IT-4F/PM6 and Y6/PM6) produced by a polymer film transfer method[4] as well as evaporated PHJs. Through optical and optoelectronic measurements, we assess the charge generation and voltage loss characteristics compared to their BHJ counterparts. A special emphasis is put on the comparison of interfacial energetics – especially the observed morphology dependent electrostatic effects due to the high quadrupole moment in high performing NFAs. Our findings have implications for the optimisation of future low voltage loss device structures as well as for the understanding of interfacial electrostatic effects in BHJs and PHJs.

Targeting Defects on Metal-Oxide/Organic Interfaces: Maximizing The Charge Extraction of Organic Solar Cells David Garcia Romero, Lorenzo Di Mario, Feng Yan, Carolina M. Ibarra Barreno, Suhas Mutalik, Loredana Protesescu, Petra Rudolf and Maria Antonietta Loi; University of Groningen, Netherlands

Metal-oxide transport layers have become an essential building block for fabricating thin-film solar cells. In particular, the robustness, inert nature, easy processability from solution, and high carrier mobilities offered by several both n-type, such as SnO_2 or ZnO, and p-type, like NiO_X or MoO_X, have made them promising candidates for improving performance and scaling up organic solar cells[1,2]. Nevertheless, the inherent formation of surface traps during the

fabrication process, originating either from structural defects or from ligand residuals, can influence negatively the solar cell characteristics and device stability, and ultimately make them fail to become a standard transport layer.
Herein, we have studied independently two different systems: firstly an n-i-p structure using SnO_2 as the bottom n-type layer and, secondly, a p-i-n structure with a bottom NiO_X as the p-type layer. In both cases, commercially available well-known colloidal inks were employed.
For the first case, s-shaped J-V curves and poor device stability evidenced the suboptimal interface quality with SnO_2. We identified the presence of potassium ions as stabilizing ligands, staying on the film surface as trap sites. By removing them with a simple washing with deionized water, we remove the s-shape and improve the device efficiency from 12.82% to 16.26% and the stability to maintain up to ≈87% after 100 hours[3].
In the second case, a low V_{OC} is found when NiO_X is used as the hole transport layer with the same active layer. Through the combination of multiple spectroscopic methods, we pinpoint the specific NiO_X structural surface defects that are limiting the charge extraction, and we propose a passivation strategy using carbazole-based self-assembly monolayers (SAMs). We demonstrate the passivation mechanism and we generalize it by screening out several SAMs. After all the optimization, solar cells with around 18% of power conversion efficiency are demonstrated.

Combined Dynamics and Nanostructure Analyses for Paths that Maximize NFA Solar Cell Performance Brian A. Collins; Washington State University, United States

Organic solar cells stand on the precipice of >20% efficiencies and large-scale commercialization. Unfortunately, constrictive processing options and a lack of direct connections between nanostructure, device dynamics, and performance hold back the promise of this exciting technology. I will describe our efforts in combining device-relevant loss analyses with quantitative nanostructure characterization to reveal key considerations in maximizing device performance. In particular, one barrier to scaleup is runaway crystallinity of NFA solar cells where slight fluctuations in additive concentrations compromise even lab-scale devices. We find that expanding processing toward non-halogenated additives both halt runaway crystallinity and work toward less-toxic manufacturing. However, only a detailed connection between the new morphology and device dynamics can reveal the opportunities for further improvements. Applying these processing and measurement strategies will be critical to understanding and mastering new materials breakthroughs that launch the technology toward a new solar future.

9:00 AM *EN04.09.02
Multicomponent Blend Strategy for Enhanced Performance and Longevity in Organic Photovoltaics Tayebeh Ameri[1,2]; [1]Kiel University, Germany; [2]University of Edinburgh, United Kingdom

Organic photovoltaics have made remarkable progress in recent years, achieving power conversion efficiencies of over 19% in laboratory-scale devices, marking a significant step towards their commercial viability. This advancement can be attributed to the integration of non-fullerene acceptor materials and the adoption of the multicomponent/ ternary blend approach within the organic photovoltaic technology.
However, the organic photovoltaic community, focused on enhancing the power conversion efficiency, had previously overlooked the critical aspects of lifetime and stability issues for more than a decade. Recent efforts have focused on addressing these concerns, with numerous studies conducted to comprehend the degradation mechanisms and improve the overall longevity of organic photovoltaics.
This presentation will delve into the development of the ternary blend approach, which has not only elevated the power conversion efficiency but also enhanced the open circuit voltage and fill factor. We will provide insights into the working principles and the underlying mechanisms governing the open circuit voltage in ternary systems, consisting of a polymer donor, a nonfullerene acceptor, and a fullerene acceptor. Furthermore, we will explore how this approach can effectively address stability issues linked to the commonly used zinc oxide electron transport layer, thereby significantly improving the photostability of organic photovoltaics.

9:30 AM EN04.09.03
Controlling All-Polymer Solar Cell Morphology and Performance via Systematic Fluorination of Both Donor and Acceptor Polymers Yilei Wu and Zhenan Bao; Stanford University, United States

The influence of the conjugated backbone fluorination on the blend film morphology and photovoltaic characteristics of all-polymer solar cells (all-PSCs) is systematically investigated. The fluorination effect analysis of both donor and acceptor polymers is enabled by implementing a random terpolymerization strategy which produces conjugated polymers with tunable fluorine-containing monomer loading. Experimental results reveal that systematic fluorination variation greatly influences both inter-chain interactions and solubility parameters, and ultimately the degree of phase separation and morphology evolution. Specifically, increasing fluorine content for both polymers reduces blend film domain sizes and enhances donor−acceptor polymer−polymer interfacial areas, affording increased short-circuit current densities (J_{sc}). Moreover, the greater temperature-dependent aggregation (TDA) of fluorinated polymers in the solution-phase minimizes disorder and intermixed feature proliferation accompanying increasing fluorination, which would otherwise promote charge-carrier recombination, reducing cell fill factors (FF). The optimized photoactive layers exhibit well-balanced exciton dissociation and charge transport characteristics, providing solar cells with a significant power conversion efficiency (PCE) enhancement versus devices with nonoptimal fluorination content. Overall, it is shown that proper and precise tuning of both donor and acceptor polymer is critical for optimizing all-PSC performance. Modification of a single component, on the other hand, may lead to local maximum PCE. This study provides a general synthetic methodology to predictably access conjugated polymer blends with desired fluorine-content and highlights the importance of optimizing both donor and acceptor components to achieve the full potential of all-PSCs devices.

9:45 AM EN04.09.04
Structurally Pure and Reproducible Polymer Materials for High-Performance Organic Solar Cells – Insights in the Chemical Structures of PM6 and D18 Sander Smeets[1,2], Jochen Vanderspikken[1,2], Quan Liu[1,2], Tyler Quill[3], Sam Gielen[1,2], Laurence Lutsen[1,2], Koen Vandewal[1,2] and Wouter Maes[1,2]; [1]Hasselt University, Belgium; [2]IMEC, Belgium; [3]Stanford University, United States

While (push-pull) semiconducting polymers are now displaying better device performances than ever before, their commercial uptake remains limited, in part due to challenges in terms of reproducibility. Next to consistent device fabrication, continuous material quality is of high importance to obtain optimal and reliable performance metrics. Often the assumption is made that the "drawn" chemical structure is representative of the active material used in applications such as polymer-based solar cells. It has, however, become clear that this is not always the case. In this work, we assess the structures of two top-performing organic solar cell donor polymers, PM6 and D18, both for commercial and synthesized samples.[1] Using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-ToF MS) we analyze the chemical structures in detail. We also introduce an approach to limit structural defects and study the impact on device performance. Next to that, we translate the synthesis of these polymer materials to a droplet flow protocol, not only to limit batch variability but also as a means to achieve reproducible molar masses. In general, flow chemistry offers benefits such as easier scalability and enhanced safety at larger scale. Droplet-flow synthesis in particular has demonstrated excellent reproducibility, both in terms of molar mass distribution and optoelectronic properties of push-pull conjugated polymers. This allows a detailed investigation of the impact of chemical structure and molar mass on blend morphology and solar cell performance.

Understanding The Crystalline and Amorphous Morphology of Organic Solar Cells using Grazing-Incidence X-Ray and Neutron Scattering Techniques Xinhui Lu; The Chinese University of Hong Kong, Hong Kong

Organic photovoltaic molecules or polymers typically form semicrystalline thin films. It is widely recognized that the bulk heterojunction (BHJ) morphology of organic photovoltaic thin films, which consists of both crystalline and amorphous regions, plays a crucial role in determining the performance of devices. However, understanding the intricate three-dimensional multi-length scale morphology of these thin films remains a grand challenge. In this talk, we will present our recent progress on decoding the complex BHJ morphology of OPVs and developing strategies to control the morphology to enhance device performance. In addition to employing conventional techniques like GISAXS/GIWAXS, we will introduce two innovative methods: GTSAXS, which allows for the quantification of vertical nanomorphology, and GISANS combined with deuteration, a technique used to detect amorphous phase structures. Armed with these state-of-the-art scattering techniques, we investigated the optimal active layer morphology for OPVs, aiming at understanding the impacts of amorphous and crystalline phase structures on device performance and to advance the practical applications of these devices. Furthermore, these scattering techniques can also be applied in material science, chemistry, biology and condensed matter physics studies. By modifying the wavelength of the probing beam and the experimental geometry, a variety of sample types, such as solutions, powders, surfaces and thin films, can be studied, covering wide length scales as well as versatile dynamic and kinetic behaviors.

11:00 AM EN04.04.06
Evidence for Entropy-Driven Charge Separation in Non-Fullerene Acceptor/Polymer Bulk Heterojunction Kushal Rijal[1], Neno N. Fuller[1], Fatimah H. Rudayni[1,2] and Wai-Lun Chan[1]; [1]University of Kansas, United States; [2]Jazan University, Saudi Arabia

Organic photovoltaics (OPVs) based on non-fullerene acceptors (NFAs) have achieved power conversion efficiencies close to 20%. These NFA OPVs can efficiently generate free carriers at the donor/acceptor (D/A) interface despite a very small energy level offset. However, why efficient charge separation can occur with a minimal energy loss is still not clear. We will present our recent time-resolved two-photon photoemission (TR-TPPE) spectroscopy measurements on exciton dynamics in a representative NFA/polymer blend, the Y6/PM6 bulk heterojunction (BHJ). We find that charge transfer (CT) excitons are formed within a few picoseconds after the photoexcitation. Subsequently, an energy uphill process occurs in which the energy of the CT exciton is increased by 0.15 eV on the 10-100 ps timescale. We attribute this energy uphill process to the conversion of bound CT excitons to free electron-hole pairs. The observed energy uphill process is rather anormal because excited electrons typically lose their energy to the environment when no external electric field is applied. We propose that the energy uphill charge separation process is driven by entropy. The entropy-driven charge separation would be promoted by the specific nanostructure of NFA BHJs. This work is based upon work supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Award No DE-SC0024525.

11:15 AM EN04.10.03
Study on The Network Formation Mechanism of The Photoactive Domains in Organic Photovoltaics Jinsung Kim[1], Yepin Zhao[1] and Yang Yang[1,2]; [1]University of California, Los Angeles, United States; [2]California NanoSystems Institute, University of California, Los Angeles, United States

Organic photovoltaics (OPVs) have emerged as a promising technology for clean energy generation, characterized by their cost-effectiveness, solution processability, and high transparency. In recent years, there has been a spike in power conversion efficiency from the continuous development of nonfullerene small molecule acceptors. However, despite recent performance improvements, a comprehensive mechanism analysis on the network formation of the donor and acceptor domains needs more investigation. In this study, the morphology transition mechanism of the bulk-heterojunction network was studied to identify the photoactive domain formation process. In-situ UV-vis absorption analysis showed that the donor polymers established a network framework, acting as a structural body in the system, with small molecules subsequently penetrating this structure. It was also confirmed by mapping the solidified network, visually showing clear donor and acceptor domains. Crucially, the drying environment during the deposition of donor and acceptor solutions plays a pivotal role in determining the network structure. Leveraging this insight, a novel additive material that effectively controls the drying speed of acceptor molecules was employed, resulting in improved performance of OPV devices. Lastly, the system was also applied to fabricate semitransparent OPV with over 3.5 light utilization efficiency values.

11:30 AM EN04.10.04

Identify The Physical Processes occurring in Poly-Small-Molecule Acceptor-Based All-Polymer Bulk Heterojunction Solar Cells Shahidul Alam and Frédéric Laquai; King Abdullah University of Science and Technology, Saudi Arabia

For some fundamental reasons, the performance of all-polymer solar cells is behind the state-of-the-art in small molecule non-fullerene acceptor bulk heterojunction organic solar cells. This work investigates the efficiency-limiting processes in all-polymer solar cells using blends of the common donor polymer PBDB-T and PM6 with two acceptor polymers, namely PYN-BDT and PYN-BDTF. These compounds function as macromolecular absorbers with large optical cross-sections extending to around 900 nm due to their π-extended naphthalene rings. Combining data from steady-state optical spectroscopy and time-resolved photoluminescence, transient absorption, electron spin resonance, and time-delayed collection field experiments provides not only a concise but also quantitative assessment of the losses due to limited photon absorption, geminate and non-geminate charge carrier recombination, field-dependent charge generation, and inefficient carrier extraction. Kinetic parameters obtained by pulsed laser spectroscopy are used to reproduce the experimentally-measured device IV characteristics and indicate that low fill factors originate either from non-geminate recombination competing with charge extraction or from a pronounced field dependence of charge generation, depending on the donor polymer. The methodology presented here is generic and can be used to quantify the loss processes in BHJ OSCs, including both all-polymer and small-molecule NFA systems.

11:45 AM EN04.10.05
Interface Energy Level Offset of Organic Solar Cells Measured by UPS and IPES and Its Correlation with Voc and CT Exciton Energy Gyuhyeon Lee[1], Younghwan Kim[1], Min-Jae Maeng[1], Kyu-Myung Lee[1], Jong-Am Hong[1], Kyung-Geun Lim[2] and Yongsup Park[1]; [1]Kyung Hee University, Korea (the Republic of); [2]KRISS, Korea (the Republic of)

In organic light-emitting diodes (OLEDs) and heterojunction organic solar cells (OSCs), the energy offset between HOMO and LUMO, also called the transport gap (E_{tr}) is substantially different from optical gaps due to the relatively large exciton binding energies. However, the inability to independently measure the LUMO levels makes it hard to elucidate important things like electron injection barrier at the cathode in OLEDs and the voltage loss mechanisms in Voc of OSCs.

We have recently developed highly sensitive inverse photoemission spectroscopy (IPES) instrument specifically for the LUMO level measurement of organic semiconductors. In combination with the existing ultraviolet photoemission spectroscopy (UPS) we determined all the relevant transport energy levels (HOMO, LUMO, Fermi level and vacuum level) in any organic semiconductor surface and interface. In addition, combination of the electron source for IPES and the electron energy analyzer for UPS allowed us to utilize reflection electron energy loss spectroscopy (REELS) to determine the gaps. We first demonstrate that all these measurements can be performed for an identical sample as a function of thickness. We also determine the energy levels at both C60/pentacene and C60/CuPc interfaces so that the factors affecting the voltage losses that led to observed Voc value of the model planar heterojunction organic solar cells can be evaluated.

In addition, we fabricated bilayer model organic solar cells using C60/pentacene and C60/CuPc pairs. The deposition sequence of each layer was alternated resulting in four different types of devices, namely, C60/pentacene, pentacene/C60, C60/CuPc, and CuPc/C60. We confirmed that their exists interfacial energy offset difference between C60/pentacene and pentacene/C60 devices, which is also reflected in Voc values of respective devices. This is due to the difference in molecular orientation for pentacene depending on the deposition sequence in this binary system. On the other hand, we could not observe any dependence of Voc on deposition sequence of C60 and CuPc devices nor could we measure any energy offset at the interface, where the molecular orientation is expected to be independent of deposition sequence. We further investigate the charge transfer (CT) exciton energies for all the devices by using sensitive external quantum efficiency (EQE) measurement. These combined measurements led us to identify the most important parameter in determining the Voc of these model bilayer organic solar cells.

This work was supported by Korea Basic Science Institute (National Research Facilities and Equipment Center) grant funded by the Ministry of Education (2021R1A6C101A437) and National Research Foundation of Korea (NRF) BRL program grant funded by the Korean government (MSIT) (2022R1A4A3030766).

SESSION EN04.11: Interrogation and Control of Structure and Dynamics II
Session Chair: Keisuke Tajima
Friday Afternoon, April 26, 2024
Room 328, Level 3, Summit

1:30 PM *EN04.11.01
Interrogating Structure, Dynamics, and Disorder in Organic Semiconductors Chad Risko; University of Kentucky, United States

The design of π-conjugated polymers for solution-deposited organic semiconductors commonly considers the chemical modulation of (i) the π-conjugated backbone to modify the electronic and optical characteristics and (ii) the alkyl-based side chains to govern solubility. During solution deposition and solidification of the semiconductor, physical interactions among these constituents and their solution environment play an important, yet not well understood, role. Here we will discuss the development of computational models to interrogate how the chemistry of π-conjugated polymers impact polymer structure and dynamics and the resulting properties of materials derived from these building blocks. The chemical insight developed through these investigations is beginning to refine and offer new understanding essential to the development of next generation organic semiconducting active layers.

2:00 PM EN04.11.02
Overcome The Limits of Conductivity in Doped Organic Semiconductors Eva Röck and Natalie Banerji; DCBP, Switzerland

We study the conductivity of doped organic semiconductors and vary (i) the electrostatic environment with anion exchange of the dopant and (ii) the dielectric constant with oligo ethylene glycol side chains. Since organic semiconductors are commonly disordered materials such as polythiophenes, it is crucial to look at the conductivity on different length scales. The comparison between electrical four point probe and optical THz time domain spectroscopy is the experimental core of this study resulting in the conductivity over the long-range (millimeters) and short-range (nanometers) respectively.
Anion exchange from F_4TCNQ^- to PF_6^- doubles the short-range conductivity of P($g_3$2T-T) up to 610 S/cm, which is related to an increased density of contributing charges. Similarily for P(g_3BTTT) upon anion exchange the conductivity doubles to 1280 S/cm. Since PF_6^- is smaller than F_4TCNQ^- we suggest the improvement stems from a better insertion of the anion rather than an electrostatic effect. Hereby, we see an increased density of contributing

charges while their mobility is limited. This is verified by fitting the short-range conductivity with the Drude-Smith model for disordered systems. Furthermore, we track the changes in absorbance in-situ during chemical doping and electrochemical doping and find a substantial relation between polaron/bipolaron ratio and the best conductivity.
Oligo ethylene glycol side chains increase the short-range conductivity by increasing the number of contributing charges and their mobility in comparison to P3HT with alkyl side chains. We find that glycolated side chains help the absolute conductivity as well as its restoration (>90%) from the short-range (nanometers) to the long-range (millimeters) transport. The improvement hereby can be assigned to (i) the higher dielectric constant as well as (ii) lower energetic disorder. Understanding the conductivity on the short- and long-range is key for designing efficient devices based on doped organic semiconductors.

Photoelectrochemical CO2 Reduction: The Spotlight on The Light Absorber Francesca M. Toma[1,2]; [1]Helmholtz-Zentrum Hereon, Germany; [2]Lawrence Berkeley National Laboratory, United States

Light-driven CO2 reduction into chemicals is considered as a promising way to meet carbon neutral targets. Photoelectrochemical (PEC) CO_2 reduction has attracted significant attention as a prevailing way to store intermittent solar energy in fuels and chemicals as well as closing the chemical carbon cycle. Unfortunately, thermodynamically viable photocathode materials for this process favor hydrogen evolution reaction (HER), thus leading to either insufficient activity or selectivity for CO2 reduction reaction (CO2RR). Besides the thermodynamic requirement, the semiconductor/electrolyte interface also plays a pivotal role in defining the performance of photoelectrodes, which can directly affect light driven CO2RR efficiency and determine the product selectivity.
Here, we show few examples of how light absorber materials can be used in integrated photoelectrochemical cells or when directly interfaced with the electrolyte for CO2RR. Specifically, we show how one can improve the stability and performance of photoelectrodes for PEC CO2R in systems that use Cu_2O or halide perovskite materials. In addition, we will discuss how ZnTe can enable photo-generated charge carrier transfer, but also acted as electrocatalyst for boosting carbon product selectivity and suppressing HER. Our work demonstrates that the fundamental understanding of the processes at the photoelectrode/electrolyte interface allows the systematic improvement of photoelectrode stability of CO2RR selectivity.

9:00 AM EN05.01.02
CO_2 Electrolysis in Aqueous Media with Almost 100% Selectivity for CO Production by Water-Soluble Cobalt Dimethyl-Bipyridine Complex
Takeshi Morikawa[1,2], Tomiko M. Suzuki[1], Kengo Nagatsuka[2], Takamasa Nonaka[1], Yuichi Yamaguchi[2], Naonari Sakamoto[1], Takeshi Uyama[1], Keita Sekizawa[1] and Akihiko Kudo[2]; [1]Toyota Central R&D Labs, Japan; [2]Tokyo University of Science, Japan

We developed a water-soluble Co complex with dimethyl-bipyridine ligands ($[Co(dmbpy)_3]^{3+}$, dmbpy: 4,4'-dimethyl-2,2'-bipyridine), which electrochemically reduces CO_2 to CO with almost 100% selectivity in an aqueous medium without an organic solvent. The reaction overpotential was 270 mV, and the Co complex (hereafter, [Co-dmbpy]) facilitated carbon dioxide reduction reaction (CO_2RR) to produce carbon monoxide (CO) with an almost 100% selectivity (against competitive H_2 production) at a low potential of −0.80 V vs. NHE (pH 6.8). We discuss a possible CO formation mechanism based on static and *operando* analyses combined with DFT calculations.[1]
A cyclic voltammetry (CV) of [Co-dmbpy] (0.3 mmol L^{-1}) measured in an aqueous $NaHCO_3$ (0.1 mol L^{-1}) solution bubbled with CO_2 exhibited a higher

reaction current than that in Ar bubbling (adjusted to pH 6.8) within the range of -0.4 to -1.6 V (vs. NHE). The DFT calculations suggested that a ligand-decoordinated species of $[Co(dmbpy)_2]^{2+}$ is formed as an active monomer catalyst by the decoordination of one dmbpy ligand, which is consistent with an observed -1.5 eV shift in *operando* X-ray absorption spectroscopy (XANES) spectra obtained under an electrical bias in the aqueous $NaHCO_3$ (0.1 mol L^{-1}) solution bubbled with CO_2. Therefore, it is strongly suggested that a one-dmbpy-decoordinated species is the active catalyst, and a rate-determining step is a CO_2 coordination to the Co center of one-electron injected species $[Co(dmbpy)_2]^{+}$.
We have also reported artificial photosynthetic systems consisting of metal complexes and two coexisting semiconductors, which produce formic acid or CO under visible light irradiation by the Z-scheme (2-step photoexcitation) mechanism like photosynthesis in plants in a particulate dispersion setup. [2-3] The use of the aqueous dispersion of particulate photocatalysts for a membrane-free and one-compartment reactor is a simple and scalable approach to producing valuable chemicals. In particular, a system containing $[Co(dmbpy)_3]^{3+}$ generated CO with a product selectivity of 98% (and H_2 of 2%). The reaction accompanied O_2 production under visible light irradiation, which suggested this photocatalytic system utilized H_2O as an electron donor for the CO formation. The ability of electrochemical CO_2RR over the [Co-dmbpy] with a nearly 100% CO selectivity contributed to the extraordinarily high CO selectivity of 98 % in the Z-scheme photocatalytic system by receiving photoexcited electrons in the conduction band of a particulate semiconductor in an aqueous media.
CO is a desirable target product made from CO_2 and H_2O because it can be converted into various hydrocarbons via Fischer–Tropsch synthesis. Gaseous CO exhibits low solubility in aqueous media, making its collection easier than liquid products such as formic acid. Therefore, photocatalytic and (photo)electrochemical CO production using H_2O is valuable.

Molecule-Derived Coatings Improve The Selectivity and Durability of CO2 Reduction on Chalcogenide Photocathodes Joel Haber[1], John M. Gregoire[1], Yungchieh Lai[1], Lan Zhou[1], Kevin Kan[1], Nicholas Watkins[1], Jonas Peters[1], Theodor Agapie[1], Christopher Muzzillo[2] and Andriy Zakutayev[2]; [1]California Institute of Technology, United States; [2]National Renewable Energy Laboratory, United States

Direct solar-driven conversion of carbon dioxide to chemicals and fuels requires identification of efficient, durable, and selective photocathodes. Chalcogenide p-type semiconductors, exemplified by chalcopyrite $Cu(In,Ga)Se_2$ (CIGS), have been effectively deployed as photocathodes. However, selectivity toward CO_2 reduction and durability of the commonly used CdS buffer layer remain unsolved challenges. We have demonstrated that for the wide band gap $CuGa_3Se_5$ chalcopyrite absorber these challenges are well addressed by an organic coating generated in situ from an N,N′-(1,4-phenylene)bispyridinium ditriflate salt in the electrolyte. The molecular additive provides a 30-fold increase in selectivity toward CO2R products compared to the unmodified system and lowers Cd corrosion at least 10-fold. This dual functionality highlights the promise of hybrid solid-state-molecular photocathodes for enabling durable and efficient solar fuel systems. This presentation will highlight the variations in product selectivity and durability observed for different combinations of coatings derived from molecular precursors in the electrolyte with photocathodes including $CuGa_3Se_5$ and $Cu(In,Ga)Se_2$, with and without CdS buffer layers.

9:30 AM EN05.01.04
CO2 Reduction under Realistic Ambient Conditions with Directly coupled PV-EC Device Tsvetelina Merdzhanova[1], Thérèse Cibaka[1], Oleksandr Astakhov[1], Guangxin Liu[2], Chuyen Pham[2], Marc Heggen[3], Peter Strasser[4] and Uwe Rau[1,5]; [1]Forschungszentrum Jülich GmbH, Institute of Energy and Climate Research (IEK-5-Photovoltaik), Germany; [2]Forschungszentrum Jülich GmbH, Institute of Energy and Climate Research (IEK-11-HI-ERN), Germany; [3]Forschungszentrum Jülich GmbH, Ernst Ruska-Centre for Microscopy (ER-C 1), Germany; [4]Technical University of Berlin, Institute of Chemistry, Germany; [5]Jülich Aachen Research Alliance (JARA-Energy) and Faculty of Electrical Engineering and Information Technology, RWTH Aachen University, Germany

Long-term storage in molecules like fuels or other industrially useful chemicals is most relevant for counterbalancing natural yearly oscillations in photovoltaic power generation. We address this challenge via ‘artificial leaf’ approach – conversion of carbon dioxide (CO2), water (H2O) and sunlight into valuable chemical products. This approach facilitates further deployment of photovoltaics and simultaneously utilizes exhaust or atmospheric CO2 with potential to entirely close CO2 cycle. Conversion of CO2 into chemical fuels such as syngas (mixture of CO and H2 products) is demonstrated with photoelectrochemical (PEC) devices, direct electrolysis, and direct photovoltaic-driven electrolysis (PV-EC). The PV-EC approach in direct connection is attractive as a good compromise between the design flexibility and high solar to chemical efficiencies. In this work we design, and test ‘A-leaves’ with emulated PV devices reproducing IV characteristics of real PV modules in the field at most relevant irradiance/temperature combinations. The characteristic operating point were obtained using the NREL public database for SHJ module installed in Eugine USA. With our newly developed PV emulator routine any PV IV can be replicated at high accuracy and at the same PV part of the PV-EC system can be adjusted to required size matching the size of the lab scale CO2 reduction EC cell. In our work PV module of emulated area of 51.7 cm^2 drives flow-type stack EC cell (area 8.8 cm^2) with silver/gas diffusion layer (GDL) cathode [1] and iridium oxide anode. The EC cell consists of two electrode chambers separated by a Nafion membrane (N117, thickness 0.007 inch) and a 1 mol/l $KHCO_3$ electrolyte saturated with CO_2 (20 cm^3min^{-1}) flowing in both chambers.
We have chosen five most probable irradiance and temperature combinations out of variety of ambient conditions with the highest PV energy generation, i.e., the PV-EC device is optimized for the region of major PV energy generation. In our case this is 1 Sun irradiance and 45°C PV temperature. Performance, power coupling and CO and H_2 products evaluation have been investigated in the context of most relevant PV irradiance (1 – 0.2 Sun) and temperature (25 – 45 °C) obtained from real PV data. Power coupling, or power matching between the photovoltaic and electrochemical components have been quantified with ‘coupling factor’ C – coefficient indicating proximity of the working point (WP) of the PV-EC device to the maximum power point (MPP) of the PV module.
High degree of coupling, more than 0.9 and solar-to-chemical efficiency in the range from 7.5 % to 10.8 % is observed at the most relevant PV irradiance (1 – 0.2 Sun) and temperature (25 – 45 °C). Successful production of CO with by-product of H2 in the ration of 3:1 with Faradaic efficiency (F_E) of 70 - 100% was measured via chromatographic analytics. Over the experiment, operating voltages of 2.6 - 3.1 V and current densities 9 - 44.9 mA/cm^2 were observed. Energy loss analysis of PV-EC device at 1 Sun 45 °C was performed. SHJ module converts 22.5 % of solar power into electric power and due to relatively low PV-EC coupling loss, 21.3 % of the initial sun power reaches the EC cell. At the working voltage (V_{WP}) of 3.1 V and working current density of 44.9 mA/cm^2, EC operates at 70 % Faradaic efficiency and 13.8% overpotential loss that translates into solar-to-chemical efficiency (STC) of 7.5 % estimated by using the equation:
$STC = PVeff. \times C \times (Ecell/V_{WP}) \times F_{E,}$ where Ecell is the energy stored in product CO or H2 in voltage.

9:45 AM EN05.01.05
Controlling Methanol Selectivity on Immobilized Cobalt Phthalocyanine on Carbon Nanotubes for Photoelectrochemical and Electrochemical

CO_2 Reduction Calton J. Kong[1,2], Thomas Chan[2,3], Grace Rome[4], Darci Collins[4], Alex King[2,1], RajivRamanujam Prabhakar[2], Sarah Collins[4], Michelle Young[2], Mickey Wilson[4], Finn Babbe[2], Tobias Kistler[2], Myles Steiner[4], Adele Tamboli[4], Emily Warren[4], Cliff Kubiak[3], Joel W. Ager[2] and Annie Greenaway[4]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, San Diego, United States; [4]National Renewable Energy Laboratory, United States

Electrochemical CO_2 reduction (CO_2R) using heterogenized molecular catalysts usually yields 2-electron reduction products (CO, formate); recently, it has been reported that certain preparations of immobilized cobalt phthalocyanine (CoPc) produce methanol (MeOH), a 6-electron reduction product. Here, we demonstrate the significance of the role mass transport plays in CoPc selectivity to different CO_2R products. Specifically, a moderate linear flow velocity of 8.5 cm/min has the highest MeOH selectivity at 35%, with higher flow rates increasing CO selectivity and lower flow rates increasing HER, suggesting that CO is a free intermediate. We use a simple, physically mixed, polymer free preparation of CoPc on multiwalled carbon nanotubes (MWCNT) to achieve moderate MeOH selectivity in near-neutral aqueous conditions at -1.2 V vs RHE. An onset potential of -0.8 V vs. RHE for MeOH was observed with increasing Faradaic efficiency until it reaches a relative maximum at -1.2V vs. RHE and lowering as the reductive potential increases. The catalyst was made compatible with Au planar substrates using a poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) adhesion layer. Using the PEDOT:PSS adhesion layer, we integrated the CoPc catalyst onto a multijunction GaInP/GaAs three terminal tandem (3TT) solar cell, that could operate two separate electrodes at different potentials. We achieved 4% FE toward MeOH on the 3TT solar cell at +0.2 V vs RHE, demonstrating that the 3TT can be used as a platform for future study of tandem photoelectrochemical systems.

SESSION EN05.02: Perovskite and Organic Semiconductors

Organic Semiconducting Polymer Photocatalysis for Water and CO2 Reduction Iain McCulloch; University of Oxford, United Kingdom

Green hydrogen, produced from water using renewable energy, is expected to become a prominent renewable fuel of the future, providing clean, carbon neutral energy for a wide range of industrial applications. It can also provide complementary energy storage in combination with intermittent solar energy. However, competitive economic solar generated hydrogen production on a large scale remains challenging. One promising approach is photochemical water splitting, using lght absorbing nanoparticle semiconductors that can drive redox reactions on their surface. The more light the photocatalytic nanoparticle absorbs, the more efficiently it can split water into hydrogen and oxygen. Traditionally, wide bandgap inorganic semiconductors have been used for photocatalytic applications. However, these materials almost exclusively absorb UV light which only carries a small fraction (<5%) of solar energy, limiting their efficiency. In this presentation, the development of photocatalysts fabricated from organic semiconductors, chemically tuned to absorb strongly throughout the UV-visible spectrum will be discussed. We demonstrate a larger solar to hydrogen efficiency than traditional inorganic photocatalysts with the potential to achieve solar hydrogen production at a lower levelized cost. We have developed organic semiconductor nanoparticles that contain an internal donor/acceptor heterojunction between two organic semiconductors with a type II energy level offset. The donor/acceptor heterojunction greatly improves charge generation within the nanoparticles, which in turn greatly improves their hydrogen production efficiency. We demonstrate a substantial increase in the H2 production efficiency by tuning the nanoparticle composition. We also observe that the high efficiency of these nanoparticles originates from their ability to generate exceptionally long-lived reactive charges upon illumination, increasing their likelihood to participate in a photocatalytic reaction. In addition, we will discuss solution-processable, linear conjugated polymers of intrinsic porosity for gas phase carbon dioxide photoreduction. The polymers' photoreduction efficiency is investigated as a function of their porosity, optical properties, energy levels and photoluminescence. All polymers successfully form carbon monoxide as the main product, without the addition of metal co-catalysts. The best performing single component polymer yields a rate of 66 μmol h−1m−2, which we attribute to the polymer exhibiting macroporosity and the longest exciton lifetimes. The addition of copper iodide, as a source of a copper co-catalyst in the polymers shows an increase in rate, with pTA-Ph (the most active) achieving a rate of 175 μmol h−1m−2. The polymers are active for over 100 hours under operating conditions. This work shows the potential of processable polymers of intrinsic porosity for use in the gas phase photoreduction of carbon dioxide towards solar fuels.

2:00 PM EN05.02.02
Defect-Passivated Perovskite Photoanode coupled with Iodide Oxidation Reaction enabling Efficient Stable Unbiased Hydrogen Production Juwon Yun, Young Sun Park, Hyungsoo Lee, Wooyong Jeong, Chang-Seop Jeong, Gyumin Jang, Chan Uk Lee, Jeongyoub Lee, Subin Moon, Soobin Lee and Jooho Moon; Yonsei University, Korea (the Republic of)

Defect-passivated perovskite photoanode coupled with iodide oxidation reaction enabling efficient stable unbiased hydrogen production

Juwon Yun, Young Sun Park, Hyungsoo Lee, Wooyong Jeong, Chang-Seop Jeong, Chan Uk Lee, Jeongyoub Lee, Subin Moon, Soobin Lee, Sumin Kim, Junhwan Kim, and Jooho Moon*

*E-mail address : jmoon@yonsei.ac.kr

The unassisted photoelectrochemical (PEC) hydrogen production is one of the promising candidates to replace the carbon-based energy sources. However, the previously reported photoanodes have suffered from low efficiency resulting from poor light absorption and limited charge separation capability. Lead halide perovskite has emerged as a promising breakthrough to overcome the limitations of conventional photoanode materials (such as $BiVO_4$, Fe_2O_3, Ta_3N_5, Sb_2S_3, and WO_3) owing to its tunable bandgaps, excellent hole mobility, and long hole-diffusion length. These superior properties enable perovskite-based photoanode to achieve remarkable high-performance parameters including a photovoltage of ~ 1.1 V and a photocurrent density of around 23 mA cm^{-2}. However, there are still challenges in achieving competitive hydrogen production, particularly in terms of onset potential and long-term stability. The poor onset potential can be attributed to the high thermodynamic potential (1.23 V with respect to reversible hydrogen electrode (V_{RHE})) required for the oxygen evolution reaction (OER) and the sluggish kinetics of OER involving a four-electron transfer process. Moreover, the charge accumulation due to interfacial defects and slow charge transfer reaction result in efficiency loss and photoelectrode degradation.
Herein, we report a straightforward strategy to improve the onset potential and durability of perovskite photoanode. This approach involves simple defect passivation method by decorating 4-methoxyphenethylamine on electron transport layer (ETL), effectively suppressing efficiency loss and charge

accumulation at ETL/perovskite interface. Furthermore, we replace the OER with the iodide oxidation reaction (IOR) by employing an active IOR catalyst ($Co_{0.2}Ni_3S_2$) to enhance the kinetics of charge transfer reaction. The combined effects of interface engineering and the IOR catalyst are manifested by the enhanced PEC performance and stability. The perovskite photoanode reveals a -0.2 V_{RHE} onset potential and improved fill factor along with a high durability for 200 h. We additionally demonstrate unbiased hydrogen production consisting of single perovskite photoanode and Pt catalyst achieving the operation current of 12 mA cm^{-2} and stable operation for 24 h.

A Polymer Overlayer Generates Long-Lived Charges in PM6:Y6 Bulk-Heterojunction Photoanodes with Improved Photoelectrocatalytic Performance Tack Ho Lee; Pusan National University, Korea (the Republic of)

Photogenerating charges with long lifetimes to drive catalysis is challenging in organic semiconductors. Here, we investigate the role of a PM6 polymer overlayer on the photoexcited carrier dynamics in a PM6:Y6 bulk-heterojunction (BHJ) photoanode undergoing ascorbic acid oxidation. With the additional polymer layer, the hole lifetime is increased in the solid state BHJ film. When the photoanode is electrically coupled to a hydrogen-evolving platinum cathode, remarkably long-lived hole polaron states are observed on the timescale of seconds under operational conditions. We demonstrate that these long-lived holes enable the organic photoanode with the polymer overlayer to show enhanced ascorbic acid oxidation performance, reaching ~ 7 mA cm^{-2} at 1.23 V_{RHE} without a co-catalyst. An external quantum efficiency of 18% was observed using 850 nm excitation. We propose that the use of an organic overlayer can be an effective design strategy for generating longer charge carrier lifetimes in organic photoanodes for efficient oxidation catalysis.

Days-Long Stable Bias-Free Solar Hydrogen Generation by Perovskite and Organic Photoanodes Matyas Daboczi, Flurin Eisner, Joel Luke, Junyi Cui, Filipp Temerov, Shi Wei Yuan, Noof Al Lawati, Jolanda Simone Müller, Ji-Seon Kim, Jenny Nelson and Salvador Eslava; Imperial College London, United Kingdom

Conversion of solar energy into hydrogen by photoelectrochemical water splitting is an emerging technology with large potential for sustainable green hydrogen generation. However, reaching the combination of high performance, stable and inexpensive photoelectrodes remains a scientific challenge. Solution-processable perovskite and organic photoactive materials have shown remarkable efficiency in solar cells, and they are extremely promising candidates for photoelectrochemical devices, but their application so far has been limited by their instability in aqueous media. In this presentation, we will show both perovskite and organic photoanodes applying NiFeOOH-functionalized self-adhesive graphite sheet, providing a simple, cost-effective approach to prevent degradation by the aqueous environment and eliminate almost all electrical losses between the photoactive layer and the water oxidation-catalyst.

The all-inorganic perovskite photoelectrodes incorporate solely Earth-abundant materials and apply a low annealing temperature carbon paste with tuned energy level $CsPbBr_3$ photoactive layer. Controlling the perovskite phase by a facile chemical bath method allows to achieve a pure 3D $CsPbBr_3$ layer with 8.1 mA cm^{-2} photocurrent density at +1.23 V_{RHE} (close to the radiative efficiency limit of $CsPbBr_3$) with record perovskite photoanode stability: 100% of stabilized photocurrent density maintained for more than 100 h. Devices with >1 cm^2 area, and low-temperature processing will also be demonstrated.[1] We will also discuss our most recent results towards reaching bias-free water splitting with these $CsPbBr_3$ photoanodes by applying high porosity electrospun top electrode layers.

The polymer:non-fullerene acceptor containing organic (PM6:D18:L8-BO) photoanodes achieve breakthrough photocurrent densities over 25 mA cm^{-2} at +1.23 V_{RHE} and remarkable, days-long operational stability. We will discuss strategies of how the continuous operation of the organic photoanode could be extended even further. Finally, polymer:polymer photoelectrodes, as well as monolithic organic tandem photoanodes (*i.e.*, two photoactive layers integrated into one photoanode to generate high photovoltage) with exceptionally low, negative onset potential and bias-free water splitting in two-electrode setup with solar-to-hydrogen efficiency reaching 5% will also be presented.

Organic Semiconductor-$BiVO_4$ Tandems for Solar-Driven H_2O and CO_2 Splitting Celine W. Yeung[1], Virgil Andrei[1,1], Tack Ho Lee[2,3], James Durrant[2] and Erwin Reisner[1]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom; [3]Pusan National University, Korea (the Republic of)

Photoelectrochemical (PEC) devices offer great promise for simultaneous solar light harvesting and chemical storage, converting water and CO_2 into value-added products.[1] While progress has been made to improve their solar-to-fuel conversion efficiencies, most conventional inorganic prototypes face challenges in terms of insufficient photovoltage, moisture instability, high material cost or toxicity.[2-5] In this work, we introduce PEC devices based on an organic π-conjugated donor-acceptor bulk heterojunction, protected by a carbon-based encapsulant to produce green H_2 and the platform chemical CO. By rationally combining design strategies from both organic photovoltaic and PEC fields, the photocathodes achieve long-term H_2 production over 300 h, which is tenfold higher than reported systems. Further interfacing the devices with a molecular CO_2 reduction catalyst allow for tunable and selective CO production under 0.1 sun. The complementary light absorption of these photocathodes with $BiVO_4$ enable their assembly into a standalone artificial leaf, demonstrating unassisted concurrent CO_2 reduction and water oxidation over 96 h. This establishes a new path for organic semiconductors, as we approach the composition, function, and efficiency of natural leaves.

Linking Defect Chemistry to Photo- and Electrocatalytic Performance Ludmilla Steier; University of Oxford, United Kingdom

Doping or alloying strategies are heavily employed in the design of new catalysts for photoelectrochemical, photochemical and electrochemical conversion reactions with enhanced solar energy harvesting efficiencies and/or desired surface chemistry. In the electrochemical reduction of CO_2 for example, efforts are focused on the development of electrocatalysts with high activity and selectivity towards C_{2+} products ideally breaking the scaling relations currently observed for metal surfaces.[1] In photoelectrochemical and photocatalytic devices research has focused on developing catalysts with light harvesting in the visible, strong surface electric fields and long charge carrier lifetimes.[2,3] In both, electro- and photocatalytic systems, perovskite oxides have been employed heavily, offering a more versatile defect chemistry platform.
Here, I will showcase some of our studies on oxide perovskite materials employed in photo- and electrocatalysis discussing links between defect chemistry and catalytic performance. One example will be the visible light absorber (La,Sr)(Rh,Ti)O_3 employed in the Z-scheme photocatalyst sheet device from Profs. Wang and Domen which led to a record 1% solar-to-hydrogen efficiency.[4,5] Taking inspiration from this material, we have been investigating the performance of other dopants and compositions in photo- and electrocatalytic conversion of CO_2 leading us to look very closely into the material surface compositions and the ways of reporting of catalytic activity.

4:00 PM EN05.03.02
$Ti_3C_2T_x$ MXene as Effective Conductive Material for Enhancing the Activity of Cu-Doped TiO_2 Nanotube Photocatalysts – Application in Photooxidation and in H_2 Production Gilles D. Berhault, Ziba Roostaei, Frédéric Dappozze and Chantal Guillard; CNRS, France

Photocatalysis is one of the most promising approach for photon energy conversion and environmental remediation. In this respect, TiO_2 is the most used semiconductor due to its high photocatalytic response. However, TiO_2 also presents a high propensity for electron-hole recombination. To solve this issue, several options were found to limit recombination: cationic doping, change of the semiconductor morphology or addition of C allotropes.
Previous studies performed in our group have shown that 1D TiO_2 nanotubes can help in enhancing the separation of electron-hole pairs resulting in higher photooxidation while doping by copper allows increasing the response under visible light. Another option is to add a conductive material which can enhance the transport of photoelectrons from TiO_2 to Cu. Previous work performed using graphene oxide showed the validity of this approach but also the instability of this material under irradiation. An alternative solution is to use the emerging class of MXene compounds which were found to exhibit very high conductivity.
The objective of this work will then be to synthesize Cu/$Ti_3C_2T_x$/TiO_2 systems in which the $Ti_3C_2T_x$ MXene will be evaluated for its propensity in enhancing the transport of photoelectrons, improving in this way the separation of electron-hole pairs. Comparison will be performed between 1D TiO_2 nanotubes and a P25 reference while Cu/$Ti_3C_2T_x$/TiO_2 will be applied for both photooxidation (formic acid photodegradation) and for H_2 production.

Materials and Methods

$Ti_3C_2T_x$ MXene layers were obtained by HF etching of Ti_3AlC_2 MAX precursors to remove Al. TiO_2 nanotubes were obtained under hydrothermal alkaline conditions. Two series of impregnation were performed: first, GO or MXene were impregnated onto P25 or TiO_2 nanotubes while $Cu(NO_3)_2.3H_2O$ was then impregnated onto the resulting materials.

Results and Discussion

Systematic comparisons between P25 and nanotubes were done during the construction of various Cu/TiO_2, MXene/TiO_2 and Cu/MXene/TiO_2 configurations. Results emphasized the important role played by surface oxygen vacancies in the enhancement of the photooxidation activity. While the addition of Cu onto P25 induces the creation of new oxygen vacancies onto P25 improving its photooxidation efficiency, on TiO_2 nanotubes, copper interacts mainly through the consumption of these surface oxygen vacancies initially present on the titanium oxide surface. Beneficial effects were the observed only at low Cu loadings. Photocurrent analysis also emphasized the strong increase in conductivity resulting from the addition of $Ti_3C_2T_x$. This high conductivity enhancement leads to a substantial increase of the photocatalytic response in photooxidation with an activity of Cu/$Ti_3C_2T_x$/P25 150 % higher than for P25 and 50 % higher than for Cu/P25 while the highest activity was reached using Cu/$Ti_3C_2T_x$/TiO_2 nanotubes.
In H_2 production, surface oxygen vacancies play a more indirect role since their consumption through copper addition favors a higher Cu-Ti interaction and a better transfer of electrons from TiO_2 to Cu. This leads to very active Cu/TiO_2 nanotube systems for H_2 production. Surprisingly, the addition of $Ti_3C_2T_x$ leads to an apparent lower H_2 evolution activity. H_2 chemisorption analysis reveals in fact that $Ti_3C_2T_x$ plays the role of an excellent trap for the hydrogen produced which is then stored inside our materials revealing in this way the ability for H_2 storage of $Ti_3C_2T_x$ MXene.

Conclusion

The utilization of $Ti_3C_2T_x$ MXenes as conductive materials enhancing the transport of photoelectrons from a semiconductor, TiO_2 to an electron acceptor, Cu has been demonstrated in photooxidation. Results also emphasized the important role played by surface oxygen vacancies while $Ti_3C_2T_x$ MXene was found to present quite interesting properties as H_2 storage material.

4:15 PM EN05.03.03
Ceria and Metal Ferrite Core-Shell Nanoparticle for Solar Thermochemical Fuel Production Ziyao Wu[1], Aniket S. Patankar[1], Ahmed Ghoniem[1], Xiaoyu Wu[2], Wonjae Choi[3] and Harry Tuller[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Waterloo, Canada; [3]Ewha Womans University, Korea (the Republic of)

Two-step metal oxide-based Solar Thermochemical Hydrogen Production (STCH) is an emerging technology that directly utilizes high-temperature heat to split water and carbon dioxide, producing hydrogen and carbon monoxide, respectively. Using heat can be a more cost-effective source than electricity, particularly for high-capacity factors and continuous fuel production. However, to achieve ambitious targets like the US DOE HydrogenShot ($1/kg-H2), significant efficiency gains and cost reductions are essential. Optimizing the redox material is pivotal in advancing STCH fuel production.

Ceria (CeO_2) is the state-of-the-art redox material in STCH systems due to its high-temperature stability, fast reduction and water-splitting kinetics, and thermodynamic properties. Yet, its limited oxygen-carrying capacity (OCC), compared to perovskites and iron oxides, results in diminished fuel productivity and solar-to-fuel efficiency. Larger quantities of ceria are needed, leading to larger reactors and higher costs.

Metal-substituted ferrites are another STCH material class with 3-5 times higher OCC compared to ceria. However, ferrites can experience sintering and rapid deactivation at high temperatures (~1500°C), causing a marked decrease in fuel productivity after a few cycles. This sintering effect enlarges particle size, and the inherent low ion diffusivity in spinel slows water-splitting kinetics, ultimately leading to material deactivation. Doping ferrites with different cations or combining with inert supports like zirconia has proven inadequate in preventing ferrite agglomeration [1].

In our previous work, we introduced a composite STCH redox material combining magnesium ferrite ($MgFe_2O_4$) and ceria. We hypothesize that such a composite can combine the high OCC of ferrites with the thermal stability and high oxygen diffusivity of ceria. Our system-level thermodynamic analysis showed that a composite with 50 wt-% ferrite produces twice as much hydrogen per unit mass as ceria and increases STCH efficiency from 33% to 35.3% [2].

In this presentation, we will discuss our experimental efforts with ceria-ferrite composites. We will present the synthesis and characterization of core-shell composites, with a Mg-ferrite core and a ceria shell. Ceria was chosen as the shell material because of its low sintering, fast redox kinetics, and high oxygen diffusivity. We compare the performance of the core-shell composite with that of simple mechanical mixtures in which ferrite and ceria powders are mixed and pressed into a porous pellet. A combination of Infrared furnace experiments and thermogravimetric analysis is used to measure the OCC of composites at STCH-relevant conditions. The experiments involve thermochemical cycles by switching the temperature between reduction(1400°C-1500°C) and water/CO2 splitting(700°C-900°C), changing the gas environment, and monitoring the real-time gas composition using an in-line mass spectrometer. We measure OCC and fuel production profiles over several consecutive STCH cycles to study the sintering or other forms of degradation composites. The ferrite content in the composite is varied to measure its impact on OCC and degradation.

Ex-situ X-ray diffraction (XRD), SEM and TEM imaging, and surface area measurements will be used to characterize the evolution of composite chemistry and morphology during STCH cycles. This work aims to demonstrate the potential of ferrite-ceria composites and core-shell structures as leading an STCH redox material, setting the stage for scaled-up studies in the future.

Nanoengineering Interfaces in The Biomolecular Devices for Solar-To-Chemical Conversion Joanna Kargul; University of Warsaw, Poland

Combining the highly active and stable natural photocatalysts with various electrode materials open an avenue for the selective production of target chemicals at ambient conditions using non-toxic and cost-effective biomaterials. Here, I present the rational bottom-up design of conductive bio-organic interfaces within the biomolecular systems based on the robust photoenzyme, photosystem I (PSI) that yields the significantly enhanced solar conversion efficiency and stability. The PSI biophotocatalyst is interfaced with various cost-efficient, transparent electrode materials in the orientation controlled manner for the generation of green electricity and fuel. The performance of such devices can be greatly improved by tailoring the structure of the organic molecular wires based on pyrene-nitrilotriacetic acid, terpyridine or diazonium salt ligands coordinated with various transition metals to ensure the generation of unidirectional electron transfer and minimisation of wasteful back reactions. Incorporating plasmonic nanoparticles in the bio-organic interface improves the light-harvesting, photocatalytic activity and long-term photostability of PSI. Such rational design paves the way for the generation of viable and sustainable technologies for solar energy conversion into fuel and other carbon-neutral chemicals.

GaAs@TiO_2 Core-Shell Nanowire-Based Electrode and Co Catalyst for Enhanced Hydrogen Generation Thomas Dursap[1], Mariam Fadel[2], Cristina Tapia Garcia[2], Céline Chevalier[1], Hai-Son Nguyen[1], Emmanuel Drouard[1], Philippe Regreny[1], Solène Brottet[1], Michel Gendry[1], Alexandru Danescu[1], Matthieu Koepf[2], Vincent Artero[2], José Penuelas[1] and Matthieu Bugnet[3]; [1]University Lyon, CNRS, ECL, INSA Lyon, UCBL, CPE Lyon, INL, France; [2]University Grenoble Alpes, CNRS, CEA, IRIG, Laboratoire de Chimie et Biologie des Métaux, France; [3]University Lyon, CNRS, INSA Lyon, UCBL, MATEIS, France

Photoelectrochemical cells (PEC) are appealing devices for the production of renewable energy carriers. In this context, III-V semiconductors such as GaAs are very promising materials due to their tunable bandgaps, which can be appropriately adjusted for sunlight harvesting. Because of the high cost of these semiconductors, the nanostructuration of the photoactive layer can help to improve the device efficiency as well as drastically reduce the amount of material needed. III-V nanowire-based photoelectrodes benefit from the intrinsically high aspect ratio of nanowires, their enhanced ability to trap light as

well as their improved charge separation and collection abilities, and thus are particularly attractive for PECs. However, III-V semiconductors often suffer from corrosion in aqueous electrolytes, preventing their utilization over long periods under relevant working conditions.
In this study, the influence of the geometry of GaAs semiconductor as photocathodes for the water reduction was investigated. Photocathodes made of GaAs nanowires [1, 2] and protected with thin TiO_2 shells were prepared and studied under simulated sunlight irradiation to assess their photoelectrochemical performances in correlation with their structural degradation [3]. A strong improvement of the cell efficiency was demonstrated for the 1-dimensional NW geometry compared to its thin film counterpart, which is mainly due to a significant reduction of light reflected by the electrode. Morphological and electronic parameters, such as the aspect-ratio of the nanowires and their doping pattern were found to strongly influence the photocatalytic performances of the system. This work highlights the advantageous combination of nanowires featuring a buried radial p-n junction with Co-nanoparticles used as hydrogen evolution catalyst. The nanostructured photocathodes exhibit significant photocatalytic activities, comparable with previous noble-metal based systems tested under similar conditions (0 V vs. RHE, pH = 7).
Furthermore, the stability of the NW-based photocathode over time was significantly improved with the deposition of a thin TiO_2 protective layer, leading to an increase of the Faradaic efficiency of the photocathodes by a factor 3 after 13 hours. The fabricated photocathodes display photocurrent density up to 1.15 mA/cm^2 at 0 V vs RHE under neutral conditions. Nevertheless, it would lead to solar-to-hydrogen performances below 1% in tandem photoelectrochemical cells. This calls for future tenfold improvement of the performances of such scalable materials to allow for a viable solar hydrogen technology. Still, such performance is at the state of the art for similar GaAs photoelectrodes, and demonstrates the potential of GaAs nanostructured semiconductor for photo-driven hydrogen production.

Single Atom Catalyst-Like Strontium Doping of Titania Nanotube Arrays for CO_2 Photoreduction Damini Vrushabendrakumar, Navneet Kumar, Harshitha Rajashekhar, Kazi M. Alam and Karthik Shankar; University of Alberta, Canada

This study focuses on the details concerning the adsorption mechanisms, surface electronic band structure and structural disorder in anodically formed TiO_2 nanotube arrays (TNTAs) due to the surface doping of strontium Sr^{2+} metal cations that end up being widely dispersed on the surface of the TNTAs. The surface doping was achieved using an electrochemical cathodic treatment in a Sr^{2+}-containing aqueous electrolyte. Sr^{2+} surface dopants also modified the crystallographic texture of the nanotubes.[3] X-ray diffraction patterns and Raman spectra confirmed the induced lattice strain, reduced crystallite size, and phonon confinement in the TNTAs due to Sr-doping.[2] The absence of segregated phases of Sr or SrO or $SrTiO_3$ led to the conclusion that Sr atoms were high entropy surface dopants in TiO_2, widely dispersed on the surface of the TNTAs and approaching single atom catalysts insofar as the surface distribution of dopant Sr atoms is concerned. Fourier transformed infrared (FTIR) spectra of the Sr cathodized TNTAs indicated the presence of a small population of bridging bidentate carbonate adsorbate on Sr doped TNTA surfaces exposed to CO_2.[3] Sr-doping reduced the work function of TNTAs and caused appreciable downward band-bending of 0.25 eV resulting in an electron accumulation layer at the surface. We hypothesize that such an electronic band-structure makes it easier for photogenerated electrons to be transferred to surface adsorbates for CO_2 reduction. The electrochemically cathodized Sr-doped TNTAs exhibited a more than 3-fold enhancement in the rate (25 µmol g^{-1} h^{-1}) of CO_2/CO transformation in surpassing the output of bare TNTA (7.7 µmol g^{-1} h^{-1}), thereby impressively improving the photocatalytic performance.

Surface Ferroelectric Effect in Oxygen Deficient (111) Strontium Titanate Single Crystals Controls Photoelectrochemical Water Oxidation Samutr Assavachin, Chengcan Xiao, Tatiana Mamani, Davide Donadio and Frank E. Osterloh; University of California, Davis, United States

Ferroelectric materials such as $BaTiO_3$ have a permanent electric polarization that can be controlled with an external applied electric field. Here we demonstrate a surface ferroelectric effect in oxygen deficient (111) $SrTiO_{3-x}$ and its application to improve photoelectrochemical water oxidation for the first time. After hydrogen-annealed (111) $SrTiO_{3-x}$single crystals are polarized with an electric field of 11 kV cm^{-1} under argon flow, the anodic water oxidation photocurrent increases from 0.99 to 2.22 mA cm^{-2} at 1.23 V RHE (60 $mWcm^{-2}$, UV illumination) or decreases to 0.50 mA cm^{-2}, for the opposite field orientation. The polarization also modifies the surface photovoltage signal of the material and its flat band potential, based on Mott-Schottky measurements. This is attributed to an electric dipole near the (111) $SrTiO_{3-x}$ surface, which controls the potential drop across the depletion layer and charge transfer at the solid-liquid junction. Based on DFT calculations the electric polarization results from the migration of oxygen vacancies between $SrTiO_{3-x}$ surface and sub-surface regions. The use of the surface ferroelectric effect to modify the junction and photoelectrochemical properties of a non-ferroelectric material is expected to be of interest for solar energy conversion and information technology applications.

11:45 AM EN05.04.05
Thermochemical Properties of ABO_3-Type Compounds for Solar Fuel Generation Sossina M. Haile; Northwestern University, United States

Solar-driven thermochemical production of chemical fuels using redox active oxides has emerged as an attractive means for storing solar energy for use on demand. In this process, a reactive oxide is cyclically exposed at high temperatures toan inert gas, which induces partial reduction of the oxide, and subsequently to an oxiding gas of eitehr H_2O or CO_2, which reoxidizes the oxide, releasing H_2 or CO. While it is widely recognized that the *capacity* for fuel production is dictated by the thermodynamic properties of the oxide, here we show that the *rate* of fuel production is also often directly given by these properties. Recognizing this behavior, we report the thermodynamic properties, specifically the enthalpy and entropy of reduction, of a range of previously unexplored ABO_3-type compounds and identify those with promising characteristics for efficient thermochemical fuel production.

Transient Absorption Spectroscopy/Microscopy of Carbon Nitride Photocatalysts for Biomass Photoreforming Robert Godin; The University of British Columbia, Canada

Polymeric photocatalysts made of Earth-abundant elements have been extensively developed over the past decade to take advantage of their synthetic tunability.[1] Within this family, carbon nitrides (CN_x) are emerging as leading photocatalysts because of their high photocatalytic performance combined with good stability and facile synthesis.[2,3] However, significant gaps remain in our knowledge of the photophysical properties of these organic polymeric materials. Determining the pathways and mechanism of photoinduced processes will greatly aid our efforts to engineer better CN_x photocatalysts for solar fuel production and other photocatalytic processes.
We are taking the next step to develop a full picture of the charge carrier dynamics by expanding our spectroscopic capabilities to transient absorption *microscopy* (TAM). Notably, our first-of-its-kind TAM system monitors the microsecond – second timescales relevant to the complex multi electron redox reactions that occur to produce solar fuels. Spatial mapping of the charge carrier dynamics on the micron scale provides novel insights into the heterogeneity in individual CN_x particles. This new tool allowed us to unearth a multiscale heterogeneity where the charge carrier dynamics differ from particle to particle and different behavior within individual particles on ~ 10 micrometer length scales can be observed. These new insights into the heterogeneity of charge carrier dynamics in CN_x particles can push the field into uncovering the optimal structure and local environment in defect-rich organic semiconductors such as CN_x. We are taking this knowledge and applying it to systems of biomass photoreforming for the simultaneous breakdown of organic matter and H_2 evolution.

2:15 PM EN05.05.02
On The Scarcity or Not of Carbon-Based Overall Water Splitting Photocatalysts Martijn Zwijnenburg; University College London, United Kingdom

Since the discovery in 2010 that carbon nitride combined with suitable co-catalysts could in the presence of appropriate electron donors and acceptors drive both the reduction of protons to molecular hydrogen and the oxidation of water to molecular oxygen, carbon-based materials have received an enormous amount of interest as potential light absorbers for photocatalytic water splitting. Now probably more than 200 different carbon-based materials, mostly conjugated polymers, are known to be active for hydrogen evolution in the presence of a sacrificial donor such as triethanolamine or ascorbic acid, and platinum or palladium nanoparticles that act as co-catalyst and site of the hydrogen evolution.[1] In contrast, a much smaller number of carbon-based materials have been reported to be active for the oxygen evolution half-reaction. The number of carbon-based materials experimentally active for overall water splitting can be counted on the fingers of one or two hands.

Based on the scarcity of materials that are active for overall water splitting one could naively assume that such activity is a rare property of carbon-based materials. That carbon-based materials generally just do not have the ionisation potential / valence band maximum position to drive water oxidation. In my contribution I'll discuss the results of computational high-throughput screening of thousands of conjugated polymers which shows that this is not necessarily the case, or at least not for polymers.[2] Approximately, a similar fraction of the library of 3000+ conjugated polymers is predicted to be thermodynamically able to drive overall water splitting as is predicted to be active for sacrificial hydrogen evolution. Although the ability to drive overall water splitting combined with a small enough optical gap that a large part of the solar spectrum is absorbed is predicted to be relatively rare for this material class. Finally, I'll discuss why we think the real reason behind the scarcity of carbon-based overall water splitting photocatalysts is not thermodynamics but the need for well-optimised co-catalysts and why thus future work on co-catalysts and/or combining polymers into heterojunctions, like recently explored experimentally by Kosco and co-workers,[3] can rescue large numbers of carbon-based phoocatalysts from the proverbial scrap heap of history.

Efficient Z-Scheme Configuration for Photocatalytic CO2 Reduction through g-C3N4 and Cs3Bi2Br9 Heterojunctions Enhanced by Reduced Graphene Oxide Yasmine Baghdadi and Salvador Eslava; Imperial College London, United Kingdom

Photocatalytic CO_2 reduction is pivotal for progressing solar fuel technologies, demanding catalysts with enhanced efficiency. Combining the optoelectronic characteristics of $Cs_3Bi_2Br_9$ and the versatility of g-C_3N_4, this study aims to create a synergistic platform for photocatalysis, harnessing the unique strengths of each semiconductor to enhance overall performance in applications such as solar fuel generation and photocatalytic CO_2 reduction. Building on our previous studies where the ratio of g-C_3N_4 to $Cs_3Bi_2Br_9$ was optimized for high CO_2 conversion to CO, this study presents a dual-modification approach to amplify the performance of g-C_3N_4 as a photocatalyst.1 Surface modifications, including exfoliation for increased surface area and surface oxidation for improved charge separation, were employed on g-C_3N_4. The introduction of reduced graphene oxide (rGO) at various ratios, integrated into both bulk and exfoliated g-C_3N_4, effectively mitigated charge recombination. An optimal rGO/g-C_3N_4 ratio was identified, showcasing superior efficiency.
Importantly, the study also introduces a hybrid inorganic/organic heterojunction by combining the optimized rGO/g-C_3N_4 with $Cs_3Bi_2Br_9$ into a $Cs_3Bi_2Br_9$/rGO/g-C_3N_4 Z-scheme composite. This synergistic integration resulted in a remarkable increase in photocatalytic activity, reaching 54.3 (± 2.0) µmol g^{-1} e^- h^{-1} on an electron basis for CO, H_2, and CH_4 production, surpassing pure $Cs_3Bi_2Br_9$ (11.2 ± 0.4 µmol g^{-1} e^- h^{-1}) and bulk g-C_3N_4 (5.5 ± 0.5 µmol g^{-1} e^- h^{-1}).
A comprehensive characterization shows the charge transfer mechanism within the composite to take place via the rGO, acting as a solid redox mediator, in

a Z-scheme heterojunction where $Cs_3Bi_2Br_9$ drives the reduction and g-C_3N_4 the oxidation, explaining its enhanced photocatalytic activity. The successful formation of this high-performance heterojunction underscores the composite's potential as an efficient photocatalyst for CO_2 reduction, promising substantial advancements in solar fuel technologies and aligning with sustainable energy goals.

Earth-Abundant Co-Catalysts to Replace Noble Metals in Photocatalysis Judith Zander and Roland Marschall; University of Bayreuth, Germany

Climate change due to rising CO2 concentrations in the atmosphere require the transformation from a fossil-fuel based energy economy towards a sustainable, emission-free one centred around renewable energy sources. Photocatalysis offers the possibility to directly obtain H2 as a green fuel from water under irradiation of a photocatalyst with a suitable band gap for light absorption. Up to date, photocatalytic hydrogen evolution (HER) can, however, still not compete with traditional hydrogen production processes, such as steam reforming, due to low efficiencies [1]. Co-catalysts can be added to a photocatalytic system to improve the separation of excited charge carriers, provide additional active sites, lower the overpotential of a reaction, and thus increase the overall activity. Many common co-catalysts are noble-metal-based, though [2]. Therefore, the addition of a noble co-catalyst increases the material costs. This is also a common problem in electrochemistry, where platinum is used as standard material for the hydrogen evolution reaction. In recent years, sulphides and phosphides, such as MoS2, have emerged as earth-abundant alternatives and subsequently been employed as co-catalysts in photocatalysis as well [3]. Nickel and iron based materials are especially interesting for the hydrogen evolution reaction, since both metals are common motifs in hydrogenase enzymes [4].
We herein present binary and ternary sulphides and oxides as novel, earth-abundant co-catalysts on TiO2, with a special focus on Ni2FeS4. All of the presented materials can be obtained as nanoparticles in a very fast microwave-assisted solvothermal reaction at temperatures not exceeding 200 °C. The synthesis time can be decreased down to 1 min, without a significant loss of product crystallinity and no impedimental effects on the activity. The addition of the transition metal sulphides to P25 TiO2 could significantly boost the activity for photocatalytic hydrogen evolution under 1 sun solar light irradiation, as well as under UV irradiation. A combination of control experiments, material characterisation and the realisation of astonishingly low transition metal loadings of 0.5 wt.% (< 0.3 wt.% of metals) underline the role of Ni2FeS4 and other sulphides as efficient co-catalysts that show promise for replacing noble metal co-catalysts.[5]

Turning Waste into High Value Chemicals with Electricity Magdalena Titirici; Imperial College London, United Kingdom

In this talk I will present out latests advances in converting bio-basedd products such as glycerol, 5-hydroxymethylfurfural or PET waste into valuable chemicals including lactic acid, FDCA and glycolic acid including some fundamental mechanistic studies, upscale oportunities and life cycle assesment of such processes.

4:00 PM *EN05.06.02
Coupling Hydrogen Production and Upgrading of Chemicals in Oxide-Based Photoelectrochemical Device Fatwa F. Abdi; City University of Hong Kong, Hong Kong

Green H_2 has been recognized as an important element in efforts to decarbonize our fossil fuel-dependent society. One method to produce green H_2 is solar water splitting in a photoelectrochemical (PEC) device. Solar-to-hydrogen (STH) efficiencies of up to 30% have been demonstrated but these high efficiencies could only be achieved using expensive and non-scalable photoelectrodes–the approach therefore still results in a hydrogen cost that is not competitive. One obvious approach is to develop novel photoelectrode materials that are low-cost and highly efficient. For example, earth-abundant complex metal oxides have been explored, and several promising ones have been identified. Here, our efforts in developing tin tungstate (α-$SnWO_4$) as a photoelectrode material will be discussed.[1-3] Alternatively, co-production of valuable chemicals can be introduced in the PEC cell to increase the competitiveness of the overall system. For example, we recently coupled a homogeneous hydrogenation reaction with PEC-generated hydrogen inside a single device.[4,5] Using the hydrogenation of itaconic acid (IA) to methyl succinic acid (MSA) as a model proof-of-concept reaction, solar-driven H_2-to-MSA conversion as high as ~50% was demonstrated using our $BiVO_4$-based PEC device. Although still demonstrated in the laboratory scale, life-cycle net energy assessment and technoeconomic analysis reveal that the concept indeed offers a very promising return. Finally, further implications and optimization potentials of this coupled PEC hydrogenation approach, also beyond the demonstrated hydrogenation of IA to MSA, will be discussed.

Aqueous Z-Scheme Photocatalytic CO_2 Reduction by Dispersed Semiconductor Particles of Metal Sulfide and Oxide in Synergy with Dual-Functional Metal-Complex Tomiko M. Suzuki[1], Shunya Yoshino[2], Keita Sekizawa[1], Yuichi Yamaguchi[2], Akihiko Kudo[2] and Takeshi Morikawa[1]; [1]Toyota Central R&D Labs., Inc., Japan; [2]Tokyo University of Science, Japan

The photocatalytic carbon dioxide reduction reaction (CO_2RR), which can generate useful chemicals, is essential for realizing a carbon-neutral society and a circular economy.
To utilize visible-light energy and water as with natural photosynthesis, a 2-step photoexcitation mechanism (Z-scheme) that transfers electrons via two semiconductor photocatalysts is feasible [1]. Although an aqueous suspension of particulate photocatalysts in one-pot is an ultimately simplified and scalable approach, previous demonstrations have suffered from very low CO_2 selectivity against undesirable hydrogen production [1-3].
In this study, we demonstrate a simple activation methodology to overcome the issue by the combination of one molecule together with two semiconductor particulates in a water-filled one-pot reactor, achieving unparalleled selectivity of almost 100% of CO.
A simple mixture of two particulate semiconductors, a metal-sulfide, $(CuGa)_{0.3}Zn_{1.4}S_2$ as a CO_2 reduction photocatalyst (0.1 g) and a metal-oxide ($BiVO_4$) as a water oxidation photocatalyst (0.1 g) and a newly designed water-soluble molecular Co complex, $[Co(4,4'\text{-dimethyl-}2,2'\text{-bipyridine})_3]^{2+}$ ([Co-dmbpy]) were added to an aqueous solution of 10 mmol L^{-1} $NaHCO_3$ (120 mL). Under CO_2 gas bubbling into the reactor and irradiation with visible light ($\lambda > 420$ nm), CO and a much smaller amount of hydrogen were continuously generated, while formate was almost undetectable. CO was generated with 98% product selectivity with respect to the total reduction products (CO, H_2, and $HCOO^-$) after 56 h. The CO generation rate of this system was increased by 1–2 orders of magnitude (38 μmol h^{-1}) relative to that obtained with a previously reported visible light-driven Z-scheme photocatalytic reaction using an aqueous suspension system, and was comparable to water splitting H_2 synthesis by the Z-scheme mechanism under similar conditions.
The simultaneous evolution of O_2 was confirmed, which clarified the extraction of electrons from water molecules with irradiated $BiVO_4$ necessary for CO_2RR in the Z-scheme mechanism. Experimental studies and calculations suggest that the Co complex acts dual-functionally in synergy with $(CuGa)_{0.3}Zn_{1.4}S_2$ and $BiVO_4$: it behaves as an efficient ionic electron mediator, and also acts as a new active CO_2RR cocatalyst after a structural change following the acceptance of photoexcited electrons from $(CuGa)_{0.3}Zn_{1.4}S_2$ [4, 5]. This simple method, operating in a self-optimizing manner in solution, has great potential to help achieve sustainable, highly active artificial photosynthetic systems.

Flow Photoelectrochemical Devices for Converting Carbon from the Ocean Bin Liu[1], Zheng Qian[2,1] and Shu Hu[1]; [1]Yale University, United States; [2]Tsinghua University, China

The capture and utilization of the dissolved inorganic carbon in seawater, i.e., 2 mM bicarbonates, offer an appealing approach to mitigate environmental concerns and advance the realization of a carbon-neutral society. Unbiased solar-driven photoelectrochemical (PEC) CO_2 reduction leads to sustainable production of chemicals and fuels. However, the development of reactors for unbiased PEC CO_2 capture and in-situ utilization in seawater has been scarcely reported, due to the lack of reactors that elegantly balance mass transfer and flow field design with PEC CO_2 reduction. We effectively achieve protons transportation and sequent in-situ conversion of freshly generated CO_2. We will describe the design and realization of 3D-printed reactors for unbiased PEC CO_2 capture and in-situ conversion in seawater, in which the locally generated CO_2 at $BiVO_4$ photoanodes can be brought to the neighboring Si photocathodes for CO_2 reduction reaction by optimized flow field, reducing the protons transfer distance and improving the local CO2 concentration on the surface of Si photocathodes. With this, we achieved excellent CO_2 capture velocity and outstanding solar to fuels (STF) efficiency of 0.71%: CO selectivity was increased from 3 to 19% compared with the conventional “artificial leaf” configuration of back-to-back photoanodes and photocathodes. A flowing reactor module is demonstrated for realistic ocean operation.

8:30 AM EN05.07.02
Atomic Layer Deposition of Defect-Engineered TiO_x and TaO_x Protective Coatings for Photoelectrochemistry Tim Rieth, Oliver Bienek, Julius Kühne and Ian D. Sharp; Technische Universität München, Germany

Photoelectrochemical (PEC) energy conversion provides a viable route to chemical fuel production from solar light. Several different PEC design approaches exist, ranging from single photoelectrodes to tandem configurations of photoanodes and -cathodes to buried photovoltaic junctions. However, common to each of these designs is a central materials challenge of achieving simultaneous stability, efficiency, and scalability. Furthermore, the coupling of the semiconducting photo absorber and catalytic components demands sophisticated solid state interface engineering. In this talk, we focus on the stabilization of this semiconductor/electrolyte interface with functional conformal coatings grown by plasma-enhanced atomic layer deposition (PE-ALD). We investigate defect-engineered electron-selective titanium oxide (TiO_x) protection layers for efficient InP photocathodes and identify ALD pathways to optimize interfacial and bulk charge transport, as well as to tune the driving force for photovoltage generation [1]. Furthermore, we use PE-ALD to deposit ultra-thin tantalum oxide (TaO_x) protective coatings showing improved chemical stability compared to titanium oxide in alkaline and acidic environments. In addition to possessing excellent optical transparency, the conductivities of TaO_x layers can be tuned over several orders of magnitude by introducing electronic defects via hydrogen plasma sub-cycles during the ALD process. Spectroscopic methods including X-ray photoelectron spectroscopy (XPS), photothermal deflection spectroscopy (PDS), and spectroscopic ellipsometry (SE) are employed to characterize and understand the introduced defects and correlate the electronic properties to the PEC performance. Overall, the demonstrated route to ALD-based defect-engineering enables precise control over the properties of ultra-thin layers, facilitating not just improved corrosion protection layers but also tunable semiconductor/dielectric interfaces.

Directing The Path with Directional Properties: Unravelling Anisotropic Carrier Mobility, Lifetime and Surface Defects in Oxides for Solar Fuels Generation Linfeng Pan[1], Linjie Dai[1], Jingshan Luo[2], Anders Hagfeldt[2], Michael Graetzel[2] and Samuel D. Stranks[1]; [1]University of Cambridge, United Kingdom; [2]École Polytechnique Fédérale de Lausanne, Switzerland

The concept of solar fuels holds great promise for the sustainable production of fuels through the utilization of solar energy. Over the last ten years, oxide photocathodes, such as Cu_2O, have showcased performance comparable to that of photoelectrodes relying on well-established photovoltaic materials. Our work has demonstrated several record tandem solar water splitting devices based on the state-of-the-art Cu_2O photocathodes featuring a radial junction design and effective hole transport strategies. Nevertheless, a significant challenge found was the occurrence of considerable charge carrier recombination within the bulk of the photoabsorber, a common issue commonly observed in oxide semiconductors. Here, we demonstrate Cu_2O photocathodes with performance beyond the state-of-the-art by exploiting a novel conceptual understanding of carrier recombination and transport in single-crystal Cu_2O thin films with adjustable crystal orientations. The combination of the unique thin film materials platform and a series of optoelectronic characterizations, including a customized broadband femtosecond transient reflection spectroscopy, precisely quantified unprecedented anisotropic carrier mobilities, lifetimes and diffusion lengths. Notably, it was discovered that these properties exhibit significant disparities along different crystal orientations, with one orientation manifesting significantly superior properties compared to the others. To exploit the findings, polycrystalline Cu_2O photocathodes with extremely pure selected crystalline orientations and terminating facets were fabricated, delivering current density 70% more current density compared to the state-of-the-art electrodeposited devices at 0.5 V versus a reversible hydrogen electrode under simulated air mass 1.5 G illumination, and stable operation over 100 hours. Furthermore, we will share recent research outcomes that elucidate the significance of facet-dependent defects in their contributions to photoelectrochemical applications.

9:00 AM EN05.07.04
Anisotropic Conductive Adhesive for Semi-Monolithic Integration of Multi-Junction PV and PEC Devices Kai C. Outlaw-Spruell[1,2], Christopher Muzzillo[3], Kai Zhu[3] and Nicolas Gaillard[1,2]; [1]Hawaii Natural Energy Institute, United States; [2]University of Hawaii, United States; [3]National Renewable Energy Laboratory, United States

Although foundational to multi-junction (MJ) photovoltaic (PV) and photoelectrochemical (PEC) device synthesis, monolithic integration presents major limitations in process compatibility. Consequently, conductive adhesive-based interconnection scheme emerged as a suitable method to overcome limitations and to integrate incompatible material classes into MJ devices without compromising the integrity of the constituent layers. As the conductive adhesive generally employ a polymer matrix, the conductivity of this composite material depends on the conductive filler material. Among which, a core-shell type silver coated PMMA (Ag-PMMA) conductive microsphere filler has gained significant interest in the PV and PEC community due to its ability to exhibit reliable out-of-plane electrical conductivity (0.1 Ω-cm^2) and good optical transparency (T > 90%), as we demonstrate for an epoxy-based transparent conductive composite (TCC) consisting of low particle loading (0.1 - 5 vol%).

By implementation of the Ag-PMMA based TCC paired with a device exfoliation method, further referred to as semi-monolithic integration, independently processed substrate-grown single junction (SJ) devices were successively bonded and exfoliated onto a single host substrate to create a MJ device. As a proof-of-concept demonstration, we constructed the world's first whole-chalcopyrite triple junction MJ device comprising 1.13 eV and 1.44 eV $Cu(In,Ga)Se_2$ and 1.85 eV CuGa3Se5 sub-cells, with the TCC acting as the recombination layer between each sub-cell. The device exhibited a V_{OC} of 1.85 V and is capable of splitting water with an STH efficiency of 3% in a PV-electrolysis configuration.

Although the use of Ag-PMMA based TCC has shown to be an effective approach to prepare MJ devices, mechanical and electrical design and optimization is required to reliably appropriate the TCC as an optoelectronic device interconnect and to scale the semi-monolithic integration method. In the context of mechanical optimization, it has been shown that the degree of deformation of conductive microsphere filler is a key factor in establishing electrical connections. Up until now, the load-deformation characteristic of a single Ag-PMMA microsphere has not been measured. As such, we present in this communication a mechanical model based on measured load-deformation characteristics of a single Ag-PMMA microsphere to facilitate a spring model to better predict the deformation of multi-particle systems with respect to applied load. Furthermore, a finite element electrical model is implemented to determine the effects of sub-cell charge transport layer properties and electrical contacts on parasitic resistive losses. Hence, we demonstrate the critical factors influencing the quality of TCC as an anisotropic electrical interconnection layer, and provide a computational mechanical and electrical model to understand and mitigate parasitic resistive losses.

9:15 AM EN05.07.05
Interface Engineering and Characterization of $BiVO_4$ Photoanodes Boosted with 2D Interlayers and Co-Catalysts Junyi Cui and Salvador Eslava; Imperial College London, United Kingdom

Photoelectrochemical conversion of water using solar energy offers a clean solution to the world energy requirements of a sustainable future. Achieving its full potential depends on developing inexpensive photoanodes that can efficiently absorb solar light and drive the difficult oxygen evolution reaction (OER), which requires 4 electrons per molecule, and currently hampers reaching high solar to hydrogen efficiencies.

In this talk, I will first present recent developments we have achieved in my group in the preparation of inexpensive $BiVO_4$ photoanodes functionalized with 2D bismuthene. Partially oxidized two-dimensional (2D) bismuthene is prepared by reduction of $BiCl_3$ and demonstrated to be an effective, stable, functional interlayer between $BiVO_4$ and the archetypal NiFeOOH co-catalyst. Comprehensive (photo)electrochemical and surface photovoltage characterizations show that NiFeOOH passivates hole trap states of $BiVO_4$; however, it is limited in influencing electron trap states related to oxygen vacancies (V_O). Loading bismuthene on $BiVO_4$ photoanodes fills the V_O-related electron traps, leading to more efficient charge extraction. This is confirmed by kelvin probe measurements. Moreover, bismuthene increases adsorption sites for reaction intermediates and increases interfacial band bending boosting hole charge flux to the electrolyte. With the synergistic interaction of bismuthene and NiFeOOH on $BiVO_4$, this composite photoanode achieves a 5.8-fold increase in photocurrent compared to bare $BiVO_4$ reaching a stable 3.4 (±0.2) mA cm^{-2} at a low bias of +0.8 V_{RHE} or 4.7(±0.2) mA cm^{-2} at +1.23 V_{RHE}. The use of 2D bismuthene also boosts other photoanodes such as hematite, demonstrating its wide potential to boost the performance of photoelectrodes for energy conversion applications.

In a second part of my talk, I will present our study on the role of composition and interactions between $BiVO_4$ and core-shell structured bimetallic nickel-cobalt phosphide co-catalysts with varying metal ratios to improve their photoanodic performance The best performance obtained from $BiVO_4/Ni_{1.5}Co_{0.5}P$ and $BiVO_4/Ni_{0.5}Co_{1.5}P$ photoanodes achieved a photocurrent of 3.2 (±0.14) mA cm-2 at +1.23 V_{RHE}, a 3.5-fold increase in photocurrent compared with bare $BiVO_4$. Through an extensive characterization considering interfacial energetics, hole storage, and catalytic ability, we have discovered that the

enhanced photoelectrochemical performance cannot be solely attributed to the catalytic activity of the co-catalysts. Instead, it arises from a synergistic interplay involving effective band bending, catalytic activity, and capacitive ability. The contact between the core-shell metal phosphides, $BiVO_4$, and the electrolyte creates three pathways for hole injection into the electrolyte, all of which are notably enhanced by the presence of a second metal cation in the co-catalysts. Kinetic studies demonstrate that the $BiVO_4$/metal phosphide photoanodes show significantly improved interfacial charge injection due to a lower charge-transfer resistance, enhanced OER kinetics, and larger surface hole concentrations. Moreover, by analysing the distribution of relaxation times, we can distinguish the kinetics of various processes, including bulk charge carrier transport, hole injection through different pathways, and surface recombination. This analysis provides deeper insights into the carrier dynamics within these photoanode/cocatalyst systems.

To conclude, these results provide key insights into the preparation of $BiVO_4$ photoanodes boosted with interlayers and co-catalysts to achieves its full potential and pave the way to rationally design other complementary photoelectrodes.

Monolithic Photoelectrochemical Tandem Devices consisting of Tunnel Oxide Passivated Contact Silicon and $BiVO_4$ enabling Unassisted Water Splitting Gihun Jung[1], Choongman Moon[1], Filipe Martinho[2], Yun Seog Lee[3], Stela Canulescu[2] and Byungha Shin[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Technical University of Denmark, Denmark; [3]Seoul National University, Korea (the Republic of)

A tandem photoelectrochemical (PEC) water-splitting device for solar hydrogen production consists of two light absorbers with different bandgaps. Silicon photoelectrodes have been widely investigated in PEC applications because their bandgap (1.12 eV) is suitable for the bottom cell of a tandem device. We apply a tunnel oxide passivated contact (TOPCon) on the front and back sides of a Si wafer to prepare a TOPCon Si PEC device. Photocathodes and photoanodes based on TOPCon Si exhibit remarkable versatility across a wide pH spectrum (0–14), generating photovoltages ranging from 640–650 mV under 1 sun illumination, marking the highest values achieved among crystalline Si photoelectrodes. TOPCon Si demonstrates excellent thermal stability, enduring a high processing temperature of up to 600 °C for 1 h in ambient air. These advantages of TOPCon Si provide high efficiency and great design flexibility for monolithic tandem cells. TOPCon Si is integrated with $BiVO_4$, a large bandgap top cell consisting of earth-abundant and non-toxic elements, in monolithic construction—a wireless PEC tandem cell. A dual-junction monolithic tandem cell consisting of NiOOH/FeOOH/$BiVO_4$/SnO_2/Ta:SnO_2(TTO)/ TOPCon Si yields a maximum photocurrent density of 1.4 mA cm^{-2} (equal to the solar-to-hydrogen conversion efficiency of 1.72%) when illuminated with air mass 1.5 G simulated solar irradiation, which is the highest value among dual-junction monolithic PEC cells except for III-V materials. Transparent and conductive TTO grown by pulsed laser deposition serves as a recombination layer to achieve effective integration. In addition, the TTO provides chemical and physical protection, allowing the surface of the TOPCon Si to exhibit 24 h of tandem cell stability under weak base electrolyte conditions. The SnO_2 hole-blocking layer inserted between TTO and $BiVO_4$ enhances the charge separation of $BiVO_4$, allowing device to achieve high efficiency. Furthermore, we present artificial leaf-type monolithic tandem cells consisting of NiFe/$BiVO_4$/SnO_2/TTO/TOPCon Si/Ag/Ti/Pt. Additionally, if time permits, I will also discuss our recent research involving the utilization of halide perovskite/Cu(In,Ga)Se_2 tandem devices for unassisted water splitting.

Photo-Electrochemical Water Splitting to Generate Hydrogen Fuel: The Importance of Accurately Benchmarking Efficiency, Challenges with System Scale Up and Protective Barriers for Corrosion Mitigation Todd G. Deutsch, Myles Steiner and James L. Young; National Renewable Energy Laboratory, United States

Solar-to-hydrogen (STH) conversion efficiency a common figure of merit for evaluating and comparing research results, and it largely establishes the prospect for successfully introducing commercial solar water-splitting systems. Present measurement practices do not follow well-defined standards, and common methods consistently overestimate performance. To remedy this need we confirmed underestimated influence factors and proposed experimental strategies for improved accuracy.
Our focus was tandem (dual absorber) devices that have the prospect for greater STH efficiency, but increased complexity that requires more careful consideration of characterization practices. We performed measurements on an advanced version of the classical $GaInP_2$/GaAs design while considering (i) calibration and adjustment of the light source, (ii) validation of results by incident photon-to-current efficiency (IPCE), and (iii) definition and confinement of the active area of the device.
We initially measured 21.8% STH efficiency using a tungsten broadband light source, a calibrated $GaInP_2$ photovoltaic reference cell, and epoxy-encased photocathodes. In contrast, integrating experimental IPCE over the AM 1.5G reference solar spectrum showed that less than 10% STH conversion is possible. We performed a set of on-sun measurements that gave 16.1% STH efficiency before eliminating indirect light coupled to the sample by using a collimating tube and 13.8% STH efficiency. However, the value still significantly exceeded the current density expected according to the quantum efficiency measured via IPCE. Finally, suspecting that the illuminated area is poorly defined by epoxy, we use a compression cell for an epoxy-free area definition, resulting in 9.3% STH efficiency – a number corroborated by our IPCE results.
The second part of this talk will identify the challenges encountered while scaling the inverted metamorphic multijunction (IMM) III-V absorber areas of from ~0.15 cm^2 up to 16 cm^2 and incorporating them in a photoreactor capable of generating 3 standard liters of hydrogen in 8 hours under natural sunlight. To successfully scale photo-electrochemical water-splitting technologies from bench to demonstration size requires addressing predictable and unpredictable complications. Despite using Comsol multiphysics to model our photoreactor and identify suitable specifications for a prototype, several practical issues were uncovered during testing that led to multiple iterations of photoreactor design between the initial and final generation. Several bottlenecks that ranged from counter electrode composition and orientation to bubble removal needed redress in order to meet our performance targets. Ultimately, the demonstration-scale system was able to generate nearly twice the target volume of hydrogen in an 8-hour outdoor trial.

While III-V semiconductors have achieved high photo-electrochemical STH conversion efficiencies, they are remarkably unstable during operation in a harsh electrolyte. The final part of this talk will focus on the degradation mechanism of IMM III-V cells and surface modification strategies aimed at protecting them from photocorrosion. We applied noble metal catalysts, oxide coatings by atomic layer deposition, and MoS_2 in an effort to protect the $GaInP_2$ surface that was in contact with acidic electrolyte. We also grew epitaxial capping layers from III-V alloys that should be more intrinsically stable than $GaInP_2$. The ability of the various modifications to protect the IMM's surface was evaluated by operating at each electrode at short circuit for extended periods of time. We will elaborate on the challenges of this mode of protection and new methods of protecting perovskite photo absorbers will be introduced.

An Artificial-Photosynthetic System Consisting of Solar-Driven Reaction and Product Isolation Processes to yield only Pure Formic Acid Yasuhiko Takeda, Shintaro Mizuno, Masahito Shiozawa, Natsumi Nojiri, Takeshi Morikawa and Naohiko Kato; Toyota Central R&D Labs Inc, Japan

We proposed a concept of an artificial-photosynthetic system to produce pure formic acid using only CO_2, water, and solar energy, generating no waste.[1] The system consists of a solar-driven reaction process and a product isolation process. We proved the concept by small-scale experiments, and constructed a practically large-sized reactor as the first step toward widespread use of artificial photosynthesis.[2,3]
We adopted a single-compartment configuration of the solar-driven reactor without ion-exchange membranes and a near-neutral pH electrolyte of a potassium phosphate buffer aqueous solution to simplify the reactor structure. The large-sized reactor was composed of eight-stacked cathode/anode-electrode pairs of 1 m×1 m in size and powered by crystalline-silicon solar cells on the reactor housing via a DC-DC converter. The raw material of 100% CO_2 gas was dissolved in the electrolyte and supplied to the cathode-electrode surfaces uniformly with the help of well-designed flow channels. The electrochemically synthesized formic acid was dissolved in the electrolyte and ejected from the reactor. We developed a Ru-complex-based cathode catalyst and a IrO_x-based anode catalyst, and achieved a Faradaic efficiency as high as 96% for the formic-acid synthesis at an extremely low operating voltage of 1.65 V (overpotential of only 0.22 V) and a large current of 65 A, resulting in a high solar-to-chemical energy conversion efficiency of 10.5%. In addition, we tackled to improve both activity and durability of the cathode and anode electrodes,[4,5] and to realize direct reduction of CO_2 in a flue gas to eliminate CO_2 capture processes.[6] Further, we designed tandem solar modules suitable for direct coupling with the reactors using organic-inorganic hybrid perovskite solar cells.[7]
The next challenge was isolation of the synthesized formic acid dissolved in the aqueous electrolyte. The formic acid cannot be isolated by distillation because of its boiling point (101 °C) almost the same as that of water. Thus, we developed an isolation process on the basis of reactive extraction, including three sequential steps.[1] The first step was reactive extraction of the formic acid from the electrolyte using an extraction solution composed of an organic base (trioctylamine, TOA, boiling point 366 °C) as an extractant and an organic solvent (dichloromethane, DCM, boiling point 40 °C) as a diluent. Although formic acid is highly miscible in water, it was extracted into DCM because the formic acid formed a complex salt with TOA that is insoluble in water. The second step was removal of DCM from the mixture of the extracted formic acid, TOA, and DCM produced in the first step, by evaporation at 40 °C. Finally, the residue was heated at 160 °C for isolation of the formic acid by distillation in the third step. The large differences in the boiling points among these three chemicals secured few contaminations in the second and third steps. In addition, the composition of the electrolyte was tuned for promotion of the formation of the formic acid-TOA complex salt. Thus, we achieved an over 90% isolation yield of pure formic acid. The new electrolyte was confirmed to lower the conversion efficiency by only 10%(relative) and to secure similarly high durability compared with the original electrolyte. The great feature of the isolation process is that all the electrolyte, TOA, and DCM are reused for the next synthesis and isolation after the formic acid is isolated. Thus, we established a highly sustainable artificial-photosynthetic system that consumes no chemicals other than the raw materials of CO_2 and water, or generates no waste.

Utilizing Three-Terminal IBC-Based Si Solar Cells as a Platform to Study The Durability of Photoelectrodes for Solar Fuel Production Darci Collins[1,2], Zebulon Schichtl[1], Nathan Nesbitt[1], Annie Greenaway[1], Valentin Mihailetchi[3], Daniel Tune[3] and Emily Warren[1]; [1]National Renewable Energy Lab, United States; [2]Colorado School of Mines, United States; [3]International Solar Energy Research Center, Germany

Unassisted, photoelectrochemical (PEC) reactions, such as H_2 generation and CO_2 reduction, are limited by the durability of the immersed semiconductor and catalyst. While great strides have been made to improve stability under illumination, dark stability remains relatively unexamined and presents great challenges. Typically, semiconductors require the use of protection layers to drive the PEC reactions of interest. Cathodic protection is an established electrochemical method for preventing electrode degradation in harsh conditions. Similar protection strategies cannot be applied to traditional two-terminal (2T) semiconductor photoelectrodes because of their inability to pass reverse bias current in the dark. New, three-terminal (3T) photovoltaic (PV) architectures can remove the limitations of traditional 2T photoelectrodes by the addition of an extra electrical contact which provides an alternative low resistance path to drive electrochemical reactions, even in the dark. 3T Si interdigitated back contacted (IBC) cells have n+ and p+ doped back contacts, similar to a traditional IBC cell, with an additional conductive front n+ contact to create the third terminal. Here, we investigate how 3T Si PV can be operated as photocathodes to understand new protection methods for photocathodes in aqueous environments without protection layers. We characterize performance of the 3T electrode in a regenerative redox electrolyte, methyl viologen, to decouple catalysis from photocathode device performance. The 3T Si electrode is used as a platform to understand the applications of cathodic protection to electrodes in photoelectrochemical systems. The 3T architecture provides additional capabilities to PEC systems such as cathodic protection, the ability to drive reactions with or without illumination, and in-situ switching between different operational modes. During experiments, the 3T photoelectrode is wired in the diode mode during illumination and wired in ohmic mode in the dark, where the cathodic protection is applied. We show that bare 3T-based Si photocathodes maintain PEC activity in methyl viologen electrolyte after several hours of light/dark cycling. This work helps advance PEC use in real-world conditions where durability under variable illumination must be considered. Future work includes modeling 3T architectures and cathodic protection in fuel forming reactions and experimentally adding Pt and Cu catalysts to extend this work to systems for H_2 generation and CO_2 reduction.

Large Scale Solar Hydrogen and Fuels Production Systems Using Particulate Photocatalysts Kazunari Domen[1,2]; [1]Shinshu University, Japan; [2]The University of Tokyo, Japan

Sunlight-driven water splitting has been studied as a means of producing renewable solar hydrogen. Overall water splitting using particulate photocatalysts is of growing interest as a means of producing renewable hydrogen, because systems based on particulate photocatalysts can be spread over large areas using potentially inexpensive processes.[1)] A solar hydrogen production system based on 100-m^2 arrayed photocatalytic water splitting panels and an oxyhydrogen gas separation module was recently built, and its performance and system characteristics, including safety issues, were reported.[2)] In addition, the hydrogen produced can be used to convert carbon dioxide into chemical fuels.[3)] However, it is essential to radically improve the solar-to-hydrogen energy conversion efficiency (STH efficiency) of photocatalysts and to develop suitable reaction systems.[4)] In my talk, recent advances in photocatalytic materials and reaction systems for hydrogen and fuel production will be presented.

The author's group has studied various semiconductor oxides, (oxy)nitrides, and (oxy)chalcogenides as photocatalysts for water splitting.[5)] $SrTiO_3$ is an oxide photocatalyst that has been known to be active in overall water splitting under UV irradiation since 1980. Recently, the apparent quantum yield of overall water splitting using $SrTiO_3$ has been improved to more than 90% at 365 nm, corresponding to an internal quantum efficiency of nearly unity, by refining the preparation conditions of the photocatalyst and the loading conditions of the cocatalysts.[6)] This observation means that particulate photocatalysts can drive the endergonic overall water splitting reaction with almost no recombination loss as in photon-to-chemical conversion processes during photosynthesis. However, for practical solar hydrogen production, it is essential to develop photocatalysts that are active under visible light. Ta_3N_5,[7)] $Y_2Ti_2O_5S_2$,[8)] TaON,[9)] $BaTaO_2N$[10)], $SrTaO_2N$[11)] have been shown to be active in photocatalytic overall water splitting via one-step excitation under visible light. It is also possible to combine hydrogen evolution photocatalysts (HEPs) and oxygen evolution photocatalysts (OEPs) to split water into hydrogen and oxygen via two-step excitation. Such a process is widely known as the Z-scheme. Particulate photocatalyst sheets consisting of La- and Rh-codoped $SrTiO_3$ as HEP and Mo-doped $BiVO_4$ as OEP immobilized on Au and C layers split water into hydrogen and oxygen with STH efficiencies exceeding 1.0%.[12,13)] Some (oxy)chalcogenides and (oxy)nitrides with long absorption edge wavelengths are also applicable to Z-scheme photocatalyst sheets and hold the promise of realizing greater STH efficiencies.

Advancing Solar Harvesting Technology with Kesterite-Inspired Absorbers and High Throughput Materials Discovery Lydia H. Wong; Nanyang Technological University, Singapore

The quest for harnessing solar energy to produce both electricity and fuel represents an enduring pursuit in the realm of renewable energy. Although conventional solar panels have found application in solar fields and rooftops, the realization of this vision necessitates the development of advanced technologies involving innovative materials and novel manufacturing processes. These advancements aim to extend the application of solar energy to diverse contexts such as windows, vehicles, and complex substrates. Despite the identification of numerous photoabsorbers with potential as solar cell materials, only a limited few have transitioned into commercial use.
This presentation will delve into the recent endeavors of our research group, focusing on kesterite-inspired absorbers [1], with a specific emphasis on the effects of doping and cation substitutions in Cu_2CdSnS_4 photoabsorbers. We will demonstrate how substitutions involving Ag and Ge impact the structure and optoelectronic characteristics of this material [unpublished findings]. Additionally, we will discuss our research in high-throughput synthesis and characterization techniques, which have led to the discovery of new dopants that enhance the charge transport properties of $FeVO_4$ photoanodes [2] and ternary Fe-Co-Ni oxide catalysts for the Oxygen evolution reaction [3].

5:00 PM EN05.10.01
Simultaneous Photo Protecting and Tuning Selectivity of $Cs_3Bi_2Cl_9$ during Photoreduction of CO_2 to HCOOH Using Ir/IrO_x Govardhan Pandurangappa, Raghuram Chetty and Aravind Kumar Chandiran; Indian Institute of Technology Madras, India

Tuning the selectivity with the improved activity of photocatalysts during the photoreduction of CO_2 to value-added chemicals is one of the main bottlenecks in the field of artificial photosynthesis. Here we have investigated lead-free, bismuth-based $Cs_3Bi_2Cl_9$ perovskites as photocatalysts for the photoreduction of CO_2 in the solid-liquid phase. The main CO_2 photoreduction products include CO, CH_4 in the gas phase, and HCOOH in the liquid phase. $Cs_3Bi_2Cl_9$ showed high activity and good selectivity towards HCOOH, with a 553 ± 21 µmol g^{-1} yield at the end of the 5-hour reaction. There was decreased activity of the $Cs_3Bi_2Cl_9$ due to the formation of the secondary phase of BiOCl. A composite photocatalyst $Cs_3Bi_2Cl_9$-Ir/IrO_X showed a higher selectivity towards HCOOH with a yield of 789 ± 43 µmol g^{-1} at the end of the 5-hour reaction which was 1.5 times higher than the yield on pristine

material. This was the highest yield of HCOOH ever reported for this class of materials. The presence of Ir/IrO_X provided the reaction with much-needed hydroxyl groups for the photoreduction of CO_2. Further, Ir/IrO_X delayed the catalyst deactivation thereby retaining its activity for longer cycles by altering the photo-generated charge recombination process and prolonging their lifetimes making them available for the valuable photoreduction of CO_2. This work provides a simple yet effective strategy to tune the selectivity and improve the performance of photocatalysts for CO_2 photoreduction.

Solar Driven CO_2 Reduction to CO Catalyzed by Mn-Complex supported on Carbon Nanohorn in an All Earth Abundant System Teppei Nishi, Shunsuke Sato, Keita Sekizawa, Tomiko M. Suzuki, Keiichiro Oh-ishi, Naoko Takahashi, Yoriko Matsuoka and Takeshi Morikawa; Toyota Central R&D Labs., Inc., Japan

CO_2 conversion technology have been developed for carbon neutral society. A lot of catalysts to convert CO_2 to chemicals have also been developed. Our group also reported CO_2 reduction catalysts. In particular, Mn-complex catalyst supported on multi-walled carbon nanotubes (MWCNTs) can catalyze CO_2 reduction reaction to CO at low overpotential (ca. 100 mV) [1]. In addition to the electrocatalytic activity, solar-driven CO_2 reduction to CO using Ni-doped β-FeOOH as a anode and Si solar cell was also reported [2]. Here, we report a carbon support effect to enhance the electrocatalytic activity [3]. We used MWCNTs, carbon nanohorns (CNHs), graphene platelets (GNPs), carbon black (CB) and carbon nanofibers (CNFs). Electrocatalytic activities Mn-complex supported on various carbon supports were measured in CO_2 saturated aqueous 0.1M $K_2B_4O_7$ + 0.2M K_2SO_4 solution at an applied potential of -1.0 V vs Ag/AgCl. Among the various carbon materials, CNHs were the best supports to enhance the catalytic activity toward CO_2 reduction to CO. Faraday efficiency of CO was 87%. The superior activity was speculated to the high specific surface area and hydrophobic nature. The water-drop contact angle revealed hydrophobicity of CNHs and MWCNTs. It is expected that a superior local environment for highly selective CO_2 reduction can be provided by hydrophobic supports by keeping water away from the electrode surface. In contrast, hydrophilic carbon supports resulted in the increase of Faraday efficiency of H_2. Additionally, specific surface area of CNHs (410 m^2/g) was larger than other carbon supports. It is concluded that these properties resulted in the enhancement of catalytic activity of Mn-complex.
Because CNHs was revealed to enhance the catalytic activity of Mn-complex for CO_2 reduction to CO, we demonstrated solar-driven CO_2 reduction to CO using Mn-complex supported on CNH as a cathode electrode, Ni doped β-FeOOH supported on single walled carbon nanotube (SWCNT) as an anode electrode and polycrystalline Si solar cell. A solar-to-CO conversion efficiency was 3.3 %.

Experimental Characterization of Three-Terminal Tandem Photoelectrode Voltages for Photoelectrochemical Applications Grace Rome[1,2], Myles Steiner[2], Emily Warren[2] and Annie Greenaway[2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

Sustainably produced liquid fuels are necessary for a clean energy future, especially for energy intensive applications such as aviation where batteries are presently not sufficiently energy dense. Photoelectrochemical carbon dioxide reduction (PEC CO_2R) is a possible route to the production of sustainable fuels. However, there are an abundance of different products from CO_2R, making selective production of a single chemical difficult and requiring expensive, energy intensive product separation. One method to improve selectivity is to design cascading reactions, such as reducing CO_2 to CO and then subsequently reducing the CO to higher order (C_{2+}) products.[1] Each reaction within the CO_2R cascade occurs at a specific thermodynamic potential, requiring a specific voltage, and has a specific stoichiometry, requiring a specific electron flux or current density. The reactions of interest for a PEC CO_2R cascade would take place on a single photoelectrode, requiring first step products to move only on the order of millimeters to the second reaction site. This work aims to develop and characterize a III-V-based photoelectrode that can drive such a cascade CO_2R photoelectrochemically, using sunlight as the energy input.

A three-terminal tandem (3TT) is a type of multijunction photovoltaic device where a middle terminal is added between the two subcells that comprise the tandem, rather than having no extra terminal (as in a two-terminal tandem) or having the two subcells electrically separated (a four-terminal tandem).[2] Connecting any two of the three contacts generates a different voltage, enabling a single device to supply the different potentials required for CO_2R cascade reactions. Current densities can be manipulated by changing the relative areas of the terminals. The GaInP/GaAs 3TT tandem used in this work has two terminals contacting the electrolyte, each of which drives one step of the CO_2R cascade; the photoelectrode is illuminated from opposite side, through a third terminal. Previous modelling work[3] has shown that a 3TT tandem could drive a PEC CO_2R cascade and possibly improve product selectivity over simpler photoelectrodes. However, the fundamental behaviors of 3TT photoelectrodes are not yet understood in relationship to the performance of 3TT photovoltaics. This work experimentally characterizes the PEC behavior of a 3TT photoelectrode. Potential and current relationships will be characterized both dry and under electrochemical conditions to provide insight into what standard reduction potentials are possible with a GaAs/GaInP 3TT device. Dry power contour plots will be used to find the max power point, as simple current-voltage curves cannot fully define 3TT operation due to presence of the middle contact.[4] Non-aqueous PEC measurements, using regenerative redox couples, will be performed in combination with light filtering (to select the GaInP or GaAs subcell) to learn about the operational window of each electrolyte terminal. In summary, this work aims to control a 3TT photoelectrode for PEC CO_2R as a step towards the goal of sustainable fuel production.

Direct Z-Scheme Heterostructure of *In-Situ* Planted ZnO Nanorods on g-C_3N_4 Thin Sheets Sprayed on TiO_2 Layer: A Strategy for Ternary-Photoanode Engineering towards Enhanced Photoelectrochemical Water Splitting Ahmed E. Aboubakr, Mahmoud K. Hussien, Amr Sabbah, Kuei-Hsien Chen and Chen-Hsiung Hung; Academia Sinica, Taiwan

In this study, we focused on optimizing the photoanode, which is crucial for the practical applications of photoelectrochemical water splitting (PEC-WS). We describe an improved fabrication method that is efficient and scalable. This approach enhanced the separation and transfer of charge carriers for photoelectrochemical water splitting in solar-driven hydrogen production. We followed a procedure that enables the in-situ growth of ZnO nanorods on g-C_3N_4, resulting in a ZnO/g-C_3N_4 composite with an enhanced specific surface area. The as-fabricated composite exhibits interfacial Zn-N bonding interactions, as evidenced by XPS Zn 2p and N 1s spectra. This composite material demonstrated improved efficiency in charge migration and a lower charge recombination rate with a Z-scheme type charge separation, supported by data from time-resolved photoluminescence spectroscopy (TRPL) and photoelectrochemical impedance spectroscopy (PEIS), as well as from theoretical calculation. We achieved this by designing a highly efficient Z-scheme

TiO_2/g-C_3N_4/ZnO photoanode. PEC-WS measurements showed that TiO_2/g-C_3N_4/ZnO photoanode improved the produced photocurrent by about 160-, 40-, 20-, 8-, 2-, and 2-fold, relative to pristine g-C_3N_4, pristine ZnO nanorods, ZnO/g-C_3N_4 composite, pristine TiO_2, TiO_2/ZnO, and TiO_2/g-C_3N_4, respectively, versus reversible hydrogen electrode (RHE) at 1.23 V. The DFT results contributed to a deeper understanding of the mechanism of the photocatalytic process and confirmed that the as-fabricated ternary heterojunction promoted the separation/transfer efficiency of the photogenerated charge carriers, thereby promoting the activity of the photocatalytic process. This work could pave the way for the better fabrication of ternary-based photoanodes; we used an airbrushing procedure under mild heating to deposit ZnO/g-C3N4 on TiO2 and obtained a photoanode with a ternary composition. This photoanode displayed efficient charge separation and transfer due to the improved interface properties. Furthermore, utilizing this strategy of spraying the as-synthesized ZnO/g-C3N4 photocatalyst over the TiO2-coated FTO under moderate heating results in a homogeneous distribution of the components. To the best of our knowledge, this is the first study to use these strategies to fabricate such ternary photoanodes. So, our strategy could pave the way for synthesizing various g-C_3N_4-based ternary composites for PEC-WS. We believe this work will be of high interest because our approach is applicable to many ternary heterostructures and could be widely used as a universal strategy to increase the photocatalytic performance of various composites toward PEC-WS.

Designing New Metallic Catalysts by Transversing The 'Hidden' Compositional Terrain Qinrui Liu, Md T. Islam and Scott Broderick; University at Buffalo, United States

To discover materials with enhanced catalytic behavior, we convert the complex elemental feature space into a connected network, representing the similarities and underlying physics of catalytic alloys. A challenge in the design is due to limited number of property measurements, thereby making typical data driven modeling inaccurate and uncetain. To address this challenge, we apply a random walk approach to capture the reaction behaviors and link the kinetic and chemical behaviors of the alloys. The results lead to a more comprehensive understanding of metallic catalysts design with the most promising chemistries identified across a variety of gas reactions. Through this work, the design space is reduced and the necessary experiments are defined.

5:00 PM EN05.10.07
Enhancement of The Photoelectrochemical Performance of TiO_2 Nanotube Arrays through Sensitization with Electrochemicallly Deposited CdSe Nanoparticles Damini Vrushabendrakumar, Harshitha Rajashekhar, Navneet Kumar, Kazi M. Alam and Karthik Shankar; University of Alberta, Canada

This study presents an approach to enhance the photoelectrochemical water-splitting performance of highly transparent TiO_2 nanotube arrays (TTNTAs) through electrochemical deposition of CdSe nanoparticles (NPs) in aqueous electrolytes containing a mixture of $CdCl_2$ and SeO_2.[1] CdSe is particularly attractive as a sensitizer due to its broad visible light absorption (enabling increased photogeneration of carriers), quantum confinement effect and strong photoluminescence emission which can be spectroscopically monitored to understand the interfacial energy level configuration and electron injection efficiency (into TiO_2). While CdSe NPs formed by colloidal and/or SILAR (sequential ionic layer adsorption and reaction) routes have been extensively used to sensitize various wide band gap semiconductor nanostructures, there are far fewer reports on sensitization using electrochemically synthesized CdSe quantum dots. TTNTAs were fabricated via a facile and well-established electrochemical anodization process.[2] The top surfaces and lateral walls of TTNTAs were selectively decorated with CdSe NPs. A major advantage of the electrochemical deposition process is the number of process variables that can be adjusted in order to deterministically control the particle size and size distribution of the CdSe NPs decorating the TTNTAs. These process variables include the concentration & relative ratio of the Cd and se precursors in electrolyte, the applied electrochemical potential and the duration of the electrodeposition process. The structural and optical properties of the CdSe-doped TNTAs were systematically characterized. Sensitization of TTNTAs with CdSe NPs led to improved light absorption and charge separation efficiency[3]. The photoelectrochemical activity for water splitting was evaluated, demonstrating enhanced hydrogen and oxygen evolution reactions under visible light illumination. The synergetic effects of transparent TNTAs and CdSe nanoparticle decoration resulted in a significant improvement in the overall water-splitting performance. This work provides valuable insights into the design of efficient and partially transparent photoelectrodes for solar-driven water splitting, paving the way for sustainable hydrogen production.

Supercharging Solar Fuel Production: Harnessing Sub Bandgap Energy in Mo-Doped BiVO4 Photoanode to Enhance Photoelectrochemical Reaction via Triplet-Triplet Annihilation Upconversion Prashanth Venkatesan and Ruey-An Doong; National Tsing Hua University, Taiwan

Developing solar-based empowered technology is an important issue to realize a zero-carbon world. Among various forms of solar energy utilization, photoelectrocatalysis (PEC), which involves a direct solar to chemical energy conversion by light-matter interaction, exhibits a relatively high theoretical efficiency. PEC uses semiconductors to absorb photons to produce effective electron-hole pairs for a redox reaction. Several concepts have been proposed and demonstrated to improve the separation and utilization of the excitons. However, few attempts have been made to engineer the light to enhance the PEC efficiency by broadening the range of the solar spectrum that the semiconductor can utilize. The upconversion (UC) process induced by triplet-triplet annihilation (TTA) is an intermolecular energy transfer process by restoring the energy in triplet-state molecules to produce a high-energy singlet state to enhance the UC process. It is noted that the UC process, which uses the solar spectrum as the light source can convert the sub-bandgap photon into the absorbing range of the PEC semiconductors. Therefore, incorporating PEC with TTA-UC appears to be the most suitable process to enhance the efficiency of PEC by utilizing the abundant visible light from solar light.
In this study, the benchmark TTA-UC chromophores, 9,10-diphenylanthracene (DPA) sensitized by platinum octaethylprophyrin (PtOEP) are used. They are dissolved in oleic acid to upconvert the green light (532 nm) to blue light (400 – 480 nm) in an ambient environment. The phosphorescence of PtOEP is quenched by DPA based on the Stern-Volmer relation, indicating that the triplet energy transfer between the two chromophores is effective. The optimal concentrations of PtOEP and DPA are 20 µM and 8 mM, respectively. For ease of implementation, PtOEP/DPA containing oleic acid is emulsified and acts as soft templates during the sol-gel process of tetraethyl orthosilicate (TEOS), yielding to UC active SiO_2 nanocapsules. The TEM images suggested that a silica shell encapsulates oleic acid with a diameter of 200 – 300 nm with a thickness of 10 nm. The upconverting composite film is prepared using the SiO_2 nanocapsules. Semitransparent Mo: $BiVO_4$ photoanode is synthesized by spin coating technique. The incorporation of upconverting composite film with Mo:$BiVO_4$ photoanode shows an enhanced photocurrent density from 1.09 $mAcm^{-2}$ to 1.24 $mAcm^{-2}$, equivalent to an increase of 14%. With a 490 nm long pass filter a 45% increase at 1.23 V_{RHE} is observed corresponding to a current density increase from 0.24 $mAcm^{-2}$ to 0.35 $mAcm^{-2}$.

5:00 PM EN05.10.09
A Novel Approach to Anti-Soiling Coatings for Solar Modules by use of Lanthanide Oxide Films Jayna K. Patel, Ivan Parkin and Claire Carmalt; University College London, United Kingdom

Advances in solar module utilities underpin an important approach for novel sources of renewable energy. However, soiling remains a major obstacle when considering the use of solar modules as a sustainable replacement for electricity generation. Thus, there is an evident need for self-cleaning solar utilities. We present the design, synthesis and application of inorganic rare oxide layers (Ce_2O_3, Er_2O_3) which have been deposited by aerosol assisted chemical vapour deposition (AACVD) with intrinsic hydrophobicity. Water contact angles of up to 103 ° were established across the deposited thin films, inferring their self-cleaning potential.

The reduced number of examples of lanthanide oxide complexes for hydrophobic coatings using AACVD within the literature, prompted our investigation into the synthesis of volatile lanthanide β-diketonate precursors, a novel approach to self-cleaning solar modules. Notably, inorganic rare Earth oxide layers (Ce, Y, Lu, Er) have proven through various applications to be durable, UV stable, oxidant resistant and have intrinsic hydrophobicity with a water contact angle range of 110-125 °.[1, 2] Likewise, β-diketone ligands complexes have proven to serve as effective and stable precursors. Compounds of the type $[M(Y)_{3,4}]$ have been synthesised via adaption of a known synthetic route to $[Ce(thd)_4]$ and $[Er(thd)_3]$.[3, 4] Where; M = lanthanide metal (Ce, Er) and Y = thd (dipivaloymethane), dbm (dibenzoylmethane).

AACVD of the synthesised complexes yielded lanthanide oxide films on fluorine tin doped (FTO) glass under a constant flow of nitrogen. Thermogravimetric analysis of these compounds indicated suitable deposition temperatures ranging from 400-600 °C. The most hydrophobic coatings were attained by deposition of cerium oxide onto FTO at temperatures between 400-500 °C. These rare oxide thin films were intrinsically analysed using surface analysis and characterisation techniques. Whereby X-ray photoelectron spectroscopy confirmed the presence of a mixed phase system of Ce(III) and Ce(IV) across the surface. Further analysis of the deposited thin films was conducted using SEM and XRD to determine the surface morphologies of these hydrophobic coatings.

Highly Efficient and Stable Dye-Sensitized Photoelectrochemical Cells via Cascade Charge Transfer Jun-Hyeok Park, Ji-Wook Jang and Tae-Hyuk Kwon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Dye-sensitized photoelectrochemical cells (DSPECs) have shown promise in artificial photosynthesis for water splitting, but they face obstacles such as low photocurrents (0.01–2.2 mA/cm^2) and limited stabilities (0.01–2 h, maintaining over 90% of initial photocurrent) due to degradation/decomposition of dye-sensitized photoelectrodes, along with inefficient charge transfer processes in aqueous electrolytes forming adaptive junction. To overcome these fundamental issues, we developed a “cascade-type” dye-sensitized photoelectrode utilizing platinum-sputtered nickel foil to encapsulate both the dye-sensitized TiO_2 layer and redox mediator electrolyte. This buried junction design enables spatially controlled cascade charge transfer, highly effective photoconversion, and active water oxidation facilitated by Ni-based catalysts, all without undesirable current leakage. By conducting a comprehensive study involving three redox electrolytes and optimizing water oxidation catalysts, our best-performing photoelectrode achieves a photocurrent of 14.5 mA/cm^2, Faradaic efficiency of approximately 98%, and photostability of 30 h under AM 1.5G illumination.

5:00 PM EN05.10.11
Effect of Protonation on The Photocatalytic CO_2 Reduction by Linear Conjugated Polymers containing Benzo[*c*]cinnoline Structure Kuang-Hao Cheng[1,2], Shih-Hsuan Lin[1], Cheng Wei Cai[2], Leeyih Wang[2], Kun-Han Lin[3] and Jyh-Chien Chen[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]National Taiwan University, Taiwan; [3]National Tsing Hua University, Taiwan

In this study, we polymerized NDI-BZC and DPP-BZC utilizing the naphthalene diimides (NDI) and diketopyrrolopyrrole (DPP) as acceptor benzo[*c*]cinnoline (BZC) as donor, and obtained the polymers NDI-BZC-H and DPP-BZC-H by hydrochloric acid protonation, respectively. We consider that the photocatalytic carbon dioxide redox reaction consists of two half reactions: the oxidation of water and the reduction of carbon dioxide. The oxidation of water is essential in this process. In this experiment, we use protonation to increase the hydrophilicity of the polymer. However, an excessive increase in hydrophilicity will lead to a competing reaction of hydrogen generation and CO_2 reduction. Therefore, it is crucial to precisely control the increase in hydrophilicity. We introduced BZC as a donor, which possesses an azo-functional group for protonation to precisely enhance the donor's hydrophilicity and facilitate the oxidation reaction with water. The precise enhancement of hydrophilicity proves to be beneficial for water oxidation efficiency without adversely affecting CO_2 adsorption. The success of protonation is confirmed by the signal shift of the azo-functional group and the appearance of Cl signals in the XPS analysis. Additionally, contact angle measurements demonstrate an increase in hydrophilicity, leading to a doubled efficiency of pure water systerm. After the addition of the sacrificer, the efficiency of DPP-BZC-H reached 235 μmol g^{-1} h^{-1}, and the efficiency of NDIBZC-H reached 343 μmol g^{-1} h^{-1}. The results clearly emphasize the critical role of increasing hydrophilicity in CO_2 reactions, particularly when it occurs at the appropriate site. The distinctive characteristic of the azo group in BZC enables precise control over the protonation position, resulting in a significant enhancement of efficiency. These remarkable capability make BZC as a highly promising candidate in the field of CO_2 reduction.

5:00 PM EN05.10.12
Two Dimensional Janus Ga_2SX_2 (X = O, S, Se, and Te) Monolayers as Efficient Piezo- and/or Photocatalyst for Green Hydrogen Generation Devender Takhar[1], Balaji Birajdar[1] and Ram Krishna Ghosh[2]; [1]Jawaharlal Nehru University, India; [2]IIIT, India

Developing innovative and environmentally friendly hydrogen generation technologies are pivotal for transition to a carbon-neutral future. In this regard, the integration of photocatalytic and piezoelectric properties of semiconductor catalyst have proved beneficial. As polar nature of piezoelectric materials provides a drive force to photo-generated charge carriers thus enhancing their separation and reducing recombination. Additionally, piezoelectric materials generate a potential under oscillatory strain, commonly known as piezo-potential, can alone initiate the water redox reaction. Therefore, in this study we explore the potential of piezoelectric Janus Ga_2SX_2 (X=O, S, Se, Te) monolayers as efficient piezo- and/or photocatalyst, leveraging density functional theory (DFT) simulations. Our investigation encompasses a comprehensive examination of the structural, electronic, optical, mechanical and piezoelectric properties. Except Ga_2SO_2 all monolayers exhibit semiconducting behaviour, featuring indirect band gaps within the range of 1 eV to 2.7 eV. The band

edges are favourable to straddle the photocatalytic water redox reaction under the solar illumination. Moreover, the generated piezo-potential exceeds 3 V which originate from superior piezoelectric and mechanical properties demonstrating the piezo-catalytic water splitting ability. In summary, these findings open new avenues for the development of piezo- and photocatalytic technologies for clean and sustainable hydrogen production.

5:00 PM EN05.10.13
Modulation of Structural, Electronic and Electrocatalytic Properties of Pulsed Laser Ablated Ruthenium Oxide Thin Films for Oxygen and Hydrogen Evolution Reactions Ikenna C. Chris-Okoro[1], Sheilah Cherono[1], Swapnil Nalawade[1], Mengxin Liu[1], Valentin Craciun[1,2], Shyam Aravamudhan[1], Maria D. Mihai[2,3], Soyoung Kim[4], Junko Yano[4] and Dhananjay Kumar[1]; [1]North Carolina Agricultural and Technical State University, United States; [2]Horia Hulubei National Institute for Physics and Nuclear Engineering, Romania; [3]University Politehnica of Bucharest, Romania; [4]Lawrence Berkeley National Laboratory, United States

This study presents a detailed optimization study of the structural, electronic, and electrocatalytic properties of ruthenium oxide thin films grown using the pulsed laser ablation (PLA) process. The study begins by growing substrate-film interdiffusion-free sub-stoichiometric (RuO_{2-x}), stoichiometric (RuO_2), and hyper-stochiometric (RuO_{2+x}) epitaxial ruthenium oxide films with controlled orientation at relatively low deposition temperatures on single-crystal substrates with different crystal structures and surface orientations, such as (110) and (100) oriented rutile TiO_2, (100) oriented perovskite $SrTiO_3$ and $LaAlO_3$, and (0001) oriented hexagonal sapphire. The synthesis of the substrate-film interdiffusion-free RuO_2 films has been possible due to the axial velocity of laser-ablated neutral and ionic species as high as ~10^5 m/s (kinetic energy ~ 3 eV), which compensates for the high substrate temperatures nearly by 50 °C. The next part of the study is focused on the use of x-ray photoelectron spectroscopy (XPS) and Rutherford Backscattering Spectrometry (RBS) measurements to confirm that the oxygen content of RuO_2 films increases from x = 0.5 to x = 1.0 with an increase in oxygen growth pressure from 5 mTorr to 100 mTorr. Further characterization of the RuO_2 films was carried out using x-ray diffraction, atomic force microscopy, four-probe resistivity, spectroscopic ellipsometry, and soft x-ray absorption spectroscopy (XAS) at the O K-edge analysis before and after electrocatalytic property measurements. The study has provided insights to overcome the stability problem of RuO_2 often encountered during the electrocatalytic water oxidation and reduction process. Using the ability to synthesize RuO_2 with the same stoichiometry on substrates with different crystal structures, lattice constants, and orientations, we have developed a better understanding of the effect of surface tension and lattice-matched interfacial structures on electrocatalytic oxidation and reduction of water.

This work was supported by a DOE EFRC on the Center for Electrochemical Dynamics and Reactions on Surfaces (CEDARS) via grant # DE-SC0023415. The authors (IK, VC, and DK) also acknowledge the support of the NSF PREM via grant # DMR-2122067 PREM.

5:00 PM EN05.10.15
Enhanced Stability, Photoluminescence and Charge Transport Properties of TiO_2-Coated $CsPbBr_3$ Quantum Dots for Photoelectrochemical Solar Fuel Production Paravee Vas-Umnuay and Parina Nuket; Chulalongkorn University, Thailand

All-inorganic cesium lead bromide perovskite quantum dots ($CsPbBr_3$ QDs) exhibit excellent optical and electrical properties such as strong light absorption, tunable band gap, long diffusion lengths, ambipolar charge transport, and high charge carrier mobility. Therefore, they have been widely used for light-energy conversion including photovoltaic (PV) and photoelectrochemical (PEC) applications. However, $CsPbBr_3$ QDs have suffered from instability against the environmental factors in broad applications due to the inherent perovskite properties. This work thus aimed for two purposes. The first is to enhance the stability of $CsPbBr_3$ QDs, and the second is to use $CsPbBr_3$ QDs as a light-harvesting material incorporated with TiO_2 electrode for PEC oxidation of methanol. For the first aspect, TiO_2 coating on $CsPbBr_3$ QDs by ex-situ and in-situ methods was performed to prevent the agglomeration of the nanocrystals and to improve the stability of $CsPbBr_3$ QDs without heat treatment at high temperatures. The stability test revealed that TiO_2-coated $CsPbBr_3$ QDs prepared from the in-situ method exhibited a significant stability improvement against toluene, ultrasonication treatment in water, and light illumination. Furthermore, the results demonstrated the remarkable enhancement of photocurrent generation due to a suitable alignment of energy levels of TiO_2 and $CsPbBr_3$ and a stable structure of QDs, which plays an important factor in improving the PEC performance. Therefore, it was proved to be used as a good light-harvesting and electrode material in various photoelectrochemical applications. For the second aspect, the photocurrent generation via PEC oxidation of methanol was studied using surface-modified TiO_2-coated fluorine-doped tin oxide (FTO) as a photoanode in combination with $CsPbBr_3$ QDs dispersed in an electrolyte solution. Detailed studies revealed that surface modification of the TiO_2 layer was crucial for good interfacial adhesion of $CsPbBr_3$ QDs, which were surrounded by hydrophobic ligands, with the TiO_2 surface. Self-assembled monolayers of octadecylphosphonic acid (ODPA) were applied on the TiO_2 surface, resulting in the change of hydrophilic nature to a superhydrophobic surface. The photoluminescence measurement of the ODPA-modified TiO_2/FTO photoanode demonstrated a significantly higher photoluminescence intensity than that of the unmodified one, indicating that $CsPbBr_3$ QDs were well adsorbed on the TiO_2 surface. The photocurrent was generated via methanol oxidation by holes in $CsPbBr_3$ QDs. The current-voltage measurements revealed that in the presence of methanol, the current density was increased from 1.2 mA/cm^2 (without methanol) to the maximum of 1.6 mA/cm^2 under visible light irradiation, indicating that methanol was a sacrificial hole scavenger. As a consequence, the multicomponent ODPA-modified TiO_2/FTO photoanode in combination with $CsPbBr_3$ QDs together with the efficient hole scavenger of methanol in the system has been shown to promote the PEC oxidation performance, which can be applied in any PEC solar fuel production.

Electrochemical CO_2 Reduction to Methane with Remarkably High Faradaic Efficiency in The Presence of a Proton Permeable Membrane Hanqing Pan; University of Nevada, Las Vegas, United States

The combustion of fossil fuels is a major contributor to rising levels of anthropogenic carbon dioxide (CO_2) in the atmosphere. Due to the adverse effects of climate change caused in large part by CO_2, new technologies must be developed that contribute to a global renewable energy supply. Electrochemical reduction of CO_2 offers a viable pathway to generating value-added products and synthetic fuels to meet our future energy demands while decreasing greenhouse gas emissions. By constructing electrocatalysts capable of modulating proton transfer, we are able to tune product selectivity. Previous studies have demonstrated that two-electron products (CO and HCOOH) can be produced with high selectivity, but multiple-electron transfer products (CH_4, CH_3OH, and C2+ products) typically are produced at much lower Faradaic efficiencies. In this work, we construct polymer-modified Cu electrodes that exhibit extraordinarily high CH_4 production (88% Faradaic efficiency). These electrodes afford a new strategy for increasing the selectivity of CO_2 reduction electrocatalysts, an attribute that is key in developing industrially-relevant CO_2 conversion devices. Nafion is a widely used fluoropolymer that is often mixed with electrocatalysts to facilitate proton transport. In contrast to these Nafion-catalyst composites, this work studies electrodes covered by Nafion overlayers for the CO_2 reduction reaction. By varying the thickness, substrates, and voltage, we perform a detailed study of the effect of Nafion overlayers on metal and carbon mesh electrodes for CO_2 reduction. Depending on the thickness of the Nafion membrane, CO_2 reduction occurs at either the polymer–electrolyte interface or electrode–polymer interface. A Nafion overlayer of 15 μm on a Cu electrode enables an extraordinarily high yield of CH_4 production (88% Faradaic efficiency) at a low overpotential (540 mV) *via* the stabilization of metal-bound CO intermediates. To the best of our knowledge, this yield is the highest for electrocatalytic CO_2 reduction to CH_4 production at room temperature reported.

Preparation of MOFs Coupled-$LaFeO_3$ Nanosheet for Electrochemical CO_2 Conversion Iltaf Khan, Munzir H. Suliman and Muhammad Usman; King Fahd University of Petroleum and Minerals, Saudi Arabia

The rapid growth of modern industries has led to increased energy demand and worsened fossil fuel depletion resulting in global warming while organic pollutants pose significant threats to aquatic environments due to their stability, insolubleness, and non-biodegradability. So, scientists are investigating high-performance materials to resolve these issues. In this study, we prepared $LaFeO_3$ nanosheets (LFONS) employing a solvothermal method via a soft template such as polyvinylpyrrolidone (PVP). The LFONS have good performance regarding surface area and charge separation as compared to $LaFeO_3$ nanoparticles (LFONP). To improve the efficiency of LFONS, it was further modified with Ag and ZIF-67 and utilized for CO_2 conversion. Herein, the results confirm that Ag-doped and ZIF-67 coupled LFONS (ZIF-67/Ag-LFONS) exhibit superior performance compared to pristine LFONP. In addition, the stability tests confirm that our optimal sample is the most active and stable among various nanocomposites. Ultimately, our studies will pave the new gateway for cost-effective, eco-friendly, and electroactive nanomaterials for CO_2 conversion.

Unveiling the Optimal Interfacial Synergy of Plasma Modulated Trimetallic Mn-Ni-Co Phosphides: Tailoring Deposition Ratio for Complementary Water Splitting Nageh K. Allam; American University in Cairo, Egypt

Designing highly active, durable, and nonprecious metal-based bifunctional electrocatalysts for overall water electrolysis is of urgent scientific importance to realize sustainable hydrogen production, which remains a grand challenge. Herein, an innovative approach is demonstrated to synthesize flower-like 3D homogenous trimetallic Mn, Ni, Co phosphide catalysts directly on nickel foam *via* electrodeposition followed by plasma phosphidation. The electrochemical activity of the catalysts with varying Mn: Ni: Co ratios is assessed to identify the optimal composition, demonstrating that the equimolar trimetallic phosphide yields an outstanding HER catalytic performance with a current density of 10 mA/cm^2 at an ultra-low overpotential of ~14 mV, outperforming the best-reported electrocatalysts. This is asserted by the DFT calculations, revealing a strong interaction of the metals and the P atom, resulting in enhanced water activation and optimized G_{H^*} values for the HER process. Moreover, this optimal composition appreciably catalyzes the OER by exposing more intrinsic active species in-situ formed on the catalyst surface during the OER. Therefore, the Mn_1-Ni_1-Co_1-P-(O)/NF catalyst exhibits a decreased overpotential of ~289 mV at 10 mA/cm^2. More importantly, the electrocatalyst sustains perfect durability up to 48 h at a current density of 10 mA/cm^2 and continued 5000 cycling stability for both HER and OER. Meanwhile, the assembled MNC-P/NF||MNC-P/NF full water electrolyzer system attains an extremely low cell voltage of 1.48 V at 10 mA/cm^2. Significantly, the robust stability of the overall system results in remarkable current retention of ~96% after a continuous 50 h run. Therefore, this study provides a facile design and a scalable construction of superb bifunctional ternary MNC-phosphide electrocatalysts for efficient electrochemical energy production systems.

5:00 PM EN05.10.19
Atomically Dispersed Transition Metal Single Atoms for Photocatalytic CO_2 Reduction and NO Removal Thang Q. Nguyen[1,2,3], Amr Sabbah[2], Li-chyong Chen[2] and Kuei-Hsien Chen[1]; [1]Institute of Atomic and Molecular Science, Academia Sinica, Taiwan; [2]Center for Condensed Matter Sciences, National Taiwan University, Taiwan; [3]National Tsing Hua University, Taiwan

The development of single-atom-supported metal oxides has inspired extensive interest in energy catalysis, offering a promising avenue for combating environmental pollution and converting greenhouse gas emissions into valuable products. Single-atom-supported metal oxide catalysts have garnered significant attention for their unique ability to bridge the gap between surface reactions and efficiency. Identifying the precise atomic-level active sites where these reactions occur is pivotal for advancing research in this domain. In this study, we presented a facile approach for synthesizing atomically-dispersed nonprecious metal-modified metal oxide catalysts. By carefully tuning the transition metal single-atom ratios, exceptional photocatalytic efficiency in the conversion of nitric oxide (NO) with an impressively low conversion of toxic nitrogen dioxide (NO_2) and enhanced photocatalytic CO_2 reduction were achieved. Insights into the mechanistic aspects of the photocatalytic NO oxidation reaction are garnered through scavenger trapping and electron paramagnetic resonance experiments employing 5,5-dimethyl-1-pyrroline N-oxide (DMPO). Furthermore, in-situ diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) and in-situ X-ray absorption spectroscopy techniques are employed to elucidate reaction intermediates and mechanisms governing the photocatalytic reduction of CO_2 into CO. This study highlights the potential of single-atom-supported metal oxides in advancing the fields of sustainable chemistry and air purification, offering a promising avenue for addressing pressing environmental challenges.

5:00 PM EN05.10.20
Chalcohalide Nanocrystals for Solar Energy Harvesting: Synthesis, Characterization and Photocatalytic Applications Irina Gushchina[1], Stefano Toso[2], Bo-An Chen[1], Carlo Giansante[3], Masaru Kuno[1,1] and Liberato Manna[2]; [1]University of Notre Dame, United States; [2]Istituto Italiano di Tecnologia, Italy; [3]Consiglio Nazionale delle Ricerche, Italy

Despite the pressing needs imposed by climate change, we have not yet managed to harvest the full potential of the sun as an abundant and fully renewable energy source. Scientists globally have invested significant resources to better understand how to capture this vast energy capital: the most renowned is arguably photovoltaics, but it is not the only one. Another promising route is storing the energy of the sun by forming new chemical bonds, through a process called photocatalysis.
Recently, a new group of semiconductors known as chalcohalides has come to the attention of the community as promising active materials. Many compounds of this class can be prepared with cheap, vastly abundant, and nontoxic elements, which would make them ideal candidates for large-scale applications. In this project, we aimed to synthesize metal chalcohalide nanocrystals with varying compositions, crystal structure, and morphology. We considered both phases that have been already obtained colloidally, but whose photocatalytic potential is still to be explored (e.g., BiSX, $Bi_{13}S_{18}X_2$, and $Pb_4S_3X_2$, where X=Cl, Br, I), as well as materials known in bulk but never explored before at the nanoscale (e.g., $Pb_7S_2Br_{10}$, or the lead-free $AgBiSCl_2$ and $CuBiSCl_2$). We optimized the synthetic methods for each material and characterized their optoelectronic properties to identify the best candidates for photocatalytic applications. Additionally, catalytically active metal tips were grown on top of chalcohalide nanocrystals to form functionalized heterostructures with improved energy conversion efficiency. Finally, the most promising candidates were tested as active materials in a liquid-medium photocatalytic test cell, leading to new industry-viable materials for light-to-chemical energy conversion.

Empirical and Theoretical Investigations into the Mechanism of Wireless CO_2 Reduction over Modified g-C_3N_4 Photocatalyst Mahmoud K. Hussien[1], Amr Sabbah[1], Putikam Raghunath[2], Shu-Chih Haw[3], Kuei-Hsien Chen[4] and Li-chyong Chen[1]; [1]National Taiwan University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan; [3]National Synchrotron Radiation Research Center, Taiwan; [4]Academia Sinica, Taiwan

The light-driven reduction of carbon dioxide holds promise for CO_2 mitigation and the conversion of CO_2 into valuable fuels and chemicals. While extensive efforts have been dedicated to elucidating the mechanistic aspects of photocatalytic CO2RR, the majority of reported studies have primarily focused on liquid-phase reactions using metal-based photocatalysts. In this investigation, we systematically explore the water-vapor assisted CO2RR employing a modified, metal-free g-C_3N_4-based photocatalyst without the incorporation of any cocatalyst, photosensitizer, or sacrificial reagent. Our

approach utilizes In-Situ FTIR, DFT calculations, and operando XAS to deepen our understanding of the reaction mechanism. Furthermore, this study yields significant insights into the dynamics of charge carriers and the identification of active sites, thereby advancing our comprehension of the entire photocatalytic process.

5:00 PM EN05.10.23
Facile One-Step Synthesis of Cu_2O Photocathode coated with ZnO Nanoparticles for Enhanced Photoelectrochemical Property Huang Yu Hao, Po Yu Lai and Chien-Neng Liao; National Tsing Hua University, Taiwan

Cuprous oxide (Cu_2O) is a promising photoelectrode material for photoelectrochemical (PEC) water splitting due to its suitable band structure, environmental acceptability, non-toxicity, and ease of fabrication. In this study, ZnO nanoparticles coated Cu_2O films (ZNC) were electrodeposited on fluorine-doped tin oxide (FTO) substrates using a $CuSO_4$ solution with varying $ZnSO_4$ content. The ZNC film exhibited a 35% enhancement in photocurrent density compared to the pristine Cu_2O film. Several characterization techniques were employed to uncover the impact of ZnO NPs on the PEC enhancement of the ZNC films, including x-ray photoelectron spectroscopy, electrochemical impedance spectroscopy, and photoluminescence spectroscopy. Additionally, Pd nanoparticles were introduced onto the surface of the ZNC films, and a thin trisodium citrate (TSC) layer was applied as a passivation treatment to improve the performance and stability of the ZNC photoelectrodes during PEC water splitting.

Improvement of Optical Properties of CZTSSe-Based Solar Cells and Photocathode Devices via Cd Doping Suyoung Jang and Jin Hyeok Kim; Chonnam National University, Korea (the Republic of)

$Cu_2ZnSn(S,Se)_4$ material is a material that replaces $CuInGaSe_2$, which is currently being researched, and is attracting attention as an eco-friendly and economical material because it does not use indium or gallium. However, various studies are being conducted to improve CZTSSe devices due to their low solar cell efficiency and low hydrogen conversion efficiency in PEC water splitting. Among them, cation doping is known to significantly contribute to improving device performance by improving the optoelectric properties of CZTSSe thin films. Cations doped into CZTSSe include various elements such as Ge, Cd, and Ag, and among these, Cd can be easily doped using the Chemical Bath Deposition method. Cd is doped into CZTSSe to control secondary phase and void formation, and when applied to a device, it improves photocurrent and improves light-hydrogen conversion efficiency. In this study, CZTSSe was doped with Cd by deposition time (9.5, 10.5, 11.5 minutes) using the CBD method to analyze its single thin film properties, and solar cells and PEC photocathodes were manufactured under the same conditions to measure device characteristics. As a result, the thin film sample doped with Cd for 11.5 minutes showed excellent photoelectric properties, solar cell efficiency was measured up to ~8%, and photocurrent was measured up to ~15 mA/cm^2 as a PEC photocathode.

5:00 PM EN03.08.02
Perylene Diimide Derivatives with Various Ionic Functionalities as Cathode Interlayers for ZnO-Free Inverted Non-Fullerene Organic Solar Cells Dong Hwan Son, Rahmatia Fitri Binti Nasrun, Qurrotun Ayuni Khoirun Nisa, Indah Salma Sausan, Young-Seok Lee, Ka In Kang and Joo Hyun Kim; Pukyong National University Daeyeon Campus, Korea (the Republic of)

Perylene diimide (PDIN) derivatives, possessing various ionic functionalities, have been synthesized and utilized as cathode interlayers (CIL) in inverted-type non-fullerene organic solar cells (NFOSCs). CILs including polyfluorene derivatives and PDIN are commonly employed as prospective non-fullerene CILs due to their advantageous low-energy levels. However, the main drawback of PDI derivatives is exhibiting strong aggregate, primarily due to their pronounced π–π stacking tendency, and this aggregation adversely impacts their morphology and transport characteristics. Therefore, it is necessary to modify the geometry with appropriate functional groups of PDI derivatives to adjust the planarity of PDIs and control their energy level. In this study, we

modified CILs based on PDIN derivatives for inverted NFOSCs. To our knowledge, perylene diimide featuring ammonium oxide as its terminal group (PDIN-O) was inserted between the active layer and the metal cathode, typically placed on top of the photoactive layer, in conventional OSCs. This positioning helped eliminate the need for heat treatment. To overcome the thermal issue, we modified PDIN by changing the side-chain functionality. We synthesized a series of materials based on PDIN with different terminals which are amino N-ethyl-iodo (PDIN-I), amino N-ethyl-bromo (PDIN-Br), amino N-butane sultone (PDIN-BS), and amino N-oxide (PDIN-O). In our study, we introduced various counterions into the PDIN to examine their impact on photovoltaic performance to replace the ZnO layer. Inverted-type NFOSCs were constructed with the following configuration: ITO/PDIN derivatives/PM6:Y6BO/MoO_3/Ag. The reference device (ITO/ZnO/PM6:Y6BO/MoO_3/Ag) was also prepared for comparison to investigate the photovoltaic characteristics of PDIN derivatives in NFOSCs. The power conversion efficiency (PCE) of the inverted-type device utilizing PDIN-O is 12.5%, which is lower due to its poor thermal stability, with degradation starting at around 100°C. In contrast, devices employing PDIN-I, PDIN-Br, and PDIN-BS achieved PCE values of 15.5%, 15.0%, and 15.0%, respectively. These values are nearly identical to the PCE of the device using ZnO (15.0%). The combined improvements of short circuit current (J_{sc}) and fill factor (FF) contribute significantly to the performance of the device. The highest PCE obtained is 15.5% achieved by PDIN-I as CIL which is slightly higher than the device based on ZnO. This improvement is a result of the increase in the J_{sc} of 28.2 mA/cm^2 from the device based on ZnO (25.9 mA/cm^2). However, in terms of the FF of the device based on PDIN-I showed a slightly lower value of 68.6% than that of the device based on ZnO (70.8%). Introducing the quaternary ammonium ion and zwitterion into the PDIN backbone enhanced the performance of the devices compared to a device based on PDIN-O. Expanding the size of the counter anion led to a reduction in the effective work function of ITO. The size of the counterion affects the magnitude of the interfacial dipole and results in increasing the device performance. In addition, these CILs retained their original PCE after 30 hours of thermal and photo-aging, proving their effectiveness as an oxygen-blocking layer at the device interface. This study demonstrates the capacity to regulate CIL and thus provides insight into the fabrication of low-temperature processible ZnO-free NFOSCs.

Physical Structure Effect of TiO2 Compact Layer for Enhanced Photoelectric Efficiencies Chia-Yi Huang[1] and Tz-Feng Lin[2]; [1]Tunghai University, Taiwan; [2]Feng Chia University, Taiwan

One of the urgent challenges for sustainable energy is to hold the global warming back before 2050 in response to the global net-zero mission. An awareness of that is the green energy in demand and the use of solar energy would continue to cover the deficient of clean energy. Dye-sensitized solar cells (DSCs) would one of the promising photovoltaic technologies for renewable applications since 1990 in balancing an infrastructure cost and electricity production. This study fabricates a planar and stereo TiO2 compact layer on a fluorine-doped tin oxide glass substrate with a Pt layer. Photolithography and physical structural design were used to build planar and stereo structures. The Pt layer gives rise to the protrusive structure of the counter electrode by sputtering and lift-off process. Then, porous semiconductor materials made of fine or coarse TiO_2nanoparticles was coated on the planar and stereo structure. Experimental results reveal that the photoelectric efficiency of the DSCs is higher than that of a DSCs without a specific physical structure one. As a result, the protrusive Pt layer not only can increase the photoelectric efficiencies of DSCs but also serves as a facilitated electron transport channels. In addition, this result was verified by the electrochemical impedance spectra of the two DSCs. The proposed method has advantages in easy fabrication of electrode structures with respect to acceptable production cost.

5:00 PM EN03.08.04
Solar-Thermal Hybrid Concept of Energy Harvesting with Printed Perovskite and Organic Photovoltaic Cells Sarath Witanachchi[1], Derick C. DeTellem[1], Christian Coris[1], Gina Pantano[1], Brianna Pecourt[1], Hasitha Weerasinghe[2], Mei Gao[2] and Luke Sutherland[2]; [1]University of South Florida, United States; [2]Commonwealth Scientific and Industrial Research Organization (CSIRO), Australia

In this paper we are reporting the results from an experimental project conducted in collaboration with CSIRO Australia to enhance power generation by integrating screen-printed flexible perovskite and organic cells with thermoelectric modules. While solar modules have the potential to generate significant currents based on the solar radiation intensity, achieving required voltages require a series connection of multiple devices. On the other hand, thermoelectric modules (TE) that convert heat into electricity generates high voltages, but the current is limited by the intrinsic properties of the thermoelectric materials. Under the new hybrid concept, high voltages generated by TE modules are combined with the high currents generated by PV cells. Four thermoelectric modules place in a 150ºC temperature gradient and connected in series can generate voltages over 7V. The printed perovskite cells used in the study showed a short-circuit current of 22 mA/cm^2 and an open circuit voltage of 4.8v. The hybrid of the PV-TE combination in a unique configuration has resulted in power outputs that are 4x higher than the PV module alone. A computational model developed for the hybrid correlate well with the experimental data. The circuit design, the IV-characteristics, and the conditions for optimum power generation in the hybrid configuration with possible waste-heat sources will be presented. The project was supported by an NSF IRES grant.

5:00 PM EN03.08.06
Assessment of Potential Environmental and Health Risks for Key Components of Solar Module Hi Gyu Moon, Jong-Su Seo and Chang-Beom Park; Korea Institute of Toxicology, Korea (the Republic of)

To address the serious challenges of climate change and global energy security, investment in renewable energy sources has increased significantly in Asia, Europe and globally. Among them, wind and solar power plants are expected to make the largest contribution to global decarbonization, ranking first and second in projected capacity by 2050. To date, the development and improvement of photovoltaic technology based on energy storage technology has received considerable attention, but the potential environmental risks are still unknown. Additionally, there is currently insufficient toxicological and environmental risk information to assess potential risks. However, several studies have reported that lead, tin, cadmium, silicon, and copper, which are the main components of damaged products, are harmful to the ecosystem and human health when discharged to landfills. Therefore, we evaluated the toxicity and human risk of the main components of solar panels, including related research trends, and then propose optimal government policies for solar cell to protect the environment and the human body.

SESSION EN03.13: Poster Session II: Sustainability of Emerging Photovoltaics

5:00 PM EN03.13.01
Eco-design Strategies from R&D Level Towards a Sustainable Perovskite Tandem Technology Nouha Gazbour[1,2], Beatrice Drevet[1], Sjoerd Veenstra[2]

and Delfina Munoz[1]; [1]Commissariat à l'énergie atomique et aux énergies alternatives (CEA), France; [2]TNO, Partner in Solliance, Netherlands

The solar photovoltaic (PV) energy has become a fast-growing competitive sector. Innovation is a prerequisite for the survival of many PV companies. In the last years, the perovskite solar cells has gained much attention in the solar community because of the high efficiencies obtained in single and multi-junction devices and low fabrication projected cost. Due to the massive scale of the energy sector, it is essential that this new emerging PV technology progresses in a way that is consistent with the requirements of sustainable development before large scale deployment.
Sustainability is defined as an interaction between economic, social, technical and environmental criteria. Nevertheless, R&D activities are often focused on technical and economic improvements as a priority to enter the market. In addition, the limitations of current eco-design tools, as identified in the literature, hinder their adoption by R&D organizations. In fact, environmental impact assessment is relatively complex for a non-mature technology under development because its characteristics and manufacturing processes are not yet fully defined. Life Cycle Assessment (LCA) is a reliable environmental assessment tool, but it is limited to the evaluation of the investigated technology without proposing eco-design alternatives.
This study proposes a methodology to provide eco-design strategies from the earliest stages of design to develop sustainable all-perovskite tandem technology. In the research stage, the device architecture is often not defined yet. Therefore, we start with a review of the existing LCA studies on perovskite solar cells to identify the hotspots from an environmental point of view. Then, the list of the reported materials that could be used for the solar cell, including packaging materials, is defined. We analyze this list from an environmental point of view based on results obtained from the literature and legislative constraints. Finally, we propose eco-design guidelines that could reduce the cost, increase the performance, and decrease the environmental impact for the development of a sustainable perovskite tandem solar cell technology.
Based on this approach, key recommendations toward a sustainable perovskite tandem technology are :
- For the Transparent Conductive Oxide (TCO), indium-containing oxides are good candidates from a technical and economical point of view. However, indium is a critical material. Aluminum-doped zinc oxide (AZO) would be a more suitable candidate but vigilance is required on the electricity required for its production process.
- For the metal electrodes, copper should replace silver for economic and environmental criteria. However, there are few studies in the literature on its technical reliability.
- Fullerene (C_{60}) remains technically one of the best electron transport layer materials, but attention must be paid to its environmental impact and its high production cost.
- The contribution of the material of the perovskite layer to the environmental impact in the module is small. Nevertheless, some components in the layer and auxiliary materials need to be eco-designed
- Compared to glass, polymer-packaging materials do not pose a problem from economic and environmental points of view. Their choice must be based on technical criteria, primarily good barrier properties.
- In view of the circularity potential, a closed loop wet chemical recycling process is preferable over other approaches such as thermal decomposition, electrochemical refinement, or physical separation routes (e.g. adsorption/desorption).
- The challenges addressed by this recycling process are i) green solvent recycling development, ii) complex perovskite composition separation and recovery (with a focus on lead recovery and reuse), and iii) functional layer recovery.

These recommendations will help to guide technological choices from the early design process to ensure the development of sustainable perovskite tandem technology.

5:00 PM EN03.13.02
Breaking News on Highly Efficient Inorganic Tin-Lead Perovskite Solar Cells Ting Zhang[1], Feng Qian[1], Shihao Yuan[1], Zhi D. Chen[2] and Shibin Li[1]; [1]University of Electronic Science and Technology of China, China; [2]University of Kentucky, United States

To date, hybrid lead halide perovskite (LHP) solar cells have achieved great advances on a PCE from 3.8%[1] to an impressive certified value of 26.1%[2] within fourteen years. Despite the high efficiency of state-of-the-art lead-based perovskite solar cells is approaching the market-dominant silicon photovoltaic technology, they still face two concerns, e.g. poisonous Pb and non-ideal bandgaps for single-junction solar cells. To addressing this issue, according to Shockley-Queisser (S-Q) limit theory[3], alloying tin (Sn) into B site is more effective to obtain less toxicity and preferable bandgap for a single-junction solar cell, which can yield the maximum efficiency with bandgap energies ranging from 1.2 to1.4 eV, at which the solar spectrum utilization and the photocarrier relaxation would be optimized and balanced. Among these Pb-Sn alloyed perovskites, inorganic tin-lead perovskites are attractive candidates owing to their additional merit of inherent compositional stability.
Inorganic tin-lead perovskites have been investigated with low exciton binding energy, high charge mobility, high absorption coefficients and thermal stability. Encouraged by these outstanding properties, lead-rich $CsPb_{0.9}Sn_{0.1}IBr_2$ PSCs with a wide bandgap of 1.79 eV were first reported in 2017[4], which obtained an efficiency of 11.33%; up to 2023, Zhang et al. reported a record PCE of 17.19% based on low-bandgap (1.34 eV) $CsPb_{0.7}Sn_{0.3}I_3$ PSCs via a post treatment method[5]. As seen from the simple development of inorganic Pb-Sn PSCs progress, the PCE still lags far behind their Pb-based analogs and Pb-Sn hybrid counterparts and the origin remains unclear. In addition to the common challenges of easy oxidation of Sn^{2+}, crystallization regulation has been crucial yet less explored in low-bandgap $CsPb_xSn_{1-x}I_3$ PSCs. This could be ascribed to the lower enthalpy of the Cs^+ in comparison with MA^+ or FA^+, which endows the crystallization kinetics quite different from their hybrid counterparts. It is thus imperative to acquire in-depth understanding of the unique crystallization dynamics of cesium tin-lead perovskites, which would provide guidance of the solidification process of cesium tin-lead perovskites and therefore high optoelectronic films and devices.
In this breaking news, for the first time, Shbin Li and colleagues reveal the B-site initiated asynchronous crystallization of inorganic tin-lead halide perovskites by comprehensive in-situ and ex-situ characterizations as well as molecular dynamics calculations[6]. Then, a novel synchronous alloying process is developed using a novel Sn-perovskite-targeted crystallization regulator. The regulator suppresses the asynchronous crystallization by enhancing the formation barrier energy of $CsSnI_3$, endowing a synchronous Sn and Pb alloying reaction in precursor film, achieving a homogeneous film after the annealing process. Finally, a record-high PCE of 17.55% is obtained for modified $CsPb_{0.7}Sn_{0.3}I_3$ solar cells, in a sharp contrast to the control device which shows a PCE of 3.6%. More importantly, B-site synchronous alloyed target devices show impressive stability with negligible degradation either at 65 °C over 3500 h for the net films or under continuous LED illumination for 700 h.
Research on Pb-Sn alloyed perovskites mostly focuses on the anti-oxidation of tin and is still at a relatively early stage, but the work of Shibin Li and colleagues provides a valuable B-site initiated synchronous crystallization approach to create highly efficient PSCs. Their proposed approach would be applicable to other high-performance and stable optoelectronic devices based on Pb-Sn alloyed perovskite.

Theoretical Guided Material and Interface Optimization for High Performance Perovskite/Organic Tandem Solar Cells Zonglong Zhu; City University of Hong Kong, Hong Kong

Addressing the pressing challenges of rising global energy needs and achieving carbon neutrality to protect the environment necessitates the development of a practical solution. The emergence of solution-processed organic and metal halide perovskite semiconductors, and their resultant solar cells, could potentially instigate a revolution in photovoltaic technology, enabling the delivery of scalable, high-performance solar cells for sustainable green energy production. Despite the power conversion efficiencies of both single-junction organic solar cells and perovskite solar cells rapidly reaching over 19% and 26% respectively, their maximum efficiency is confined to around 30% as per the Shockley-Queisser model for single-junction devices. However, by fabricating a multi-junction device with multiple light absorbers possessing significantly varied bandgaps, the efficiency of solar cells could potentially be augmented to over 40%.
In this talk, I will introduce high-performance monolithic perovskite/organic tandem solar cells with PCE>26%. These encompass a wide bandgap perovskite front cell and a narrow bandgap organic rear cell connected via a recombination junction. We have selected wide bandgap perovskite solar cells for the front cell due to their robust absorption for visible light, minimal voltage loss, and superior photoresponse. Meanwhile, narrow bandgap organic solar cells could potentially offer superior near-infrared absorption tunability and stability, making them ideal candidates for the rear cell of the tandem cells. To demonstrate the potential of perovskite/organic tandem solar cells, we employ an integrated strategy that combines materials, interface, optical, and process engineering.

Systematic Study of The Effect of A-Site Engineering on The Crystallization Kinetic of Sn-Pb Perovskite Changyong Kim, Ayoung Lee, Sangheon Lee, Sangjun Park and Donghoe Kim; Korea University, Korea (the Republic of)

Perovskites with narrow band gaps exhibit high theoretical efficiency, and there is still considerable room for improvement at the current stage. Introducing a combination of Sn and Pb into metal halide perovskites is way to obtain narrow band gap perovskites. For high-quality Sn-Pb perovskite formation requires delicate controlled crystallization rate of the perovskite precursor solution. However, due to the fast crystallization kinetics of high Lewis acidic Sn^{2+} the reaction between SnI_2 and methylammonium iodide (MAI)/ formamidinium iodide (FAI) proceeds notably quicker than that involving PbI_2. Consequently, as the Sn content increases in Sn-Pb binary perovskite films, the rapid nucleation rate by Sn^{2+} crystallization kinetics leads to smaller crystal grain sizes and a higher density of defects. This uncontrollable crystallization and reaction competition of organic ammonium with Sn and Pb make it hard to fabricate of high-quality perovskite film.
At present, the most high-performing Sn-Pb perovskite based solar cells consist of an A-site mixture of FA and MA. The doping of various inorganic cations on the A-site of perovskite has been reported as one of the advantageous candidates for controlling the crystallographic kinetics to improve the performance and stability of perovskite solar cells. However, in the binary B-site of Sn-Pb perovskite, there is a lack of systematic research on the effect of the A-site composition by reacting more complex.
In this study, we have carried out a systematic study of the effect of inorganic cations on the fast and complex crystallization process of Sn-Pb perovskites. Finally, we have demonstrated the several composition design rule of Sn-Pb perovskites to reach a photovoltaic conversion efficiency exceeding 22%.

Stable and Efficient Halide Perovskite Solar Cells by Using Guanidinium-Incorporated Quasi-2D Perovskite Layer Matthew T. Bamidele and Do Young Kim; Oklahoma State University, United States

Halide perovskite solar cells are a rising star in the photovoltaic community due to their remarkable performance and rapid progress. Solution processability of hybrid perovskite semiconductors makes these materials especially attractive for low cost and scalable manufacturing. While halide perovskite solar cells already show remarkable improvement with a power conversion efficiency above 25%, poor stability under ambient environmental conditions of heat, humidity, and light is the major issue hindering the commercialization of this technology. Layered two-dimensional (2D) perovskites have been extensively investigated for improving the stability of perovskite solar cells while sacrificing efficiency. In this study, we have explored pathways to improve the stability of perovskite solar cells while maintaining their efficiency by using a 2D perovskite layer. First, halide perovskite solar cells using quasi-2D guanidinium-based halide perovskites synthesized with lead acetate (PbAc) have higher efficiency and stability compared to perovskite solar cells with quasi-2D perovskite synthesized from traditional lead iodide (PbI). This is due to a characteristic perpendicular orientation of the quasi-2D perovskite crystal structure, which can facilitate charge extraction. The power conversion efficiency of quasi-2D perovskite solar cells using PbAc is approximately two times higher than solar cells using PbI. Another intriguing aspect of guanidinium-based quasi-2D perovskite solar cells is a continuous improvement in efficiency that spans several weeks. This observed enhancement is attributed to age-induced recrystallization, showcasing the material's potential for prolonged stability and delay in the onset of device degradation. As a result, the quasi-2D perovskite solar cells maintained almost the same performance even after 3,000 hours. Also, we present an alternative approach that improves the performance of halide perovskite solar cells by introducing an orderly stacking of $MAPbI_3$ film as a 3D halide perovskite light-harvesting layer on top of a quasi-2D $GA_2MA_4Pb_5I_{16}$ halide perovskite layer. The power conversion efficiency of quasi-2D/3D perovskite solar cells is approximately 20% higher than that observed for 3D perovskite-based solar cells fabricated under the same conditions. The observed improvement is attributed to the superior crystallinity and excellent film quality achieved by the coherent stacking of 3D $MAPbI_3$ on top of quasi-2D $GA_2MA_4Pb_5I_{16}$ perovskites. Additionally, the improved photovoltaic performance of these quasi-2D/3D perovskite solar cells does not compromise their durability. Even after 1,900 hours of storage, the devices maintained about 98% of their initial performance.

Biocarbon from Algae, Cellulose and Sewage Sludge as Sustainable Composites for Energy Storage Theotime Béguerie[1], Amel Cydric Ghogia[1], Lina María Romero Millána[1], Shamala Gowri Krishnan[1], Majd El Saddik[1], Elsa Weiss[1], Claire White[2,2], Kuo Zeng[3] and Ange Nzihou[1,2]; [1]Université de

Toulouse, France; [2]Princeton University, United States; [3]Huazhong University of Science & Technology, China

This presentation will discuss the synthesis, characterization, and utilization of a novel family of biocarbon-based composites for electrochemical and heat storage. The composites are produced by the pyrolysis and carbonization of various biomass (algae, cellulose biomass, and municipal sewage sludge) inherently containing or doped with catalytic metal such as Iron and Calcium at lower temperature (<1400°C) than the standard carbonization temperature (>1800°C) or processed with molten salt (Na_2CO_3-K_2CO_3). In this process, the biocarbon is transformed from a randomly organized carbon to a graphite-like material (organized and structured carbon) showing a high graphene rate structure. The Carbon structure and composition changes in the composites have been investigated from nano to bulk scales in combining XRD, HRTEM and RAMAN. This has enabled to probe changes in biochar nanostructure and crystalline graphitic domains catalyzed by the inclusion of metal such as iron and Calcium. The encapsulation of iron particles by graphitic phase (graphene sheets) and the carbon-metal bonding during the pyrolysis and carbonization were uncovered using XPS. Key properties for energy storage applications such as the remanent magnetization, the coercive field, the specific heat, the thermal and electric conductivities, the thermal stability including the mechanical properties will be discussed. Biocarbon from algae for example, rich in nitrogen showed a high specific surface area of 2009.26 m2/g with high specific capacitance of 230.2 F/g at 0.25 A/g and a capacitance retention of 75.54% at 2 A/g. This work provides a green and promising approach to produce heteroatom-doped capacitive biocarbon with superior properties for energy storage.

8:45 AM EN06.04/EN03.04.02
Heteroepitaxial Crystal Growth of Halide Perovskite for n-i-p Structure Yun-Kyeang Hong, Sanghee Yang and Hui-Seon Kim; Inha University, Korea (the Republic of)

Perovskite solar cells (PSCs) have rapidly achieved high power conversion efficiency since its first solid-state application in 2012, leading to an outstanding PCE of 26.1% in 2023. Nevertheless, the stability issue still hinders the commercialization. While the chemical composition of perovskite material has been carefully engineered to extract the best optoelectronic properties and the phase stability as well, the lattice strain has recently emerged as one of the key parameters determining the phase stability of perovskite film. Here we employ an interlayer, formamidinium tin halids ($FASnCl_xBr_y$), between SnO_2 (electron transport layer) and perovskite, where the heteroepitaxial crystal growth of perovskite film on the interlayer is enabled by tuning its lattice distance (*d*), ranging from 0.342 nm ($FASnCl_x$) from 0.365 nm ($FASnBr_y$), as evidenced by transmission electron microscopy. While the large difference in *d* between the interlayer and the perovskite film (>10%) negligibly affect the crystal growth, the smaller mismatch in *d* (<10%) affects the perovskite crystal growth and thus leads to a strain relaxation at the interface of perovskite film. Therefore, the resulted relaxation of tensile strain at the bottom interface of perovskite film is comparably beneficial for the phase stability of α-$FAPbI_3$, though 2% in-plane residual tensile strain is still remaining, which is in accordance with the monitored film stability in ambient air. Kelvin probe force microscopy is also measured to elucidate the effect of $FASnCl_xBr_y$ interlayer on energy level alignment, where the changed band banding, coupled with defect reduction, at the interface is likely responsible for the enhanced recombination resistance and open-circuit voltage of PSCs.

9:00 AM EN06.04/EN03.04.03
New Dopant for $FAPbI_3$ Film in Perovskite Solar Cells Ju-Hye Choi[1], Yu-Na Kim[2] and Hui-Seon Kim[1]; [1]Inha University, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of)

A great effort has been made on the chemical composition of perovskite film in perovskite solar cells (PSCs), where formamidinium lead iodide ($FAPbI_3$) recently achieved the highest power conversion efficiency (PCE) of 26.1% in 2023. One of the most important challenges is securing the phase stability of $FAPbI_3$, which is prone to convert from α-phase to δ-phase without additive engineering. Therefore, additive plays an important role in $FAPbI_3$ not only by affecting the phase stability via interaction in the grown lattice but also by controlling the crystal growth through interaction with precursors. In this study we incorporate hydroxylammonium formate (HAHCOO) in the perovskite precursors for $FAPbI_3$, coupled with methylammonium chloride. Fourier transform-infrared spectroscopy reveals that lone pairs in HA^+ and $HCOO^-$ effectively act as Lewis base and interact with Pb^+ as Lewis acid in perovskite precursors and leads to increased grain size (~1500 nm) and uniformity (1500 nm of FWHM), as evidenced in scanning electron microscope images. In the meantime, HA^+ is assumed to substitute for FA^+ because the ionic radius of HA^+ (0.216 nm) ranges between methylammonium cation (MA^+, 0.18 nm) and FA^+ (0.22 nm), which is indirectly evidenced with a variation in binding energy from x-ray photoelectron spectroscopy measurement. On the other hand, $HCOO^-$ acts as an anion vacancy passivator at grain boundaries and top surface and closely correlates with the increased surface recombination resistance of PSCs. The inclusion of new additive, HAHCOO, therefore successfully leads to PCE increase from 18.9% to 20.1% with an increased long-term stability.

9:15 AM EN06.04/EN03.04.04
A Strategy for Modifying ZnO-Free Inverted Organic Solar Cells using a Naphthalene Diimide as Cathode Interlayers Rahmatia Fitri Binti Nasrun, Qurrotun Ayuni Khoirun Nisa, Dong Hwan Son, Indah Salma Sausan, Young-Seok Lee, Ka In Kang and Joo Hyun Kim; Pukyong National University, Korea (the Republic of)

Perylene diimide featuring ammonium oxide as its terminal group, often referred to as PDIN-O, is a widely recognized cathode interlayer utilized in conventional organic solar cells (OSCs). As naphthalene diimide demonstrates a lower LUMO level compared to perylene diimide, we selected it as the core to gain additional control over the LUMO level of materials. Small molecules (SMs) generate a favorable interfacial dipole through the introduction of ionic functionality at the side chain of naphthalene diimide. When employing SMs as cathode interlayers in conjunction with an active layer composed of a non-fullerene acceptor (PM6:Y6BO), the power conversion efficiency (PCE) showed an enhancement. The results revealed that the OSC using naphthalene diimide with ammonium oxide as its terminal group (NDIN-O) exhibits inadequate thermal stability, resulting in irreversible damage to the interlayer-cathode contact, thereby contributing to a low PCE of 11.1%. To overcome the disadvantage, we have introduced NDIN-Br and NDIN-I, both of which possess a higher decomposition temperature. We achieved an impressive PCE of 14.6% in the device utilizing NDIN-Br as an interlayer, which is almost the same as the PCE of the ZnO-based device (15.0%). The device incorporating NDIN-I demonstrates an enhanced PCE of 15.4%, slightly surpassing the ZnO-based device. These results suggest a viable alternative to the ZnO interlayer, which typically requires precise control of the sol-gel transition through high-temperature annealing, often reaching up to 200°C. This alternative approach could potentially reduce the manufacturing costs of OSCs.

9:30 AM *EN06.04/EN03.04.05
Organic Photovoltaic Materials: Decreasing Synthetic Complexity through Scalable "Cascade" Approaches Dario Pasini[1], Andrea Nitti[1], Riccardo Po[2] and Gabriele Bianchi[2]; [1]University of Pavia, Italy; [2]Eni S.p.A., Italy

Organic electronic materials offer advantages such as flexibility, low cost, and easy processability using simple solution processing methods. They are π-extended organic compounds and polymers with suitable semiconducting properties, typically obtained through linear and multi-step synthetic approaches. Such approaches have yielded highly performing compounds and polymers through complex, multi-step synthesis, limiting their scalability for industrial applications. Sustainability and scalability of the synthetic process plays a fundamental role for definitive consecration of the organic electronic materials, and generally they depend on: (a) the number of synthetic steps; (b) the cost of the materials; (c) yields; (d) the number of steps of purification that require

column chromatography. A unique parameter (synthetic complexity, SC) have been recently proposed to rationalize the field of materials used in the Organic Photovoltaic arena (OPV).[1]
In this contribution, we will report recent developments on the use of "cascade" reaction protocols to address annulations and formation of π-extended polymers for OPV. Such protocol condenses in an one-pot cascade fashion both direct (hetero)arylation (DHA) and intramolecular cross-aldol condensations.[2-5] The application of such protocol has been used with success for the synthesis of thienoacene scaffolds such as naphthothiophenes (NTs), benzodithiophenes (BDTs) and anthradithiophenes (ADTs) in a single and double annulation fashion. ADT and BDT derivatives were incorporated into polymers and the properties of bulk-heterojunction solar cells will be presented.

Lead Sequestration and Recycling in Perovskite Solar Cells Kai Zhu; National Renewable Energy Laboratory, United States

Organic-inorganic hybrid halide perovskites have rapidly become a focal point of the photovoltaic (PV) community as a promising next-generation PV technology. The certified efficiencies of single-junction perovskite solar cells (PSCs) and perovskite-based tandem cells have reached 26.1% and 33.7%, respectively. However, all of the current state-of-the-art perovskite-based PV devices contain lead (Pb) ions. The toxic Pb could pose a potential threat to the environment and public health. To address this potential challenge for future market adoption of perovskite PV technologies, we need to develop proper Pb management strategies for both perovskite devices in operation and those at the end-of-life. In this talk, I will first provide an overview of the potential Pb toxicity issue and some common strategies to address it. Then I will present our recent studies in this research area. Specifically, I will discuss our efforts on developing on-device Pb sequestration to prevent the leakage of Pb ions from broken perovskite PV devices under severe weather conditions. I will also discuss how to make our Pb sequestration approach scalable for industrial applications. In addition, I will discuss our efforts on recycling Pb from end-of-life perovskite PV devices. Finally, I will present our perspective on making perovskite PV a sustainable technology.

11:00 AM EN06.05/EN03.05.02
Environmental Impacts of Pb Leaching from Halide Perovskites Iris Visoly-Fisher[1], Arindam Mallick[1], Mendez Lopez Rene D.[2] and David Cahen[3]; [1]Ben-Gurion University of the Negev, Israel; [2]Bar Ilan University, Israel; [3]Weizmann Institute of Science, Israel

A significant concern is accidental Pb leaching from PSCs and modules, due to the well-documented Pb toxicity. Review of the current knowledge shows that this threat is found to be comparable to that posed by currently used Pb-containing products, and a plethora of measures are available to mitigate the environmental impact of Pb.[1] However, Pb leaching from damaged PSCs may imply a significant environmental impact on the surrounding soil in the case of module damage. We have examined the penetration profile of Pb from aqueous solutions of dissolved Pb-perovskite into the soil, and the Pb^{2+} adsorption mechanism to soil particles. The penetration profiles in all studied soils showed high affinity for Pb adsorption to soil, hence shallow immobilization of the Pb cations in all studied soils, with negligible odds of reaching and contaminating ground water. We, therefore, suggest that Pb in PSCs and its effect on the environment are not as concerning, as they seem to be.[2]

11:15 AM EN06.05/EN03.05.03
Tautomeric Mixture Coordination Enables Efficient Lead-Free Perovskite LEDs Virginia Carnevali[1], Lorenzo Agosta[1], Nikolaos Lempesis[1], Haizhou Lu[1,2], Ursula Rothlisberger[1] and Michael Graetzel[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Southeast University, China

Lead halide perovskite light-emitting diodes (PeLEDs) have demonstrated remarkable optoelectronic performance. However, there are potential toxicity issues with lead and removing lead from the best-performing PeLEDs—without compromising their high external quantum efficiencies—remains a challenge. Here we report a tautomeric-mixture-coordination-induced electron localization strategy to stabilize the lead-free tin perovskite TEA_2SnI_4 (TEAI is 2-thiopheneethylammonium iodide) by incorporating cyanuric acid. We demonstrate that a crucial function of the coordination is to amplify the electronic effects, even for those Sn atoms that aren't strongly bonded with cyanuric acid owing to the formation of hydrogen-bonded tautomeric dimer and trimer superstructures on the perovskite surface. This electron localization weakens adverse effects from Anderson localization and improves ordering in the crystal structure of TEA_2SnI_4. These factors result in a two-orders-of-magnitude reduction in the non-radiative recombination capture coefficient and an approximately twofold enhancement in the exciton binding energy. Our lead-free PeLED has an external quantum efficiency of up to 20.29%, representing a performance comparable to that of state-of-the-art lead-containing PeLEDs. We anticipate that these findings will provide insights into the stabilization of Sn(II) perovskites and further the development of lead-free perovskite applications.

SESSION EN06.06/EN03.06: Joint Session: Advances in Recycling and Circularity

1:30 PM *EN06.06/EN03.06.01
Circular Economy for Photovoltaics in Service of Energy Transition Heather Mirletz, Silvana Ovaitt and Teresa Barnes; National Renewable Energy Laboratory, United States

The challenge of energy transition is immediate and immense; current projections target 75 TW of photovoltaics (PV) capacity by 2050. While any transition to renewable energy technology is preferable to the current fossil-based system, it is ideal to improve the sustainability of PV to minimize negative environmental and social impacts. Circular economy (CE) has been proposed as a method to improve the sustainability of PV, especially for emerging materials like perovskites. CE is a set of actions, principles, and systems which aim to design out waste and keep products and materials in use, to reduce environmental impacts and enable sustainable development. At the most basic level, CE is “reduce, reuse, recycle”, the R-actions, in ranked order. CE of a PV technology can be metricized in a variety of ways, such as the Material Circularity Indicator (Smith and Jones, Ellen MacArthur Foundation, 2019) or recycling rates. Unfortunately, standard CE metrics have several shortcomings for measuring renewable energy technologies in the context of deployment for energy transition (Figge 2018, Saidani 2019):
only measure mass flows
de-prioritization of the use phase in favor of mass circularity when scoring
tight focus on a single product scale
The use phase and energy flows of PV are key to energy transition, and therefore need to be quantified. Additionally, correlating product-scale to system-scale is necessary for quantifying the environmental impacts of energy transition. Life Cycle Assessment (LCA) can address some of these concerns, but also focuses on a single product scale and has trouble capturing the dynamics of system-scale energy transition, such as the interaction of module lifetime with manufacturing demands for energy transition deployment schedules.
Therefore, we developed an open-source Python-based system dynamics model to quantify the mass, energy and carbon impacts of CE R-actions for PV technologies in the energy transition; PV in the CE (PV ICE) (Ovaitt & Mirletz 2021). The tool captures supply chains from material extraction through end of life, incorporating 5 circular end of life pathways. PV ICE takes in any evolving bill of materials, module properties and deployment schedule to support researchers and decision makers with data-backed insights.
In this work, we quantify and compare proposed CE sustainable PV module designs and lifecycle management strategies, spanning currently commercialized technologies, government and industry technology targets, and several low Technology Readiness Level (TRL) emerging PV technologies, including perovskites. Our analyses capture the projected evolutions of lifetime, efficiency and material circularity of these PV technologies, as well as their material supply chains.
Our analyses emphasize the importance of examining a suite of metrics to identify priorities and tradeoffs, and inform design or lifecycle management decisions holistically. Previous analyses have demonstrated the central importance of PV module lifetime to support energy transition while minimizing impacts. High levels of material circularity (>90%) enable minimizing lifecycle wastes, can reduce virgin material demands if paired with improving efficiency, but demonstrate tradeoffs in energy return on investment.
In the fervor of new material and technology development, it is important to remember that CE is not the end goal; decarbonization and energy transition are the end goal. CE should be used in service to improve the sustainability of PV, and R-actions evaluated for their usefulness and efficacy to this end.

2:00 PM EN06.06/EN03.06.02
Novel Mechano-Chemical Approach to Achieve Rapid Delamination of Glass from Solar Panels Ankit Ankit, Jeremy K. Ang, Ying Sim and Nripan Mathews; Nanyang Technological University, Singapore

With growing global cumulative photovoltaics (PV) installation, end-of-life (EoL) PV panels are expected to grow as well, with reports predicting this number to reach 78 million tonnes by 2050. This huge amount of PV waste does not only present a looming environmental challenge but also an opportunity to recover valuable materials embedded in the panels.

Different generations of PV technologies (1st Gen - Crystalline silicon (c-Si), 2nd Gen - Thin film (CIGS, CdTe) and 3rd Gen - Emerging PV (Perovskite, Bifacial)) have presence in the market currently. Out of all of these technologies, c-Si modules have the largest market share. Irrespective of their differences, the device stack for these PV technologies follows a sandwich structure, with the active layer (comprising metals and semiconductors) layered between polymeric encapsulants and glass. These insulating layers ensure a longer lifetime for panels in the field.

However, the same device structure creates challenges to recover valuable materials efficiently. Different approaches have been developed to separate the layers of solar panels. Thermal approaches burn the polymeric layers. However, they can produce toxic gases and affect the purity of active layer materials. Mechanical approaches crush the panel and sieve into different fractions. However, that often leads to undesired cross-contamination and affects the output yield and quality. Chemical approaches can give high output yield and purity and rely on dissolution of the polymeric encapsulant to separate the layers. However, they can take a long time (up to 7 days) making it less attractive.

Herein, we report a novel mechano-chemical approach that relies on weakening of bonds between glass layer and encapsulant layer through use of a green solvent. Cleaving of glass from the solar panels is achieved through mechanical processing. This process achieves rapid delamination of glass from solar panels (<4 hours) and high purity (>98%) glass cullet, while providing access to the active layer of the panel. The process has been demonstrated for c-Si panels and can be translated to different generations of solar panels.

2:15 PM EN06.06/EN03.06.03
From Lead Bullets to Solar Cells: A Two-Step Approach to Repurpose Contaminated Lead Misha Sytnyk[1], Zhenni Wu[1,2], Jiyun Zhang[1,2], Benfang Niu[1,2], Jens Hauch[1], Christoph J. Brabec[1,2] and Ian Marius Peters[1,2]; [1]Forschungszentrum Jülich GmbH, Germany; [2]Friedrich-Alexander-University Erlangen-Nuremberg (FAU), Germany

Lead perovskite solar cells have emerged as a groundbreaking technology. The unique properties of lead perovskite materials, such as their high absorption coefficient and tunable bandgap, make them ideal candidates for next-generation photovoltaic applications.
Despite their promise, perovskite solar cells pose environmental concerns, particularly in the recycling and sourcing of lead halides. Conventional methods of lead extraction and processing contribute to ecological degradation. To address these challenges, this research proposes a sustainable solution grounded in the principles of a circular economy, aiming to repurpose lead waste into valuable materials for solar cell fabrication.
The environmental challenge posed by lead waste is twofold. On the one hand, there is the potential for lead waste from the burgeoning perovskite

industry. On the other, there are existing sources of lead waste, such as metal plating industry, mining industry, homes built before 1986, lead-acid batteries, that are highly contaminated and pose a long-standing environmental hazard. It's important to note that even so-called "lead-free" plumbing may contain up to 8 percent lead.
Our approach is a two-step process designed to tackle this issue head-on. The first step involves a novel electrochemical method that will be presented in detail at the conference to convert contaminated lead into lead iodide (PbI2). As the lead waste source, we utilized XVII century lead bullet balls. The electrochemical recovery process is robust, accommodating a wide range of contaminants including the 15% Carbon, 10% Oxygen, 0.5% Silicon, 1% Bismuth, 1% Copper, and 1% Zinc we found in the bullets. Remarkably, the process achieves a Faradaic efficiency close to 1, indicating near-complete conversion of lead to PbI2.
The second step involves further purification of the synthesized PbI2 through single-crystal growth. This results in a 35% yield of pure PbI2, with the remaining material being recyclable for subsequent purification loops.
The synthesized PbI2 is not only suitable for immediate use in solar cells but has also been successfully utilized to fabricate a working solar cell. Additionally, it offers a high yield rate of approximately 1g per hour. This yield rate is scalable by simply increasing the electrode area, making the process suitable for industrial applications.
This research has far-reaching implications. It not only addresses the immediate problem of recycling perovskite solar cells for a circular economy but also offers a viable solution to the broader issue of lead waste management. By converting contaminated lead into a valuable material for efficient perovskite solar cell fabrication, we can potentially eliminate both current and future concerns related to lead waste.

Scalable Routes to Functional Materials: Photocatalytic, TCO and Anti-Soiling Coatings Claire Carmalt and Mingyue Wang; University College London, United Kingdom

The search for efficient materials for sustainable infrastructure is a key challenge to address the global environmental crisis. Sunlight-activated coatings, particularly those produced from scalable technologies, are sought in the glass industry for applications in self-cleaning windows. Current research involves developing processes towards sustainable and inexpensive functional materials including photocatalysts, anti-soiling coatings, transparent conducting oxides (TCOs) and photoelectrochemical films on float glass. For example, we have been developing sustainable upscaled routes to TCO materials from precursors containing earth abundant elements (titanium, aluminium, zinc) with equivalent or better figures of merit to existing TCOs. Our method uses aerosol assisted chemical vapour deposition (AACVD) to develop large scale coatings. Compared to conventional CVD, the AACVD method uses aerosol droplets to transport precursors, with the aid of an inert carrier gases. Therefore, in AACVD volatility is no longer crucial and this allows for a wider choice of precursors being available for use and can lead to high quality films at low cost.

Recent work has also investigated a range of bismuth-based materials for a number of applications. For example, adherent coatings of phenethylammonium bismuth iodide have been deposited via AACVD. The film morphology was found to depend on the deposition conditions and substrates, resulting in different optical properties to those reported from their spin-coated counterparts. Bismuth oxyhalides, BiOX (X = Cl, Br, and I), are of interest in a range of applications including photoelectrochemical (PEC) sensing, pollutant degradation and water splitting, with particular focus as emerging materials in photocatalytic applications. We recently reported visible-light-active iodide-doped BiOBr thin films fabricated via AACVD. The impact of dopant concentration on the structural, morphological, and optical properties was studied and the photocatalytic properties of films were evaluated. An optimized material was identified as containing 2.7 atom% iodide dopant. We have also synthesised BiOI and ZnO heterojunction materials. It was found that the BiOI/ZnO structure was far less active towards PEC water oxidation, while the ZnO/BiOI heterojunction showed a significant enhancement in activity compared with its parent materials. The ZnO/BiOI heterojunction, with a 120 nm thick ZnO film, exhibited the best PEC performance through studying the

influence of the ZnO film thickness and deposition temperature.

AACVD has also been used to develop thin films of other functional materials, including processes towards sustainable and inexpensive anti-soiling coating on float glass and photocatalytic films.

8:30 AM EN03/EN04/EN05/EN06.02
Preparation of High-Efficiency All-Perovskite Tandem Solar Cells Huan Bi[1], Hiroshi Segawa[2], Saulius Grigalevicius[3], Qing Shen[1] and Shuzi Hayase[1]; [1]The University of Electro-Communications, Japan; [2]The University of Tokyo, Japan; [3]Kaunas University of Technology, Lithuania

Although the efficiency of the organic-inorganic hybrid perovskite solar cell (PSCs) has reached 26.2%, it still has not surpassed silicon-based solar cells. At the same time, poor stability also makes the competitiveness of single-layer PSCs not obvious compared with silicon solar cells. Since 2015, narrow bandgap PSCs have been widely reported due to their better light absorption. However, wide bandgap perovskites should not be neglected as they are important for fabricating tandem PSCs. Here, we demonstrate a series of monolayer molecules with different alkyl chain lengths as interfacial modifiers to modify the PTAA and perovskite layer for improving the optoelectronic properties of PSCs by improving the quality of perovskite films and increasing the transport and extraction of interfacial carriers. The target device achieves a PCE of 16.57%, which is one of the highest PCE of the WBG-PSCs. Besides, the all-perovskite tandem solar cells with the WBG-Pb-perovskite solar cells and the narrow bandgap Sn/Pb perovskite solar cells gave a high PCE of 25.24%.
Here, we fabricated the wide bandgap PSCs with or without SAM modification. We found that the champion control device with a PCE of 14.46% (a short circuit current (J_{SC}) of 17.15 mA/cm^2, an open-circuit voltage (V_{OC}) of 1.117 V, and a fill factor (FF) of 75.53%), while the devices based on 3,3PrPACz, 4,3BuPACz, and 6,3HePACz modification got the highest PCE of 15.49% (a J_{SC} of 17.59 mA/cm^2, a V_{OC} of 1.141 V and an FF of 77.20%), 16.57%, and 15.29%, respectively. According to the corresponding incident photon-to-electron conversion efficiency (IPCE) spectra of the best-performing control device and PTAA/monolayer molecules devices, with the integrated current densities of 16.99 mA/cm^2 for the control device, 17.34 mA/cm^2 for the 3,3PrPACz-modified device, in good agreement with the *J-V* characterization. Finally, all-perovskite tandem solar cells were fabricated further to improve the PCE of PSCs. The *J-V* curves of all perovskite tandem solar cells modified by 3,3PrPACz show a high PCE of 25.24% was obtained (a J_{SC} of 17.115 mA/cm^2, a V_{OC} of 1.814 V, and an FF of 81.3%) with forward scan and 24.50% with reverse scan (a J_{SC} of 17.161 mA/cm^2, a V_{OC} of 1.800 V and an FF of 79.3%), which shows the negligible hysteresis.

8:45 AM EN03/EN04/EN05/EN06.03
Efficiency Improvement Mechanism by Light and Dark Soaking for $CdSe_xTe_{1-x}$ Thin-Film Solar Cells through Novel *In-Situ* Dopant Profiling Sanghyun Lee[1] and Kent Price[2]; [1]University of Kentucky, United States; [2]Morehead State University, United States

Cadmium Telluride (CdTe) thin-film solar cells have shown remarkable efficiency and durability in the past decade, reaching over 22.1 % in laboratory-scale tests, close to the theoretical Shockley-Queisser limit of ~30 %. Furthermore, they have also been widely deployed in commercial applications, with more than 30 GWp of modules installed worldwide. CdTe is the leading thin-film technology for cost-effective solar energy production due to its low fabrication costs, high-power conversion efficiency, reasonable long-term performance stability, and short energy-payback time. Recently, researchers have explored the use of Se to create band grading either in addition to or as a replacement for CdS. $CdSe_xTe_{1-x}$ is a promising material with bandgap lowering below 1.4 eV, which allows the short-circuit-current (Jsc) to approach its theoretical limit. For a long period, CdS was regarded as a crucial component for achieving high performance. Cells made without CdS (i.e., a direct CdTe junction to the transparent conducting oxide electrode) exhibit very low open circuit voltages (Voc and fill factors (FF), implying that the CdTe/oxide interfaces were of low quality. Although CdS has a benefit in that intermixing eases the lattice mismatch at the interface, this approach has a drawback: it also reduces the photocurrent by absorbing light in the 300 - 525 nm range. This means less light reaches the active layer of the solar cell, resulting in efficiency loss. Hence, recent efficiency improvement has focused on introducing Se to create band grading either in addition to or as a replacement for CdS. $CdSe_xTe_{1-x}$ is promising, with bandgap lowering below 1.4 eV, enabling Jsc to be close to its theoretical limit.
In this study, we have fabricated $CdSe_xTe_{1-x}$ devices by vapor transport technology (VTD) and investigated the detailed improvement mechanism of efficiency improvement through in-situ Cu dopant profiling under various light and dark soak conditions. Moreover, devices were stressed at elevated temperatures simultaneously under various bias conditions, both with illumination and in the dark. During light soaking, different intensities of light and wavelengths were tested to characterize devices. In addition, we modeled the result with our in-house MATLAB modeling suites, which we developed in our group to understand the efficiency improvement mechanism. Connected to the external TCAD simulators (Synopsys Sentaurus), we modeled and explained the results with different input parameters based on the dopant in-situ profiling. The results indicate that $CdSe_xTe_{1-x}$ devices have shallow donor and acceptor energy states near the main front junction interface, and acceptor activation energy (Ea) is approximately 0.3 – 0.4 eV based on light and voltage-biased quantum efficiency at different temperatures. The Cu dopant concentration is approximately 5 x 10^{14} cm^3 under no bias conditions. However, a peak doping concentration evolves toward the front $CdSe_xTe_{1-x}$ junction during in-situ measurements. The weak blue light (0.01 sun at 450 nm) can dramatically improve the carrier collection as compared to the same intensity of red light (660 nm). Interestingly, the stability of $CdSe_xTe_{1-x}$ solar cells was found to be bias-dependent and device-specific during light and dark soaking. $CdSe_xTe_{1-x}$ devices without Cu dopant demonstrated a reduction of depletion width under voltage and light-biased conditions. The depletion width of $CdSe_xTe_{1-x}$ devices without Cu is reduced to approximately 24 % under applied voltage biases and dark soaking conditions as compared to no bias condition, while efficiency, Jsc, and Voc decreased. Under light soaking conditions at 85 C, the increase in Voc and efficiency depends on the thickness of CdSe deposition thickness.

9:00 AM EN03/EN04/EN05/EN06.04
Investigation and Application of Thin Films of Photoluminescent Pigment for Utilization of Ultraviolet Light in Solar Cells Otávio J. Oliveira, Thais Crestani, Natália F. Coutinho, Ana P. Monteiro, Tárcio A. Barros and Francisco C. Marques; State University of Campinas, Brazil

Although silicon and perovskite solar cells have achieved efficiency as high as 26 %, their efficiency is still limited by several factors. One of the proposed mechanisms to circumvent these problems is to use wavelength shifters materials. Here we investigate the properties of thin film of low-cost photoluminescent pigment currently used in coatings, graphic arts, cosmetics and adhesives. The aim was to evaluate the capability of shifting the

ultraviolet light to the wavelength where silicon solar cells are more efficient (around 600 nm). Precursor solutions were prepared by dissolving the orange pigment on ethanol. Thin film deposition was performed by spin-coating technique. After each deposition, the substrates were placed on a heating plate in order to evaporate the solvent. The pigment was characterized by X-ray diffraction, AFM, UV-Vis transmittance, photoluminescence. The XRD difractograms are compatible with the expected structure of organic pigments, they present an amorphous characteristic. Photoluminescence measurements show the PL emission covers a range of 500 – 650 nm, which are in the region of the highest efficiency of silicon solar cells. Thin films deposited by spin coating show good uniformity. UV-Vis spectra show some absorption bands related to specific structures of the pigment and/or impurities. The absorption occurs in the wavelength range from 300 to 700 nm, been more intense in the UV range. This absorption corresponds to the one associated with the conversion of the UV light in visible light. The PL emission, on the other hand, is shifted to the 550 to 700 nm range. This result shows that the film made of pigment, deposited by spin coating, works as a wavelength shifter.

9:05 AM EN03/EN04/EN05/EN06.05
Exploring Carbon Nanoflake Based Materials for Charge Transport Layers of Perovskite Solar Cells: A Combined DFT-DFTB Study Including Effects of Solid-State Packing Ruicheng Li[1], Keisuke Maeda[1], Man-Fai Ng[2], Keisuke Kameda[1], Sergei Manzhos[1] and Manabu Ihara[1]; [1]Tokyo Institute of Technology, Japan; [2]Institute of High Performance Computing, Singapore

One of the biggest difficulties in the commercialization of perovskite solar cells (PSCs) lies in their charge transport layers. Charge transport materials are needed to achieve high performance with PSCs, but hole transporting materials (HTM) and electron transporting materials (ETM) used in high-performance lab-scale PSCs are relatively high-cost. Meanwhile, high-performance HTMs typically require the use of dopants that are detrimental to cell stability, while the commonly used metal oxide ETLs suffer from low electron mobility and photo-generated oxygen vacancies, which result in photocurrent hysteresis and serious interface recombination that affects the performance of the device.
Carbon-based materials, in particular carbon nanoflakes (CNF) and carbon quantum dots (CQD), have been increasingly used in charge transport layers and electrodes for PSCs. There are practically limitless possibilities of designing such materials with different sizes, shapes and functional groups, which allows modulating their properties such as band alignment and charge transport. Solid-state packing further modifies these properties. However, there is still limited insight into electronic properties of this type of materials as a function of their chemical composition, structure, and packing.
Here, we study the dependence of band alignment and charge transport characteristics on chemical composition and structure of commonly accessible types of nanoflakes and functional groups and further consider the effect of their solid-state packing. We use a combination of density functional theory (DFT) and density functional-based tight binding (DFTB) to get electronic structure level of insight at scales relevant to experiments. We find that CNFs must have sizes as small as 1.3 nm to provide band alignments suitable for their use as hole transport materials with the commonly used $MAPbI_3$, certain functional groups are able to change the band alignment so strongly that the same carbon nanoflake might act as either hole transport material or electron transport material. We show that both the shape of the CNF and inter-flake interactions can significantly modify band alignment by more than half an eV; solid-state packing has a moderate effect on HOMO of less than half an eV, whereas the effect on LUMO can be on the order of one eV.

9:20 AM EN03/EN04/EN05/EN06.06
Design and Synthesis of Zn-Based Metal Organic Frameworks (MOF) for Adsorptive Removal of Pharmaceutical Contaminants Anam Afaq and Sarang Gumfekar; IIT Ropar, India

Metal- organic frameworks (MOFs) are porous, crystalline, hybrid materials with high surface area, large pore volume, various topologies and tuneable functionality that make them unique. Conventionally, MOFs are synthesized using the autoclave-based hydrothermal method at relatively higher temperatures in a batch process. In this study, we synthesized Zn-based MOFs using a continuous flow reactor at a lower temperature. We compared the properties with the same MOF synthesized using a batch hydrothermal reactor. A continuous flow microreactor was fabricated for large-scale production of MOFs with homogeneous morphology. It was a circularly coiled reactor made of 316 stainless steel with a total volume of 14 ml. It offered improved heat and mass transfer which resulted in less reaction time, high space-time yield, higher reaction rate, precise control of residence times and control of MOF size and morphology. In this work, we showed that the Zn-based MOF can be synthesized in a continuous flow reactor in less time (2 hours) and at low temperatures (55oC) as compared to the batch process (48 hours and 180oC).
Further, the MOF was used to remove pharmaceutical contaminants **Estradiol valerate** and **17α-ethylestradiol** from model wastewater. Estradiol valerate and 17α-ethylestradiol are synthetic estrogens found in contraceptive pills and are considered emerging pollutants. The batch adsorption experiments were performed at different adsorbent amounts, extraction time, temperature, pH and ionic strength for both the contaminants to optimize the adsorption process. **Langmuir model** fitted the isotherm data, and the **pseudo-second-order model** fitted the kinetic data for Estradiol valerate and 17α-ethylestradiol adsorption. Overall, this study presents a continuous flow reactor system to synthesize MOFs at large scale with reproducible properties and its use as an adsorbent to remove pharmaceutical contaminants.

9:25 AM EN03/EN04/EN05/EN06.07
Synthesis of Green Metallic Nanoparticles by Plants: A Sustainable Approach Krishna Yadav[1] and Dharmveer Yadav[2,2]; [1]Malaviya National Institute of Technology, India; [2]Indian Institute of Technology Bombay, India

The synthesis of metallic nanoparticles has gained significant attention in the field of nanotechnology due to their unique physicochemical properties and diverse applications. However, conventional methods for nanoparticle synthesis often involve the use of hazardous chemicals and energy-intensive processes, leading to environmental concerns. Therefore, there is an increasing demand for the development of sustainable and eco-friendly approaches for nanoparticle synthesis. This eco-friendly and sustainable approach utilizes the bioactive compounds present in various parts of plants, such as leaves, stems, and roots, to facilitate the reduction and stabilization of metallic ions into nanoparticles. These compounds can effectively convert metal ions into metallic nanoparticles, eliminating the need for harsh chemicals and reducing the detrimental impact on the environment. Green metallic nanoparticles synthesized by plants exhibit unique optical, electrical, and catalytic properties, making them ideal for a wide range of applications. These include biomedical applications, such as drug delivery, imaging, and antimicrobial agents, as well as environmental remediation. Lastly, this work highlights the various challenges and future perspectives to further synthesize biogenic metal nanoparticles toward environmental and pharmaceutical advances in the coming years.

9:30 AM EN03/EN04/EN05/EN06.08
Effect of Solar Concentration on Poly (ethylene terephthalate) Degradation Using a Compound Parabolic Concentrator (CPC). Lol-chen Alegria[1] and Maria D. Baeza[2]; [1]Universidad Autónoma del Estado de México, Mexico; [2]Centro de Investigacion en Tecnologia Avanzada (CIATEQ), Mexico

This study provides insights into the termal properties and composition changes in PET after exposure to concentrated solar radiation using a Compound Parabolic Concentrator (CPC). We compare these effects to those resulting from exposure to an accelerated weathering chamber and the ambient conditions, aiming to assess the advantages and disavadvantages of using solar concentrators for polyester degradation.

The observed alterations in coloration, increased fragility and deformation of the PET sheets indicate that a degradation process occurs during the CPC

exposure periods. Results obtained from Differential Scanning Calorimetry (DSC) reveal a significant increase in crystallinity fraction in the material exposed within the concentrator; whereas specimens subjected to weathering chamber and ambient conditions displayed effects related to physical aging. Furthermore, data obtained from Thermogravimetry Analysis (TGA) exhibited a reduction in thermal stability and maximum degradation temperature, whith more pronounced effects observed in the specimens degraded within the CPC. Fourier Transform Infrared spectroscopy (FTIR) also displayed reduced intensity in the spectra as a result of degradation, without the presence of functional groups that indicate the formation of final products.

9:35 AM EN03/EN04/EN05/EN06.09
High-Performance Ternary Organic Solar Cells based on Peryleneimide Acceptors Yong Zhang, Ming Liu, Xianxian Ge and Daoyuan Chen; Harbin Institute of Technology, China

Organic solar cells (OSCs) have received widely attention in the recent years, the power conversion efficiencies (PCEs) of OSCs based on non-fullerene acceptors have beyond 17%. In terms of further improving the photovoltaic performance, a lot of strategies have been conducted from materials and device engineering. Among them, ternary blending is believed to be the most effective method to enhance the PCEs. In the ternary blend OSCs, it contains two or more donors and one acceptor, or two or more acceptors and one donor, which could be tune the morphologies of active layers, and enhance the Voc, Jsc and/or FF so as to obtain a higher PCE than that of binary device. In the current state-of-the-art ternary OCSs, the third component commonly is based on the fullerene, ITIC or Y-series acceptors, however, these third component (acceptor) mostly possess the weak sun-light absorption, multi-steps synthesis with high cost, the overlap on absorption with the main acceptor. Thus, the development of low cost third component (acceptor) will be a promising way to further lower the fabrication cost of OSCs, and also face a lot of challenges. Recently, based on our previous works[1,2], we have developed a quasi-two dimensional perylene diimide FPDI-2PDI, and apply it in the ternary devices of PM6:Y6. The results showed that PM6:Y6:FPDI-2PDI ternary OSCs gave a Voc of 0.848V, a Jsc of 27.47 mA/cm^2 and a FF of 77.2%, providing a PCE of 18%, which is much higher than the 16.63% of PCE in the binary PM6:Y6 device.[3] Further, we developed another novel three-dimensional TPA-4PDI, and the ternary OSC can obtain the PCE of 18.29% with simultaneously enhanced Voc, Jsc and FF.[4]

9:50 AM EN06.09/EN03.09.05
The Genesis Device®: A Revolution in Large Scale Decarbonization Stuart Licht[1,2,3]; [1]George Washington University, United States; [2]Carbon Corp, Canada; [3]C2CNT LLC, United States

CO_2 is a highly stable molecule. This stability had been considered an insurmountable barrier to Its transformative removal from its role as a greenhouse case. The C2CNT® (CO_2 To Carbon Nanomaterial Technology) process breaks through this barrier by using an energetic (high temperature), carbon rich (molten carbonate), transition metal nucleated environment, electrolytically splitting of CO_2 to graphitic carbon nanomaterials (and O_2). Built from the same fundamental graphene structure as graphite, which has a geologic lifetime, these nanocarbon products can permanently bind the transformed CO_2 to mitigate global warming. Their value arises from the properties of graphene such as high strength and conductivity, solid lubrication, electronic and catalytic activity tuned by distinctive 0D, 1D and 2D morphologies.

Control of the electrochemical conditions tuning C2CNT® to selectively produce 17 unusual nanocarbons is described in:
"Controlled Growth of Unusual Nanocarbon Allotropes by Molten Electrolysis of CO_2",
Liu, Licht, Wang, Licht, ***Catalysts***, **12**, 125, 2022.
and
"Controlled Transition Metal Nucleated Growth of Carbon Nanotubes by Molten Electrolysis of CO_2",
Liu, Licht, Wang, Licht, ***Catalysts***, **12**, 137, 2022.

The value of these nano graphitic carbons arises from the unique properties of graphene such as exceptional strength, high conductivity, solid lubrication, electronic and catalytic activity as modified by their distinctive 0D, 1D and 2D shapes. These nanocarbons are useful in a range of applications in the carbon fiber, polymer, electronic, medical, transportation, steel, cement and power sectors.

The C2CNT® process received the 2021 Carbon XPRIZE XFactor award for producing the most valuable product from CO_2. The process and new materials chemistry has been rapidly scaled as described in a growing body of proprietary IP, including selected US patents: US9,080,244, US9,297,082, US9,683,297, US9,758,881, US10,637,115, US10,730,751, US11,028,493, US10,982,339, US11,094,980,

and from 2022 onward patents: US11,346,013, US11,401,212, US11,402,130, US11,434,574, US11,512,398, US11,542,609, US11,613,815, US11,616,659, US11,633,691, US11,643,735, US11,680,325, US11,724,939, US11,732,368, US11,746,424, US11,767,260, US11,767,261, as well as a growing list of international patents and patents pending.

A C2CNT process® Genesis Device® CCUS demonstration using the has been built in Calgary, and a large-scale Genesis Device® CCUS plant, the GC3 project, is scheduled in Edmonton, producing 7,500 tonnes of carbon nanotubes transforming the CO_2 emission at the Genesee power plant.

10:30 AM *EN06.01/EN03.01.01
"Deep Materials Sustainability": From Sourcing, to The Use Phase, to End-Of-Life Vanni Lughi; University of Trieste, Italy

For a material to be truly sustainable, all phases of the material's life cycle should be sustainable: sourcing, manufacturing, transport, use, End-of-Life (EoL). In this contribution, I will introduce the concept of "Deep Materials Sustainability", where all phases of the life cycle are addressed simultaneously, and will discuss some examples.
The ideal case is one where a material is synthesized through a sustainable process utilizing renewable and/or recycled material sources, it minimizes the transport phase impact (e.g. by being lightweight), it is used in applications aimed at increasing the sustainability of a system (e.g. an efficient thermal insulation for buildings), and it can be recovered and reused with minimal loss and downcycling. The metrics for measuring "sustainability" depend on the goal. For environmental sustainability, typical metrics are energy consumption, CO2 emitted, tonnage of raw materials – all measured throughout the entire life cycle. Social sustainability is also gaining interest, and meaningful metrics are being developed in the field of critical and strategic materials. Most desirably, however, sustainability should be considered as a combination of all of the above.
I will review some examples where new materials are designed with the specific purpose of optimizing the environmental sustainability of the phases of the material's life cycle. This underlying approach resembles that of "design for disassembly" or that of "design for recycling". However, these approaches are focused on the design of the overall system, in order to favor the recovery of the materials and their recycling, respectively; in these approaches, the material is seen as a passive element, which is recycled simply by virtue of its intrinsic properties (good examples of this are thermoplastic materials and metals). Instead, here we shift our focus on new materials, where there is an effort of conceiving, designing and realizing them to optimize the specific properties that maximize the performance in environmental applications, while simultaneously pursuing circularity by both using sustainable material sources (e.g. renewable and/or recycled), and laying out an EoL path enabling reuse, remanufacture, or recycle.
I will discuss in more detail one example of such a material characterized by "deep sustainability", where we co-developed a highly efficient thermal insulation foam along with its recycling process, and the foam material was a composite consisting of an alginate matrix and recycled fiber glass as the filler – i.e. a combination of renewable and recycled materials. The recycling process exploits the reversibility of the molecular assembly mechanism in the ion-assisted gelification of alginate, which is the first step in the fabrication of our material. At the end of life of the insulating foam – e.g. when the highly porous microstructure of the material starts degrading, along with the thermal insulation performance – a chelation agent is utilized to sequestrate the ions and disassemble the matrix, making possible the full recovery of the initial material source. Reversing chelation by changing the pH enables re-gelification and successively re-creation of the foam. The process can be repeated multiple times, and the new foam shows unaltered thermal insulation properties, as assessed via thermofluximetry and calorimetry. SEM and micro-computed tomography are used to characterize the microstructure of the foams, and a Life-Cycle Assessment is carried out, showing a rather promising environmental footprint.
This case shows the feasibility of a sustainable material for a sustainable energy application: a foam based on a natural source, incorporating waste material, fully recyclable, and that is an effective thermal insulator – simultaneously addressing, in the spirit of circular economy, the issue of energy efficiency, of sustainable materials sourcing, and the material end-of-life.

11:00 AM EN06.01/EN03.01.02
Enhancing Thermal Insulation Performance through Entropy Stabilization in Rare-Earth Zirconate Structures Myeungwoo Ryu, Ganggyu Lee, Seungwoo Lee, Seunggun Choi, Seungcheol Myeong, Minsung Kim, Gunwoo Cha, Chanjin Park, Ungyu Paik and Taeseup Song; Hanyang University, Korea (the Republic of)

Thermal barrier coating (TBC) materials utilize ceramics with low thermal conductivity and exceptional thermal durability. The gas turbine market has recently seen a growing demand for thermally insulating materials suitable for operating temperatures exceeding 1200 °C, achieved aiming greater thermal conversion efficiency. In this study, we synthesized high-entropy $A_2Zr_2O_7$ zirconate ceramics by incorporating five cations of similar ionic radius into the A^{3+} cation site through a conventional solid-state reaction, and we demonstrated their superior thermophysical properties. The high-entropy oxide (HEO) ceramics exhibited consistently low thermal conductivity, ranging from room temperature to 1000 °C, mainly due to lattice distortion induced in the crystal structure. Furthermore, we introduced divalent cations to the A^{3+} cation site to increase oxygen vacancies within the structure, thereby reducing heat transfer caused by phonons. These $A_2Zr_2O_7$ zirconate HEOs demonstrate improved thermal barrier performance compared to yttria-stabilized zirconia (YSZ), which is a conventional TBC material. This highlights their potential application as next-generation TBC materials.

11:15 AM EN06.01/EN03.01.03
Investigation of Deposition Methods for Self-Cleaning Polymer Coatings Cesar III Reyes; University College London, United Kingdom

A self-cleaning effect can be achieved using superhydrophobic surfaces (i.e., water contact angle > 150°) through the Lotus effect, where water droplets can remove contaminants such as dust as they slide across a water-repellent surface.[1] This effect is achieved by a combination of a rough surface morphology and a low surface energy material. Surface morphology is typically determined through the deposition method, and aerosol-assisted chemical vapour deposition (AACVD) has often been used as a one-step method to attain both properties using an innately hydrophobic material (e.g., polymers).[2] Often, these coatings require reapplication once physically damaged; therefore, a self-healing approach was of interest. Transparent, self-healing hydrophobic coatings have been synthesised using polymeric materials such as epoxy resin (EP) and PDMS (polydimethylsiloxane, Sylgard184) components with contact angles ca. ~105° and optical transparencies ~88% with respect to pristine glass at 91% transparency in the 400-800 nm wavelength range. Coatings were deposited using easy-to-scale methods such as spray, spin, and dip-coating and compared to other methods such as

AACVD.[3] Contact Angle Hysteresis (CAH) measurements were used to determine the optimal easy-to-scale method. Samples were subject to plasma-treatment testing, UV-exposure, and scratch testing, followed by heat treatment at 200 °C as the trigger to the self-healing process. The optimal coating (through spray-coating) was EP/PDMS in an ethyl acetate solvent without the PDMS curing agent, which displayed the most consistent self-healing character whilst still being transparent and hydrophobic. Coatings were characterised using FTIR, XPS, SEM, EDS, AFM, and UV/Vis spectroscopy. Templating materials with a desired morphology such as a diffraction grating, sandpaper, Cunanoneedles, and physically/chemically etched Al sheets was also investigated by creating PDMS templates which were applied onto polymer coatings to replicate the surface morphology. Using the templating approach, these techniques were studied to find a pathway to create self-healing superhydrophobic surfaces with supplementary characteristics either from additive nanoparticles or replicated surface morphologies.

Transparent Liquid-Repellent Coatings from Fluorine-Free Building Blocks with Excellent Substrate Independent Adhesion Priya Mandal, Vikaramjeet Singh and Manish Tiwari; University College London, United Kingdom

The research on liquid-repellent surfaces/interfaces has progressed rapidly in the last decade owing to their universal importance in fundamental research and practical applications. Ranging from energy and healthcare sectors to contamination prevention, (anti-)condensation, anti-icing, anti-biofouling, etc. The issue that limits the practical implementation of such materials can be broadly divided into two categories: i) the use of hazardous fluorine-based molecules due to their extremely low surface energy which are bio-persistent, and ii) low adhesion with underlying substrates which makes them susceptible to mechanical damage. Due to global warming and the increasing scarcity of resources, there is an immediate need to find ways toward more robust and sustainable developments. To this end, engineering robust and resilient surfaces with overall durability using environmentally safe chemicals can address some of these challenges.
Herein, we come up with a strategy to address these important challenges by rationally selecting polyurethane due to its excellent substrate-independent adhesion and metal-organic frameworks (MOF) which provide precision nanotextures (nanohierarchy) and impeccable intercalation characteristics.
We present a water-based spray formulation of non-fluorinated amphiphobic (repellent to water and low surface tension liquids) coatings by combining commercial polyurethane and nanohierarchical MOF followed by post-functionalization with flexible alkyl silanes. The resulting surfaces are smooth, highly transparent, and exhibit excellent amphiphobicity towards a wide range of low surface tension liquids from water to alcohols and ketones. These coatings are able to sustain heating up to 200 °C and cyclic tape-peeling, are resistant to high-speed water jets (~35 m/s), and feature very low ice adhesion of ≤30 kPa which is well below the threshold of anti-icing surfaces (<100 kPa). Multi-functionality, robustness, and scalability (production and applicability, both), make this formulation a potential alternative to PFC-based hazardous coatings.

Session Chairs: David Cahen, Jihye Kim, Clara Santato and Anke Weidenkaff
Tuesday Afternoon, April 23, 2024
Room 333, Level 3, Summit

1:30 PM *EN06.02/EN03.02.01
High Performance Flexible and Scalable Thermoelectric Device and its Application as a Self-Sufficient Power Supply for Wearable Electronic Devices Deepa Madan; University of Maryland, United States

Additive manufacturing has been investigated as a more time, energy, and cost-efficient method for fabricating thermoelectric generators (TEGs). Early results have been promising but are held back by the necessary inclusion of a high-temperature, long-duration curing process to produce high-performance thermoelectric (TE) films. This work investigates the synergistic effect of four factors – a small amount of chitosan binder (0.05wt%), a heterogeneous particle size distribution, the application of mechanical pressure, and thickness variation – on the performance of p-$Bi_{0.5}Sb_{1.5}Te_3$ (p-BST) and n-$Bi_2Te_{2.7}Se_{0.3}$ (n-BTS) TE composite films. The combination of these four factors controls the micro and nanostructure of the films to decouple their electrical and thermal conductivity effectively. This resulted in figures of merit (ZTs) (0.89 and 0.5 for p-BST and n-BTS, respectively) comparable to other additive manufacturing methods despite eliminating the high-temperature, long-duration curing process. The process was also used to fabricate a 6-couple TEG device which could generate 357.6 µW with a power density of 5.0 mW/cm^2 at a temperature difference of of 40 K. The device demonstrated air stability and flexibility for 1000 cycles of bending. Finally, the device was integrated with a voltage step-up converter to power a LED and charge and discharge capacitor at a temperature difference of 17 K, demonstrating its applicability as a self-sufficient power source.

2:00 PM *EN06.02/EN03.02.02
Pursuing Sustainable Thermoelectrics Wenjie Xie[1,2], Xingxing Xiao[1], Jinxue Ding[1], Wei Li[1] and Anke Weidenkaff[2,1]; [1]Technical University of Darmstadt, Germany; [2]Fraunhofer IWKS, Germany

Thermoelectricity offers a direct and highly efficient approach for converting heat into electricity, relying on two key factors: Carnot efficiency and the materials-dependent property, *ZT*. In the last two decades, tremendous efforts have been made to develop high *ZT* thermoelectric materials, and the bulk *ZT* has reached above 3. Energy converters for renewable or sustainable energy technologies have to be based on materials that are not a burden to the environment, do not contain critical elements and guarantee a short energy payback time. Besides improving the conversion efficiency and other performance factors, sustainability has to be considered when designing novel thermoelectric materials and devices. In this talk, we will introduce novel synthesis strategies for oxide and silicon-based thermoelectric materials. We will delve into the concept of Entropy Engineering, a method that can extend the lifetime of (oxide) thermoelectric materials. Moreover, we will showcase one example where waste Si from the solar cell industry is transformed into valuable products, specifically in the synthesis of $MnSi_{1.75}$ alloy. This underscores the potential to convert waste into valuable resources, contributing to both sustainable energy and responsible material usage.

2:30 PM EN06.02/EN03.02.03
High-Performance CNT-Based Green Thermoelectric Composites and Device Siqi Liu[1] and Chaobin He[1,2]; [1]National University of Singapore, Singapore; [2]Institute of Materials Research and Engineering (IMRE), Singapore

Thermoelectric (TE) materials and devices which can harvest electricity in the low-temperature range from the temperature difference of human body and surroundings therefore attracts great attention. However, conventional TE devices are mainly assembled on general plastics, where materials for TE legs assembly normally are costly and scarce and environmentally damaging. Therefore, development of environmenal-friendly TE materials and devices attracts huge attention in perspective of sustainablility. Biodegradable composites are termed as green composites and effectively used as sustainable alternative. In this work, CNT/polycaprolactone (PCL) composites were fabricated. Beside the biodegradability, the composites showed enhanced TE properties with the exisitence of PCL with nearly 4 times power factor increase compared with neat CNT. This work provides a novel strategy for high-performance green TE composites for sustainable future.

2:45 PM EN06.02/EN03.02.04
Emerging Chalcogenides: A New Family of Perovskite-Inspired Sustainable Energy Materials Ivan Caño Prades[1], Cibrán López Álvarez[1], David Rovira Ferrer[1], Marcel Placidi[1,2], Claudio Cazorla[1], Joaquim Puigdollers[1] and Edgardo Saucedo[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Institut de Recerca en Energia de Catalunya, Spain

In the last ten years, lead-halide perovskites have achieved outstanding performance in photovoltaics, X-ray detectors and other optoelectronic applications. Significantly, they can be synthesized via cost-effective low-temperature methodologies, which represent an improvement in terms of sustainability compared to physical vapor processes, normally requiring high temperatures and vacuum. However, the presence of Pb and stability issues have raised the question of whether the exceptional properties present in lead-halide perovskites could be replicated in other materials. Among the different known approaches to develop perovskite-inspired materials, here we have fabricated emerging chalcogenide semiconductors with structure analogous to perovskite, and others which have different structure but similar electronic features.

Belonging to the first group, silver and copper chalcohalides - $(Ag,Cu)_3SX$ (X=I,Br) - stand out for their crystalline structure analogous to perovskites, albeit switching cation sites by anions and vice-versa. They are constituted by earth-abundant and non-toxic components, and their bandgap in the 0.9 - 1.1 eV range indicates that they could be suitable for single-junction solar cells or tandem configurations. So far, powders and pellets have been mostly fabricated using costly and time-consuming approaches which involve high temperature and vacuum, and lack adaptability in terms of composition and doping. Alternatively, in this work we present a novel procedure to prepare $(Ag,Cu)_3SX$ (X=I,Br) polycrystalline thin films by molecular precursor ink deposition, using thiol-amine solvent mixtures. This methodology offers advantages in terms of cost-effectiveness, versatility, scalability and sustainability, opening the door to explore new compositions, properties and applications of the ecologically benign chalcogenide anti-perovskite system. Samples have been extensively studied by X-ray diffraction, microscopy and optoelectronic characterizations.

Another approach to develop perovskite-inspired materials consists in developing materials which are electronically analogous, i.e., they have similar electronic characteristics at the band structure. In this regard, it is particularly interesting to seek materials which exhibit the same features which make lead-halide perovskites tolerant to defects. Indeed, despite having high defect densities, hybrid perovskites exhibit low non-radiative recombination rates. This phenomenon has been suggested to emerge from having bonding orbitals at the conduction band, and antibonding contributions at the valence band.[1] Therefore, it is expected that materials with similar electronic structure, such as ternary chalcohalides SbSX and BiSX (X=I,Br), can replicate the beneficial defect tolerance of perovskites. In addition, these materials are constituted by relatively earth-abundant and low toxic components, they are stable, have bandgaps in the 1.5 - 2.0 eV range, and can be synthesized at low temperatures, which makes them ideal as a viable alternative to perovskites. In this work, experimental and theoretical analyses will be presented, including the characteristics of the band structure (obtained by first-principle calculations), structural and optical properties (X-ray diffraction, spectroscopy analyses), and prototype PV devices, demonstrating their potential as a sustainable alternative for energy harvesting applications.

To sum up, this work presents two different families of emerging chalcogenide materials, constituted by relatively earth-abundant elements and manufactured by low-temperature environmentally-friendly techniques, which are inspired in different ways by the successful lead-halide perovskites (structure analogous and electronic analogous respectively), suggesting new, more sustainable ways to develop semiconductor materials for energy applications.

4:00 PM EN06.03/EN03.03.02
Fabricating Air-Stable Copper Films with Exceptional Electrical Conductivity without Sintering Jessica Pereira[1,2], Oleg Makarovsky[1], David

Amabilino[3] and Graham Newton[1]; [1]University of Nottingham, United Kingdom; [2]University of Southampton, United Kingdom; [3]Consejo Superior de Investigaciones Científicas, Campus Universitari de Bellaterra, Spain

Copper is an excellent electrical conductor, nearly matching the conductivity of silver (Cu: 5.96×10^7 S/m *vs* Ag: 6.30×10^7 S/m), but at a fraction of the cost (Cu: $ 0.28/oz *vs* Ag: $ 21.6/oz) making it an ideal choice for cost sensitive large area applications which are in high demand. However, unlike silver, copper has a much higher susceptibility towards oxidation, a risk that is particularly acute in particulates and suspensions with high surface to volume ratio, which generates additional processing complications including the need for surface passivation and inert environments for processing as well as sintering. The use of fossil fuel based long-chain hydrocarbon ligands to passivate copper is the common approach in the field but decomposition of such ligands to fabricate functional conductive films require high sintering temperatures and controlled conditions. Moreover, with the rapid growth of the flexible and wearable electronics industry, sintering becomes increasingly less practical as most substrates used in this sector are temperature sensitive. Herein, a new approach to fabricating conductive air-stable copper films with resistivities close to that of bulk copper is demonstrated which only requires compression at room temperature, completely removing the need for any form of sintering. This approach facilitates the generation of highly conductive simple unsupported copper films as well as intricate patterns on paper and printed circuit board substrates with an aqueous, biopolymer stabilised copper ink formulation. The remarkable conductivity and oxidative stability of the copper films, coupled with the sustainability of the approach have the potential to precipitate a paradigm-shift in the use of copper inks for printable electronics.

4:15 PM EN06.03/EN03.03.03
Designing Sustainable Permanent Magnets: Alloying Additions and Magnetocrystalline Anisotropy in $L1_0$ FeNi Christopher D. Woodgate[1], Laura H. Lewis[2,2] and Julie Staunton[1]; [1]University of Warwick, United Kingdom; [2]Northeastern University, United States

We report results from an holistic approach for modelling both atomic ordering and subsequent magnetocrystalline anisotropy energy (MAE) of magnetic materials with application to the design of novel, rare-earth-free permanent magnets. This computationally efficient technique allows for fast exploration of the materials design space and could open up a new route for materials discovery and manufacturing. Here we report recent results concerning the class of magnetic materials which chemically order into the $L1_0$ structure. These materials typically have large MAE values appropriate for advanced permanent magnets, with prime examples being FePt and CoPt that contain elements of high criticality. *Ab initio* theory has previously confirmed that it is the tetragonal, $L1_0$ order that produces the high MAE values measured in these materials [1]. There is therefore a desire to discover new $L1_0$ materials which are made using more-abundant elements, but which still retain desirable magnetic properties. One such candidate material is $L1_0$ FeNi, found in meteoritic, tetrataenite samples. This material is known to have a high uniaxial anisotropy, but a low chemical ordering temperature and sluggish kinetics make it challenging to manufacture in a laboratory setting.

Here, we consider introducing a third element into the binary Fe-Ni composition to promote ordering tendencies and enhance its predicted MAE. Systems with the general formula $Fe_{50-x}Ni_{50-y}X_{x+y}$ (X=Pd, Co, Pt, Al) were investigated. Crucially, our modelling predicts the nature of any chemical order [2] and goes on to predict the MAE for a given system [1], using the same ab initio formalism for both aspects of the modelling approach. The ordering behaviour predicted on adding these dopants is rich and a variety of chemical orderings are obtained. Interestingly, we find that it is often the addition of light elements such as Al which enhance the MAE the most. We are also able to study the impact of magnetic order on predicted atomic order and show that annealing samples in an applied magnetic field may enhance chemical ordering [3].

Room 333, Level 3, Summit

3:30 PM *EN06.07/EN03.07.01
Lead-Free Perovskite Derivatives Toward Eco-Friendly Indoor Photovoltaics Vincenzo Pecunia; Simon Fraser University, Canada

Indoor photovoltaics present a compelling solution for powering the ever-expanding array of Internet-of-Things (IoT) smart sensors in a sustainable manner. The emergence of halide perovskites as promising absorbers for indoor photovoltaics has ignited significant interest due to their favorable optoelectronic characteristics. Nevertheless, the deployment of indoor photovoltaic devices in close proximity to end-users raises concerns about the toxicity associated with the lead content found in mainstream halide perovskites. This has spurred the search for alternative, lead-free perovskite derivatives for efficient indoor photovoltaics without lead toxicity concerns. We first demonstrated this concept with $Cs_3Sb_2I_{9-x}Cl_x$, enabling indoor photovoltaic efficiencies already in the range of mainstream, commercial indoor photovoltaics. Furthermore, our investigations revealed that the spectroscopic limited maximum efficiency for this and other lead-free perovskite derivatives under indoor lighting conditions can reach approximately 60%, showcasing their immense potential through further materials and device optimization. In fact, the demonstrated photovoltaic efficiency of $Cs_3Sb_2I_{9-x}Cl_x$ was sufficient to power printed digital gates via millimeter-scale indoor photovoltaic devices, confirming the opportunity already provided by this technology toward self-powered electronics with potentially low environmental impact. We extended our exploration to Cu-Ag-Bi-I absorbers, tailoring the microstructure and device architecture to achieve enhanced indoor photovoltaic efficiencies and ensuring reliable operation under realistic illuminance levels as low as 200 lux, all while exhibiting favourable air stability. Recognizing the importance of sustainability in emerging technologies, we additionally conducted a thorough assessment of the environmental impacts of various lead-free perovskite derivatives in the context of indoor photovoltaics. Our findings identified the most promising compositions from a sustainability perspective, offering crucial guidance to the research community developing lead-free perovskite derivatives to enable eco-friendly self-powered smart sensors for a green IoT revolution.

4:00 PM EN06.07/EN03.07.02
Oxide-Halide Perovskite Composites for Simultaneous Recycling of Piezoceramics and Solar Cells Mohadeseh Tabeshfar[1], Sivagnana Sundaram Anandakrishnan[1], Mikko Nelo[1], Maliha Siddiqui[2], Jani Peräntie[1], Pavel Tofel[3], Heli Jantunen[1], Jari Juuti[1] and Yang Bai[1]; [1]University of Oulu, Finland; [2]CEITEC-Central European Institute of Technology, Czechia; [3]Brno University of Technology, Czechia

Global concerns regarding energy and the environment have created an urgent demand for sustainable manufacturing, usage, and disposal of electronic components. Piezoelectric and photovoltaic components are being extensively used due to the rapid development of the Internet of Things (IoT) and green energy production, which require large quantities of piezoelectric sensors/energy harvesters and solar cells as functional components and power sources. Thus, recycling these two essential types of components needs to be carefully considered. This work develops upside-down composites to recycle waste oxide perovskite-based piezoceramics and organometal halide perovskite-based solar cells. Production of the recycled and reusable materials requires only a marginal energy budget, while achieving a high level of material densification and excellent sensing capabilities. This work offers an energy- and environmentally friendly approach for recycling hazardous and high energy-consuming elements, as well as giving a second life to the functionality of waste piezoelectric and photovoltaic components.

4:15 PM EN06.07/EN03.07.03
Enhancing Fluorophore-Induced Plasmonic Current for Converting Solar Energy Lahari Saha[1] and Chris D. Geddes[1,2]; [1]University of Maryland, Baltimore County, United States; [2]Institute of Fluorescence, United States

Biological chromophores and certain model organisms present a unique opportunity in solar energy harvesting. Currently, solar energy conversion efficiency rates are in the low 20s, necessitating multiple panels to generate electricity. This is a problem since many agricultural farms are transitioning into solar farms, supporting the growing demand for electricity and further deepening existing food crisis. Therefore, the system's efficiency, stability, and longevity are crucial. Advances in plasmonic materials offer promising results due to their compatibility with fluorescent biosensors and various fluorophores, suggesting potential applications in solar energy conversion. In this presentation, we discuss a technology called fluorophore-induced plasmonic current (FIPC), where plasmonic thin films and a fluorophore solution are used to generate current. We consider a few methods to increase current produced by FIPC for example, annealing thin films and incorporating metallic colloids in the fluorophore solutions. Key takeaway on annealing thin films suggests an increase in current response within the working range and lowering signal to noise ratio, leading to a stable baseline current. Preliminary data on metallic colloids mixed with fluorophore solutions indicate an *exceptional* increase in current generation. Future work in this project will translate our present findings to biological chromophores.

4:30 PM EN06.07/EN03.07.04
Carbon-Based Photoabsorbers for Sustainable Energy Applications Demetra S. Achilleos[1], Caoimhe Maher[1], Hatice Kasap[2] and Erwin Reisner[2]; [1]University College Dublin, Ireland; [2]University of Cambridge, United Kingdom

The continuous air and water pollution arising from the accelerated consumption of fossil fuels and organic pollutants, respectively, emphasize the need for society to move towards renewable "green" resources, and environmentally sustainable processes. Photocatalysis is a promising approach for mitigating simultaneously both the energy and environmental concerns.[1] However, the development of economically and environmentally sustainable photocatalytic processes creates the pressing need for new materials of low cost and toxicity, such as photoabsorbers and catalysts, which maintain substantial performances.

Carbon dots (CDs) and carbon nitride (CN_x) can efficiently serve as photoabsorbers for this purpose since they fulfil these requirements.[2-6] In particular, they are hydrophilic materials of low toxicity which are chemically and photochemically robust, can be synthesized at low cost, and show optimum photocatalytic properties upon pre-designed synthesis. In this work, we describe the synthesis of CN_x and CDs from low-cost organics and/or Earth abundant waste (circular economy), the structure of which bestows the derived photoabsorbers with distinctive photocatalytic performances. These light harvesters, when combined with noble-metal free catalysts in aqueous photocatalytic systems, not only facilitate "green", solar-driven fuel synthesis but also waste/water pollutant utilization. The use of waste and aqueous pollutants, eliminates the need for additional sacrificial reagents traditionally used in great excess, which add to the overall cost of the process, and result in toxic by-products.[7] We anticipate that this approach could be a breakthrough in the development of scalable, economically, and environmentally sustainable systems, which can efficiently serve energy and environmental applications.

Hybridization of Magnetic Fe3O4 with Mn-MOFs for High Performance Supercapacitor Saumaya Kirti, Shobha Shukla and Sumit Saxena; Indian Institute of Technology Bombay, India

Encapsulating guest compounds in metal–organic frameworks (MOFs) architectures is one of the most promising paths to achieve properties beyond those of the pristine MOFs and/or guest species. Contrary to the conventional host/guest composites encapsulating guest species inside MOF cavities, core–shell architectures exhibit a better accessibility to the pores ensuring an optimal diffusion of the substrate while presenting a unique structure that prevents the aggregation and the runoff of the active guests and ensures a tight interaction between core and shell, leading to synergistic effects. Herein, the integration of Fe3O4 with manganese-based MOF i.e., Fe_3O_4@Mn-MOF-NH_2 with varying shell thickness and hierarchical pore structure is synthesized. As a proof of concept, the obtained Fe_3O_4@Mn-MOF-NH_2 composite is used as an active material for supercapacitor applications which showed an enhancement of ~ 80% with respect to pristine compounds.

Closed-Loop, Rapid Polymer Welding Using Radio-Frequency Heating Aniruddh Vashisth and Surabhit Gupta; University of Washington, United States

Polymer components are becoming more prevalent in load-bearing applications due to their superior strength-to-weight ratio. Thermoplastics, particularly, have gained traction in recent years due to their ability to be molded, recycled, and reused. Effective welding and joining methods are essential to facilitate the assembly of intricate thermoplastic parts; but these manufacturing processes are energy expensive and depend on the processed materials. We have developed and energy efficient closed-loop method that utilizes a recent discovery that radiofrequency (RF) fields rapidly heat up carbonaceous materials. We developed a machine capable of monitoring the material's pressure, deformation, and thermal response during the assembly process; this closed-loop system does not require human intervention to process the materials. In this work, we will show that the closed-loop machine can rapidly weld thermoplastics using RF heating at the bondline; to process these materials, we can control the pressure or displacement of the welds to ensure desired mechanical properties. Our initial experiments showed that we can successfully weld polylactic acid (PLA) coupons with graphitic RF susceptors at the bond line in less than 2 minutes, utilizing less than 50 W of RF power. The weld properties show no significant variation within a 0 to 0.3 MPa pressure range. However, an increase in out-of-plane welding displacement enhances the modulus and strength of the weld. This work introduces an energy-efficient, automated system for welding polymer composites using RF fields, showing promise for diverse manufacturing applications. The machine can be used in three control settings: hold, displacement, and pressure control. We saw excellent RF heating response of conductive carbonaceous coatings on polymers; this rapid heating was used for RF processing and bonding thermoplastics using less than 50 W of RF input powers in an automated manner.

5:00 PM EN06.08.02
Electrochemical Methods of Carbon-Negative Ironmaking for Green Steel Paul A. Kempler, Berkley Noble and Anastasiia Konovalova; University of Oregon, United States

Iron and steel are important feedstocks for energy materials and infrastructure but are produced with concomitant greenhouse gas emissions. Iron reduction, typically accomplished using coal or natural gas, can be driven electrochemically which provides a potential path to a fully electrified and carbon-neutral steelmaking process. We have developed the chlor-iron process, a low-temperature (<100 C), electrochemical cell that directly reduces solid iron oxide particles to high-purity iron metal at the cathode while co-producing sodium hydroxide and chlorine. The production of co-products consumed at the ~100 million tons per year scale provides a cost-competitive pathway for electrochemical ironmaking. Moreover, the co-produced hydroxide can be used for direct CO_2 capture and mineralization, leading to a net-negative process for ironmaking. Here, we report results on the mechanism of electrochemical direct oxide reduction, the effects of iron ore feedstocks on selectivity towards iron metal, and prototypes for a cell producing iron and chlorine at current densities > 100 mA cm^{-2}.

5:00 PM EN06.08.03
Reinforcing Strategy in The Fabrication of GO-Reinforced Al-Matrix Composite Using Single Pass Friction Stir Processing Soumyabrata Basak[1,2], Han-Gyeol Yoo[3], Van Cong Phan[2], Sung Tae Hong[2], Sam Y. Anaman[3] and Hoon-Hwe Cho[3]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]University of Ulsan, Korea (the Republic of); [3]Hanbat National University, Korea (the Republic of)

The influence of carbonaceous components (graphene oxide, GO) on the microstructure and mechanical properties of aluminum (Al) matrix composite fabricated by single-pass friction stir solid-state processing (FSP) is studied. GO powder is introduced onto the commercially pure Al plate using adhesive, eliminating typical secondary manufacturing stages. As a result, this technique becomes more cost-effective and energy-efficient than other conventional approaches. The presence of GO within the Al matrix is initially characterized using Raman spectroscopy and secondary ion mass spectrometry, followed by detailed electron microscopy studies. TEM studies show a reasonable amount of dislocation accumulation at the matrix particle interface without other chemical reactions. Due to continuous dynamic recrystallization, EBSD analysis reveals a significant grain refinement in FSPed Al (FSP-only condition without GO reinforcement) and FSP with GO conditions. The microhardness map of FSP with GO characterizes an overall improved hardness value than the FSPed Al and reveals the maximum hardness zone at the advancing side of the stir zone. The advancement of mechanical properties is primarily due to GO particles and their interaction with the Al matrix. The tensile strength and ductility are improved in the FSP with GO condition compared to the base material and FSPed Al condition.

5:00 PM EN06.08.04
Boron Nitride Nanomaterials for Gas Storage and Separation Using Mechanochemistry Srikanth Mateti and Ying Chen; Deakin University, Australia

2D h-BN, also known as white graphene, has a similar honeycomb structure to graphene, with alternating boron and nitrogen atoms consisting of strong sp^2 covalent in-plane bonding and weak van der Waal forces between layers. h-BN has unique properties; it is a lubricant due to its layered structure. BN is an electrical insulator (with a bandgap of approximately 5.9eV)at the same thermally conductive and also has high mechanical strength, large thermal conductivity and low dielectric constant. Hydrogen is increasingly being touted as one sustainable solution to globe clean energy problem. But one of the main challenges is the lack of a safe and cost-effective storage and transport technique. Solid-state storage technology is considered to overcome this challenge by storing enormous quantities of gases in solid materials. Currently, hydrogen storage and transport happen majorly in three ways, compressed gas and carrier gas then decompose. Due to reasons of material properties and operating costs, large amounts of gaseous hydrogen are usually not stored at pressures exceeding 100 bar in aboveground vessels and 200 bar in underground storages [1]. Currently commercially available have utilized an onboard storage pressure of 700 bar, but storage tanks capable of storing hydrogen at such pressures are expensive. To decompose ammonia to form hydrogen, transport losses are 34-36% [2]. And Liquid hydrogen storage needs an extremely low boiling point of hydrogen (-253°C at 1 bar) which is energy intensive and expensive. Thus, urgent need to find alternative and sustainable ways to store hydrogen gases. In this, we discuss possible and sustainable and safe ways of storing and transporting hydrogen in powder form. This talk will provide insights on the mechanochemical approach to store and separate various gases.

5:00 PM EN06.08.05
A Novel Cobalt Chloride Hydrate Modified Co-MOF Derived Carbon Microspheres as Anode Materials for Lithium Ion Batteries Lei Jiang[1,2] and Bohejin Tang[2]; [1]KU Leuven, Belgium; [2]Shanghai University Of Engineering Science, China

In this work, the carbon-microsphere loaded with cobalt chloride hydrate (CCH@CM) was prepared via a collaborative and chlorination strategy derived from ZIF-67 precursor, which exhibits a superior electrochemical performance as a lithium-ion battery anode material. The synthesized CCH@CM obtained a high initial discharge capacity (947 mAh g^{-1}) and the capacity attenuation rate is close to zero after 200 cycles at the current density of 100 mA g^{-1}. The porous structure derived from ZIF-67 not only can provide a conductive path, which increases the transport of electrons and lithium ions, but also alleviate volume expansion. The presences of -Cl-/H_2O groups provide active sites for the anchoring of Li+. As the first successful synthesizing the cobalt chloride hydrate (CCH) from ZIF-67, good electrochemical performance provides a promising for the large-scale application in lithium ion batteries.

5:00 PM EN06.08.06
Recycle Waste Gloves for Oxygen Evolution Reduction in Alkaline Water Electrolysis Tzu Hsuan Chiang, Ji-Min Chang and Rui En Li; National United University, Taiwan

Nitrile gloves have gained widespread use as disposable gloves in various sectors, including hospitals, scientific laboratories, manufacturing facilities, halls, and museums, thanks to their superior mechanical strength compared to vinyl gloves and other alternatives. Due to the ongoing COVID-19 pandemic, the global production of discarded gloves has soared, estimated at more than 76 million monthly. Unfortunately, dealing with and reintroducing this waste into the reuse cycle is costly and time-consuming. Regrettably, many disposable gloves eventually find their way into oceans and other water bodies, slowly deteriorating and fragmenting into microplastic particles. Marine animals swiftly ingest these microplastics, leading to blockages and permanent damage to their internal organs. Consequently, finding a practical solution to this substantial waste issue is paramount.

A study was conducted to create FeWOx-NG electrocatalysts by recycling waste nitrile gloves through the oxygen evolution reaction (OER) in alkaline water electrolysis (AWE). While AWE is a preferred technology for green hydrogen production, its adoption has been impeded by the high cost associated with the necessary capital investment in electrolysis and renewable energy systems. Furthermore, the commonly used precious electrocatalysts contribute to AWE's elevated costs and superior gas evolution performance. The oxygen evolution reaction (OER) is the rate-limiting step in alkaline water electrolysis. It makes electrocatalyst performance in OER a crucial factor in enhancing its hydrogen evolution reduction (HER) capabilities. Leveraging recycled waste nitrile gloves, this study developed an OER electrocatalyst with Fe and W precursors (FeWOx-NG) to reduce the electrocatalyst's cost.

The study results demonstrate that FeWOx-NG exhibits a smaller overpotential and Tafel slope at a 10 mA/cm^2 current density in alkaline electrolytes compared to RuO_2. This improved performance could enhance alkaline water electrolysis efficiency and promote more efficient hydrogen evolution.

5:00 PM EN06.08.07
Exploring The Potential and Performance Constraints of Ni-Rich $LiNi_{0.9}Co_{0.1}O_2$ through DFT Research Temitayo O. Ikuerowo[1], Omotayo Salawu[2] and Olusegun Tomomewo[1]; [1]University of North Dakota, United States; [2]Texas A&M University, Qatar

The high-capacity but unstable $LiNiO_2$ (LNO) cathode material for lithium-ion batteries can be improved through partial substitution with cobalt. First-principles calculations were performed to study the impact of 10% cobalt doping on the structural, electronic, defect, and lithium diffusion properties of $LiNi_{0.9}Co_{0.1}O_2$ (NC91). The layered structure is retained but the band gap decreases significantly with 10% Co. Formation energies reveal oxygen vacancies and antisite defects still occur; however, Ni sites near Co are least favorable for antisite formation. The energy barrier for Li migration is substantially lower in NC91 than LNO, indicating enhanced Li mobility with 10% Co. While the Co doping improves Li transport, additional doping is likely required to sufficiently suppress cation mixing and oxygen loss. This work provides fundamental insights into the structure-property relationships resulting from low levels of cobalt doping in Ni-rich cathodes.

5:00 PM EN06.08.08
Utilizing Date Seed-Derived Hard Carbon in Lithium-Ion Batteries Operating at Low Temperatures Nurbolat Issatayev[1], Kazna Tassybay[1], Arailym Nurpeissova[1,2,3], Zhumabay Bakenov[1,2,3] and Gulnur Kalimuldina[1]; [1]Nazarbayev University, Kazakhstan; [2]National Laboratory Astana, Kazakhstan; [3]Institute of Batteries LLC, Kazakhstan

The performance of traditional Li-ion batteries deteriorates when operating at sub-zero temperatures. This is mainly due to the slow diffusion of Li-ions in the commercial graphite anode, which can retain about 12% of its capacity at -20 °C. To solve this issue, recently, many alternative anodes have been explored. However, most of the electrodes proposed to date involve complex fabrication methods, complicating their practical implementation. Therefore, we propose cost-effective anode material as porous structured nitrogen-doped hard carbon synthesized from biowaste (date seeds) with further LiF modification to achieve an artificial LiF-rich SEI layer. The prepared anode material achieved a specific 525 and 280 mAh g^{-1} capacity after 100 cycles at 0.1 C at room and -20 °C temperatures, respectively. It could deliver 72 mAh g^{-1} after 500 cycles, even at a high current of 2C at -20 °C.
To elucidate the superior electrochemical performance of LiF-modified hard carbon, post-mortem Transmission Electron Microscope (TEM) and X-ray Photoelectron Spectroscopy (XPS) analyses and the Li-ion storage mechanism at low temperatures were studied. The former showed that the LiF-modified electrode has a uniform, thin, and LiF-rich SEI layer that alleviates the penetration and/or integration of ions into graphic layers of hard carbon. The latter illustrated the dominance of the pseudo-capacitive storage mechanism of hard carbon anode, which contributes significantly to high performance at low temperatures.

5:00 PM EN06.08.09
Synergistic Interaction between Ruthenium Catalysts and Grafted Niobium on SBA-15 for 2,5-Furandicarboxylic Acid Production using 5-Hydroxymethylfurfural Hyun Sung Kim[1] and Hangil Lee[2]; [1]Pukyong National University, Korea (the Republic of); [2]Sookmyung Women's University, Korea (the Republic of)

This study entailed the synthesis of a novel Ru-bound catalyst decorated on Nb-grafted SBA-15. An Nb-grafted SBA-15 support with varying Si/Nb ratios was utilized as a support for Ru nanoparticles. The effect of Nb grafting on the immobilized Ru nanoparticle catalyst was systematically investigated, and its catalytic performance in the synthesis of furan dicarboxylic acid using 5-hydroxymethylfurfural (HMF) under base-free reaction conditions was evaluated. The results indicate the increased productivity of the Ru/Nb-grafted SBA-15 catalyst, with a yield exceeding 99%, representing a significant advancement in catalysis. This study also affords insights into the complex relationship between the catalytic activity and selectivity and its unique surface attributes. Moreover, acidic sites were created, and the electron density within the active sites was modulated by generating monomeric Nb oxide species on the SBA-15. Additionally, the role of high-electron-density Ru atoms in facilitating the efficient adsorption and activation of HMF, resulting in enhanced catalytic efficacy, was highlighted.

5:00 PM EN06.08.10
Material advancement for iron-based redox flow batteries for grid-scale storage Buddhinie S. Jayathilake, Anna Ivanovskaya, Alexandra Overland, Swetha Chandrasekaran and Auston Clemens; Lawrence Livermore National Laboratory, United States

Iron- based redox flow batteries are low-cost candidates for grid-scale energy storage due to their scalability and low cost. Compared to the current state-of-the-art redox flow batteries based on vanadium redox chemistry, iron shows the potential to achieve DOE's cost targets LCOS, $0.05/kWh due to its natural abundancy and eco friendliness. Our recent studies show pathways for overcoming material challenges associated with iron-based systems. Iron deposition process limits the storage capacity and efficiency of the system. Our findings shows that engineered electrolytes and 3D electrodes can minimize parasitic losses by 15%, improve the durability and enhance storage capacity by 25%.

5:00 PM EN06.08.12
Lead Halide Perovskite Pixel Arrays Fabricated by Ultrathin Reusable Metal Mask Zhao Sun[1], Zhuofei Gan[1], Jianwen Zhong[1], Liyang Chen[2], Zijie Jiang[1] and Wendi Li[1]; [1]The University of Hong Kong, China; [2]ETH Zurich, Switzerland

In recent decades, metal halide perovskites have emerged as a highly promising class of materials for optoelectronic devices, owing to their exceptional properties, which include a tunable bandgap, a significant optical absorption coefficient within the visible light, and long carrier diffusion length[1-4]. Nonetheless, achieving high-resolution patterning of perovskite arrays presents challenges due to their inherent instability when exposed to conventional photolithography solvents. In this work, we proposed a universal approach to pattern high-resolution perovskite arrays using an ultrathin reusable metal mask. A two-step sequential approach utilizing a designed metal mask is employed to achieve the controlled fabrication of micro and nanometer-resolution perovskite arrays. Through this generic and straightforward patterning process, we successfully fabricated perovskite arrays in red, green, and blue (RGB) colors, varying in shapes and sizes, with a minimum diameter of 500 nm perovskite pixel arrays. Moreover, the patterned perovskite arrays exhibit excellent photoelectric properties, including comparable light absorption and considerable lifetime. Furthermore, we investigated a transfer method to assemble multi-color perovskite arrays, enabling the creation of full-color images that significantly contribute to the progress of screen display technologies. Additionally, we presented photodiode stack arrays with a sandwich structure for each stack, demonstrating the capability of our approach in both solution and evaporation processes, which is unprecedentedly achieved. The patterned perovskite photodiode stack arrays exhibit outstanding electronic performance, showcasing lower open circuit voltage and comparable stability under diverse levels of illumination intensity. The fabricated ultrathin and high-resolution metal mask holds significant potential in the development of micro and nanoscale photoelectronic devices such as LEDs and solar cells. This method enables the patterning of perovskite micro-arrays on versatile substrates with reusable metal mesh templates and can be further applied to other materials to facilitate the development of micro-structured optoelectronic devices.

Sustainable Electroceramics in a Circular Economy Jinxue Ding[1,2], Anke Weidenkaff[1,2] and Wenjie Xie[1,2]; [1]Technical University of Darmstadt, Germany; [2]Fraunhofer Research Institution for Material Recycling and Resource Strategies IWKS, Germany

Defossilisation with renewable energy converters require tailored electroceramics and an infrastructure partially based on critical materials. The renaturation and transformation to a future green circular economy has to be based on a fundamental recovery of nature with circular materials and innovations. The development of recyclable materials for energy harvesting and conversion requires sustainable large-scale production from secondary raw materials. The decision making for future resilient energy systems has to be based on environmental aspects as well as on performance criteria defined by a holistic life cycle assessment.
Here efficient synthesis methods for materials with a programmable lifetime and regenerativity will be introduced as a suitable approach. The design of circular high performance materials uses theoretical predictions and the criticality analysis of applied elements to improve the cycle life of future solar and wind energy converters.

5:00 PM EN06.08.14
Remarkable Enhancement of Thermal and Dielectric Properties of Layered Double Hydroxides and Graphene Fillers Reinforced Poly(vinyl alcohol) Nanocomposite for Energy Applications Ritu .[1,2,3], Shadi Houshyar[1], Lijing Wang[1], Manoj Kumar Gupta[4,3] and Manoj Kumar Patel[2,3]; [1]RMIT University, Australia; [2]CSIR-Central Scientific Instruments Organisation, India; [3]Academy of Scientific and Innovative Research, India; [4]CSIR-Advanced Materials and Processes Research Institute, India

In this work, we have synthesized the zinc-aluminum layered double hydroxide (ZnAl LDH) nanostructures using cost-effective hydrothermal technique. The ZnAl LDH and graphene-based poly(vinyl alcohol) (PVA) nanocomposites are fabricated. The crystal structure, morphology, thermal, and dielectric properties of pristine PVA and ZnAl LDH and graphene-based PVA nanocomposites films were investigated using X-ray diffraction, HR-transmission electron microscopy, thermo gravimetric analysis, and impedance analyzer. HRTEM analysis reveals the hexagonal nanoplates shape-like morphology of Zn-Al layered double hydroxides with an average thickness of 40-50nm and size of 400-600nm. High thermal stability was observed from ZnAl LDH and graphene-reinforced nanocomposite. Enhanced thermal stability of 250°C and low weight loss was observed from ZnAl LDH reinforced PVA-based nanocomposites compared to pristine PVA. Zn-Al LDH nanoplates-graphene-PVA based nanocomposites showed ultra-high dielectric constant of 794 as compared to the ZnAl LDH-PVA nanocomposites (334) and pristine PVA sample (35). Low dielectric loss of 0.27, 0.18, 0.38 was observed for pristine PVA, ZnAl-LDH-PVA and ZnAl-LDH-graphene-PVA nanocomposites. The large enhancement of the dielectric constant and thermal stability were discussed in terms of improved crystallinity, interfacial polarization and formation of nanodipoles in the matrix. This study reveals a significant role of LDH-graphene-based hybrid nanocomposites in optoelectronics, energy storage, sensors, energy conversion and thermally stable devices.

Exploring Hydrogen Storage Efficiency in MgH_2 Using Charred Nanomaterials: A Computational Analysis Integrating DFT and Machine Learning Approaches Fernando Soto and Joshua Lilly; Penn State University Greater Allegheny, United States

Hydrogen, as a clean energy carrier, holds significant potential for reducing CO_2 emissions and diversifying the energy mix (1-3). However, the practical implementation of solid-state hydrogen storage, particularly in hybrid energy systems (HES), faces challenges related to kinetics, stability, and safety (4). This study performs a computational exploration of magnesium hydride (MgH_2) integrated with char nanomaterials, aiming to enhance the efficiency of hydrogen storage systems. We investigate the use of charred nanomaterials as a novel approach to address the fire risk and safety concerns associated with MgH_2, as well as to improve its hydrogen desorption kinetics. We hypothesize that charred nanomaterials can act as dual-function agents, catalyzing hydrogen release while also offering protection against combustion.

To test our hypothesis, we employ Density Functional Theory (DFT)-based simulations complemented with machine learning techniques. Our study

models include various configurations of MgH_2 clusters in contact with charred carbon fragments doped with heteroatoms like Oxygen, Nitrogen, and Iron, alongside O_2 molecule environments to simulate combustion processes. These models are analyzed to understand the stability and interaction dynamics under varying conditions. Our findings reveal that charred nanomaterials significantly influence the hydrogen desorption properties of MgH_2, indicating a promising pathway towards safer and more efficient hydrogen storage. The charred structures, particularly when doped with heteroatoms, not only catalyze hydrogen release but also mitigate risks associated with MgH_2's reactivity, offering a holistic solution to the current limitations in hydrogen storage technology.

This computational study provides crucial insights into the design of advanced materials for hydrogen storage, offering a sustainable solution to energy storage challenges in HES. It opens up avenues for further experimental validation and development of MgH_2-based hydrogen storage systems, contributing to the advancement of clean energy technologies.

Building a Rechargeable Voltaic Battery via Reversible Oxide Anion Insertion in Copper Electrodes Jose F. Florez Gomez[1], Nischal Oli[1], Songyang Chang[2], Shen Qiu[2], Swati Katiyar[2], Ram Katiyar[1], Gerardo Morell[1] and Xianyong Wu[2]; [1]University of Puerto Rico at Rico-Rio, Puerto Rico; [2]University of Puerto Rico at Río Piedras, Puerto Rico

The Voltaic battery (zinc-copper battery) is the very first battery built by humanity, which plays a critical role in battery development history. However, the inevitable copper ion dissolution-crossover issue leads to its primary battery nature. The ion-exchange membranes and alkaline electrolytes represent two leading approaches to mitigate this issue; however, they incur the disadvantages of complicated battery design, high cost, and zinc anode corrosion. Herein, we build a rechargeable zinc-copper Voltaic battery from simple and cost-effective electrode/electrolyte materials, where the cathode is a nano-sized copper, and the electrolyte is a near-neutral zinc sulfate solution. Interestingly, the copper electrode experiences a synergistic cation-anion insertion reaction, where copper transforms to zinc-copper alloy (Zn_xCu) during discharge and converts to copper (I) oxide (Cu_2O) during charge. Therefore, multivalent Zn^{2+} cations and multivalent O^{2-} anions participate in the redox reaction, giving a high capacity of ~370 mAh g^{-1}. Moreover, the structural similarity between Zn_xCu, Cu, and Cu_2O endows high reaction reversibility, leading to impressive cycling of ~500 cycles. Such a concerted cation-anion insertion is rarely reported in the battery field, which offers a mechanism-based approach for developing high-capacity and long-cycling multivalent-ion batteries.

Fit-To-Purpose Batteries. An Ecodesign-Based Approach to Power Portable Applications Marina Navarro-Segarra[1], Carles Tortosa[2,1], Neus Sabate[3,2] and Juan Pablo Esquivel[1,4,2]; [1]BCMaterials, Spain; [2]Fuelium, Spain; [3]Instituto de Microelectrónica de Barcelona, IMB-CNM (CSIC), Spain; [4]Ikerbasque, Spain

Batteries have become an essential power source, due to their capability to deliver high energy densities in a portable manner. However, a close look into conventional portable battery life cycles reveals, that they still follow an obsolete linear model. They are manufactured at specific locations causing scarce material exhaustion, transported thousands of kilometres for its use and then disposed of, sometimes before even its complete depletion. Then, during portable batteries' end-of-life, only a small percentage are recycled, typically using energy intense processes, whereas the rest ends up incinerated or in landfills, generating greenhouse gas emissions and poisoning terrestrial and marine ecosystems. Furthermore, it is forecasted that the upcoming wave of power-hungry Internet-of-Things (IoT) sensing nodes will increase exponentially the portable battery demand in the near future. Thus, aggravating the environmental impact associated with electronic devices production and the generation of waste electrical and electronic equipment (WEEE). For portable batteries to stop contributing to environmental damage, and become an example for sustainable technological development, it is crucial to change the way the batteries value chain is approached.
This work presents a rationale for ecodesign portable batteries by re-thinking their life-cycle under an environmentally conscious framework. Through careful device design and advocating for a 'fit-to-purpose' approach, the development of these batteries is paired with the application value chain, in such a manner that even the power source end-of-life is redefined according to the use-case scenario. In order to ground these ideas, several examples of these ecodesigned portable power sources will be presented.
First, a paper-based battery in a lateral flow assay format intended to power portable diagnostic devices. These liquid activated batteries can be fabricated under the same procedures used in the rapid test industry and have shown the ability to power the most relevant features needed in portable medical devices, such as sensors, displays, wireless communications or heating.
Secondly, a bio-based battery using laser induced graphene current collectors in a cardboard tape format for smart packaging. These batteries have the capability to power typical applications envisioned by the sector, such as digital displays and wireless trackers. As validated by normalized evaluation methods, these batteries are complaint with current paper and cardboard recycling processes.
Finally, different approaches of biodegradable batteries for precision agriculture will be presented. These batteries made with organic materials can power sensing devices that measure parameters in soil and the environment and then send the data by Bluetooth communication. The capability to undergo biodegradation has been assessed experimentally using normalized tests as a way to minimize energy consumption at the end-of-life.
Developed under this rationale, environmental sustainability has been placed as a core priority to guide the batteries' conception and materialization, from materials to end-of-life. Hence all materials used as electrodes, electrolytes, or structural components are abundant, non-toxic and renewable; selected to meet the specific end-of-life requirements and endow a safe and ethical manufacturability.

8:30 AM EN06.09/EN03.09.02
A Coplanar Edible Rechargeable Battery with Increased Capacity and Durability Valerio Galli[1,2], Valerio F Annese[1], Giulia Coco[1,2] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

Edible electronics is an emerging research field focused on developing safe-to-ingest devices entirely made of food and food additives. Being intrinsically non-toxic and biodegradable, this technology can find applications in many scenarios, from healthcare to agrifood. Starting from common food additives like activated carbon, edible gold, ethyl cellulose, and beeswax, we developed the first edible rechargeable battery entirely made of food materials. The chemistry is based on two small redox-active molecules found in food, riboflavin, and quercetin, used as the anode and the cathode, respectively. [1]
Here we present a coplanar edible battery, characterized by an electrode configuration that eases compatibility and integration with electronic components. The battery provides an open-circuit voltage of ~0.65 V with a specific capacity of 20 µAh cm^{-2}, a two-fold increment with respect to our first prototype, thanks to increased electrode mass loading. The beeswax encapsulation yields excellent operational stability, characterized over a two-week period and in different environmental conditions. As proof of the compatibility with traditional electronic devices, the battery was successfully used to power up resistive sensors, including thermistors and photoresistors. Multiple batteries were also employed to supply power to an Internet of Things module which can acquire humidity and temperature information and transmit data in real-time via Bluetooth.
The high degree of versatility of our technology goes beyond the proposed proof-of-concept: we envision edible batteries as a promising alternative to traditional ones in low-power applications, such as agrifood sensor networks and food monitoring.

Advanced Characterization and Modeling to Understand Hydrogen Production by Solid Oxide Electrochemical Cells David S. Ginley[1], Michael J. Dzara[1], Brandon Wood[2], Harry W. Abernathy[3], Olga A. Marina[4], Brian Gorman[5], Heather Slomski[5], Mike Tucker[6], Micah Casteel[7], Nicholas Strange[8] and Sarah Shulda[1]; [1]National Renewable Energy Laboratory, United States; [2]LLNL, United States; [3]NETL, United States; [4]Pacific Northwest National Laboratory, United States; [5]Colorado School of Mines, United States; [6]Lawrence Berkeley National Laboratory, United States; [7]Idaho National Laboratory, United States; [8]SLAC National Accelerator Laboratory, United States

Functional oxides are becoming more important in a wide variety of renewable applications, ranging from high temperature electronics, electric vehicles, and solid oxide electrolysis/fuel cells (SOEC/SOFC). They must meet a diversity of characteristics to achieve desired functionality in these harsh environments. Hydrogen is considered an enabler for the transition to sustainable and renewable society. Production of green hydrogen is a strong focus of modern research given the current global market of 170 billion dollars. Among the approaches for hydrogen generation are the use of SOECs. These utilize a stack of high temperature oxides operating in H_2/steam. While direct electrochemical measurements are key for quantifying progress towards the DOE Hydrogen Earthshot Goal of 1$/kg in the next decade they are insufficient to provide detailed materials science investigation of degradation pathways. We report on the development of a suite of synchrotron and conventionally based analysis tools to provide a set of detailed morphology, phase, and composition data which both provide detailed information about degradation mechanisms and provide foundational information for predictive models leading to ultimate materials improvement.

The solid oxide layers that comprise SOECs typically feature a layered structure composed of a Ni-YSZ fuel electrode/YSZ electrolyte/Gadolinium doped Ceria barrier layer and a Lanthanum Strontium Cobalt Iron Oxide oxygen electrode. The phase behavior especially at interfaces is complex starting from the deposition of materials to behavior during extensive aging. Recent analysis has confirmed a number of potential degradation mechanisms are operable including Sr, Ni, and Ag migration, interfacial phase formation and grain coarsening. We will discuss how a combination of synchrotron X-ray diffraction(XRD), nanoscale X-ray computed tomography (nano-XCT), and other X-ray spectroscopy techniques combined with electron microscopy can provide coupled insights on the nature of these mechanisms which can be incorporated into computational models which can provide predictive insights on cell/stack longevity. We also discuss how button cells can inform large area and stack behavior.

We will discuss our recent development of an in-operando system intended for the synchrotron techniques, especially XRD, to probe cell performance in real time.

Advanced characterization can couple to cell development and electrochemical testing towards achieving DOE Hydrogen Earthshot Goals.

Artificial Chlorophyll-Inspired: Photonic Crystals-Based Photocatalyst for Carbon Dioxide Conversion as Gaseous Fuel Fang-Yu Liang[1], Po-Jung Huang[2] and Yen-Ping Peng[1]; [1]National Sun Yat-Sen University, Taiwan; [2]National Central University, Taiwan

The PCN-222(M)/IOT heterostructure is constructed (created) by combining the narrow bandgap metalloporphyrin metal-organic framework (PCN-222) with the wide bandgap inverse opal TiO_2(IOT). PCN-222 grows in situ on the surface of the inverse opal under hydrothermal conditions, forming a tightly connected interface that enables the rapid separation and transfer of electrons and holes.

Inspired by natural photosynthesis, this research contributes to the development of artificial CO_2 photoreduction catalysts. The construction of Z-scheme heterojunctions is an effective strategy for enhancing the photocatalytic activity of semiconductor materials by isolating photogenerated electron-hole pairs. In this study, the morphologies , structures, and photoelectric characteristics of materials acquired through the synthesis of P(M:metal)/IOT heterostructures were characterized. These heterostructures were evaluated for their photocatalytic CO_2 reduction capabilities, revealing their superior performance compared to IOT and PCN-222. Under visible light illumination, the P(Fe)/IOT heterostructure achieved impressive yields of CH_4 and C_2H_4. The enhanced photoactivity is attributed to the efficient spatial separation of photogenerated electrons and holes via a Z-scheme charge transfer mechanism. This research provides valuable insights into the design and fabrication of novel Z-scheme photocatalytic systems for environmental remediation and energy conversion.
The P(M)/IOT heterostructure combines a narrow band gap metalloporphyrin metal-organic framework (PCN-222) with a wide gap inverse opal TiO_2 (IOT) via in-situ growth under hydrothermal conditions. This results in a tightly connected interface that facilitates rapid electron-hole separation and transfer. The high photocatalytic activity of P(M)/IOT is attributed to its strong visible light absorption and efficient charge separation within the heterointerface, also providing bionic chloroplast microenvironmental strategies for effective photocatalytic carbon dioxide reduction.

9:30 AM EN06.09/EN03.09.06
Highly Efficient Carbon Mineralization Using Amine-Functionalized Magnetic Nanoparticle Clusters Hyunsoo Han and Sangmin Jeon; POSTECH, Korea (the Republic of)

Carbon mineralization, which transforms carbon dioxide (CO_2) into a stable form such as calcium carbonate or magnesium carbonate, has emerged as a promising technology for long-term CO_2 storage. In this study, we developed amine-functionalized magnetic nanoparticle clusters (A-MNPs), that enhance both CO_2 capture and its subsequent mineralization, by hydrothermal method and immobilization of (3-Aminopropyl)triethoxysilane (APTES). The surface of A-MNPs was covered by the APTES monolayer with approximately 100% coverage. A-MNPs expanded the surface area of CO_2 bubbles and led to amine-CO_2 coupling, improving CO_2 uptake. Subsequently, the injection of calcium chloride into the CO_2-saturated A-MNP solution resulted in carbon mineralization (i.e. $CaCO_3$ formation) with improved efficiency. Additionally, the shapes of $CaCO_3$ could be adjusted by adding anionic surfactants to the solution. Since A-MNPs can be controlled by magnetic force, they can be recovered using a magnet and reused more than 10 times without a loss in their catalytic activity, offering an efficient and sustainable method for CO_2 storage.

9:45 AM EN06.09/EN03.09.07
N-Doped Carbon Dots Embedded in Electrospun Cellulose-Derived Nanofibers: A Novel Approach to Pseudosupercapacitors with Enhanced Faradic Activity Jesus Vazquez-Chavez, Michael W. Thielke, Carlos Mingoes and Ana Jorge Sobrido; Queen Mary University of London, United Kingdom

The sustainable energy storage landscape is rapidly evolving, with innovations driven by the necessity to meet increasing global energy demands. In this context, pseudosupercapacitors emerge as a new solution, closing the gap between batteries and supercapacitors, by achieving the high energy density of batteries with the rapid charge-discharge cycles of supercapacitors. The key to harnessing the potential of pseudosupercapacitors lies in the development of electrodes that demonstrate superior faradic activities and high-capacity retention.
Our research presents a pioneering effort in this direction, focusing on the synthesis of pseudosupercapacitor electrodes from electrospun cellulose acetate nanofibres embedded with N-doped carbon dots. Electrospinning is a widely used technique known for its adaptability in fabricating carbon fibres. With its intrinsic capability to produce fibres boasting a high surface-to-volume ratio, electrospinning not only permitted the integration of the N-doped carbon dots in the fibres, but also allowed fine control over the fibre diameter and nitrogen concentration. By manipulating electrospinning parameters, we achieved fibres ranging from 220 nm to 850 nm, presenting a trade-off between surface area and mass transport efficiencies. Cellulose acetate was chosen as carbon source and as an alternative to usually employed polyacrylonitrile (PAN), to increase the sustainability of our approach.
The carbon dots, synthesized through a microwave-assisted method using citric acid and urea, showcased a high faradic activity (here include values for faradic capacity and capacity retention after xx cycles) even after the deacetylation and carbonization as they were incorporated into the cellulose acetate matrix. Their N-doped nature contributes to enhanced electronic properties. Pyridinic N and pyrrolic N have been shown to be responsible for active redox sites for faradic activity whereas graphitic N is thought to contribute to the enhancement of conductivity of the resultant electrodes.
In conclusion, we present a multidimensional approach to a novel pseudosupercapacitor electrode fabrication. By integrating microwave-assisted synthesized n-doped carbon dots within electrospun cellulose acetate nanofibres, we not only address the technical challenges of achieving high specific capacitance, but also present an environmentally conscious blueprint. With promising preliminary results in electrochemical and analytical characterization, our research aims to expand the current design of pseudosupercapacitor and their implications for sustainable energy storage.

Recovery of Lithium and Heavy Non-Ferrous Metals from Spent Lithium-Ion Batteries Valery Kaplan, Ellen Wachtel and Igor Lubomirsky; Weizmann Institute of Science, Israel

When compared with nickel-cadmium or nickel-hydride batteries, lithium-ion batteries (LIBs) provide significant advantages as a power source for electric vehicles and for small mobile devices. However, LIBs contain a variety of toxic and ecologically harmful substances, such as heavy metals, organic and inorganic compounds, thereby creating a challenge for clean end-of-life (EoL) disposal. But why throw away EoL LIBs when the grade of cobalt and lithium in the complex lithium/cobalt oxide cathodes is higher than that in pristine lithium and cobalt ores? Recycling these valuable metals efficiently and with minimal environmental impact has therefore become an effort of significant economic, health and ecological importance, as well as of reducing tense international relations. To this end, we have worked to develop a (laboratory–scale) procedure for recycling EoL laptop LIBs containing $LiCoO_2$, $LiNiCoO_2$, and/or lithium-nickel-cobalt-aluminum oxide without the necessity of using acid/bases or costly reagents and without generating hazardous liquid waste. Following removal of the non-metallic container, the battery elements undergo crushing/milling; no other component separation procedure is performed or required. One hour dilute natural gas (4 vol.% in N_2) sintering under reducing conditions (673– 1123 K), followed by ice-water leaching, is used to efficiently separate Li from the heavy metals in the form of lithium carbonate at high yield and purity; 0.5 h smelting (1773 K) of the remaining metal clinker in air with sodium tetraborate as flux, allows recovery of the heavy, non-ferrous metals (Ni, Co, Cu and their alloys) as mm-size ingots (39% Co, 32.2% Ni, 26.3% Cu). Iron compounds, remanent Li, Al and unburnt graphite are removed as slag. Neither corrosive acids nor costly reagents are required, and hazardous liquid waste is not generated.

11:00 AM EN06.10/EN03.10.02
Separating Materials for Recycling Processes Mmantsae M. Diale; University of Pretoria, South Africa

Recycling is a circular economy system that allows participants to add value to cleaning the environment. Materials have been the major role player in improving old engineering systems and producing newest technologies to reduce the carbon footprint. There is a great effort in plastic recycling where profits are made, and poverty reduced to address the UN sustainable goals for 2030. Phosphors and other identifiers have been used to identify different plastics during separation. Similarly, paper and bottles can have additives and nanostructures that will make it easy to separate such materials during recycling. We report on the work done to identify glass, paper and plastic in recycling and make it a smooth process to produce new products. In addition, we have also embarked on educating the garbage pickers to enhance profits by proper separation.

11:15 AM EN06.10/EN03.10.03
Electrochemical Separation Technologies for Resource Recovery and Recycling Seoni Kim[1] and Jin Soo Kang[2]; [1]Ewha Womans University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Global efforts toward carbon neutrality have impacted the industry and the market in various directions, and this is causing rapid changes in the production, use, and supply chain of various resources. For instance, explosive growth of the electric vehicle (EV) market induced significant increments of demands for lithium and other relevant elements. Meanwhile, it should be noted that the production of such resources from ores often result in a large amount of CO_2 emission and environmental pollutions, which endangers the sustainability of our world. Therefore, there is a wide agreement on the importance of developing clean technologies for recovering and recycling resources from various sources, which even include wastes. Herein, our recent research works on electrochemical separation technologies for efficient resource recovery and recycling will be presented. Electrode materials that have favorable crystal structures for highly selective extraction of specific elements are introduced, together with discussions on their behaviors during the operation. Based on these understandings, rationally designed resource-recovery electrodes are developed, and their performance and reliability are evaluated and demonstrated.

11:30 AM EN06.10/EN03.10.04
Selective and Sequential Precipitation for Critical Mineral Extraction from Electronic Waste Qingpu Wang[1], Elias Nakouzi[1] and Chinmayee Subban[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

The recycling of critical materials from electronic waste (e-waste) shows a great potential for urban mining. However, convectional separation methods are often chemical- and energy-intensive as they mainly rely on organic ligands, ionic liquids, and ion-selective membranes and/or electrodes. The sustainable production of valuable critical elements from e-waste requires a paradigm shift away from currently used resource-intensive processes. We present a novel approach based on the coupling of ion diffusion and precipitation kinetics. Simply by placing a mixed salt solution on top of a hydrogel loaded with a precipitating agent, we obtained spatially separated precipitates along the reactor. Our proof-of-concept has been demonstrated for sequentially precipitating transition metals with modeled feedstocks representative of lithium-ion battery cathodes and rare earth elements from NdFeB permanent magnets. We expect this approach to be broadly relevant to chemical separations from complex feed streams and diverse chemistries—enabling more sustainable materials extraction and processing.

11:45 AM EN06.10/EN03.10.05
Economically Sustainable Recycling of $MAPbI_3$ Perovskite Solar Cells Zhenni Wu[1,2], Misha Sytnyk[1], Jiyun Zhang[1,2], Gülüsüm Babayeva[2], Simon Arnold[2], Jens Hauch[1,2], Christoph J. Brabec[1,2] and Ian Marius Peters[1,2]; [1]Forschungszentrum Jülich, Helmholtz Institute Erlangen-Nürnberg for Renewable Energies (HI ERN), Germany; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Recycling becomes ever relevant with exponentially expanding photovoltaic deployment. Yet, the recycling of commercial silicon photovoltaic modules often falls behind in preserving the quality of materials due to inadequate separation of mixed components. Conversely, the solution processing feature of nascent but propitious perovskite solar cells facilitates simplified component separation. Herein, we report a recycling approach for a planar $MAPbI_3$ perovskite solar cell, resulting in recycled materials that can be integrated into new cells without compromising their quality. Prior to integration into cell construction, all the collected materials underwent corresponding purification or modification treatments. The hole transport material, Spiro-OMeTAD, was purified with column chromatography. The absorber material, $MAPbI_3$, was crystalized using anti-solvents. And the recovered old ITO/SnO_2 was coated with fresh SnO_2 for quality rejuvenation. The resulting recycled materials, whether used individually or combined, all lead to cell efficiencies comparable to those of cells constructed with entirely virgin materials. Based on a techno-economic analysis, the developed recycling approach has demonstrated economic viability at both laboratory and industrial scales.

SESSION EN06.11/EN03.11: Joint Session: Energy Systems II

Sustainable Off-Grid Hybrid Energy Systems: The Case of The Astronomical Telescope AtLAST Sabrina Sartori; University of Oslo, Norway

Production and use of hydrogen as a green and renewable fuel are increasingly considered as a central component in the transition to a green economy. Green hydrogen, i.e. hydrogen produced by water electrolysis with electricity from renewable energy sources, could abate CO_2 emissions and replace fossil fuel usage within transport, heating, stationary applications and various industrial processes. In this talk we will present our latest work on off-grid low carbon renewable energy-based systems (RES) setups for the newly planned Atacama Large Aperture Submillimeter Telescope (AtLAST) and compare them to business-as-usual diesel power generated systems. We consider systems built near the telescope on the Chajnantor plateau at ∼5000 m and systems at a Valley Site, 2500 m above sea level, near the town of San Pedro de Atacama (also off-grid).
Technologies included in the designed systems are photovoltaics, batteries, and hydrogen technology, sizing them according to the telescope's projected energy demand and reliability requirements, cost assumptions for the year 2030 and site-specific characteristics (including a particular interest on the effect of high altitudes on hydrogen-based components). We assess whether 100% RES scenarios are favorable from an environmental point of view in the categories climate change, mineral resource depletion and water use. The system boundary includes the production of components, their transport to the energy system site, and the operation and maintenance of the system.
We find that 100% RES scenarios have a lower CO_2e impact than high-renewable scenarios, however, the latter lower the mineral resource depletion and water use by about 27% compared to 100% RES scenarios. Applying hybrid energy storage systems increases the water use impact, while reducing the mineral resource depletion.
An additional aspect of interest in our study is the proposition of a socially accepted renewable energy system where we combine an energy system model with a participatory multi-criteria analysis.
Results reveal that a renewable energy system supplying the telescope could also cover 66% of the nearby community's energy needs of San Pedro de Atacama, without additional capacity. Stakeholders inputs show this as the most attractive solution by developing an energy system where all of them benefit. Replicating similar energy systems at nearby telescopes could reduce fossil fuel-based energy generation by 30GWh annually, cutting emissions by 18-24ktCO_2eq while contributing to acceptability of new infrastructures and energy justice.

2:15 PM EN06.11/EN03.11.02
Analysis of Inception Sites of Vented Water Trees in a Laboratory Aged High Voltage XLPE Subsea Cable Sofie B. Hårberg[1], Cedric Lesaint[2], Sigurd Wenner[3], Inger-Emma Nylund[1], Per Erik Vullum[3], Sverre Hvidsten[2] and Mari-Ann Einarsrud[1]; [1]NTNU, Norway; [2]SINTEF Energy, Norway; [3]SINTEF Industry, Norway

The use of lead sheaths in future subsea high voltage power cable designs will not be possible, or subject to a strict authorization processes because lead is a candidate for future inclusion by the European Chemicals Agency in the REACH Annex. "Wet design" subsea cables with no metallic barrier have been developed and are available for voltages up to 66 kV. Using the wet design also for higher voltages is very attractive to avoid the use of lead or metallic sheaths. However, in such cables, water molecules can permeate into the polymeric cable insulation system during service. As subsea high voltage cable cores have up to now been in dry service conditions, the knowledge on their performance when subjected to water is not known.

In this work, XLPE cable cores have been subjected to wet ageing following the recommendations in CIGRE TB 722. The electrical ageing was performed at 500 Hz with an equivalent electrical stress at the conductor screen of 10 kV/mm. The cable was helically spiralized into 2 mm thick samples. The vented water trees which appeared from the semi-conductive screens were made visible using a water pre-treatment supersaturating the tree channels. The water trees were located, and the inception sites were cryo-microtomed. The sites were assessed using Energy Dispersive X-Ray analysis (EDX) and Electron Energy Loss Spectroscopy (EELS) to determine the chemical composition of the section analyzed by Scanning Transmission Electron Microscopy (STEM). More than 5 vented water tree inception sites from the same cable were analyzed. The overall composition of inorganic elements was analyzed using Inductively Coupled Plasma Mass Spectrometry (ICPMS).

The cable insulation and semi-conductor sections that were analyzed by ICPMS revealed the presence of ionic species such as Na^+ or K^+. More localized investigation at the inception sites of the water trees was conducted by EDX and EELS analysis with respect to inorganic elements, and the results were compared to those obtained by ICPMS.

2:30 PM EN06.11/EN03.11.03
Innovative Energy Harvesting from Salinity Gradients: Asymmetric Flow-Electrode Capacitive Mixing with MnO_2-Coated Activated Carbon Insung Hwang[1], Seungcheol Myeong[1], Seunggun Choi[1], Hyungjun Lee[1,2], Minsung Kim[1], Han Seung Min[1,2], Hongjun Park[1], Bobae Lee[1], Ungyu Paik[1] and Taeseup Song[1,1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Salinity gradient power represents a promising source of renewable energy, and flow-electrode capacitive mixing (F-CapMix) offers an innovative approach to harnessing this energy potential. However, conventional F-CapMix systems encounter limitations in power density due to the restricted charge storage capacity inherent in porous carbon materials, which operate via the electrical double-layer mechanism. In this study, we introduce manganese dioxide-coated activated carbon (MO@AC) as a novel flow-electrode material for F-CapMix applications, placing specific emphasis on the introduction of an asymmetric flow-electrode system. We conduct a comprehensive assessment of the electrochemical properties of both activated carbon (AC) and MO@AC-based flow-electrodes, with particular attention to their suitability as positive and negative electrodes for symmetric and asymmetric F-CapMix configurations. Notably, it becomes evident that remarkable performance enhancements are exclusively observed in the context of the asymmetric F-CapMix system, thus underscoring the heightened efficacy of the MO@AC material within this asymmetric framework. Remarkably, employing MO@AC as the flow-electrode in the asymmetric F-CapMix configuration yields an impressive power density of 2.22 W/m^2 through reversible redox reactions involving Na^+ ions. These findings not only expand the horizons of potential applications but also underscore the transferability of our strategies to various materials engaged in redox reactions with Na^+ and Cl^- ions within the realm of F-CapMix systems.

Stretchable Plant-Based Redox-Diffusion Battery Aiman Rahmanudin[1,2] and Klas Tybrandt[1,2]; [1]Linköping University, Sweden; [2]Wallenberg Wood Science Centre, Sweden

Stretchable batteries are essential for the realisation of autonomous and conformable wearable electronics that interface intimately with the human body. In existing battery designs, the predominant use of unsustainable transition metal-based active materials and non-biodegradable petroleum-based elastomers contribute to the environmental problem of e-waste and the mining of finite resources. Moreover, increasing the active material content often leads to stiffer electrodes with poor mechanical properties. Here, we developed a stretchable battery design – the redox-diffusion (RD) battery - based on soluble plant-based redox-active biomolecules infiltrated within a cellulose-based 3D porous electrode scaffold. The redox reaction is mediated by diffusion of dissolved biomolecules within the pores of the 3D scaffold. It decouples the active material loading from the mechanical structure of the electrodes to afford high mass loadings (> 40 mg cm^{-2}) of the redox-active biomolecules. The electrode achieved a high capacity of 28.6 mAh/cm^3 with a skin-like Young's modulus of 110 kPa and stretchability up to 200 % strain. The RD design is facilitated by the development of a stretchable ion-selective membrane separator to allow the utilisation of two separate redox couples while preventing crossovers. This enabled a full cell with stable electrochemical performance under stretching. The utilisation of plant-based materials for the battery components (electrode, separator, current collector, and encapsulation) enabled the full degradation of the cell into benign products. The work emphasises on the importance to encompass not only high battery performance but considers the human and environmental impact of the materials used and disposal of the cell at the end-of-life.

Unlocking the Catalytic Potential of $LiCoO_2$: Innovative Exfoliation Strategies and Applications Alp Sehirlioglu[1], Kevin Pachuta[1], Benjamin Hirt[1], Huaixuan Cao[2], Micah Green[2] and Emily Pentzer[2]; [1]Case Western Reserve University, United States; [2]Texas A&M University, United States

$LiCoO_2$ (LCO) stands as a prototypical cathode material within the realm of Li-ion batteries, bearing the critical elements of lithium (Li) and cobalt (Co), which are concurrently acknowledged for their potential toxicity. The foremost frontier for repurposing LCO lies in the catalytic realm, precisely aimed at decomposing environmental contaminants. Past endeavors in employing LCO for photocatalysis, electrocatalysis, and thermocatalysis have borne fruits of considerable promise. LCO not only contains a transition metal oxide but also boasts a layered structure, facilitating the processes of delithiation and intercalation. These techniques are conventionally wielded in the chemical exfoliation of layered oxide materials.
The typical process of chemical exfoliation in crafting nano-sheets from layered oxide materials comprises two primary steps: protonation and intercalation, involving the integration of bulky molecules with counter ions. While the ultimate outcome manifests in the form of nanosheets, the exfoliation process provides an array of intermediate forms and byproducts, all with promising structural and functional attributes, particularly in the context of catalytic performance.
In this presentation, we utilize three distinctive forms of LCO powder: (i) post-protonation via acid treatment, (ii) post-base treatment – marking the powders as ready for exfoliation, and (iii) nanosheets integrated into armored particles via Pickering emulsions. Our case of applications spans diverse domains, including methylene blue degradation, carbon monoxide oxidation, ammonium perchlorate decomposition, and bisphenol A (BPA) removal from water. Realizing the full potential of these applications necessitates a profound comprehension of the chemical, structural, and morphological forms that emerge during these processes.
Our exploration will be enriched by novel processing methods that expand beyond the conventional two-step procedure, rendering it possible to fabricate these products in a pH-neutral aqueous medium as opposed to the highly alkaline nanosheet solution with a pH exceeding 13, typical of traditional techniques. Furthermore, we will delve into supplementary methodologies designed to stabilize the nanosheets in various non-aqueous solvents and enhance nanosheet production yields. The precise yield is intricately governed by an interplay of parameters, encompassing acid concentration, base concentration, and base type, akin to a 'Goldilocks effect.' These processing conditions also exert a profound influence on the efficacy of the resulting powders and nanosheets as catalytic materials, with exceptionally narrow processing windows dictating extraordinary performance metrics.
The intricate interplay of parameters is also critical to the stability and uniformity of Pickering emulsions, with key variables encompassing the type and concentration of salts, the nature of the oil medium, and the specific nanosheet type employed, encompassing exfoliated LCO and graphene oxide (GO).
The catalytic performance for all the examples provided is underpinned by the inherent attributes of Co as the transition metal, the presence of H^+ within the structure, A-site vacancies, oxygen vacancies, and the stratified architecture itself.

4:00 PM EN06.12/EN03.12.02
Nanostructured Sustainable Materials for Solar Energy Conversion: Fe-Based Absorbers and Catalysts Roland Marschall; University of Bayreuth, Germany

Efficient conversion and storage of solar energy are crucial steps in the establishment of a renewable and carbon neutral energy supply. Photocatalysis and photoelectrochemistry are considered promising to make use of the large amounts of sunlight that reach the surface of earth. They render the direct conversion of light into chemical energy possible, e.g. solar fuels like hydrogen or ammonia. In recent years, earth-abundant Fe-based materials like spinel ferrites have emerged as auspicious materials for these applications. They have the inherent ability to absorb a large part of the visible light spectrum with band gaps around 2 eV, while some of them being also very good electrocatalysts. My group utilizes modern synthesis techniques to prepare nanostructured Fe-based materials for the generation of solar fuels.
In recent years, we have developed fast microwave-assisted sol-gel syntheses yielding phase-pure spinel ferrite nanoparticles of e.g. $MgFe_2O_4$, $CuFe_2O_4$, $NiFe_2O_4$, $MnFe_2O_4$ and $ZnFe_2O_4$ at temperatures as low as 170-200 °C.[1,2] The crystallite size can be tailored in-situ or by post-synthetic heat treatment, however the materials are already (partly) crystalline as-prepared, with specific surface areas of around 200 m^2/g and good colloidal stability. Some syntheses even take only several minutes. Photocatalytic and electrocatalytic experiments will be presented, as well as the conversion of some spinel oxides into (oxy)sulfides and pendlandites for electrocatalytic water splitting.[3,4] Moreover, a direct microwave-assisted synthesis for nickel-iron sulphide nanosheets for electrocatalytic CO_2 reduction and photocatalytic HER will also be presented.[5,6]
Finally, the potential of using a heterojunction of iron sulphide and carbon nitride for light-induced reduction of N_2 to ammonia will be introduced.[7]

4:15 PM EN06.12/EN03.12.03
Mesoporous Zn-Doped $MnCo_2O_4$ Nanoparticles for Asymmetric Supercapacitor Application Prem Sagar Shukla[1], Anant Agrawal[2], Anurag Gaur[3] and Ghanshyam D. Varma[1]; [1]Indian Institute of Technology Roorkee, India; [2]National Institute of Technology Kurukshetra, India; [3]Netaji Subhas University of Technology, India

Energy sources that are reliable as well as sustainable have become essential in the present technological world. Our dependency on fossil fuels has its limitations, is not sustainable, and has a number of consequences, including greenhouse gas emissions, water pollution, and hazardous waste. Researchers have focused on supercapacitors as next-generation energy storage devices due to their quick charge/discharge rate and outstanding cycle stability. Because of their excellent power delivery and quick charging characteristics, supercapacitors have significant advantages for high-power applications. This study aims to determine how Zn doping at the cobalt site of $MnCo_2O_4$ affects its electrochemical properties. In this approach, we have synthesized Zn-doped $MnCo_2O_4$ nanomaterial abbreviated as ZMCO for supercapacitor electrodes. The XRD and HRTEM results confirm the presence of cubic phase of ZMCO. Surface area and morphology were also studied through BET and FESEM measurements, respectively. Among all the samples, $MnZn_{0.4}Co_{1.6}O_4$ shows better electrochemical performance due to its larger specific surface area and mesoporous distribution of pore size. Moreover, the single electrode showed excellent cycling stability along with good coulombic efficiency. To evaluate the practical utility of the synthesized nanomaterial, an asymmetric supercapacitor (ASC) device was fabricated. The device was fabricated with the ZMCO nanomaterial as a cathode and activated carbon as an anode electrode. The device exhibited a higher power density and specific energy density. The device also shows excellent cycling stability in PVA/KOH gel electrolyte. Additionally, a single device illuminates a red LED, while connecting two devices in series illuminate red and green LED. We believe Zn doped $MnCo_2O_4$ provides a lot of potential for making higher-performance supercapacitor devices because of its simple synthesis process and superior electrochemical characteristics.

4:30 PM EN06.12/EN03.12.04
Forming Nanoscale Sculptured Surfaces for Advanced Electrical Bonds by Environmentally Friendly Electrochemical Etching Jannik Rank, Jörg Bahr, Jürgen Carstensen and Rainer Adelung; Kiel University, Germany

With the modern advances in high performance adhesives, bonded joints are more and more competitive or are even outperforming mechanical joints and welds. Bonded joints exhibit many benefits compared to mechanical joints in respect of thickness, weight, force distribution, application and especially for dissimilar material bonding. The connection of different materials with fundamentally different properties is crucible for applications such as multi-material automotive bodies and composite materials for the aerospace sector. Thereby, the wide range of different favorable materials and the resulting different surface properties create high demands on the adhesives and often require complex surface preparation involving hazardous chemicals.
This work uses an electrochemical nanoscale sculpting process with a seawater-like electrolyte for an eco-friendly surface preparation and nearly perfect bonding on various metals such as aluminum, stainless steel and brass.
The strong adhesion is achieved by creating sub-micron undercuts that facilitate mechanical interlocking of adhesive and material. Chemical surface-to-surface interaction becomes less relevant, resulting in bonds that are limited by intrinsic fracture strength of the used adhesive. The undercuts are produced by a highly selective pulsed electrochemical etching, resulting in three-dimensional formation of chemically stable surfaces.
Additionally, brass can selectively leached by the same process. Upon leaching, the structured surfaces are copper-rich and show extraordinarily good wettability for solder. For common tin-based solders, this work shows a contact angle near zero with several times larger spreading compared to a mechanical cleaned and roughened surface.
Since the chemical surface interaction is no longer decisive for the bonding strength, it also becomes possible to use completely new types of adhesives with superior bulk properties, that would otherwise lack the chemical properties for sufficient surface adhesion. This can not only be used to increase mechanical strength of a joint but is also promising for joining with electrically conductive adhesives as an alternative to soldering. Typical conductive adhesives consist of a conductive filler (, e.g., metal particles) and an adhesive as binder, resulting in a tradeoff between bonding and conductivity properties.
This work will evaluate nano structured surfaces and their use for mechanically strong, conductive-bonded joints.

4:45 PM EN06.12/EN03.12.05
A Biodegradable and Stretchable Battery Filippa Wentz[1,2], Aiman Rahmanudin[1,2] and Klas Tybrandt[1,2]; [1]Linköping University, Sweden; [2]Wallenberg Wood Science Center, Sweden

Next generation wearables will interface intimately with the human body. They will be used for health monitoring, soft robotics, and futuristic consumer electronics such as e-skin and e-textiles. For seamless integration with the human body, mechanical properties such as stretchability, softness and bendability need to be optimized. Extensive research has already been done on improving the mechanical properties of various components, such as transistors, conductors, diodes, sensors etc., to complement next-generation wearables. Batteries give autonomy to these wearables, by providing a portable power source. However, as the complexity of wearable devices increase, so would the energy demand and form factor. Capacity is often sacrificed increasing stretchability and reduction of size, since lowering the loading of active material reduces the capacity. Additionally, a growing issue is the accumulation of hazardous e-waste and mining of finite resources. Since the battery is often the most toxic and unsustainable part of electric devices, due to the use of harmful organic electrolytes and critical raw materials. Therefore, the development of batteries that are environment and human friendly is urgently needed.

Zn-ion batteries show great potential as a sustainable alternative to current Li-ion battery technology. Zn has a high theoretical capacity, is biodegradable and abundant, and can operate in safe and sustainable aqueous electrolytes. Today, most biodegradable batteries lack the mechanical properties needed (i.e. stretchability) for next-generation wearables. Only a handful biodegradable and stretchable batteries have been reported. However, their electrochemical performance is limited. The aim of this work is to address the abovementioned challenges by designing the first biodegradable and stretchable Zn-ion battery that can also deliver a high capacity.

Here, we studied the use of biomass-derived polymers in all components of the biodegradable and stretchable battery. For the active electrode, we developed a new biodegradable elastomeric binder by copolymerizing a polyester, poly(glycerol sebacate) (PGS), with a protein (gelatine). The gelatine improved the electrolyte uptake and the stretchability of the active electrode which resulted in improved capacity. A gelatine/cellulose-based composite was used in the electrolyte. It enhanced the adhesion to the electrodes which is critical for stretchability and increased the electrochemical stability by supressing Zn dendrite and passivation layer formation. PGS was also used in the encapsulation which permitted the biodegradation of the full cell. Lastly, at the battery's end-of life the components are degraded into non-toxic products, many of which are today used in skincare or dietary supplements.

Optimized Extraction of Mesoporous Nanocomposites from Spent Li-Ion Batteries and Their Use to Construct High-Performance Supercapacitor Devices with Ultra-High Stability Nageh K. Allam; American University in Cairo, Egypt

Lithium-ion batteries (LIBs) are one class of the most significant energy storage devices used nowadays. However, a huge number of spent batteries bring harmful resource waste and environmental hazards as LIBs are mainly composed of heavy metals and organic electrolytes. Consequently, recycling spent LIBs has become a hot topic lately, where researchers are actively working to develop a plethora of methods to extract valuable metals and components. In this study, mesoporous Li–Ni–Mn–Co oxide nanoparticles have been successfully extracted from spent Li-ion batteries using a simple microwave/precipitation method. The as-extracted Li–Ni–Mn–Co oxides were used to construct functional supercapacitor devices. However, the as-extracted oxides showed poor stability and low conductivity. To enhance their cycling stability and conductivity, fullerene (C_{76}) is used as a carbon additive to form Li–Ni–Mn–Co oxide/C_{76} nanocomposite materials. The morphological, structural, and compositional analyses of those composites were performed using FESEM, HRTEM, XRD, and XPS techniques. The Li–Ni–Mn–Co oxide/C_{76} nanocomposites exhibit higher conductivity and wettability with an enhanced gravimetric capacitance of ~357 Fg^{-1} at 1.0 Ag^{-1}. The asymmetric supercapacitor devices deliver specific energy as high as ~10 Wh/kg at a specific power of ~800 W/kg with a superior retention rate of ~115% after 20,000 cycles with ~100% Coulombic efficiency.

8:45 AM EN06.13/EN03.14.02
Unleashing Moisture Content as a Capacitance Deciding Factor for Supercapacitors derived from Wild Orchid Abhay Deshmukh; Rashtrasant Tukadoji Mharaj Nagpur University, India

All carbonaceous materials manifest Electrical double layered capacitor (EDLC) type behaviour. Still, drawbacks like cost-effectiveness and availability of precursor materials provide a spotlight on “Biomass derived carbons” as electrode material for supercapacitors. Nevertheless, different types of biomasses show uniqueness in their properties and thus reveal differences in carbon materials derived from them. During carbonizing or pyrolysis of biomass, a factor called moisture is generally ignored or removed by simply drying the sample in an air oven. Here in this work, we choose leaves of a wild orchid (Vanda Tasselleta) which is an abundantly available species of plant from the Indian subcontinent to Indochina, to establish a relation between moisture content in biomass, rate capability and capacitance of electrode material. Interestingly out of five variations viz normal leaves without treatment, dried leaves, soaked leaves, a mixture of dried and normal leaves, and -20 ^{0}C samples, carbon derived from normal leaves shows the highest capacitance of 213.43 F/g at 0.5 A/g without any activation. But fascinatingly normal leaves without treatment show the lowest rate capability of only 35.53 % which is approximately half of the rate capability obtained for dry leaves of wild orchids exhibiting 124.78 F/g capacitance at 0.5 A/g. Moreover, our work demonstrates the dependence of pore size distribution on the amount of moisture intact in wild orchid leaves with the help of characterization techniques. Finally, a two-electrode symmetric device was fabricated showing high capacitance and capacitance retention which shows practical application of wild orchid leaves as supercapacitor electrode material.

9:00 AM EN06.13/EN03.14.03
Cost-Effective Fabrication Process in 24 Hours for Supercapacitors Satnam S. Mattu; Rastrasant Tukadoji Maharaj Nagpur University, India

In the ever-expanding realm of modern science and electronics, the demand for miniaturized and flexible energy storage devices is growing to enhance people’s lives with compact and adaptable electronics. Currently, the prevalent use of micro-batteries in potable devices presents a significant drawback, marked by their short life spans of only a few hundred to several thousand cycles, thus frequent replacement is required but becomes problematic in the context of implantable biochips. Not only this, connecting micro-batteries by some combination to provide high power makes it even bulkier. In stark contrast, micro-supercapacitors with an increase in a number of advantages like flexibility, remain lightweight with high power discharge. Apart from this manufacturing cost-effective micro-supercapacitors in less time is a task. Thus, this work addresses the making of micro-supercapacitors from highly porous pseudocapacitive material MOFs (metal organic framework) using LASER ablation technique. The substrate used here is a normal paper where deposition of material is exhibited using a very simple method and finally scribing it using CO_2 LASER scribing. Different designs of MSCs are also explored and finalized in-plane concentric shape which provides a wide voltage window from 0 to -0.8 V as well as from 0 to 0.8 V at high scan rates showing the highest areal capacitance of 57 µF cm^{-2}. Moreover, making use of gel electrolyte and showing capacitance in microns increases its feasibility for flexible devices. Finally, to show the practical application of the electrode several LEDs were blinked by stacking prepared MSC. Thus, the cost-effective method is implemented with a claim of manufacturing micro-supercapacitors in a single day.

9:15 AM EN06.13/EN03.14.04
Fabrication of Fully Sustainable Electrospun Fiber-Reinforced 3D Carbon from Waste as Scalable Electrodes in Energy Storage Materials Michael W. Thielke, Luis M. Murillo Herrera, Carlos Mingoes and Ana Jorge Sobrido; Queen Mary University of London, United Kingdom

Carbon fibers for the new batteries have been of interest for a long time based on their advantageous shape that provides stability, flexibility and a high surface area, lightweight, and high electrical conductivity. Most of the current reported and commercial carbon fibers are derived from using polyacrylonitrile, a synthetic polymer obtained from crude oil. Due to the finite nature and environmental impact of sourcing and refining crude oil, it is necessary to find sustainable alternatives to ensure the filling of the demand in the future.
Fully sustainable alternatives have been reported based on the use of biopolymers. A promising candidate as precursor for carbon fibers is lignin, the main byproduct of the paper and pulp industry and the second most abundant biopolymer that is rich in aromatic carbon groups. Carbonizing lignin therefore, results in a high yield of carbon fibers. To ensure enough entanglement of the molecular chains, that allows the formation of stable fibers, the high molecular weight fraction of lignin is extracted, allowing the fabrication of pure lignin fibers without the use of additional synthetic polymers as carrier. One technique to fabricate fibers that have been of particular interest is electrospinning. Through the use of a high voltage field, the electrostatic forces draw a polymer solution to fibers in submicron diameter ranges, lower than any of the other commercially used techniques to fabricate fibers. Due to the enormous surface area to volume ratio, these fibers have been at the center of interest in various applications, including energy storage systems and (electro)catalysis. In addition to the relatively simple setup, electrospinning is the ideal technique to explore the properties of new materials in a laboratory scale. In larger scaled energy storage systems, such as flow batteries, electrospun fibers show a disadvantage due to the limited thickness of the fiber mat can reach compared to other spinning processes due to the relatively small fabrication scale and process that uses the electric field.
To overcome this issue, we created a 3D structure based on lignin fibers through the lyophilization of the electrospun lignin fibers. The structure was obtained through a sonification process of the fibers in an aqueous solution of potato-based protein, another byproduct of the potato starch industry.
n addition to enhancing stability in its dimensions, the soluble protein increases the mass of the resulting carbon, as well as the introduction of heteroatom doping of nitrogen and sulfur within the carbon for electrocatalytic improvement. After the lyophilization process, the combination of the lignin fibers and the potato protein form a fiber-reinforced sponge structure, an ideal precursor for fully sustainable 3D carbon structures, and adjustable in size and dimensions.
It was shown that with the ideal ratio of protein to lignin fibers, a full coverage of the fiber could be achieved, and in addition, the carbon shows an improvement in the electrochemical catalysis of V^{4+}/V^{5+} redox reaction, important for the use of the redox-flow battery. In comparison to the unsustainable, commercial felts that are predominantly used in the past, the sustainable alternative 3D freeze-dried carbon shows significantly better performance in cyclic voltammetry measurements and electrochemical impedance spectroscopy (EIS), and could further improve the performance of an asymmetrical flow battery.

9:30 AM EN06.13/EN03.14.05
Long-Term Stability of Hygroscopic Hydrogels by Preventing Metal Ion-Mediated Degradation Chad Wilson, Carlos D. Diaz, Lorenzo Masetti, Xiao-Yun Yan, Will Chang Liu, Shucong Li, Gang Chen and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Recent developments in material chemistry highlight hygroscopic hydrogels as promising candidates for use in sorption systems, with applications ranging from atmospheric water harvesting to energy storage and thermal management. However, material lifetime remains a significant limitation to realizing cost-effective high-performance devices. In this work, we consider deployment of lithium chloride-loaded polyacrylamide (PAM + LiCl) hydrogels at elevated temperatures on a variety of potential system substrates, correlating lifetime and cyclability of the gels to device design and material choice. We show that the presence of metallic ions in the system leads directly to material degradation via radical formation in the gels. Moreover, metallic ion absence results in consistent cyclic sorption performance and a gel lifetime of over 8 months. This work demonstrates the long-term stability of PAM + LiCl hydrogels, and provides initial design guidelines for its repeatable, cost-effective implementation in future sorption systems.

9:45 AM EN06.13/EN03.14.06
Recycling Polystyrene Waste into Electromechanically Responsive Materials by Producing Multilayered Films from Bilayers with Asymmetric Triboelectric Properties Andris Sutka[1], Anna Šutka[1], Artis Linarts[1] and Peter C. Sherrell[2]; [1]Riga Technical University, Latvia; [2]RMIT University,

Australia

Millions of tons of foamed polystyrene (FPS) are produced annually. FPS is a major environmental problem. Polystyrene is slow to biodegrade, with an estimated decomposition time of up to 500 years. FPS contains 95% of air, and thus, it has a very low extent of recycling. According to a study by the California Integrated Waste Management Board, less than 1% of FPS was recycled in 2019. At the same time, FPS fills up 25% to 30% of landfill space by volume around the world.
Here, we report the upcycling of FPS waste into electromechanically responsive triboelectric laminates (TLs). These TLs possess internal triboelectric dipoles offering an alternative to ferroelectric fluoropolymers. The piezoelectric contact-mode testing showing a FPS laminate is comparable to state-of-the-art piezoelectric fluoropolymers for overall electromechanical conversion. Piezoelectric fluoropolymers are critical electromechanically responsive materials for flexible energy harvesting and sensors. However, their production results in the release of significant amounts of toxic substances into the environment, and as such, these fluoropolymers are at risk of being banned by the European Union. Our alternative flexible electromechanically responsive materials can replace piezoelectric fluoropolymers, thus enabling rapid integration into current technology standards.

10:00 AM BREAK

10:30 AM EN06.13/EN03.14.07
Waste to Product: Green Production Processes for a Circular Economy Anke Weidenkaff, Wenjie Xie and Jinxue Ding; Technical University of Darmstadt, Germany

The energy transition to defossilisation will be built on renewable energy converters which require tailored materials and a new infrastructure partially based on critical materials. This transformation to a future fossil free green circular economy will be based on sustainable materials production processes and ecologic innovations. The development of renewable materials for renewable energy converters requires sustainable large-scale production from secondary raw materials. The decision making for future resilient energy systems has to be based on environmental aspects as well as on performance criteria defined by a holistic life cycle assessment.
In this lecture an efficient recyclate precursors production for materials with a programmable lifetime and regeneration will be introduced as a suitable approach. The design of circular high performance materials uses theoretical predictions and the criticality analysis of applied elements to improve the cycle life of future energy converters such as thermoelectric generators and refrigerators, batteries, electrolysers, fuel cells, plasmalysers, hydrides and solar watersplitting cells.

10:45 AM EN06.13/EN03.14.08
Supercritical CO2 Assisted Aerosol Synthesis of HKUST-1 Nanoparticles in a Continuous Flow Reactor Ji Feng, Almond Lau and Igor Novosselov; University of Washington, United States

Metal-organic Frameworks (MOFs) are very promising materials for gas sensing, catalysis, energy storage, water purification and drug delivery due to their high porosity, tunable pore sizes, adequate chemical and thermal stability, and various structures and compositions. Downsizing MOFs to the nanoscale brings superior properties over their bulk analogs, such as high surface-to-volume ratio, rich exposed metals and ligands, short diffusion path for reactants, which all contribute to improved performances. While great efforts have been made to reduce the particle sizes by controlling the reaction kinetics or terminating the particle growth with additives, large-scale synthesis of MOF nanoparticles with simple methods remains a challenge. Here, we report supercritical CO2 assisted synthesis of HKUST-1 nanoparticles in a continuous flow reactor. This method yields pure and thermal stable HKUST-1 nanoparticles with median sizes of 98-212 nm and BET surface area of 1613-1887 m^2/g in the residence time of just 3 seconds without any additives. Supercritical CO2 and ethanol with a mole ratio of 9:1 are used as co-solvents for the fast precipitation of HKUST-1 nucleus and crystal growth. A typical dry yield of 53.7 wt% is achieved with 0.1 M copper precursor at 75 °C and 13 MPa. Size analysis of the products obtained at different copper concentrations shows the influence of supersaturation and fluid phase behavior to the nanoparticle formation. Fractal dimension analysis indicates that the growth is caused by aggregation of primary nanocrystals, indicating a non-classical crystal growth mechanism. The use of supercritical CO2 saves the use of organic solvents. In addition, super critical CO2 has physical properties such as natural abundance, non-flammability, and low toxicity, making this synthesis a green and sustainable method for the scalable production of MOF nanoparticles.

11:00 AM EN06.13/EN03.14.09
Laster-Induced Graphitization of Lignocellulosic Cellulose Nanofiber Films Intended for Electronic and Energy Storage Applications Anna Fall; University of Washington, United States

Graphitic carbon is a popular crystalline form of carbon commonly used in electronics and energy storage applications (Bressi et al., 2023). There is a large push to reduce the environmental impact of the production of graphite and graphene by finding environmentally and economically friendly alternative methods of production. It is possible to synthesize graphitic carbon utilizing laser irradiation on lignocellulosic cellulose nanofiber (LCNF) films to produce graphitic carbon intended for flexible electronic and energy storage devices (Lee & Jeon, 2019).

Flexibility and durability of the films were improved by adding polyvinyl alcohol (PVA) to create an LCNF and PVA nanocomposite. This study used a 10W Snapmaker CO2 laser module to convert a film comprised of this nanocomposite into a graphitic carbon structure. LCNF was produced by alkaline peroxide pulping of wheat straw, mechanical treatment, and peracetic acid (PAA) treatment (Pascoli et al., 2023). Characterization of the prepared material includes Raman Spectroscopy, XRD, SEM, and conductivity. After testing various film compositions and laser settings, optimal conditions were discovered and are ready to be implemented for creating flexible electronic and energy storage devices.

Production of High-Quality Biogas Using Recycled Trimetallic Nanoparticles from Electronic Waste Nageh K. Allam; American University in Cairo, Egypt

A plethora of nanoparticles (NPs) significantly enhanced the biogas production from organic waste anaerobic digestion upon their optimized addition to the reactors. In this study, trimetallic Sn-Mn-Fe.NPs, recovered from waste-printed circuit boards, were used to enhance the quality and productivity of the anaerobic digestion (AD) of cow manure as an organic substrate. This study aims to make the biogas production process more efficient and economically sustainable, taking into account the environmentally friendly nature of the AD process. The obtained nanoparticles were characterized using scanning electron microscopy (SEM), high-resolution transmission electron microscopy (HRTEM), and X-ray diffraction (XRD) techniques. Various concentrations (20, 50, and 100 mg/L) of the trimetallic Sn-Mn-Fe NPs were added to the biogas reactors, which were made of 1000-ml autoclave glass bottles to host the animal waste during the AD process. The pressure of the biogas produced was monitored daily for 45 days as retention time, and the volume of the produced biogas was calculated at a constant temperature (15 °C) and pressure (1.013 bar). Generally, NP-based reactors showed superiority in biogas production over blank reactors. Also, among the different concentrations, the best biogas-producing digester (RC2200) revealed the highest performance with a 113.6% enhancement in biogas production. In addition, it showed a significant increase of 231.2% in methane production.

Material Stability and Durability Testing Using the Extreme Space Environment in Low Earth Orbit Phillip Irace, Ryan D. Reeves and Michael Roberts; International Space Station National Laboratory, United States

The extreme environment of space provides an ideal domain for testing the stability and durability of materials for use in multiple applications both in space and on Earth. Materials exposed to the harsh space environment in low Earth orbit (LEO) are subject to atomic oxygen (AO) erosion, ultraviolet (UV) radiation, ionizing radiation, vacuum, thermal cycling, and temperature extremes. Depending on the material, each of these factors can lead to significant material degradation. For materials used in space applications, space exposure testing is critical for evaluating the performance of the material. For materials designed for Earth applications, long-term space exposure provides a mechanism for accelerated material degradation testing, where the impact of space-exposure can be correlated to degradation via Earth-based testing to identify failure modes and evaluate the lifespan of the material.
The International Space Station (ISS) National Laboratory offers an ideal platform for long-term exposure to the extreme space environment in LEO, particularly because power, data, and imaging can be provided *in-situ* and samples can be returned to Earth for postflight analysis and comparison to ground samples. Some materials that have been investigated using ISS external platforms include silicon-, organic-, copper-zinc-tin-sulfide (CZTS), and perovskite-based 3D photovoltaic cells; methylammonium lead tribromide ($MAPbBr_3$) and methylammonium lead triiodide ($MAPbI_3$) perovskites; Beta Barium Metaborate (BBO) lenses; biomaterials; polymers; ceramics; and metals. In addition, several electronic, photonic, and other devices have been tested in the harsh space environment outside the ISS.
In this work, we will introduce the damage mechanisms present in the extreme space environment. We will discuss how the magnitude of each damage mechanism is affected by sample orientation: nadir (Earth-facing), zenith (space-facing/opposite of nadir), ram (direction of travel), and wake (opposite of ram). We will present case studies of materials and devices for both space- and Earth-based applications that were investigated using ISS external platforms, including the performance of 3D photovoltaic cells, perovskites, and polymers. We will also discuss translational lessons learned from space-exposure experiments that inform and direct terrestrial research and materials science. Finally, we will present opportunities for future space-exposure experiments and access to ISS facilities through the ISS National Lab.

Solid-State Electrochemical Thermal Transistors with Large Thermal Conductivity Switching Width Ahrong Jeong[1], Zhiping Bian[1], Mitsuki Yoshimura[1], Bin Feng[2], Yuichi Ikuhara[2], Yusaku Magari[1] and Hiromichi Ohta[1]; [1]Hokkaido University, Japan; [2]The University of Tokyo, Japan

Thermal transistors that electrically switch heat flow on and off have attracted growing attention as thermotronic devices such as thermal shutters and

thermal displays. In 2023, we demonstrated the world's first solid-state electrochemical thermal transistors with $SrCoO_x$ ($2 \leq x \leq 3$) as the active layer.[1-3] The thermal conductivity (κ) on/off ratio was approximately 4 and κ switching width was 2.85 W m^{-1} K^{-1}. Here, we demonstrate solid-state thermal transistors with a large κ switching width of 9.5 W m^{-1} K^{-1}. We used CeO_2 thin films as the active layer directly deposited on the solid electrolyte YSZ substrate using the PLD method. A Pt thin film was deposited on the surface of the CeO_2 thin film and the back surface of the YSZ substrate using the sputtering method to create an all-solid-state thermal transistor. When the CeO_2 thin film was once reduced and then oxidized, the κ was approximately 2.5 W m^{-1} K^{-1} in the most reduced state, and κ increased with oxidation to 11.8 W m^{-1} K^{-1}. This reduction/oxidation was repeated 5 times and the average value of κ was 2.5 W m^{-1} K^{-1} after reduction and 12 W m^{-1} K^{-1} after oxidation. The CeO_2-based solid-state electrochemical thermal transistors might have the potential for thermotronic devices such as thermal shutters and thermal displays.

11:00 AM EN07.01.02
Multi-Luminophores-Multi-Waveguide Architecture Luminescent Solar Concentrator with Record Power Conversion Efficiency of 7.8% Waad Naim[1,1,2], Fahad Mateen[1,1,2], Christopher Herrera[1,1,2], Aria Vahdani[1,3], Jesse Cantrell[1,3], Babak Borhan[1,3] and Richard Lunt[1,1,2]; [1]Michigan State University, United States; [2]Molecular and Organic Excitonics Lab, United States; [3]Department of Chemistry, United States

Among the different solar technologies, luminescent solar concentrators (LSCs) display a versatile solar harvesting platform due to the broad spectrum of color options, low cost, and their ability to harvest both direct and diffuse sunlight. LSCs consist of a lightguide doped or coated with luminophores that absorb sunlight and re-emit photons at a longer wavelength. The majority of emitted photons are waveguided via total internal reflection towards the edge-mounted photovoltaic (PV) cells. Indeed, the maximum theoretical efficiency of a black LSC absorbing throughout the visible spectrum is 33.7%, similar to the Shockley-Queisser limit of a single junction solar cell. This value is obtained assuming that the absorption, luminescence, and collection efficiencies are all 100%. However, based on practical considerations, this value is reduced to 23.5% for an ideal condition, and 18.0% for a general one, due to non-ideal luminescent molecules and re-absorption losses. Today, the highest reported power conversion efficiency (*PCE*) of an opaque LSC (5×5 cm^2, paired with four GaAs cells attached in parallel to the sides) is 7.1% based on a set of two organic luminophores with total absorption ranging from 350 nm to 600 nm. The reported External Quantum Efficiency (*EQE*) measurement highlighted that at higher wavelengths (beyond the bandgap of both used luminophores), there is still a response due to incident light that is scattered at the diffuse backside mirror. Recently, it has been agreed upon in a consensus statement that the direct illumination of the edge-mounted PV is considered a mismeasurement or an artifact, significantly leading to an overestimated short-circuit current density (J_{SC}).
Diverse classes of luminophores with various wavelength-selectivity have emerged, including organic dyes, nanoclusters, quantum dots, and rare-earth ion complexes. Combining multi-luminophores in LSC allows maximizing the light-absorbing ensuring a full-spectrum harvesting. However, the coupling between different luminophores often leads to a reduction in the efficacy of this approach. This suggests that the optimization of the architecture of the LSC is just as crucial as that of the luminophores. To demonstrate the potential of full-spectrum LSC, we present a novel LSC design based on an optimized multi-waveguide architecture with multi-luminophores. In contrast to existing designs, our methodology involves effectively harvesting through the ultra-violet (UV), visible (VIS), and near-infrared (NIR) regions of the solar spectrum, highlighting the airgap strategy to isolate the absorption/emission bands. We then select, synthesize, and optimize luminophores that target each of these spectral regimes with the highest achievable photoluminescence quantum yield (*PLQY*). Thus, our LSC design comprises of organic molecules, quantum dots, and nanoclusters, each discreetly incorporated within an independent waveguide. Among these luminophores, a newly synthesized Donor-Acceptor-Donor (DAD) organic molecule, distinguished by its near-unity *PLQY* and absorption spectrum spanning the 300 nm to 600 nm wavelength range, leads to one of the highest *PCE*s reported for a single component LSC of 5.7% (4.5% with black background). By optimizing the single components and the architecture, we demonstrate that this multi-luminophores LSCs (50.8×50.8 mm^2) achieve a *PCE* of 7.8% with a specular-reflective background, establishing a new benchmark for *PCE* among opaque LSC devices.

11:15 AM EN07.01.03
Active Heat Transfer Fluids: Liquid Coolants Containing Self-Propelled Microparticles for Heat Transfer Enhancement Jacob Velazquez[1], Darsh Devkar[2], Sajad Kargar[1], Amit K. Singh[1] and Jeffrey L. Moran[1]; [1]George Mason University, United States; [2]University of Virginia, United States

Liquid coolants are critical components of many modern technologies, such as hybrid electric vehicle batteries, solar receivers, and cooling systems for electronics. Sustaining the growth of these technologies while limiting their carbon footprint requires coolants that transfer heat efficiently. Since the 1990s, significant research has been conducted into the use of suspended nanoparticles to improve coolant performance. The resulting suspensions, known as *nanofluids*, typically exhibit higher thermal conductivity than the liquids alone, since the particle material is typically more thermally conductive than the liquid. However, the improvements provided by nanoparticles are fundamentally limited by the particles' inability to move on their own through the liquid, and thus agitate convective mixing that could dramatically improve performance.

In this work, we explore the use of self-propelled particles (SPPs), which are colloids that can move autonomously in liquids using energy from their local environment, to accelerate heat transfer in liquids. As they move, SPPs induce disturbance flows in the surrounding liquid, and we hypothesize that this "micro-stirring" effect can enhance the heat transport rate by an amount depending on the SPPs' size, speed, and volume fraction. We demonstrated this concept experimentally by placing an SPP suspension in contact with a heated surface; for a constant heat flux, a more effective coolant should result in a lower temperature of the heated surface. By measuring the temperatures of the heater & background fluid, as well as the heat flux, we can quantify SPP-induced increases in the convective heat transfer coefficient (HTC), a widely-recognized metric of heat transfer efficiency. We present data for the HTC of various SPP suspensions under various experimental conditions. The results will inform the prospective use of coolants containing SPPs, which we refer to as "active heat transfer fluids," in a variety of cooling applications in the energy, environmental, and biomedical sectors.

11:30 AM EN07.01.04
Intelligent Radiative Thermostat Induced by Near-Field Radiative Thermal Diode Yang Liu and Yi Zheng; Northeastern University, United States

A radiative thermostat system senses its own temperature and automatically modulates heat transfer by turning on/off the cooling to maintain its temperature near a desired set point. Taking advantage of far- and near-field radiative thermal technologies, we propose an intelligent radiative thermostat induced by the combination of passive radiative cooling and near-field radiative thermal diode for thermal regulation at room temperature. The top passive radiative cooler in thermostat system with static thermal emissivity uses the cold outer space to passively cool itself all day, which can provide the bottom structure with the sub-ambient cold source. Meanwhile, using the phase-transition material vanadium dioxide, the bottom structure forms a near-field radiative thermal diode with the top cooler, which can significantly regulate the heat transfer between two terminals of the diode and then realize a stable temperature of the bottom structure. Besides, the backsided heat input of the thermostat has been taken into account according to real-world applications. Thermal performance of the proposed radiative thermostat design has been analyzed, showing that the coupling effect of static passive radiative cooling and dynamic internal heat transfer modulation can maintain an equilibrium temperature approximately locked within the phase transition region. Besides,

after considering empirical indoor-to-outdoor heat flux, rendering its thermal performance closer to that of passive solar residential building walls, the calculation result proves that the radiative thermostat system can effectively modulate the temperature and stabilize it within a controllable range. Passive radiative thermostats driven by near-field radiative thermal diode can potentially enable intelligent temperature regulation technologies, for example, to moderate diurnal temperature in regions with extreme thermal swings.

Thermoreflectance-Based Thermometry of Silicon Thin Films with Resonantly Enhanced Temperature Sensitivity Xinchao Wang, Changxing Shi, Qifan Zheng, Jan Maroske and Dakotah Thompson; University of Wisconsin-Madison, United States

We demonstrate a thermoreflectance-based thermometry technique with an ultimate temperature resolution of 60 μK in a 2.6 mHz bandwidth. This temperature resolution was achieved using a 532 nm-wavelength probe laser and a ~1 μm-thick silicon transducer film with a thermoreflectance coefficient of -4.7×10^{-3} K^{-1} at room temperature. The thermoreflectance sensitivity reported here is over an order-of-magnitude greater than that of metal transducers, and is comparable to the sensitivity of traditional resistance thermometers. Supporting calculations reveal that the enhancement in sensitivity is due to optical interference in the thin film.

SESSION EN07.02: Thermal Transport Across Interfaces/Thermal Transport in Nanoscales

Rethinking Evaporation and Condensation Gang Chen; Massachusetts Institute of Technology, United States

Although ubiquitous in nature and industrial processes, transport processes at the interface during evaporation and condensation are still poorly understood. Experiments have shown temperature discontinuities at the interface during evaporation and condensation but the experimentally reported interface temperature jump varies by two orders of magnitude. Even the direction of such temperature jump is still being debated. In this talk, I will first discuss a thermomolecular emission for thermal evaporation, analogous to the thermionic emission mechanism. Starting from the kinetic theory, we derive interfacial mass flux and heat flux conditions, which are used to solve the coupled problem between the liquid and the vapor phase during evaporation and condensation. Our model shows that when evaporation or condensation happens, an intrinsic temperature difference develops across the interface, due to the mismatch of the enthalpy carried by vapor at the interface and the bulk region. The vapor temperature near the interface cools below the saturation temperature on the liquid surface during evaporation and heats up above the latter during condensation. However, many existing experiments have shown an opposite trend to this prediction. We explain this difference as arising from the reverse heat conduction in the vapor phase. Our model results compare favorably with experiments on both evaporation and condensation. We show that when the liquid layer is very thin, most of the applied temperature difference between the solid wall and the vapor phase happens at the liquid-vapor interface, leading to saturation of the evaporation and the condensation rates and the corresponding heat transfer rate. This result contradicts current belief that the evaporation and condensation rates are inversely proportional to the liquid film thickness. For the two parallel plate problem with evaporation on one side and condensation on the other, we will explain several paradoxical predictions including inverted temperature profile in the vapor phase.

Evaluating The Vibrational Character of Thermal Carriers across Order–Disorder Phase Transitions Rahil Ukani[1], Qichen Song[1], Catherine Thai[1], Alexander D. Christodoulides[2], Yukyung Moon[1], Dehong Yu[3], Caleb Stamper[4], Jinyoung Seo[1], Jonathan A. Malen[2] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]Carnegie Mellon University, United States; [3]Australian Nuclear Science and Technology Organisation, Australia; [4]University of Wollongong, Australia

Materials containing aligned alkyl chains have shown considerable promise for energy applications, including solid-state cooling through caloric effects. Understanding how heat flows through these chains—particularly during phase transitions—can enable precise manipulation of their thermal transport properties, which are critical to optimizing efficiency in practical applications. Many of these materials offer tunable interchain chemistries and thermally responsive structural dynamics, which can offer molecular-level insights—and thus control—of heat conduction mechanisms. Here, we examine thermal transport in two classes of two-dimensional (2-D) layered crystals whose alkyl chains undergo thermally induced order–disorder transitions: (1) hybrid perovskites, and (2) organic salts. Variable temperature frequency-domain thermoreflectance (FDTR) measurements of analogous 2-D perovskite and organic salt structures allow us to describe the role of chemical interactions and chain confinement in dictating thermal conductivity. Microscopy and nanomechanical characterizations similarly describe the influence of structural features and microstructure. Through quasielastic and inelastic neutron scattering, we highlight how the vibrational nature of thermal energy carriers changes as the alkyl chains in these materials transition from ordered to dynamically disordered states. These complementary techniques allow us to detail the key chemical levers that tune thermal transport in phase change materials. Our investigations reveal a comprehensive picture of the mechanisms underlying thermal conduction across phase changes of confined alkyl chains, and how interlayer chemistry regulates heat flow in complex crystals.

11:30 AM EN07.02.03
Non-Equilibrium Thermal Resistance from Phonons and Electrons Across Solid Interfaces Jinchen Han and Sangyeop Lee; University of Pittsburgh, United States

Understanding interfacial thermal resistance has focused on atomistic-scale phenomena such as carrier transmission functions across the interface. In this presentation, we discuss a phenomenon at micrometer scale for interfacial resistance: relaxation of non-equilibrium carriers through scattering. The widely used Landauer formalism assumes incident carriers have an equilibrium distribution, but the actual distribution can be highly non-equilibrium due to the interfacial scattering. The carriers with non-equilibrium distribution are relaxed by carrier scattering at micrometer scale and the Boltzmann’s H-theorem

dictates entropy generation and thermal resistance during this relaxation process. To capture such process, we solve the Boltzmann transport equation with ab initio inputs. Our work shows two important facets of carrier non-equilibrium near interface and interfacial thermal resistance. First, we highlight significance of spectral heat flux mismatch for the interfacial thermal resistance. An example is a Si-SiGe alloy interface where the phonon dispersion is matched exactly but exhibits a substantial interfacial resistance. Second, we discuss the energy exchange between electrons and phonons in metal-insulator interfaces. We focus on how electron-phonon scattering influences the relaxation of thermal carriers near the interface as well as its impact on the entropy generation and non-equilibrium thermal resistance.

11:45 AM EN07.02.04
Modelling Hydrodynamic Heat Conduction Signatures in Experiments Using The Full Scattering BTE Aleksei Sokolov[1,2], Jamal A. Haibeh[2] and Samuel C. Huberman[2]; [1]Technical University of Berlin, Germany; [2]McGill University, Canada

The early experimental studies of anomalous thermal transport include second sound observations by Jackson et al (PRL 1970) and ballistic transport observations by Northrop and Wolfe in PRL (1979). Recent experimental techniques allow gathering temperature data with high spatial and temporal resolution, one can directly observe the evolution of a transient temperature field, such as the decay of ultrafast Gaussian heating in Transition metal dichalcogenides, as demonstrated by Varghese et al. in (Rev. Sci. Instrum. 2023) or a ring heating geometry which yielded an observation of 'lattice cooling', i.e., the temperature field may locally become lower than the initial background temperature (Jeong et al. in PRL 2021).
These contemporary experimental techniques drive a need for theoretical descriptions based on microscopic principles. One such approach requires solutions to the Boltzmann Transport Equation where the collision term is described by the full scattering matrix, going beyond the Relaxation Time Approximation which fails to describe the heat conduction process in the hydrodynamic phonon regime. As shown by Chiloyan et al (PRB 2021), the BTE with a full scattering matrix can be efficiently solved for an initial sinusoidal temperature profile, also known as the Transient Thermal Grating (TTG) geometry, yielding a semi-analytical solution. Building upon this result, we propose a novel numerical method. It is based on pre-sampling solutions of the BTE with a full scattering matrix for TTG initial conditions with different sinusoidal excitation wavelengths, calculated using ab initio force constants and a semi-analytical solution. This response is then used to construct the solution of the Linear Boltzmann Transport Equation for arbitrary heating geometries as a superposition of responses of different spatial spectra. This approach is used to simulate the Gaussian and ring heating geometries for a few materials, including graphene, graphite and MoS2.

SESSION EN07.03: Radiative Heat Transfer

Tuesday Afternoon, April 23, 2024
Room 327, Level 3, Summit

1:45 PM *EN07.03.01
Thermal Transport and Conversion Using Photonic Nanostructures Renkun Chen; University of California, San Diego, United States

Photonics can be harnessed to engineer and in certain cases enhance thermal energy transport and conversion processes due to favorable characteristics of thermal photons relative to phonons under certain conditions, such as long wavelength, long propagation length, high speed, and spectral tunability. Here we present our work on thermal transport and conversion in nanostructures over the past few years. First, we showed that the coupling between photons and traditional heat carriers such as phonons and electrons can be utilized to manipulate radiation and conduction heat transfer in polar dielectric and metallic nanostructures. In particular, we observe enhanced effective emissivity and thermal conductivity in rationally designed nanostructures of polar dielectrics and metals. Second, we developed high-temperature selective emitters based on photonic metamaterials. While selective emitters have been extensively studied previously, they are often not stable at high temperature due to the presence of nanoscale interfaces. We use novel material and structural designs to achieve high temperature stability. These selective emitters could be utilized for converting optical and electrical energy more efficiently into thermal energy within a desirable spectrum that are useful for systems such as thermophotovoltaic and infrared heating.

2:15 PM *EN07.03.02
Energy Transfer and Conversion in Nanoscale Gaps Pramod Sangi Reddy; University of Michigan, United States

Understanding radiative heat transfer in nanoscale gaps and devices is of considerable interest for creating novel energy conversion devices. In this talk, I will first describe ongoing efforts in our group to experimentally elucidate nanoscale radiative heat transfer. I will present our recent experimental work where we have explored how radiative heat transfer is modified in nanoscale gaps at room temperature and cryogenic temperatures. Specifically, I will describe a variety of instrumentation including novel nanopositioning platforms and microdevices, which we have developed to accomplish these measurements. Further, I will discuss possible applications of near-field thermal radiation for energy conversion and photonic cooling. Finally, I will briefly outline how these technical advances can be leveraged for future investigations of nanoscale heat transport and near-field thermophotovoltaic energy conversion.

2:45 PM EN07.03.04
Optical Interrogation of Subsurface Nanogap Thermal Transport Zachary T. Piontkowski, Amun Jarzembski, Wyatt Hodges, Anthony McDonald, Matthew Bahr, William Delmas, Ping Lu and Julia Deitz; Sandia National Laboratories, United States

Nanoscale thermal transport has received significant attention for next-generation energy conversion and thermal management applications. In particular, state-of-the-art experiments have shown for vacuum gap distances down to 10 nm that thermal transport is governed by near-field thermal radiation, and can be enhanced by orders of magnitude above the Planck black body limit. Moreover, radiative thermal transport is bridged to heat conduction by so-called acoustic phonon tunneling at contact, which can be controlled via external forces. However, to perform such complex experiments, precision measurement of heat flow and isolation from parasitic conduction are required. Here, we demonstrate the utility of hyperspectral frequency-domain

thermoreflectance (FDTR) for the interrogation of thermal transport across subsurface nanogaps, alleviating the extreme challenges faced by nanoscale thermal transport experiments.

FDTR is a pump-probe optical technique sensitive to the thermal properties of an underlying material system. Here, a periodically modulated pump beam deposits energy into the sample, where subsequent temperature oscillations are monitored by a continuous wave probe beam via the thermoreflectance effect. Measurement of the phase lag between the thermal oscillations and periodic heating enables quantification of thermal properties though parametric fitting with the heat diffusion equation. In particular, FDTR at low pump frequencies can quantify and image interfaces up to 200 um below the surface. We demonstrate FDTR's ability to interrogate subsurface nanogaps by looking at heterogeneously integrated gallium nitride (GaN) with diamond substrates and silicon with silicon substrates. We show that FDTR can precisely quantify the thermal conductivity of air trapped in sub-200 nm gap that is 15 um below the GaN surface. Similarly, we use hyperspectral FDTR imaging to map a mechanical standing wave in a silicon membrane supported by a silicon substrate, which spatially modulates the gap thermal conductance. Thus, FDTR eliminates the need for microfabricated precision calorimeters and thermally insulated gap supports through spatial mapping of subsurface thermal boundary conductances.

TDTR-Based Thermal Conductivity Mapping – Challenges and Applications Yee Kan Koh; National University of Singapore, Singapore

Over the past two decades, time-domain thermoreflectance (TDTR) has been developed into a versatile tool to measure the thermal conductivity of thin films and substrates. Variants of TDTR have been developed, to address the specific needs. For example, beam-offset TDTR has been developed to measure the in-plane thermal conductivity of the thin films. Dual-frequency TDTR has been developed to measure the thermal resistance of buried thin films and interfaces. These various TDTR variants are paramount to advance the knowledge of heat transport in different types of nanostructures and across interfaces. One variant of TDTR that is less explored is to use TDTR for thermal conductivity mapping. In this talk, we will present our recent work to develop and apply TDTR for thermal conductivity mapping. We will share the challenges we faced, including how to ensure smooth surfaces for mapping and how to interpret the results. We will also share our recent works to apply TDTR the map the thermal conductivity of twisted bi-layer graphene and electrodes in the Li-ion batteries. For the first example, we map the thermal conductivity CVD-grown twisted bilayer graphene on single-layer graphene substrates. With the mapping, we are able to accurately measure the thermal conductivity difference between the bilayer and single layer graphene, as a function of the twisted angle between the graphene flakes. In the second example, we map the thermal conductivity of graphite and LCO electrodes of Li-ion batteries. We discuss how we interpret the mapping results, including our measurements near the boundaries of the electrode powders. Our works suggest that TDTR-based thermal conductivity mapping could be a powerful tool to study heat transport in complex composites.

4:00 PM EN07.04.02
Nanoscale Temperature Mapping for Operating Devices with Reflection Electron Elastic Energy Thermometry (REEET) Menglong Hao[1,2], Qiye Zheng[3,2,4], Ziwen Zou[1], Xing Xiang[3], Saad Sbsafiullah[3], Yuhang Cai[2], Junqiao Wu[2,4] and Chris Dames[2,4]; [1]Southeast University, China; [2]University of California, Berkeley, United States; [3]The Hong Kong University of Science and Technology, Hong Kong; [4]Lawrence Berkeley National Laboratory, United States

Experimental characterization of nanoscopic temperature distribution and heat transfer in devices with ever-decreasing feature size is fundamental to realizing next-generation chip-level thermal management and validating and unifying fundamental non-diffusive thermal models. However, existing scannable thermal metrologies have their limitations. For instance, scannable far-field optical methods suffer from diffraction-limited spatial resolution; scanning probe techniques are complex due to the tip-sample thermal contact and sometimes perturb the sample thermal field, despite offering nanoscale resolution; TEM-based thermometries require impractically thin, electron-transmissible samples. A flexible metrology that can directly map temperature fields with 10s of nanometer spatial resolution for practical working devices is still lacking.

In this work, we develop a novel nanoscale thermal imaging methodology built upon Reflection Electron Energy Loss Spectroscopy (REELS) in SEM. This method, termed Reflection Electron Elastic Energy Thermometry (REEET), directly measures the mean kinetic energy of thermally-vibrating atoms in materials leveraging the quasi-elastic peak of electrons in the spectrum. Our calibration experiments and first-principles-based calculation of kinetic energy confirmed the physical model for REEET based on simple individual electron-nucleus scattering constrained by conservation laws under the Born approximation. The relative temperature sensitivity of the technique is estimated as ~0.09%/K for light elements such as C and Si at 300-600 K, which compares favorably with other electron-beam-based thermometry.

We used REEET to demonstrate far-field temperature mapping of nanostructured graphitic thin film devices with 300-400 nm feature size, as well as a 250-nm diameter multiwalled carbon nanotube, both under Joule heating. Local hotspots with peak temperature rise of 500-800 K in these nanodevices can be visualized with a spatial resolution estimated as 30-50 nm. The temperature profiles can be well described by our analytical and finite element modeling based on modified Fourier's law using suppressed thermal conductivity of ~480 and ~360 W m^{-1} K^{-1} for graphite and MWCNT, respectively. These results

are consistent with prior reports on such carbon materials on substrates due to the Casimir size effect and interface scattering. Additionally, the 2-kV 3-nA electron beam is found to have negligible impact on the lattice temperature rise (<0.1 K) in such devices based on our Monte Carlo simulations (CASINO) and a multi-temperature model.

4:15 PM EN07.04.03
Thermal Diffusivity Measurement of Thin Films by Fourier Transform Thermo-Reflectance Method under Front Heat – Front Detect Configuration Takahiro Baba[1], Tetsuya Baba[1] and Takao Mori[1,2]; [1]National Institute of Materials Science (NIMS), Japan; [2]University of Tsukuba, Japan

Thermo-reflectance method is one of the few methods which can measure thermal transport properties in the cross-plane direction of thin films. Thermo-reflectance method under front heat – front detect (FF) configuration, so-called time domain thermo-reflectance (TDTR), is commonly used because it can be applied to a wide variety of samples including non-metallic thin films. In FF configuration, both pump beam and probe beam are focused at the same spot on the surface of a sample and temperature response from the surface is observed. In this case, the temperature response is significantly affected by the penetration of pump beam, which depends on the absorption coefficient of the surface. In TDTR method, a metallic layer, sometimes called transducer, is generally deposited on a sample to safely observe thermo-reflectance signals. In most cases, heat diffusion time in the transducer is assumed to be infinitesimal and the layer can be regarded as heat bath with known heat capacity. To determine thermal effusivity of the sample below the transducer, the rate of temperature decrease is analyzed. This means the penetration of pump beam, which affects the initial distribution of temperature, is not considered. This approach has some ambiguity because thermal diffusion in the transducer can significantly affect the determination of the thermal effusivity of the sample. To examine this issue, we propose an analytical approach which considers the effect of penetration of pump beam. Our approach attributes to recent developments in thermo-reflectance method. The electrical delay technique has enabled the technique to observe temperature response in longer timescale than pulse interval of pump laser, which demonstrates the periodic nature of the temperature response. In our recent study, we developed an analytical approach based on Fourier analysis, which can consider the periodicity and improve the robustness and reliability of determination of thermal properties by thermo-reflectance method. Thanks to this new analytical approach, we could also develop a mathematical model which can consider the contribution from the penetration of pump beam, whereas our conventional model assumes that the energy of pump beam is entirely absorbed at the surface without penetration. We could examine how the penetration affects the temperature response and improve the robustness and reliability of determination of thermal properties by thermo-reflectance method under FF configuration. We measured some actual thin films by picosecond thermo-reflectance method under FF configuration. We are going to introduce notable developments in thermo-reflectance method and actual results obtained from these samples, and discuss the robustness and reliability of the determination.

Direct Measurement of Ballistic Electron Transport and Negative Thermal Diffusion during Nonnequilibrium Heating of Metals Pravin Karna[1], Md Shafkat Bin Hoque[2], Patrick Hopkins[2] and Ashutosh Giri[1]; [1]University of Rhode Island, United States; [2]University of Virginia, United States

We experimentally show that the ballistic length of hot electrons in laser-heated gold films can exceed ∼150 nm, which is ∼50% greater than the previously reported value of 100 nm inferred from pump–probe experiments. We also find that the mean free path of electrons at the peak temperature following interband excitation can reach upward of ∼45 nm, which is higher than the average value of 30 nm predicted from our parameter-free density functional perturbation theory. Our first-principles calculations of electron–phonon coupling reveal that the increase in the mean free path due to interband excitation is a consequence of drastically reduced electron–phonon coupling from lattice stiffening, thus providing the microscopic understanding of our experimental findings. We also show that the strength of electron-phonon coupling not only dictates the mean free paths, but also controls a peculiar spatial shrinking of the electronic temperature profile immediately after the electrons have thermalized with the ‘colder’ lattice.

Experimental Extraction of Phonon Scattering Lifetimes in MoS_2 Using Transient Grating Nikhil Malviya and Navaneetha Krishnan Ravichandran; Indian Institute of Science Bangalore, India

In crystalline semiconductors, heat is predominantly transported via the collective vibrations of lattice atoms, and the quanta of the normal modes of these lattice vibrations are called phonons. The resistance to thermal transport in a crystal is caused by the scattering of phonons among themselves, which is driven by the anharmonic crystal potential in pristine semiconductors. During these scattering events, phonons tend to attain equilibrium, and the corresponding time involved, called the phonon lifetime, is an important quantity to determine phonon-specific thermal properties, for example, the distribution of heat-carrying phonons. The transient grating (TG) is a well-established non-contact optical pump-probe technique that is often used experimentally probe the phonon specific mean free paths, and hence the phonon lifetimes [1,2]. Here, we probe the phonon lifetimes for van der Waals materials like layered MoS_2 using the TG setup. For MoS_2, by comparing our measurements with the predictions from the complete solution of the governing equation for phonon transport, the Peierls-Boltzmann equation (PBE), from first principles, we uncover a significant contribution of momentum conserving Normal scattering as well as the higher-order scattering among four phonons to the total phonon lifetimes. We also discuss the suitability of the computationally inexpensive approximation to the PBE - Callaway model for MoS_2, motivated by its widespread success for several ultrahigh thermal conductivity materials uncovered recently [3].

In the TG technique used in this work, two short pump lasers are made to interfere and get absorbed into the sample, resulting in a spatially sinusoidal temperature grating, with a characteristic period Λ. The decay of this impulsive temperature profile is probed using another probe laser beam. By comparing the observed temperature decay with that calculated from the PBE, the effective thermal conductivity of the sample as a function of Λ can be obtained, from which phonon-specific properties, such as the phonon lifetimes, can be extracted [1,2]. Our experimental measurements highlight the significant contribution of four-phonon scattering to thermal resistance in MoS_2 around and beyond room temperature. By comparing our experimental measurements on phonon lifetimes with the first-principles predictions, we conclude that the Normal processes dominate the total scattering rates at low phonon frequencies in MoS_2, particularly around and below room temperature. Interestingly, we find that four-phonon Normal scattering rates are much stronger than the three-phonon Umklapp scattering rates, which is quite unusual compared to several other materials studied earlier [4]. The comparison of our experimental measurements with first principles predictions also reveal strong anharmonic renormalization of phonon frequencies in MoS_2, even at room temperature, thus significantly affecting its thermal conductivity. We believe that our experimental findings, with insights from predictive first principles calculations, will provide clarity on the nature of phonon-phonon interactions in layered and low-dimensional materials.

Thermal Conductance of Buried AlN Interfaces Measured by Dual-Frequency Time-Domain Thermoreflectance Yi Jiang[1], Ravikiran Lingaparthi[2], Casimir Chan[2], Alex Tian Long Seah[2], Kirill Shabdurasulov[2,3], Nethaji Dharmarasu[2], K Radhakrishnan[2,3] and Yee Kan Koh[1]; [1]Department of Mechanical Engineering, National University of Singapore, Singapore; [2]Temasek Laboratories, Nanyang Technological University, Singapore; [3]School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore

Thermal management is a critical concern in microelectronic devices, especially for third-generation semiconductor devices that are based on GaN and AlN due to high power density during operations. An in-depth understanding of their thermal properties is essential for thermal management, such as interfacial thermal conductance between different layers. However, accurately measuring the thermal conductance in buried interfaces, particularly in epitaxial growth interfaces, is substantially challenging due to its low measurement sensitivity. Conventional time-domain thermoreflectance (TDTR) technique can only achieve around 40% of uncertainty, or not able to separate the thin film thermal conductivity and the buried interfacial thermal conductance. In this study, we utilize dual-frequency TDTR technique with Monte Carlo simulations to precisely quantify the thermal conductance of buried AlN interfaces with various substrates.
Firstly, we deposit AlN on common substrates, specifically, sapphire, silicon, and 4H-SiC, using molecular beam epitaxy (MBE). We carefully control the thickness of AlN to be 100 nm for the best experiment sensitivity. The quality of the AlN films is assessed by atomic force microscopy (AFM) and the picosecond acoustics technique of TDTR. Subsequently, TDTR measurements are performed at modulation frequencies of 18.9 MHz and 5.4 MHz, which leads to two different thermal penetration depths. To enhance the sensitivity of thermal conductance of AlN/substrate interfaces, we analyse the ratio of TDTR signals between 18.9 MHz and 5.4 MHz measurements. In addition, we employ Monte Carlo simulations to statistically estimate the uncertainty by considering results from both measurements and their ratio. The measurement uncertainty is reduced to approximately 1/3 of the conventional single-frequency TDTR measurements.
Our method can accurately measure the interfacial thermal conductance between AlN and different substrates with each result exhibiting an uncertainty of less than 16%. Among these substrates, the high interfacial thermal conductance of AlN/4H-SiC (~450 MW/m^2K) provides a promising prospect for effective heat dissipation across the interface.
In summary, this study demonstrates a dual-frequency TDTR technique with Monte Carlo simulations that significantly enhances the precision by 3 times in interfacial thermal conductance measurements of buried interfaces with just 100 nm of AlN. This technique contributes to a guidance of interfacial thermal conductance measurements and exploring thermal management further in electronic devices.

Dual-Functional Wood for Thermal Management of Buildings through Radiative Cooling and Thermal Energy Storage Bernadette Magalindan[1], Lyu Zhou[1] and Shuang Cui[1,2]; [1]The University of Texas at Dallas, United States; [2]National Renewable Energy Laboratory, United States

Passive thermoregulation of buildings presents a sustainable means to alleviate the ever-growing demand for thermal comfort. Although emerging radiative cooling technologies effectively enable one-way heat rejection and achieve cooling, they alone cannot fully satisfy the thermal comfort needs that arise from all types of weather – namely, the need for warmth in cold weather. In this work, we developed a dual-functional material, composed of microencapsulated phase change materials (MPCMs) embedded in delignified wood pulp, for energy-efficient thermal management of buildings through radiative cooling and thermal energy storage (TES). In warm weather, radiative cooling assists the re-crystallization of MPCMs; in cold weather, TES serves as a valuable complement to radiative cooling by preventing excessive cooling and offering space heating. The dual-functional material exhibits 92% of solar reflection that ascribes the scattering by the wood pulp and MPCMs, whereas the intrinsic emissivity of cellulose produces a strong radiative cooling effect. Meanwhile, TES through MPCMs achieves a latent heat of 150 J/g with excellent shape stability. This material's superior thermoregulation enabled by the synergistic TES and radiative cooling properties is demonstrated by outdoor testing, showcasing the substantial energy-saving potential of this innovative approach. Additionally, fabricating the material from abundant cellulose promotes carbon sequestration and offers a promising avenue for the development of sustainable building materials for energy-efficient thermal regulation.

Decoupling Electronic and Thermal Transport in Spinel Oxide Ashutosh Srivastava, Madhubanti Mukherjee and Abhishek K. Singh; Indian Institute of Science, Bengaluru, India

Decoupling electronic and thermal transport properties remains the biggest challenge in finding efficient thermoelectric materials. We demonstrate an approach to decoupling the complex interdependence among electrical conductivity, Seebeck coefficient, and lattice thermal conductivity in spinel oxides. Utilizing the effects of tetrahedral and octahedral coordination on bonding characteristics, we demonstrate tuning the electronic and thermal transport properties of cobalt-based spinel oxides ACo_2O_4. Tetrahedrally coordinated cation A (Zn/Cd) controls the electronic transport, while thermal transport has been controlled by octahedrally coordinated cation B (Co). The combination of heavy bands and contribution of the tetrahedrally coordinated environment of Co near valence band maxima (VBM) and conduction band minima (CBM) results in an enhanced power factor. Additionally, the substitution of Cd for Zn on an octahedrally coordinated cation site leads to one order of magnitude reduction in the lattice thermal conductivity (κ_l). This reduction is attributed to the significant mass difference, phonon modes, phonon lifetime, and remarkably strong anharmonic scattering introduced by Cd. Simultaneously achieved high power factor and low lattice thermal conductivity resulting in an enhanced figure of merit value of 1.68 for Cd-spinel. The approach of decoupling atomic contributions utilizing various cationic sites demonstrates a potential route to enhance thermoelectric performance.

Temperature Dependent Electron Emission in Focused Ion Beam Microscopes Wyatt Hodges, Julia Deitz, Luis Jauregui, Daniel Perry, Joeseph Boro and Jessica Duree; Sandia National Laboratories, United States

Transistors in mass produced consumer electronics have characteristic dimensions on the nanometer scale, with companies such as Intel and Samsung

continuously working to increase transistor density by fabricating smaller components. Thermal management (i.e., temperature during use) plays a key role in effective operation of these devices. However, measuring temperature of nanometer scale components presents a challenge. Optical techniques commonly used in failure analysis, such as IR thermography, are diffraction limited and cannot effectively access the nanoscale. Contact techniques such as scanning thermal microscopy offer nanoscale resolution, but parasitic losses from the scanning tip limit temperature sensitivity. Transmission electron microscopy has been used to demonstrate thermal effects with nanometer resolution but can only accommodate devices that have been thinned to ~100 nm. Scanning electron microscopy shows some promise as a noncontact technique that has topographical resolution of ~1 nm and has shown preliminarily to have temperature dependence in secondary electron counts.

Here we examine thermal effects in Focused Ion Beam (FIB) microscopes. FIB microscopes offer several advantages over using a single beam SEM instrument: (1) the ion beam does not generate backscattered electrons, improving signal to noise ratio, (2) the ion beam can mill samples, allowing measurements of subsurface features in devices without breaking vacuum, and (3) FIB tools are almost exclusively manufactured as dual beam FIB-SEMs, so electron beams are simultaneously accessible. Using the FIB-SEM we demonstrate temperature dependence in grayscale intensity in semiconductor images. We additionally show results of energy mapping at different temperatures at multiple temperatures using the through lens detector built into FIB-SEM microscopes. Comparison of temperature dependent effects in SEM and FIB images are discussed. We also examine the additional considerations of accelerating voltage, power normalization, ion implantation, and spatial resolution.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Electromagnetic Wave-Absorbing and Heat-Managing Magnetic Composite Membrane Engineered via an Atomized Aerosol Process Jeong Seung-Jae, Mi Se Chang, Jae Won Jeong, Sangsun Yang and Young-Tae Kwon; Korea Institute of Materials Science, Korea (the Republic of)

Rapid advancements in fifth-generation (5G) telecommunications have generated a demand for enhanced connection and data transmission, which are expected to significantly affect various fields. The rise of networks operating within higher frequency bands compared to previous wireless technologies has prompted the need for the development of electromagnetic wave (EMW) absorbers to alleviate signal interference, EMW pollution, and potential health risks. Among the notable materials, soft magnetic materials with high saturation magnetization and low coercivity facilitate effective EMW absorption ranging from 2 to 18 GHz. However, the low complex permeability of commonly available soft magnetic materials shows limited EMW absorbing characteristics. Here, we present the shape-modulated FeCo-boron nitride (BN) soft magnetic particles prepared via an atomized aerosol process for EMW absorption and thermal management. Shape modulation has become a widely used method to raise the Snoek's limit of spherical particles and thus enhance the complex permeability and the ferromagnetic resonance of the material. New class of the chemical process designed in this work allows a one-step synthesis of composites with three different structures, including spheres, cubes, and hollows, without requiring any shape-controlling additives. The FeCo-BN composite membrane demonstrates enhanced complex permeability and effective impedance matching, leading to a high reflection loss value of -46.4 dB at 11.3 GHz. In addition, the incorporation of BN nanomaterials enabled the effective dissipation of heat converted from EMW energy. Overall, our research findings in shape modulation process and material designs highlight promising opportunities for the EMW absorbing and thermally managing membranes.

Precision Microengineering of Curved Metallic Heat Transfer Surfaces for Fouling Inhibition Liyang Chen[1], Julian Schmid[1], Tobias Armstrong[1] and Thomas Schutzius[1,2]; [1]ETH Zurich, Switzerland; [2]University of California, Berkeley, United States

Crystallization fouling, an undesirable process where scale forms on surfaces, is pervasive in nature and technology, negatively impacting the energy and water industries. Work has progressed towards realizing surfaces with intrinsic antifouling properties, however, realizing precise, defect-free topography over large areas with complex curvature remains challenging. In this work, we successfully developed a technique allowing us to impart precise surface microstructure array patterns onto metallic heat transfer surfaces with isotropic and anisotropic curvatures. The patterning on curved surfaces is realized by four steps: photoresist microstructure generation on planar substrates; structure transfer to curved metallic surfaces under heat and pressure; metal deposition by electroplating/electroless plating; photoresist removal. We conducted preliminary tests on the heat transfer performance of copper substrates with and without micropatterns in heat-exchanger-like conditions and the results show that the surface micropatterns can effectively modify the heat transfer coefficient of the metallic substrate and the structures possess good tolerance to fluidic friction. Durable curved (super)hydrophobic metallic surfaces can be realized with such stable microstructures, which are promising to mitigate fouling issues and energy loss by inhibiting the onset of nucleation and reducing the adhesion of limescale crystallites.

5:00 PM EN07.05.07
Understanding Phonon Mediated Lattice Thermal Conductivity in Magnetic Trihalides Ashutosh Srivastava[1], Heda Zhang[2], Chunqiang Xu[2], Subhendra D. Mahanti[2], Xianglin Ke[2] and Abhishek K. Singh[1]; [1]Indian Institute of Science, India; [2]Michigan State University, United States

The investigation of phonon-mediated behaviours in transition metal trihalide systems is becoming an area of growing interest in fundamental research. The insulation of quantum magnet trihalides in both bulk and two-dimensional (2D) layers is a valuable avenue for investigating spin liquid phenomena, spintronics, magnetism in 2D and bulk systems, and thermal transport. The investigation of thermal transport mechanisms involving phonons in the presence of spins has received limited attention thus far. The present study has investigated the harmonic and anharmonic vibrational characteristics of magnetic bulk $CrCl_3$ and CrI_3 by the use of density functional theory (DFT) and subsequent experimental validation. Theoretical findings underscore the significance of van der Waals and magnetic interactions in ensuring the dynamical stability of these systems. The vibrational spectra of $CrCl_3$ and CrI_3 exhibit notable distinctions, mostly due to the presence of a phonon band gap in CrI_3. In particular, low-energy phonons in CrI_3 are predominantly influenced by iodine contributions. The phononic vibrational spectrum of $CrCl_3$ exhibits an intriguing anisotropic lattice thermal conductivity (κ_l), with higher κl values observed in the in-plane direction compared to CrI_3. Conversely, CrI_3 demonstrates larger κ_l values in the out-of-plane direction when compared to $CrCl_3$. It is demonstrated that despite the higher scattering strength of phonons in $CrCl_3$ due to its higher phonon group velocities, the heat transfer capacity of $CrCl_3$ surpasses that of CrI_3. Our study offers a fundamental comprehension and valuable insights into the phononic heat conduction in magnetic bulk transition metal trihalide materials.

5:00 PM EN07.05.08
Synergetic Effect of Radiative Cooling and Thermal Energy Storage for Advanced Thermal Management Lyu Zhou, Roma Avhad and Shuang Cui; University of Texas at Dallas, United States

Recent research endeavors strive to develop sustainable thermal management methods to confront the threats posed by extreme weather events and global

energy crisis. Thermal energy storage (TES), which harnesses the latent heat of phase change materials (PCMs), is a promising technology that has been extensively explored for thermal management. However, the practical implementation of TES in buildings faces inherent limitations, including issues related to shape stability, supercooling, slow charging/discharging rates, and limited storage capacity. Here we report a shape stabilized PCM composite that overcomes these challenges by exploring the synergetic effect of TES and passive radiative cooling (PRC), which consists of polyethylene glycol (PEG) as PCM and functionalized boron nitride (fBN) particles as solar scatterers. The inclusion of fBN particles induces a Mie-scattering effect and combines with the intrinsic thermal emission of PEG, resulting in an impressive solar reflectivity of 84.5% and a thermal emissivity of 95.0%. Meanwhile, the composite also achieved a latent heat of 97.1 J/g with excellent shape stability promoted by the interaction between fBN with PEG. Compared to traditional TES, this synergetic effect of PRC and TES promises more efficient thermal regulation by (1) effectively charging PCM during nighttime, (2) maximizing daytime cooling capabilities, and (3) mitigating the impact of supercooling effect. Our modeling study showed that the proposed dual-functional composite could extend the effective TES period by over 50% within a 24-hour cycle. The field test also demonstrated a PRC effect of 3.5 °C below ambient during night, which facilitated the charging of PCMs via crystallization. All these benefits are particularly promising for developing sustainable building thermal management.

5:00 PM EN07.05.09
Temperature-Dependent Optical Properties of Monocrystalline CaF_2, BaF_2, and MgF_2 Qifan Zheng, Xinchao Wang and Dakotah Thompson; University of Wisconsin-Madison, United States

The alkaline earth metal difluorides are critical optical components for applications in non-contact temperature sensors, thermal imaging, and infrared spectroscopy due to their characteristically low refractive index and wide optical transparency spanning the ultraviolet to mid-infrared. Despite their technological importance, a systematic investigation into the temperature dependence of their optical properties is lacking. In this study, spectroscopic ellipsometry was used to obtain the refractive index of monocrystalline CaF_2, BaF_2, and MgF_2 for wavelengths between 220 nm and 1700 nm, and for temperatures between 21 °C and 368 °C. The refractive index of CaF_2 and BaF_2 was observed to decrease linearly with increasing temperature, which can be largely attributed to a reduction in the mass density due to thermal expansion. In contrast, the refractive index of MgF_2 was found to vary nonlinearly with temperature, which suggests competing effects from the material's electronic polarizability. The temperature-dependent refractive index data reported here provide a finely-resolved mapping of the thermo-optic coefficient for these three materials, which could inform the development of optical devices operating at elevated or unsteady temperatures.

5:00 PM EN07.05.10
Transient Active Cooling of Microscale Hot Spots Using Thermoelectric Devices Yihan Liu[1], Hao-Yuan Cheng[2], Jonathan A. Malen[2] and Feng Xiong[1]; [1]University of Pittsburgh, United States; [2]Carnegie Mellon University, United States

Thermal management of microprocessors suffers from transient local hot spot induced by circuits such as clock generator. Embedded thermoelectric devices (TEDs) are promising to remove heat from local hot spots with passive cooling by the Fourier law and active cooling by thermoelectric effect with transient electrical power supplied. In this work, we introduce an analytical model to describe the temperature response of a periodically heated hot spot, which is actively cooled by a thermoelectric cooler operating at the same frequency. The analytical result is experimentally validated with frequency domain thermal reflectance (FDTR) measurements made directly on an actively cooled Si TED where the transient local hot spot is replicated by laser. We further demonstrate a practical and energy efficient method to actively cancel the TED's surface temperature variations based on our model's analytical result. We then apply this method to cancel the transient temperature variation of 2.35 ± 0.26K at 10 kHz on the Si TED's hot side surface. Our model's result and the active cooling method is promising for analysis and optimization of cooling systems for transient localized hot spots in integrated circuits.

5:00 PM EN07.05.11
Improved Durability Nanotextured Aluminum Surfaces for Jumping Droplet Thermal Rectification Trevor J. Shimokusu[1], Frank Robinson[2], Alia Nathani[1], Zhen Liu[1], Te Faye Yap[1], Daniel Preston[1] and Geoffrey Wehmeyer[1]; [1]Rice University, United States; [2]NASA Goddard Space Flight Center, United States

Jumping droplet thermal diodes (JDTDs) offer new capabilities for passive thermal rectification in thermal management of buildings, electronics, and batteries.[1–3] However, the durability of JDTD devices is limited because the superhydrophobic (SHPB) surface degrades upon continuous exposure to condensing water vapor.[4] In addition, most prior JDTDs documented in the literature have been constructed with copper surfaces, although aluminum surfaces are preferable for lightweight applications.[2,3,5–8]

In this work, we quantify the durability of novel SHPB aluminum surfaces and JDTD devices. We manufacture our Al-based surfaces using scalable surface functionalization techniques based on hydrothermal nanostructuring, silanization, and a dip coat deposition of Teflon AF (amorphous fluoropolymer). We show that dip-coating Teflon AF on top of TFTS monolayer-coated nanostructured surfaces enhances surface durability compared to non-Teflon coated surfaces, thereby enabling prolonged operation and comprehensive thermal testing of the JDTD. Contact angle measurements, environmental scanning electron microscope (ESEM) images, and X-Ray photoelectron spectroscopy (XPS) measurements indicate slight changes in the surface topology and chemical composition after dip coating, confirming that the deposited coating is thin (<20 nm).

Using our SHPB surfaces, we parametrically study steady-state thermal rectification as a function of gap height, fluid fill ratio, and heating orientation of the JDTD. We identify tradeoffs between the performance and the orientation dependence of operation by controlling the gap height and charge level. At larger gap sizes and lower charge levels, we observe enhanced thermal rectification only when the JDTD is heated from the bottom, while minimal thermal rectification is measured when the JDTD is heated from the top. At moderate charge levels and smaller gap sizes, operation is sustained in both orientations, but thermal rectification is reduced. We demonstrate a maximum thermal rectification ratio of 30 plus/minus 1.

To investigate potential implementation in thermal energy storage and harvesting applications, we show that the Al JDTD enables a half-wave thermal rectifier circuit that rectifies time-periodic temperature profiles, achieving thermal circuit effectiveness values up to 30 % of the ideal-diode limit at rectification ratios near 5. When coupled with thermal capacitances, such time-periodic thermal rectification could aid cold energy storage for passive cooling of components subjected to time-periodic thermal boundary conditions. Thus, our findings showcase the functionality of Al-based surfaces for thermal rectification and could guide future work aiming to apply Al JDTDs for improved thermal management.

Effect of Fluorination on The Thermal Conductivity of Graphite Fluoride (CF) Wonsik Lee, Seungbin Han and Hyejin Jang; Seoul National University, Korea (the Republic of)

For thermal management applications, there are surging demands for materials with high thermal conductivity and electrically insulating properties. Graphite fluoride (CF), one of the novel graphene-based layered materials, has emerged as a promising thermal management material owing to its similar crystal structure to that of graphite yet electrically insulating properties, i.e., electronic band gap of over 3 eV. CF is expected to show high thermal conductivity due to its structural similarity to graphite. However, the degree of which fluorination alters the thermal conductivity is largely unexplored, and even the thermal conductivity is not experimentally established. Here, we report the through- and in-plane thermal conductivity of mechanically exfoliated CF flakes for the first time by using time-domain thermoreflectance (TDTR). At room temperature, a 70-nm-thick CF flake shows (1700±300) W m^{-1} K^{-1} for in-plane direction, which is about 90 % of that of graphite, and (4.0±0.8) W m^{-1} K^{-1} for through-plane direction. The through-plane thermal conductivity of CF flakes shows quasi-ballistic behavior for thicknesses < 200 nm, which is similarly observed in graphite but shows two times higher through-plane thermal conductivity than that of graphite. We calculate the phonon properties of monolayer graphene and graphene fluoride to reveal the intrinsic phonon transport mechanisms by solving the phonon Boltzmann transport equation (BTE). BTE estimates the thermal conductivity of graphene and graphene fluoride as 3000 W m^{-1} K^{-1} and 270 W m^{-1} K^{-1}, respectively. Phonon mode thermal conductivity indicates that the fluorination opens an out-of-plane acoustic (ZA) phonon scattering channel and the ZA phonon contribution to the thermal conductivity of CF is greatly suppressed, compared to the case of graphene. To understand the discrepancy in thermal conductivity between the experimental and theoretical results, we characterize the chemical and optical properties of exfoliated CF flakes to correlate those properties with thermal conductivity results. We believe this work reveals the role of functional groups on thermal conductivity in graphene/graphite-derivative materials.

5:00 PM EN07.05.13
Development and Validation of Calcium Chloride Hexahydrate-Based Eutectic Systems Denali Ibbotson, Derian Morphew, Bryan Duong and Patrick Shamberger; Texas A&M University, United States

As the use of different renewable energies becomes more common and widespread, the need for different technologies to store that available energy to use at a later time will only grow. Therefore, in order to move towards the decarbonization of the energy grid, effective thermal energy storage systems will be integral in this process. One method that is used to increase HVAC system efficiency and to allow for more efficient load displacement is the incorporation of phase change materials (PCMs) into thermal energy storage systems. PCMs can passively store and release heat, thus allowing for a pathway in order to displace peak energy load for buildings that will better align with the available excess energy generation. However, robust and economical phase change materials that are tailorable to a specific desired energy storage temperature are needed to accomplish this task. Salt hydrates represent one class of PCMs of interest due to their high volumetric energy densities, low cost, and the ability to tailor the energy storage temperature through the design of custom salt hydrate eutectics. However, they can also experience undercooling, a nucleation-limited phenomena which results in the existence of a metastable liquid below the melting point. This phenomena can lead to undesired issues, including incongruent melting and phase segregation. Thus, eutectic mixtures of salt hydrates are often used, as they tend to melt at a single-valued temperature and are a chemically related family of PCMs that enable bespoke PCMs with specifically defined eutectic temperatures. Though, within eutectics, undercooling can still be prevalent, and thus nucleation particles can be added to the system to induce nucleation. However, the effect of nucleation particles is not well understood when the nucleating system contains multiple compounds, as the different phases present within the eutectic can affect how and where nucleation will occur.
In this study, we first explored pseudo-binary and ternary eutectic systems with the intent of identifying systems with closely spaced eutectic temperatures. Specifically, we investigated several different pseudo-binary and ternary calcium chloride hexahydrate ($CaCl_2.6H_2O$) - based eutectic systems, with several different eutectic components such as calcium bromide hexahydrate, magnesium chloride hexahydrate, potassium chloride, ammonium chloride, and urea. Calcium chloride hexahydrate is a stoichiometric salt hydrate of interest for use in thermal energy storage systems because it is a low cost salt hydrate that melts at 29°C. However, calcium chloride hexahydrate is also prone to undercooling and phase segregation related to incongruent melting behavior. Therefore, several different calcium chloride hexahydrate-based eutectic systems were identified and evaluated, in order to develop a family of PCMs with specifically defined eutectic temperatures. We utilized calorimetric techniques to measure undercooling in small quantities of calcium chloride hexahydrate with different eutectic components, and differing weight percentages of the other component. We observed in several cases that the eutectic composition can have a reduced melting temperature by up to 10°C, which allows for a wider available range of melting temperatures. We will present several different eutectic systems and how melting and solidification in these eutectic systems can often be affected by the addition of nucleation particles, when compared to the base stoichiometric system. Additionally, we will also present the effects of the presence of multiple phases and how they can affect the nucleation behavior.

Impact of Cooling Rate and Thermal Mass on Supercooling in a Salt-Hydrogel Complex for Thermal Energy Storage Youngmun Lee, Daniel Hsieh, Sung Bum Kang, Paul V. Braun and Sanjiv Sinha; University of Illinois at Urbana Champaign, United States

Glauber's salt is a promising phase change material for building thermal management because of its high latent heat, acceptable melting temperature of 32.3 °C for indoor air[1,2]. Despite these advantages, the practical application of Glauber's salt in thermal energy storage systems is still challenging due to supercooling and phase segregation[1–3]. Here, we report the impact of temperature ramp rate and thermal mass on the supercooling of Glauber's salt through the DSC and T-history experiment. The ramp rate effect was studied with a wide range of ramp rates in 1 to 10 °C/min in DSC and 1 to 4 °C/min in the T-history experiment. The thermal mass effect was investigated by comparing DSC and T-history experiment. The latent heat was also analyzed for different ramp rates and thermal mass conditions. The melting temperatures of Glauber's salt from the two techniques were identical while freezing temperatures were different because of the thermal mass effect. During freezing in the T-history experiment, the latent heat was reduced by around 75% to the latent heat in melting due to supercooling and phase segregation. To overcome this bottleneck, we developed a novel hydrogel complex that reduces the supercooling and prevents phase segregation to maintain volumetric energy density for 100 cycles. Thermodynamic analysis accounting for composition shows that a higher salt composition can further enhance the volumetric energy storage density. For example, a 10% increase in the weight percentage of salt leads to about 50% enhancement in volumetric energy storage density.

Thermal Conductivity of Individual Ceramic Fillers and Their Application to Thermal Interface Materials Woo Hyun, Jee-Hoon Kim and Hyejin Jang; Seoul National University, Korea (the Republic of)

Oxide ceramic fillers, such as Al_2O_3 and MgO, have been commonly used for thermal interface materials (TIMs) due to their affordable cost and decent thermal conductivity, i.e., 30 and 48 W m^{-1} K^{-1} for each bulk material. In addition, hydroxide fillers, such as $Al(OH)_3$ and $Mg(OH)_2$, have recently been noticed due to their shorter processing time, lightweight nature, and excellent flame retardancy, which are beneficial compared to oxide fillers. While the thermal conductivity of ceramic fillers is one of the most important properties for the performance of TIM, the direct evaluation of the fillers has remained challenging. Thus, the thermal conductivity of bulk materials has been assumed for the fillers when designing the TIMs. In this study, we employed time-domain thermoreflectance (TDTR) to measure the thermal conductivity of individual ceramic filler particles at 300K. For Al_2O_3 and MgO, the filler size in the range of 60-120 μm is investigated, and thermal conductivity varies depending on the filler size. For example, the thermal conductivity of Al_2O_3 decreases from (30±6) to (7.0±1.2) W m^{-1} K^{-1} when the filler size is reduced from 120 to 70 μm. The thermal conductivity of MgO decreases from (47±7) to (23±3) W m^{-1} K^{-1} when the filler size decreases from 100 to 60 μm. The hydroxide fillers show much smaller and a broad range of thermal conductivity, i.e., 3.4-10 W m^{-1} K^{-1} for $Al(OH)_3$, and 0.7-3.0 W m^{-1} K^{-1} for $Mg(OH)_2$. We attribute this distribution of thermal conductivity to the layered structures and weak hydrogen bonding between layers of the hydroxide fillers. The effects of crystal structures and microstructures on the thermal conductivity will be discussed. Furthermore, to reveal the relation of the thermal conductivity of fillers to that of TIM, we prepare the TIMs using these fillers and measure their thermal conductivity using the steady-state ASTM D5470 method. We expect our work to provide a practical guideline for selection of filler types and sizes for TIMs, based on the thermal conductivity values of actual fillers measured by using TDTR.

Supramolecular Interactions lead to Remarkably High Thermal Conductivities in Interpenetrated Two Dimensional Porous Crystals Jaymes Dionne[1], Ashutosh Giri[1] and Patrick E. Hopkins[2,2,2]; [1]University of Rhode Island, United States; [2]University of Virginia, United States

The design of innovative porous crystals with high porosities and large surface areas has garnered a great deal of attention over the past few decades due to their potential for a variety of applications, including flexible electronics, gas storage, and catalysts, among others. However, heat dissipation poses a major challenge in porous crystals and enhancing heat dissipation is key to realizing their potential. In this work, we use systematic atomistic simulations to show that the interpenetration of two, two-dimensional frameworks possess remarkable thermal conductivities at high porosities compared with their single three-dimensional framework and interpenetrated three-dimensional framework counterparts. Typically, high thermal conductivities are associated with low porosities; however, this work provides an alternative method to retain high porosities while drastically enhancing the thermal conductivity of the porous crystal. We attribute this to lower phonon-phonon scattering and vibrational hardening from supramolecular interactions that restrict atomic vibrational amplitudes, enhancing heat conduction. We also show this for realistic systems, with a two-dimensional interpenetrated framework of COF-1 achieving an order of magnitude increase in thermal conductivity when compared to its three-dimensional counterpart, COF-300. This introduces a new regime of materials design that combines ultrahigh thermal conductivities with ultralow mass densities via the interpenetration of two-dimensional porous crystals.

Investigation of Grain Effect in Heat Transfer for less than - 10nm Local Areas of HfO_2 Thin Film Deposited with Atomic Layer Deposition Seunghoe Koo, Jaehee Park, Junki Jung and Kyeongtae Kim; Incheon National University, Korea (the Republic of)

Recently, the rapid development of the material science and nano-atomic technology has led to the development of device made up of dozens of atoms such as nanoparticles(0D), nanowires(1D), 2D atomic materials, ultra-thin film. In particular, the atomic layer deposition(ALD) method is attracted attention as a key technology that can produce ultra-thin films at the atomic level. In the ultra-thin film, because the size of a material becomes similar to or less than the size of the quantum mechanical wave of particle or the energy carrier's collision distance (mean free path, MFP), a novel quantum mechanical characteristics occurs. Therefore, novel heat transfer mechanisms should exist in angstrom-scale materials. We can predict that a difference or a restriction in the quantum heat transfer exist based on the crystal structure and thin-film thickness obtained from previous theoretical studies. However, the heat transfer mechanism has not been proven owing to the difficulty of the experimental approach and the lack of measurement techniques in the atomic or angstrom scale. In addition, only the totally averaged thermal conductivity is reported regarding the annealing effect of the thin film, and the relationship between grain size and heat transfer by annealing is not closely analyzed. In this study, we used scanning thermal microscopy(SThM) to investigate heat transfer differences occurring in a local area less than ~10 nm in HfO_2 thin films. The difference in averaged thermal conductivity and distribution of thermal conductivity in the local area according to the thickness of the thin film was investigated. In addition, the crystal structure was changed through annealing, and the thermal conductivity of the thin film according to grain size was investigated. The thermal transfer mechanism investigated in this work according to the crystal structure will be an important background for the development of innovative device using ALD method. It is also expected that the SThM system used in this study will be actively used for future research that can provide insight of new heat transfer mechanisms in the atomic scale.

5:00 PM EN07.05.18
Low Thermal Conductivity and High Thermoelectric Performance in Toxic-Element-Free Inverse-Perovskite Oxide Xinyi He[1], Shigeru Kimura[1], Takayoshi Katase[1], Terumasa Tadano[2], Satoru Matsuishi[1], Hidenori Hiramatsu[1], Hideo Hosono[1] and Toshio Kamiya[1]; [1]MDX Research Center for Element Strategy, International Research Frontiers Initiative, Tokyo Institute of Technology, Japan; [2]Research Center for Magnetic and Spintronic Materials, National Institute for Materials Science, Japan

Given the recently increasing energy crisis, there has been a growing focus on thermoelectric technology for converting waste heat energy into electrical power. The energy conversion efficiency (ZT) of thermoelectric materials, defined as $ZT = S^2\sigma T\kappa^{-1}$, is determined by the key factors: the Seebeck coefficient (S), the electronic conductivity (σ), and thermal conductivity (κ), which includes both electronic (κ_{ele}) and lattice (κ_{Lat}) contributions. Therefore, high ZT thermoelectric materials require large S and high σ to achieve a high power factor (PF = $S^2\sigma$), along with low κ to create a sizable temperature gradient. To date, high thermoelectric ZT values has primarily been demonstrated in heavy metal chalcogenides, but the use of toxic elements, such as Pb and Te, is not preferred for widespread practical applications of thermoelectricity. In this study, we propose inverse perovskite-type oxide Ba_3SiO as a novel class of toxic-element-free thermoelectric materials with high ZT reported so far. First, we experimentally demonstrate that undoped Ba_3SiO bulks exhibit rather high ZT = 0.16–0.84 at T = 300–623 K. In addition to these promising experimental results, we demonstrate that the maximum ZT is estimated to be 2.14 for Ba_3SiO at T = 600 K when optimally doped, based on the first-principles carrier and phonon transport calculations. The maximum ZT value of Ba_3SiO is notably higher than those of environmentally benign thermoelectric materials, and it is comparable to those of the high ZT

thermoelectric materials composed of heavy and toxic elements in the same temperature range.
We elucidate the origin of high *ZT* for Ba_3SiO and the underlying physical mechanisms through a combination of the experimental analysis and the first-principles calculations. We observed that Ba_3SiO bulks exhibit remarkably low lattice thermal conductivity (κ_{Lat}) of 1.00 W/(mK) at T = 300 K, which is significantly lower than 8.2 W/(mK) of the normal perovskite $SrTiO_3$ bulk, and even lower than 1.7–2.0 W/(mK) of Bi_2Te_3 and PbTe bulks. The crystal structure of Ba_3SiO is constructed from the highly distorted O–Ba_6 octahedra framework with weak O–Ba ionic bonds, which provides low phonon group velocity and strong phonon scattering. Additionally, Ba_3SiO possesses favorable band structures for achieving a high PF, where the valence band around the Fermi level arises from the *p* state of the negatively charged Si anion with large ion size, and their highly dispersive bands with multiple valley degeneracy enable both high σ and high *S*, simultaneously, leading to the high *ZT* for Ba_3SiO originating from the low κ_{Lat} and the high PF. These results suggest that inverse-perovskite oxides are promising and environmentally benign thermoelectric materials, offering a compelling alternative to current practical materials composed of heavy and toxic elements.

5:00 PM EN07.05.19
Binder-Free Boron Nitride Spheres Enhanced Quasi-Isotropic Thermal Conductivity of Polymer Composites Hongbo Jiang, Qiran Cai and Ying Chen; Deakin University, Australia

Heat dissipation has become increasingly crucial in modern highly integrated and miniaturised electronic devices to improve their reliability and performance. Thanks to the high thermal conductivity and electrical insulation, boron nitride nanosheets (BNNSs) are usually used as fillers to construct thermally conducive polymer composites for heat dissipation. However, limited to the low dispersibility, high aspect ratio, and anisotropic thermal conductivity of BNNSs, the resulted thermal conductive composites based on polymer matrix showed an unsatisfied thermal conductivity, especially in the out-of-plane direction, due to the "lie-down" structures of the BNNSs fillers. In this work, micro-sized, binder-free boron nitride spheres (BNSs) have been successfully synthesized using a two-step process of thermal spray drying and high-temperature sintering; and a facile and efficient method to measure the thermal conductivity of BNSs, based on the factors impacting the BNSs' thermal conductivity, including precursor, polymer binder and sintering temperature, was developed. With optimised conditions, BNSs have a high, isotropic thermal conductivity of 37.2 W/mK. Based on the high thermal conductive and binder-free BNSs, a poly(vinyl alcohol) (PVA)/BNS composite film was successfully fabricated, and the out-of-plane thermal conductivity of this composite film is significantly enhanced to 8.1 W/mK, while the in-plane thermal conductivity, up to 10.6 W/mK, is not sacrificed, indicating the quasi-isotropy in thermal conductivity. The significant thermal conductivity enhancement (~3700%) of PVA is attributed to the formation of isotropic thermally conductive networks within the polymer matrix and strong interactions between BNNSs inside BNSs. This study provides a practical route to fabricate BN-enhanced composite films with isotropic thermal conductivity and promising materials that are valuable for heat dissipation in new-era advanced electronics and related applications.

5:00 PM EN07.05.20
Thermal Interface Engineering Using Layer-By-Layer Carbon Nanotube-Polyethylenimine Functional Nanostructures between Phase Change Materials and Aluminum Heat Sinks Jiheon Kim, Jaemin Lee and Wonjoon Choi; Korea University, Korea (the Republic of)

Phase change materials (PCMs) and heat sinks (HSs) can be integrated rationally to complement the inherent constraints of both technologies. However, adding PCMs to HSs frequently causes additional thermal resistances and unstable contact interfaces during solid-liquid phase transitions. In this study, we present the utilization of layer-by-layer (LbL) assembly to enhance functional interfaces between a multiwalled carbon nanotube (MWCNT) and polyethyleneimine (PEI) on the surfaces of PCMs and HSs to enhance thermal management capabilities. The MWCNT-PEI percolation networks on an aluminum HS are effectively created by the LbL approach reported in this study, which involves the direct synthesis of electrostatically attached nanocoatings using a solution-based process. The HS channels are filled with a phase change substance (n-eicosane) to complete the PCM-HS assembly. The PCM and HS interface is stabilized over repeated solid-liquid phase transitions owing to the functional interface's optimization of the porous structures and a large increase in the active surface area enabling effective thermal transport. A comparison between the developed specimens (bare and PCM-filled HSs without LbL interfaces) highlights the improved thermal performance, particularly in transient and static operating conditions. The LbL functional interfaces show lower temperatures than the PCM-HS without MWCNT-PEI bilayers under different thermal loads (30, 40, and 50 W). The set point temperatures (SPTs) are chosen to be 40°C, 50°C, and 60°C for an objective and precise comparison. The LbL-assembled MWCNT–PEI coatings considerably increase the times to reach all SPTs. Using the LbL interface improves the effectiveness by more than 10%, according to experimental assessments of real-time temperature responses under different heating power levels and the time required to reach target temperatures. Furthermore, the LbL interfaces effectively mitigate thermal shock and overload issues during intermittent thermal loads. The developed LbL interface presents a versatile and scalable approach for creating PCM-filled HSs with advanced thermal properties that surpass the capabilities of traditional heat sinks.

5:00 PM EN07.05.21
Nanostructured Anodic Aluminium Oxide (AAO) with Metal Coating Optimized for Passive Radiative Cooling Alba Díaz-Lobo[1], Marisol Martín-González[1], Angel Morales-Sabio[2] and Cristina V. Manzano[1]; [1]Micro and Nanotechnology Institute, Spain; [2]Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas, Spain

Currently, one third of the total energy consumption is already used for cooling in modern countries. An alternative way to achieve thermal comfort is becoming crucial to face this trend, and a passive cooling technology is a strong candidate that should be considered. Specially, when passive thermal management is achieved by using low-cost and easy-scalable to industry materials. In this sense, this study shows the possibilities of nanostructured anodic aluminium oxide (AAO) for passive radiative cooling: first, we analyse in detail the influence of all morphological parameters and the effect of the chemical structure on the optical response as well as on the passive radiative cooling performance; second, considering the most suitable kind of AAO nanostructures for passive cooling, we characterise different metal coating on the AAO nanostructures. Hence, we found the wavelength regions where the alumina thickness, the pore diameter, the interpore distance, the porosity and the incorporated counterions show the major impact in the optical response of the AAO nanostructures. We also improve the cooling performance of these AAO nanostructures by metal coating. A maximum temperature reduction of 11.7 K is experimentally measured under direct sunlight in a summer day in Spain. The results of this work demonstrate the enormous potential of AAO nanostructures to be used in thermal management applications and to contribute to a sustainable future energy.

5:00 PM EN07.05.22
Remarkable Suppression of Thermal Transport by Inhomogeneous Strain Lin Yang[1], Deyu Li[2] and Peng Gao[1]; [1]Peking University, China; [2]Vanderbilt University, United States

There is a mantra in the realm of material mechanics, "smaller is stronger", the science of which took root in the 1950s and is vigorously developing today. As nanomaterials are mechanically much stronger, significantly higher strains can be applied to tune their physicochemical properties than is possible with traditional materials. Based on this, we can rationally engineer a spectrum of advanced functionalities ranging from transistors, solar cells and photodetectors to batteries, superconductors, and electrocatalysis. Despite extensive investigations into strain-engineered electronic properties, the intricate phonon transport mechanism subjected to inhomogeneous strain remains an issue of debate. This is especially frustrating given that precise thermal

management stands as a critical bottleneck to device efficiency and lifespan.

One prevalent method for introducing strain involves growing thin epitaxial layers on substrates with lattice mismatch, such as Si on SiGe, and research has been conducted to investigate thermal transport through various epitaxial layers. However, although low thermal conductivity (κ) values even below their alloy counterparts have been observed, the effects of strain gradient through the epitaxial layers are experimentally difficult to decouple from the interfacial phonon boundary scattering effects, which presents a daunting challenge to draw a solid conclusion on the physical origin of the ultra-low κ. Similarly, although dislocations and vacancies could scatter phonons in various functional devices, it remains a formidable challenge to isolate their effects from that of long-range strain fields introduced by these defects, which could also impede thermal transport via an increase in vibrational anharmonicity. Consequently, questions regarding the cause of the unusual and somewhat perplexing thermal behavior in these functional materials have lingered unanswered.

To date, while elastic strain engineering often relies on highly inhomogeneous stress produced by nanoscale deformation (e.g., by epitaxial layer growth, defects and vacancies, or lithography patterning), most studies of strain effects on thermal transport have centered around materials under simplified condition of uniform stress. The major challenges in experimentally quantifying the effects of inhomogeneous strain on thermal transport include applying stress exclusively without introducing confounding factors (e.g., interfaces and defects), and combining thermal measurements with atomically resolved characterization of the strain field and phonon spectra. Here, we induce inhomogeneous strain through bending individual silicon nanoribbons on a custom-fabricated microdevice, and measure its effect on thermal transport while characterizing the local strain and vibrational spectra using atomically resolved electron energy-loss spectroscopy (EELS). Our results show that a strain gradient of 0.112% per nanometer could lead to a drastic thermal conductivity (κ) reduction of 37.4%, which is over 3-fold of previously demonstrated κ modulation under uniform strain. Taking advantage of recent progress in electron energy loss spectroscopy equipped with a monochromator in an aberration corrected scanning transmission electron microscope (STEM), we directly measured the local phonon modes and correlated them with the nanometer-scale strain gradient. Results show that the bending-induced lattice strain gradient significantly alters the vibrational states and broadens the phonon spectra. Coupled with ab initio theoretical modeling, this broadening effect is shown to enhance phonon anharmonicity and shorten phonon lifetimes, ultimately contributing to suppressed thermal conductivity.

5:00 PM EN07.05.23
Assessing Multivariate Thermal Transport Relationships in Pump-Probe Experiments Using Sensitivity Matrix Jing Tu and Wee-Liat Ong; Zhejiang University, China

Sensitivity analysis is a powerful technique to analyze the behaviors of models and experimental data in diverse fields.[1–4] Most state-of-the-art characterization techniques rely on fitting experimental data to a theoretical multivariate model. Such a model often has multiple unknown parameters at the same time. These unknowns are either determined independently or, when impractical, are fitted together in a single set of measured data. It is well-known that such a multivariate fit can become invalid, especially when these unknowns are related.[5] To complicate matters, such a relationship can change with a different sample configuration and measurement conditions. Unfortunately, few rigorous methods exist to evaluate the validity of such a fit or uncover the governing transport relationships under different measurement conditions.
Here, we formulate a systematic approach based on sensitivity analysis to uncover the governing physics in a complex multivariate theoretical model and assess the feasibility of performing a multivariate fit. A sensitivity matrix of the unknown variables is constructed and, later, decomposed using the singular-value decomposition (SVD) method. The resulting solution of three matrices provides insight to the fitting process. The rank of the rectangular diagonal matrix with non-negative real numbers on the diagonal reveals the number of independent fit-able variables within the tested range. Under certain conditions, the associated complex unitary matrix contains information of the thermal transport relationships in the measured system.
Different pump-probe techniques for thermal characterization are used to illustrate the capability of this method. We found that the existing experience-based criteria,[5,6] e.g., the overlapping sensitivity curves to identify related parameters or the non-overlapping and distinct sensitivity curves for multivariate suitability, are inadequate and applicable only in certain situations. Also, our method can uncover the governing heat transfer relationships through different multilayer samples and measurement conditions. This method can apply to most measurement techniques relying on multivariate theoretical models in various disciplines and can help to improve their measurement validity and throughput.

***In-Situ* Long Term Stability Analysis of Hygroscopic Hydrogels for Energy and Water Applications** Joseph P. Mooney[1,2], David Keisar[1], Carlos D. Diaz[1] and Bachir El Fil[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Limerick, Ireland

Thermal energy storage serves a pivotal role in bolstering both energy efficiency and sustainability by enabling the controlled capture and release of heat, thus mitigating energy wastage and facilitating the seamless integration of renewable energy sources. Desiccant-based thermal energy storage (TES) systems leverage moisture-absorbing materials to efficiently store and discharge heat, offering a promising avenue for sustainable and efficient energy management. Hygroscopic hydrogels, as potential desiccant materials, offer a compelling prospect due to their high energy densities and cost-effectiveness. While our understanding of the kinetics and transport mechanisms of hygroscopic hydrogels is advancing, there remains a critical knowledge gap concerning their long-term stability and performance. Furthermore, the translation of insights gained from Dynamic Vapor Sorption (DVS) cyclability analysis to a larger scale and its relevance to TES systems operating in pure vapor environments warrants comprehensive investigation.
In this study, we have developed a comprehensive test facility that assesses the long-term stability of hygroscopic hydrogels and other sorbents in pure vapor at vacuum pressures. With this facility, we can control the relative vapor pressure and chamber temperature that the sorbents are exposed to, emulating relative humidity (RH) conditions. Moreover, insights into aspect ratio and thickness scaling on a device size sample can inform the limits of diffusion limits of the material.
In this study, we fabricate PAM-LiCl hygroscopic hydrogels with salt loadings of 1 gg^{-1} and 5 gg^{-1}. We subject the gels to an RH swing of 30% to 70% – allowing the hydrogels to equilibrate at each RH level. This is achieved through the thermal cycling of the gels between 30 °C and 60 °C on a 25 mm x 50 mm temperature-controlled plate while fixing the chamber vapor pressure at 3 kPa. We measure both the kinetics and load swing of these hydrogels by mounting the plate to a precision strain gauge (< 0.1 g error). This analysis demonstrates that the hydrogels maintain > 90% of their performance, after 100 thermal desorption-adsorption cycles. We also qualitatively show that no visual variation between cycles was observed in the gels. These novel insights

have significant implications for understanding the long-term stability and, importantly, for optimizing the design of hygroscopic hydrogels for broader and more efficient energy storage systems.

Phonon Transport of Disordered Materials with Nanostructures Junichiro Shiomi; The University of Tokyo, Japan

Phonon engineering of crystalline materials by nanostructures has made great progress in the past decades, and the next non-trivial challenge is how to engineer phonons in disordered materials. We have studied nanostructured amorphous materials such as amorphous superlattices [1] and amorphous phononic crystals (amorphous thin films with holes) [2]. There, by applying the Allen-Feldmann theory, which divided heat carrier into propagons, diffusons, and locons, we found that not only the transport of propagons but also that of diffusons is effectively hindered by the nanostructure interfaces. To gain further direct insight, inelastic x-ray scattering was performed. Partially disordered materials are also of great interest from an academic and industrial point of view. This includes materials consisting of crystalline and amorphous portions, e.g., polycrystals with disordered interfaces. Disordered grain boundaries have been found experimentally to selectively inhibit phonon transport rather than electron transport. Furthermore, a black box model of disordered silicon grain boundaries was successfully performed, revealing that the main structural factors that determine transport are different for phonons and electrons [3]. Crystalline materials with distorted lattices, such as cellulose nanofibers, are also interesting. The thermal conductivity of cellulose nanofibers was found to be greatly enhanced by controlling the arrangement of the constituent cellulose nanofibrils and the hydrogen bonds between the fibrils [4].

Effect of Linker Chemistry, Linker Length and Temperature on The Thermal Conductivity of Vinylogous Urethane Dynamic Network Peng Lan, Seongon Jang, Christopher M. Evans and David Cahill; UIUC, United States

Covalent adaptable networks (CANs) have been heavily studied in recent years as promising candidates for recyclable polymer in applications like shape memory materials, shockwave energy-dissipative materials, and flexible electronics. However, the thermal management of polymeric materials in these devices is still an urgent issue, since polymers generally have low thermal conductivity (as 0.2 W/m K) which can lead to thermally-induced aging. Moreover, the effect of bond exchange dynamics, linker chemistry and temperature on the thermal conductivity of CANs is still unclear. In this work, a series of vinylogous urethane dynamic networks (VU-*x*E) were synthesized from tris(2-aminoethyl)amine and di-acetoacetates with ethylene linkers (E = ethylene) and varied linker length (x = 2-22 carbon atoms). Thermal conductivity was measured by frontside frequency-domain probe beam deflection (FD-PBD). In comparison to the ethylene network with benzene diboronic acid bonds, neither linker length dependence nor temperature dependence of thermal conductivity shows a monotonic trend as in the case of VU-*x*E network. The thermal conductivity of these VU networks at room temperature varies from 0.20 W/m K to <0.1 W/m K as the linker length increases from x = 2 to x = 22. At high temperature approaching glass transition ($T_g \sim T_g$ + 20K), a drop of thermal conductivity is observed by FD-PBD and as the temperature grows higher (> T_g + 30K), the thermal conductivity retains to that of low temperature (< T_g). We hypothesized that this drop of thermal conductivity near T_g in FD-PBD is due to combined dynamics of monomer chain motion and bond exchange. The morphology of these VU-*x*E networks were also studied using WAXS for both fresh and annealed samples. Apart from amorphous halo peak at ~ q_I = ~14 nm^{-1} and broad ethylene chain stacking peak at ~ q_{II} = ~4 nm^{-1}, no obvious crystalline peak is seen for all networks. Such a behavior is different from our previously studied ethylene network with boric acid dynamic bonds, where longer network (x > 10) exhibits slow crystallization (with crystallinity>78% in WAXS) at room temperature. We attributed this difference to the fact that VU bonds have a much slower bond exchange than boric acid. Furthermore, we investigated the effect of linker chemistry on the thermal conductivity, by changing the ethylene linker to ethylene oxide (VU-*x*EO, x = 6, 9, 12, 18, 36 atoms). Similar linker length dependence of thermal conductivity is observed for these ethylene oxide VU network. But no EO chain stacking peak q_{II} is seen in WAXS spectra as the linker length increases, suggesting that the presence of oxygen atoms in EO linker will disturb the chain stacking and make the network less capable of crystallization. This work provides new design rules for thermal conductivity of dynamic polymer networks and how to control the crystallization depending on linker length, chemistry, and dynamic bond type.

9:30 AM EN07.06.04
Thermal Conductivity of 2H and 2H3R Niobium Diselenide Polymorphs Sungjin Park[1], Kyomin Kim[2], Kwangrae Kim[1], Jong-wook Roh[3], Aloysius Soon[1], Wooyoung Lee[1] and Woochul Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]LIG Nex1, Korea (the Republic of); [3]Kyungpook National University, Korea (the Republic of)

Niobium diselenide($NbSe_2$) is a two-dimensional van der Waals material whose 2H3R polymorph was discovered recently [1]. The 2H3R polymorph of $NbSe_2$ possesses a different stacking sequence when compared to the 2H polymorph due to the weak van der Waals bonding between the layers and therefore possesses different physical properties. Previous research has shown that difference in stacking sequence in two-dimensional materials can alter their electrical and thermal properties [1,2]. In this work the thermal conductivity of the 2H and 2H3R polymorphs of $NbSe_2$was measured and compared. The in-house T-bridge method was used in the measurement of thermal conductivity [3]. The T-bridge method measures the thermal conductivity of a sample through difference in heat conduction from a suspended heater to a heatsink. $NbSe_2$ samples of various thicknesses were prepared for both polymorphs. Measured thermal conductivity results showed that the 2H3R polymorph shows lower thermal conductivity compared to the 2H counterpart of similar thickness. Theoretical calculation was performed to study the cause of the difference in thermal conductivity and revealed that the lower thermal conductivity of the 2H3R polymorph was induced by the greater phonon-phonon scattering of the 2H3R polymorph than that of the 2H polymorph.

Modulating The Thermal Transport of $MAPbI_3$ Hybrid Perovskites and The Effect on its Population-/Coherence-Channel Jin Yang[1], Yuting Yu[1], Ankit Jain[2] and Wee-Liat Ong[1]; [1]Zhejiang University, China; [2]IIT Bombay, India

Hybrid halide perovskites, with their favorable carrier recombination time and ultrashort phonon mean-free paths, are potential candidates for numerous energy conversion applications like photovoltaics and thermoelectrics. The origin of the ultralow thermal conductivity in the prototypical methylammonium lead triiodide ($MAPbI_3$) is of intense research interest for improving and modulating its energy conversion performance.[1] So far, such an understanding remains elusive in the $MAPbI_3$ at above room temperatures (that exists as a cubic phase) despite numerous efforts[2] and under external modulation fields.
Using molecular dynamics and the Wigner transport equation,[3] we first report the discovery of several cubic-phase $MAPbI_3$ (c-$MAPbI_3$) local energy minimum structures.[4] These stable structures are amenable to lattice dynamics-based calculations to produce positive phonon dispersions. Our results reveal a coherence-channel-dominated thermal transport mechanism in the c-$MAPbI_3$ crystals. Interestingly, an inter-conversion between the population- and coherence-channel occurs when the c-$MAPbI_3$ changes across these energetically equivalent structures at the same temperature. Such an effect is yet to be observed in simple atomic crystals.
Next, we looked at how external pressure fields and electric fields affect the thermal transport of $MAPbI_3$. An external pressure increases the c-$MAPbI_3$ thermal conductivity of the phonon population-channel contribution, similar to trends in many crystals. However, little effect on the coherence-channel contribution is observed. This unusual trend impedes the thermal conductivity increase for this c-$MAPbI_3$ and imparts a trend that mirrors that of a diamond[5]. On the other hand, the electric field has little effect on c-$MAPbI_3$ although the polar MA cations are affected by the electric field.
Our work also shows that existing thermal transport intuitions based on the phonon gas model can be misleading in such hybrid crystals. Further, the dominance of the non-traditional coherence-channel of phonons can affect the interpretation of other phonon-mediated processes in $MAPbI_3$ and other hybrid perovskites.

Unconventional Approaches to High or Tunable Thermal Conductivity in Solids Li Shi; The University of Texas at Austin, United States

Materials with an either high or tunable thermal conductivity can find applications ranging from thermal management of microelectronics to electrification of industrial heating processes. Wide-bandgap diamond and semi-metallic graphite achieve record-high thermal conductivity values because strong covalent bonding of light carbon atoms gives rise to a large thermal conductivity contribution from phonons, the energy quanta of lattice vibrations. Such conventional criteria for a high lattice thermal conductivity have recently been upended by the establishment of a phonon band engineering approach to high-thermal conductivity semiconducting cubic boron arsenide (c-BAs) made of both light and heavy elements. This paradigm shift is not only motivating heterogeneous integration of c-BAs heat spreaders with other semiconductors for enhanced thermal and electronic performance, but also the search of other compounds with a high thermal conductivity, including semi-metallic theta-tantalum nitride (theta-TaN). Compared to this recent progress in the research of ultrahigh-thermal conductivity materials, the study of tunable solid-state thermal transport has still been largely limited to tuning of the lattice and electronic contributions through structural and magnetic phase transitions, respectively. Besides providing an update on experimental progresses and applications of high-thermal conductivity c-BA, theta-TaN, and graphitic materials, this presentation will introduce recent efforts of utilizing interlayer excitons and flat moiré electron bands to realize tunable thermal transport along and between two-dimensional heterostructures.

Extreme Materials Design for Thermal Transport and Energy Conversion Yongjie Hu; University of California, Los Angeles, United States

Controlling thermal transport is critical for many applications including electronics and energy technologies. In this talk, I will highlight my group's recent efforts [1-6] in creating innovative materials and devices to push the boundaries of heat dissipation. First, I'll discuss our advancements in developing emerging semiconductors with high thermal conductivity and their integration with wide-bandgap/ultra-wide bandgap semiconductors to enhance heat dissipation in power electronics. Notably, we discovered cubic boron arsenide (BAs) and boron phosphide (BP) with a high thermal conductivity up to 1300 W/mK at room temperature, surpassing most common semiconductors and metals [1]. We've successfully integrated BAs with GaN HEMTs [2], achieving a record thermal boundary conductance and outperforming diamond/SiC cooling devices. Using self-assembly manufacturing [3], we've developed scalable and flexible high-conductivity BAs-polymer interfaces for efficient cooling in LEDs and wearables. Moreover, our fundamental study has explored BAs as a showcase platform for high-order phonon anharmonicity physics [4] and non-perturbative quantum theory [5]. Finally, I'll discuss our recent advances in solid-state thermal regulation for heat flow and phonon control [6]. References:[1] *Science* 361, 575-578 (2018). Origin of Extreme Thermal Properties in Amorphous Diamond Jaeyun Moon and Zhiting Tian; Cornell University, United States

Structural disorder hinders propagation of vibrational heat carriers, leading to intrinsically low thermal conductivity in amorphous solids. Recently, bulk amorphous diamond with hardness and elastic modulus exceeding those of its crystalline counterpart was synthesized and thermal conductivity of ~ 25 $Wm^{-1}K^{-1}$ was reported at room temperature, higher than any other bulk amorphous solids and even some crystals. In this work, we explore the microscopic thermal transport mechanism in amorphous diamond through both computational and experimental techniques and discuss its implications in thermal transport in solids.

11:45 AM EN07.07.04
Proton Collective Quantum Tunneling Induces Anomalous Thermal Conductivity of Ice Under Pressure Yufeng Wang, Kuang Yu and Bo Sun; Tisnghua University, China

Ice is one of the most ubiquitous substances in the universe. Understanding its thermal conduction properties is crucial for exploration of the evolution and dynamics of icy planets. Moreover, ice itself serves as an ideal model to study proton's quantum effects in the hydrogen bond networks, which has received enormous attention in physical chemistry and condensed matter physics.
It is believed that protons tunnel in the hydrogen bond network in ice and the tunneling is local compared with the wavelength of heavy phonon; as such, the quantum nature of the proton dynamics would not strongly affect the thermal conduction of ice, and the thermal conductivity as a function of pressure should increase following the classical Leibfried-Schlömann equation.
In stark contrast, we observed anomalous, nonmonotonic behavior in the thermal conductivity of H_2O and D_2O ice above 20 GPa that breaks the classical rule. Such anomaly is revealed to be caused by global collective quantum tunneling involving several tens of molecules. It is the first time that quantum tunneling in ice is observed at such a large spatial scale, opposing to all previous studies which assumed that local or synchronized tunneling within a limited size (such as six-member rings) dominates in ice.
Moreover, the tunneling dynamics in the ice VII-X phase transition region has been a long-standing challenge to understand using conventional spectroscopic methods. In this work, we provide a completely new approach that can directly probe the global dynamics of the phase transition with unambiguous experimental measurements.

SESSION EN07.08: Polaritonic Heat Transfer
Session Chairs: Yongjie Hu and Li Shi
Wednesday Afternoon, April 24, 2024
Room 327, Level 3, Summit

1:30 PM +EN07.08.01
Thermal Transport Mediated by Non-Equilibrium Surface Phonon Polaritons Zhiliang Pan[1], Guanyu Lu[1], Xun Li[2], Lucas Lindsay[2], Joshua D. Caldwell[1] and Deyu Li[1]; [1]Vanderbilt University, United States; [2]Oak Ridge National Laboratory, United States

Surface phonon polaritons (SPhPs), hybrid quasi-particles resulting from coupling between infrared photons and optical phonons, could play significant roles in near-field radiation. More recently, it has been predicted that SPhPs can also contribute to heat conduction along polar thin films and nanowires; however, direct and conclusive experimental evidence for SPhP-mediated heat conduction has been scarce. Here we report on significant enhancement of the thermal conductivity of 3C-SiC nanowires when the end(s) of the nanowires are coated with a thin layer of gold that can serve as efficient SPhP launchers. Through measuring the same 3C-SiC nanowires with and without gold coating at the end(s), we show that the SPhPs launched by the gold coating can remarkably enhance the thermal conductivity of the uncoated wire segment from the value of the same wire without gold coating. Interestingly, it is found that the SPhP-mediated thermal conductivity is orders of magnitude higher than the Landauer limit predicted based on the equilibrium Bose-Einstein distribution function over the entire measurement temperature range. We attribute this unexpected discovery to the partial ballistic propagation of SPhPs along the SiC nanowire with a number density well beyond the value determined by the Bose-Einstein distribution function. The understanding of non-equilibrium SPhP transport is supported by the observation that the extracted SPhP-mediated thermal conductivity is proportional to the length of the gold coating at the end(s) of the nanowire, which provides important insights into the SPhP excitation process. The highest SPhP-mediated thermal conductivity at room temperature reaches a value of 5.8 W/m-K, a few times of the phonon-mediated thermal conductivity for some technologically important thin films such as silicon oxide and nitride. This discovery of non-equilibrium SPhP-mediated heat conduction implies novel cooling strategies utilizing SPhPs as effective thermal energy carriers.

2:00 PM EN07.08.02
Guided Polariton Thermal Radiation Sebastian Volz; CNRS, France

Phonons are the quasiparticles of lattice vibrations and represent the primary heat carriers in bulk dielectric materials. The thermal conductivity of dielectric membranes is thus typically driven by acoustic phonons that is usually assimilated to a gas of particles, and generally reduces with the membrane thickness due to the increasing frequency of surface scattering events. In the light of the ever-increasing miniaturization of devices with enhanced rates of operation, this reduction in the thermal conductivity causes overheating, low reliability, and reduced lifetime of electronic components. Yet, while the thermal transport via acoustic phonons might be at the limit, the heat dissipation might be enhanced via optical phonons coupled with surface electromagnetic waves.
Over the past decade, substantial research efforts have been devoted to the study of these surface waves, because the surface effects predominate over the volumetric ones in nanostructures with high surface-to-volume ratio. Some types of surface electromagnetic waves may even carry heat and thus improve the thermal performance and stability of nanoscale devices.
One type of such surface waves is the surface phonon-polaritons (SPhPs), which occurs as a hybrid of optical phonons and surface electromagnetic waves. The SPhPs are essentially evanescent waves that propagate along the surface of polar dielectric membranes.
We will first demonstrate the existence and the properties of those SPhPs in thin SiO2 films and especially uncover that the propagation lengths of those waves reach the range of hundreds of micrometers, which is orders of magnitude longer than the typical mean free path of acoustic phonons. Theoretical models predict that such a long propagation length enables SPhPs to conduct more thermal energy than phonons when the membrane thickness is reduced below 100 nm.

We will then corroborate the significant contribution of SPhPs to heat flux in silica membranes, in a restricted temperature range and also, in a wide temperature range, in silicon nitride membranes where SPhP thermal conductivity becomes predominant at 800K. An additional confirmation was finally provided by showing the size dependence of thermal conductivity due to the ballistic contribution of SPhP.

2:15 PM EN07.08.03
Long-Range, Short-Wavelength and Ultrafast Heat Conduction driven by Three Plasmon Modes supported by Graphene Jose Ordonez[1,2], Yuriy Kosevich[2], Masahiro Nomura[2,1] and Sebastian Volz[1,2]; [1]CNRS, Japan; [2]The University of Tokyo, Japan

By leveraging the unique two-dimensional structure of graphene with its ability to support the propagation of surface plasmon-polaritons, we demonstrate the existence and propagation of three hybrid modes of surface plasmon polaritons supported by two graphene monolayers coating a solid film. These modes propagate long distances with short wavelengths, which are suitable features to enhance the heat conduction along the film interfaces. For a Si film with a thickness of 15 nm and a length of 5 mm at 300 K, we find a plasmon thermal conductivity of 13.6 Wm−1K−1, which represents 67% (26%) of its phonon Si (Si+graphene) counterpart. This thermal energy appears due to the coupling of plasmons propagating at speeds comparable to the speed of light in vacuum. The plasmonic heat conduction driven by two-dimensional materials thus appears as a major and unexpected mechanism for controlling temperature in solid-state systems without changing their internal structure and at rates faster than the ones of phonons and electrons.

3:30 PM *EN07.09.01
Engineering and Probing Phonons and Thermal Transport Begoña Abad Mayor, Chaitanya Arya, Giulio de Vito, Yashpreet Kaur, Grazia Raciti, Aswathi K. Sivan, Jose Manuel Sojo Gordillo, Saeko Tachikawa, Johannes Trautvetter and Ilaria Zardo; University of Basel, Switzerland

The recently growing research field called “Nanophononics” deals with the investigation and control of vibrations in solids at the nanoscale. Phonon engineering leads to a controlled modification of phonon dispersion, phonon interactions, and transport [1, 2]. However, engineering and probing phonons and phonon transport at the nanoscale is a non-trivial problem.
In this talk, we discuss how phononic properties and thermal transport can be engineered and measured in nanowires and the challenges and progresses in the measurement of the thermal conductivity of nanostructures and low dimensional systems. The concept of phonon engineering in nanowires is exploited in GaAs/GaP superlattice nanowires [3]. We experimentally show that a controlled design of the nanowires’ phononic properties can be decided à la carte by tuning the superlattice period [4].
We also investigated thermal rectification in semiconducting gallium arsenide nanowires with an abrupt change in diameter [5], also called telescopic nanowires. We measured rectification values ranging from 2 to 7% at a range of ambient temperatures, with rectification values increasing for larger temperature gradients. The direction of rectification and its dependence on temperature gradient is con-firmed by ab-initio calculations using the acoustic mismatch model, taking into account the contribution from interfacial thermal resistance.
Finally, Raman thermometry is used to probe the temperature profile in nanostructures upon application of a thermal gradient, enabling the differentiation between different thermal transport regimes.

Narrowband Thermal Phonon Motion Under Atomic-Scale Local Resonance Conditions Albert Beardo[1], Paul Desmarchelier[2], Prajit Rawte[1], Chia-Nien Tsai[1], Konstantinos Termentzidis[2] and Mahmoud Hussein[1]; [1]University of Colorado Boulder, United States; [2]University of Lyon, France

Thermal energy conduction in nanostructures involves various atomic-scale phonon mechanisms with a complex interplay between wavelike and particle behavior. In nanoscale configurations where the feature sizes are smaller or on the order of the phonon mean free path, it is possible to engineer the wavelike behavior to, for example, impede heat conduction—which is favorable for thermoelectric energy conversion. While reducing the dimensionality or introducing obstacles to the heat flow in nanostructures can reduce the thermal conductivity [1], it can also limit the thermoelectric figure of merit ZT. Control of sub-phonon mean free path properties, on the other hand, offers the potential to improve ZT. One approach along this path involves the introduction of resonating substructures to a conventional material, such as silicon, to form a *nanophononic metamaterial* (NPM) [2]. These substructures create standing phonon waves that couple with the in-plane propagating phonons causing a significant modification of the dispersion relation, reduction of the phonon group velocities, creation of mode localizations, and ultimately decreasing the lattice thermal conductivity—all without affecting the electronic properties [3].

In this work, we use narrowband wave-packet excitations to investigate the impact of local resonances on the room temperature phonon transport in NPMs in the form of nanopillared membranes and compare with corresponding nanostructures that do not include local resonances. Our results provide an in-depth analysis elucidation of the underlying phonon localization effects associated with the local resonances. By controlling the wave-packet frequency, we are able to distinguish the role of the local resonances on the thermal energy propagation from other effects that also influence the total lattice thermal conductivity such as phonon-boundary scattering. These observations open exciting new possibilities for experiments to further unlock the potential of atomic-scale local resonances.

4:15 PM EN07.09.03
Unrevealing The Unexpected Large Thermal Boundary Resistance induced by Inelastic Heat Carrier Trapping at GaN-Diamond Interface Bin Xu[1], Shiqian Hu[2], Rulei Guo[1], Fengwen Mu[3] and Junichiro Shiomi[1]; [1]The University of Tokyo, Japan; [2]Yunnan University, China; [3]Chinese Academy of Sciences, China

The rapid advancements in the wide band gap semiconductors like gallium nitride (GaN), silicon carbide (SiC), and gallium oxide (Ga_2O_3), have revolutionized various fields, including electric vehicles, mobile devices, and next-generation telecommunications. With the increase in power and the reduction in device size, the elevating heat density via self-heating makes thermal management a significant issue. One of the most promising solutions is integrating the devices with high thermal conductivity diamond substrates. However, this will introduce additional thermal boundary resistance (TBR) at the semiconductor/diamond interface and impedes heat dissipation.
In such kinds of interfaces, the substantial differences in Debye temperature between diamond and semiconductors like SiC, GaN, or Si would lead to a significant mismatch in phonon modes at the interface, where the traditional acoustic mismatch model (AMM) and diffuse mismatch model (DMM) are no longer applicable as the inelastic phonon scattering is non-negligible. Moreover, this interface is typically composed of amorphous layers when using room temperature bonding techniques, which is essential to avoid thermal damage and thermal-induced strain in the devices. The amorphous layers not only bring large TBR but also increase the complexity of the behavior of heat carriers at the interface because the heat conduction in amorphous materials differs from crystalline materials and involves different heat carriers: the delocalized heat carriers (propagons and diffusons) and localized heat carriers (locons). The mechanism of heat conduction at such an interface is still to be elucidated, posing difficulty in interfacial structure design for reducing TBR for the semiconductor-on-diamond systems.
This study investigated the thermal boundary resistance (TBR) in the GaN/diamond system, a representative case of semiconductor-on-diamond structures. We employed an innovative room-temperature surface-activated bonding (SAB) technique to control the thickness and structure of the interfacial layer precisely. As a result, a multi-layer heterogeneous interfacial layer was generated, bonding the GaN to the diamond substrate. This interface includes a SiO_x-enriched region sandwiched between two diffusive regions as characterized by transmission electron microscope (TEM) and energy dispersive X-ray spectroscopy (EDX) analysis. We then used time-domain thermoreflectance (TDTR) measurement to investigate the TBR. The increase in the total thickness of the interfacial layer leads to a nonlinear variation in TBR. More surprisingly, the increase in the thickness of the interfacial layer provides counterintuitively huge thermal resistance, far exceeding its diffusive limit. To unravel this phenomenon, we performed molecular dynamics (MD) simulations to analyze the density of state (DOS) of heat carriers and their spectral heat conduction at the interfacial, which shows the existence of the local low-frequency states in the SiO_x-enriched region and the resultant conversion of phonon frequencies through an inelastic process in this region. This discovery challenges the traditional belief that interfacial inelastic scattering consistently improves heat conduction by opening up new inelastic pathways, while the pathways were limited in our specific case instead. This phenomenon can be further intensified by increasing the thickness of either the SiO_x-enriched region or the two diffusive regions, ultimately promoting the TBR of the GaN/diamond interface. Leveraging these innovative insights into the physics of interfacial heat conduction, a record low TBR of 8.3 m^2-K/GW among direct bonded GaN/diamond interface was achieved. This breakthrough has significant implications for efficient interfacial heat dissipation

Thermal-Response Functions computed from First Principles with Applications to Two-Dimensional Materials Patrick K. Schelling and Antonio Martinez Margolles; University of Central Florida, United States

Thermal response, or alternately thermal suscpetibility, is a useful way to describe the propagation of energy in response to an external heat pulse. The particular advantage of this approach is that there is no a priori assumption made as to whether transport is ballistic or diffusive. Here I present an approach to compute thermal response functions using input from Density-Functional Theory (DFT) calculations. Calculations are presented for two-dimensional materials at low temperatures. The results demonstrate the propagation of second sound in graphene, with insight into length and timescales where ballistic transport can be expected. Comparison is made to recent experimental results. Finally, the work is discussed in the context of phonon Boltzmann theory in the relaxation time approximation.

4:45 PM EN07.09.05
Effective Interface Engineering for Phonon Manipulation in Multi-Layered Semiconductor Systems Hong Lu; Nanjing University, China

Effective thermal management in functional devices has become more and more important as the demands on device performance keep increasing continuously [1]. Interfaces are crucial to device functionality. However, they could inevitably cause heat accumulation. So, it is essential to be able to manipulate the thermal transport through interface engineering. The semiconductor/semiconductor and metal/semiconductor interfaces are two types of important interfaces in the study of thermal transport, especially in semiconductor devices. The change of interface structure is bound to affect its transport properties. Therefore, it is expected that the regulation of phonon transport behavior can be realized through the design of unique multi-layered structures and utilization of effective interface engineering.

In this work, we have designed a series of multi-layered semiconductor structures and grown them using molecular beam epitaxy (MBE). Owing to the atomic-level control of growth, MBE offers us more freedom to realize high quality multi-layered samples with delicate structural parameters, including single monolayered superlattices. Manipulation of long-wavelength phonons is especially important for these structures as their developments continue to pursue the limit of thermal conductivity. Here, the experimental demonstration of manipulating and probing long-wavelength phonon thermal transport in $Al_xGa_{1-x}As/Al_yGa_{1-y}As$ and InAs/AlAs superlattices will be reported. A direct experimental approach is demonstrated to probe and monitor the contribution of long-wavelength phonons to the thermal conductivity, based on the quasi-ballistic transport principle of phonons. In addition, we have observed evidence of coherent phonon transport up to 500 K. Effective interface manipulation in some artificial metal/semiconductor interfaces will be presented and discussed too. This demonstration holds the very promise to be a universal strategy for manipulating and probing phonon thermal transport in various application scenarios, including microelectronics, thermoelectrics, and optoelectronics.

Towards Scalephobicity: Soft Surface Microengineering for Microfoulant Repellency Julian Schmid[1], Tobias Armstrong[1], Fabian J. Dickhardt[1], SK Rameez Iqbal[1] and Thomas Schutzius[1,2]; [1]ETH Zurich, Switzerland; [2]University of California, Berkeley, United States

Particulate and crystallization fouling, ubiquitous in nature and technology, pose significant challenges to the efficiency of water treatment, desalination, and energy conversion processes. Current solutions rely heavily on active methods like antiscalant additives or mechanical removal, necessitating a shift towards sustainable, passive strategies, such as surfaces with inherent self-cleaning or anti-fouling properties. Existing research has focused on modifying the surface energy and texture of rigid materials for anti-fouling surfaces, overlooking the potential of compliant materials with intrinsic foulant-repellent properties. The intricate interplay of substrate compliance, composition, and surface texture in an aqueous environment and their impact on microfoulant adhesion at the microscale remain largely unexplored. In this study, we employ a micro-scanning fluid dynamic gauge (μ-sFDG) setup to conduct in-situ shear removal experiments for calcium carbonate and polystyrene micro-foulants on compliant anti-fouling surfaces. Guided by adhesion and fluid mechanics theory, and through rational micro-engineering of compliant materials, our findings reveal counterintuitive results: compliant materials surpass their rigid counterparts in anti-fouling performance. This research provides promising insights for the design of compliant interfacial materials capable of achieving high anti-fouling efficacy against particulate and crystallization fouling across various industrial applications including water and energy conversion systems.

5:00 PM EN07.10.02
Thermoelectric Properties of Monolayer HfI_2, an Electride with Electrons on The Interstitial Sites Yi-Ming Zhao, Chun Zhang, Sunmi Shin and Lei Shen; National University of Singapore, Singapore

Two-dimensional (2D) thermoelectric materials are particularly suitable for wearable devices due to the flexible monolayer structure, which will supply power for other carried devices.[1] However, the electrical conductivity (σ) of 2D material is usually lower compared with the bulk counterparts because of a lower electron mobility induced by a higher density of scatterings.[2] Recently, Zhang et el. found that two MoS_2-like structures, ZrI_2 and HfI_2 with long carrier-lattice distance (d_{c-l}) exhibit a high hole mobility up to 4000 $cm^2V^{-1}s^{-1}$.[3] We notice that the ZrI_2-type structures are electrides with excess electrons occupying the interstitial sites increasing the d_{c-l}.[4] Such a unique charge distribution should undergo a weaker perturbation under the displacements of atoms, then the carrier mobility and the σ will be high. The figure of merit (ZT) of ZrI_2 reaches 1.2 at 900K under hole doping,[5] but the relation between the charge distribution and the transport properties is still not clear enough in these electrides.
Here, we investigate the thermoelectric properties of monolayer HfI_2 using first-principles calculations by fully considering the electron-phonon interaction using EPW[6] code. The thermoelectric properties including Seebeck coefficient (S), σ and electron thermal conductivity (κ_e) are calculated by solving the Boltzmann transport equation beyond the constant relaxation time approximation implemented with BoltzTraP2 code.[7] The lattice thermal conductivity (κ_l) is calculated by the ShengBTE code.[8]
We found that the hole doping tends to soften the acoustic phonon modes due to the interstitial distributed charge states and low density of states (DOS) near the valence band maximum (VBM), while the electron doping decreases the phonon relaxation time obviously because of a stronger electron-phonon interaction (EPI) induced by the high DOS near conduction band minimum (CBM). The carrier relaxation time at the VBM is obviously higher than that near the CBM due to the weaker lattice perturbation. The p-type σ is also higher than the n-type one under the same concentration. But the p-type S value is lower than the n-type one due to a lower DOS near VBM. The p-type power factor (PF) is larger than the value of n-type more dominated by σ.
The κ_l of HfI_2 is only 9.1 W/m-K within three-phonon interaction at room temperature lower than that of ZrI_2 (20.3 W/m-K[5]). The phonon relaxation time contributed by the electron-phonon scattering is even smaller than that of the three-phonon scattering at low phonon frequency range. The electrons near CBM will scatter the phonons due to the strong EPI. As a result, the κ_l decrease by 1.5 W/m-K when considering the electron-phonon scattering. The final ZT value reaches 0.86 at 1200K under p-type doping.
In summary, the HfI_2 with anionic electrons near the VBM exhibit a high mobility and σ under hole doping due to the weaker lattice perturbation. Our work reveals the role of interstitial distributed anionic electrons on the electron and phonon transport in the electride system, which gives insights for the further design of high-performance thermoelectric materials.

Near-Field Thermal Radiation across Solid-State Gaps Mackey Long, Hakan Salihoglu and Joshua D. Caldwell; Vanderbilt University, United States

Near-field thermal radiation has attracted great interest due to heat transfer exceeding blackbody radiation by several orders at nanoscale separation gaps. Although extensive research is devoted for understanding of physics, feasibility of near-field based thermal devices with large scales is extremely low owing to the difficulty in controling and sustaining the corresponding separations between heat exchanging materials in macroscales. In this study, we explore near-field radiation through solid-state gaps sandwiched between heat exchanging materials with large lateral dimensions. Our theoretical design employs solid-state thin films as a separating medium. We derive a multimode, nanoscale heat transfer model by incorporating Boltzmann's equation to fluctuational electrodynamics, and compare energy transport capacity of thermal radiation and conduction across the thin film and interfaces at both sides of the film. Our systematic approach enables defining key dimensions and parameters that govern radiation and conduction heat transfer through the solid-state gap. Using quasi steady-state approximation, this study also investigates and compares heat transfer dynamics of radiation and conduction across the film and the interfaces of the film in time domain. This study will shed light on the feasibility of solid-state based near-field thermal radiation and has potential to open a new avenue for possible application of near-field enhancement using macroscale devices.

Inhibiting Crystallization Fouling Using Nano-Micro-Engineered Heat Transfer Surfaces Julian Schmid[1], Tobias Armstrong[1], Niklas Denz[1], Diego R. Piñeiro[1] and Thomas Schutzius[1,2]; [1]ETH Zürich, Switzerland; [2]University of California, Berkeley, United States

Fouling of heat transfer surfaces is a widespread problem in the energy conversion and water treatment industries where thermally insulating deposits lead to significant performance reduction. Crystallization fouling, an important subset of fouling, occurs when water containing retrograde soluble salts like calcium sulfate, makes contact with a heated surface leading to the nucleation and growth of a surface deposit, termed “scale”. However, we currently lack detailed information on the effect of surface texture, composition, and environmental conditions on the onset of scale nucleation, growth, and adhesion which is crucial for comprehending the complexity of scaling since it is a multiphase problem that starts at the nano-micro scale. Furthermore, we lack rational strategies for passively combatting this important problem. Here we show that nano- and micro-textured superhydrophilic surfaces outperform hydrophilic, hydrophobic and superhydrophobic surfaces regarding the delay of nucleation and observable growth of forming deposits in laminar and turbulent conditions. For this purpose, a novel continuous flow experimental setup mimics a cooling section of a heat exchanger and allows to holistically investigate the onset, growth, removal of deposit with its influence on the heat transfer process. Simultaneous visual microscopic *in-situ* observation and heat transfer resistance measurements provide insight into nucleation, growth, and adhesion of nano-micro-engineered substrates. We found that the degassing of dissolved gases on the heated substrate, their affiliation to the substrate, and the subsequent evaporation of water into the new phase is important for scaling in flow conditions. We anticipate that our holistic experimental setup provides profound information on the fundamental aspects of scaling and our nano-micro-engineered surfaces contribute to the development of advanced thermal interface materials that inherently prevent and/or repel scaling to contribute to a sustainable future in energy conversion.

5:00 PM EN07.10.05
Thermal Characterization of Ultra-Thin Suspended Silicon Nitride Platforms Hwijong Lee[1], Ethan Scott[1,2], John N. Nogan[1], Don Bethke[1], Peter A. Sharma[1], Tzu-Ming Lu[1] and C. Thomas Harris[1]; [1]Sandia National Laboratories, United States; [2]University of Virginia, United States

Silicon nitride is widely used in the microfabrication of thermal sensors due to its favorable material properties. While numerous studies have leveraged thin silicon nitride membranes for highly sensitive thermal measurements, there have been limited reports concerning membranes and platforms with thicknesses well below 100 nm. Herein, we report on the development of low-stress, suspended platform devices designed to facilitate the thermal characterization of membranes spanning a thickness range from 120 nm down to less than 10 nm. Depending upon the membrane thickness, we observe a substantial reduction in the thermal conductivity from 2.4 W m^{-1} K^{-1} to 1.2 W m^{-1} K^{-1} near room temperature. These platforms in this low thickness regime can significantly enhance the performance of devices requiring thermal isolation, such as bolometers, calorimeters, and gas sensors.

Super-Resolution Thermometry via Computational Correction to Overcome Diffraction Limit Edward D. Walker and Thomas Beechem; Purdue University, United States

A computational enhancement is proposed, allowing for the realization of optical thermometry at spatial resolutions beyond the diffraction limit. Since the temperature measurement is a weighted average over the beam spot, the spot needs to be much smaller than the region of interest for accurate measurements. If it is too large, averaging creates a smoothing effect, flattening the measured profile. The simple solution is to more tightly focus the beam in order to create a smaller spot size. However, there is a limit to how much a beam of a given wavelength of light can be focused, known as the diffraction limit. For a diffraction limited system, then, there is a minimum temperature profile that is resolvable. To counter this, the relationship between the true profile, flattened profile, and beam shape can be put into the form of an integral equation, whose solution is the "true" profile. This equation takes a form that is similar in structure to problems in fields such as electromagnetism, image processing, and heat conduction. By studying how those fields approach the problem, their solutions can be used to create a set of corrective methods to undo the smoothing effect. Applying these to existing Raman systems allows for accurate measurements at scales up to 5x smaller than currently possible, improving spatial resolution without changing the underlying hardware.

Reversible Polymerization Chemistry for Compact Thermochemical Energy Storage Systems Mayur S. Prabhudesai, Meysiva Veerabagu, Paul V. Braun and Sanjiv Sinha; University of Illinois at Urbana Champaign, United States

Thermal energy storage (TES) can be an effective alternative to electrochemical batteries in applications where the end usage is primarily heat[1]. Within TES, thermochemical energy storage (TCS) based on reversible chemical reactions have been demonstrated for high-temperature applications via gas-gas or solid-gas reactions based on ammonia, sulfuric acid, limestone, etc[2]. However, the development of these inorganic systems is limited by material degradation with cycling, hysteresis losses, and complex equipment and operation. Recent studies have explored organic reactions that operate in a homogeneous phase for low to medium temperature TCS applications[3]. With significant advances in chemically recyclable polymers[4], we investigate here the polymerization/depolymerization chemistry of ε-caprolactone/polycaprolactone as a viable candidate for TCS. This chemistry is advantageous from an applications perspective due to a simple operation as a closed system and a broad range of charge/discharge temperatures suitable for water heating (100 – 200 °C). Preliminary studies confirm high conversion in the forward direction (polymerization) and selective formation of the monomer in the reverse direction. We find the heat of reaction obtained from DSC experiments (~ 140 J/g) to be consistent with prior literature values[5]. We discuss ongoing experiments to enhance the monomer yield during depolymerization and to quantify heat of polymerization (storage capacity) using a laboratory-scale reactor. This work advances the usage of organic compounds for TES applications and could form the basis for further identification of similar chemistries.

A Personal Cooling Garment with Flexible Thermoelectric Devices and Heat Sinks Ethan Sun[1,2], Tianshi Feng[2] and Renkun Chen[2]; [1]The Bishop’s

School, United States; [2]University of California, San Diego, United States

Global warming is causing more intense, more frequent, and longer periods of extreme heat events, which have caused numerous diseases and, in some cases, fatalities, among patients, the elderly, and outdoor workers such as those in the agriculture and construction sectors and firefighters. A lightweight personal cooling garment could be a game-changing solution to protect at-risk population and workers. However, today's personal cooling garments are not adequate as they are often too bulky and heavy, have limited cooling duration, and have no or limited temperature controllability. Hence, there is a strong need for a personal cooling garment with effective cooling, adjustable temperature, lightweight, is flexible & wearable, consumes less power (high coefficient of performance), and has low cost. Here we present our work on a personal cooling garment with flexible thermoelectric devices and heat sinks. This work leverages our earlier concept of developing flexible thermoelectric devices using high-performance rigid thermoelectric pillars. Here, we integrated individual thermoelectric devices into a flexible garment with the hot side cooled by flexible heat sinks. The garment is optimized with a finite element model for minimal weight. The performance of the garment under various heat flux levels and environmental temperatures was characterized. The results show that the garment can deliver high-flux cooling in a hot environment with high coefficient of performance (COP > 1). The technoeconomics and potential applications of this garment are also discussed.

5:00 PM EN07.10.09
Identifying Molecular Scale Interactions of Nucleating Agents with Salt Hydrates for Thermal Energy Storage Applications Mayur S. Prabhudesai, Sung Bum Kang, Youngmun Lee, Daniel Hsieh, Jay M. Taylor, Paul V. Braun and Sanjiv Sinha; University of Illinois at Urbana Champaign, United States

Latent heat based thermal energy storage is of interest as a method to mitigate and time-shift thermal load peaks and hence reduce energy demands for heating and cooling buildings. Notably, Glauber's salt (GS) presents a good choice as a phase change material (PCM) for building applications because it has a melting point near room temperature (i.e., 32.4 °C), a large heat of fusion and energy density, and is low cost (~ $100/ton). However, there are several known limitations to using GS as a PCM, such as incongruent melting, high degree of supercooling, and formation of other hydration states, which renders GS unsuitable for practical use. Inorganic crystals acting as nucleating agents can avoid some of these issues with GS [1]. Understanding nucleation behavior through typical calorimetry experiments offers limited insight into the molecular-scale mechanisms. Here, we report isothermal titration calorimetry [2] to investigate the interactions between sodium sulfate salt and an organic nucleating agent - glycine. Our experiments provide qualitative and quantitative understanding of how glycine interacts with sodium sulfate across various temperatures. The findings offer insights into the nucleation onset temperature (24°C) and underscore the pivotal role of glycine's zwitterionic structure in facilitating nucleation. This preliminary work provides a foundation for subsequent exploration of nucleating agents that would be incorporated in different salt hydrate systems.

Prediction and Characterization of Barocaloric Effects in Plastic Crystals Using Molecular Dynamics Carlos Escorihuela Sayalero, Luis Carlos Pardo Soto, Pol Lloveras, Josep Lluís Tamarit and Claudio Cazorla; Universitat Politècnica de Catalunya, Spain

The energetic challenges of the present times demand the renewal of the technologies that harm the global environment. Amongst them, the scientific efforts towards developing cooling technologies based on the barocaloric effect (BC) present as a promising alternative to the conventional use of greenhouse-effect gases. Materials displaying BC present typically a large entropy change across a first order solid to solid phase transition. Such large entropy difference is usually related to order-disorder phase transitions, as is the case in some plastic crystals such as [CH3NH3]PbI3. There is however a lack of understanding of the atomistic mechanisms driving this effect, which is necessary in order to move towards a feasible solid-state cooling technology. In this work we revise the atomistic origin of the entropy in disordered systems, and present a novel general methodology to calculate the BC estimators by using molecular dynamics NpT simulations using any source of atomistic potential available to the user. We present aswell the application of this method to the analysis of [CH3NH3]PbI3 and LiCB11H12 barocaloric potential.

Thermal Transport in Quasi-1D Van der Waals Crystal Nanowires Zhiliang Pan, Lin Yang, Qian Zhang and Deyu Li; Vanderbilt University, United States

van der Waals (vdW) crystals represent a class of interesting materials with extraordinary bonding anisotropy. The break of symmetry induces rich physics and exotic transport phenomena. So far, extensive efforts have been made to explore the thermal properties of a plethora of two-dimensional (2D) vdW crystals. However, efforts on one-dimensional (1D) vdW materials remain largely in theory except some experimental work on single-walled carbon or boron nitride nanotubes.
Here we report on systematic studies of the thermal/mechanical properties of a group of quasi-1D vdW crystal nanowires composed of covalently bonded molecular chains assembled together via weak vdW interchain interactions. In the study of $Ta_2Pd_3Se_8$ nanowires, the thermal conductivity increases with the wire diameter up to 110 nm despite the weak interchain interaction. Measurements of the thermal conductivity for different sample lengths suggest a partial ballistic phonon transport over 13 µm at room temperature, which is induced by the propagation of phonons along the molecular chains. One interesting property of quasi-1D vdW crystals is charge density wave (CDW) phase transition, which can alter the free electron density without introducing dopants. Taking advantage of the CDW phase transition in $NbSe_3$ nanowires, we have observed distinct signatures of the electron-phonon (e-ph) interactions on the lattice thermal conductivity of $NbSe_3$ nanowires. With the development of CDWs, the carrier concentration reduces dramatically, which suppresses the e-ph interaction strength and results in an uprise in the lattice thermal conductivity. Furthermore, a tunable e-ph interaction is achieved through modulating the electric field along the chain. Above the threshold electric field strength, the condensed free electrons due to CDW can be depinned, leading to a higher electron thermal conductivity. Counterintuitively, the total thermal conductivity upon depinning is suppressed, which is due to the lower lattice thermal conductivity as a result of the enhanced e-ph scattering. The most exotic feature is found in ultrathin $NbSe_3$ nanowires where the thermal conductivity increases with the wire length following a 1/3 power law up to >42.5 µm, a signature of superdiffusive transport of 1D phonons. It is shown that this superdiffusive transport is due to excitation of 1D phonons as a result of the enhanced along-chain Young's modulus when the nanowire diameter becomes smaller than 26 nm. Our results show that as the wire diameter reduces from 26 nm to 6.8 nm, the Young's modulus increases by more than 5 times, which leads to a thermal conductivity enhancement by about 25 folds. The enhanced Young's modulus allows for excitation of high frequency 1D phonons along the molecular chains, which are responsible for the superdiffusive phonon transport in ultra-thin $NbSe_3$ nanowires. These findings disclose interesting thermal transport phenomena in quasi-1D vdW crystal nanowires, and the unique thermal properties could find important applications in thermal engineering.

5:00 PM EN07.10.12
Anharmonic Effects in Heat Capacity of Solids Jaeyun Moon; Cornell University, United States

Heat capacity is a measure of how much energy heat carriers carry; therefore, it directly impacts performance and efficiency of various energy applications such as thermal storage and heat exchangers. For dielectric solids, heat capacity is most typically described by a purely harmonic oscillator model. This coupled with how these weakly interact anharmonically determine lattice thermal conductivity in various calculation schemes. In this work, we explicitly characterize individual mode contributions to heat capacity in some simple crystals such as argon and silicon and find that in contrast to common assumptions based on harmonic oscillators, each mode is strongly anharmonic especially at high temperatures, leading to the breakdown of the equipartition theorem. We discuss implications of our findings in the context of thermal transport in solids.

5:00 PM EN07.10.13
Predicting Phonon Transport in Disordered Alloys from a Highly Accurate Machine Learning Interatomic Potential Hsin Lin[1], Hao-Jen You[1], Liang-Zi Yao[1], Yi-Ting Chiang[1], Yen-Fu Liu[2], Tzen Ong[1], Yueh-Ting Yao[2] and Tay-Rong Chang[2]; [1]Academia Sinica, Taiwan; [2]National Cheng Kung University, Taiwan

The II_2IV family of materials, such as Mg_2Si, Mg_2Sn, Sr_2Si, and Sr_2Ge, among others, are highly regarded as promising high-performance thermoelectric materials. In our previous research, we calculated the maximum figure of merit ZT for the promising II-IV family thermoelectric compounds Sr_2Si and Sr_2Ge, yielding values of 1.15 and 1.44 at 900 K through first-principles calculations. To improve thermoelectric performance, the common practice involves alloying to reduce lattice thermal conductivity and enhance the Seebeck coefficient. Nevertheless, determining the optimal alloy ratios through first-principles calculations can be quite challenging because disordered effects require a large supercell in the computations. Here, we introduce a highly accurate machine learning interatomic potential (MLIP) for $Sr_2Si_{1-x}Ge_x$ disordered alloys. This MLIP is created through a machine learning technique trained on first-principles density functional theory (DFT) data, and it attains accuracy levels comparable to those achieved with DFT. This approach empowers us to carry out efficient molecular dynamics simulations for entire alloy concentration $0 \leq x \leq 1$ in $Sr_2Si_{1-x}Ge_x$ and make accurate thermal property predictions. Our work provides a solution to explore compositions that offer the most potential for high-performance thermoelectric disordered alloys while assessing the contributions of phonon modes to phonon transport.

5:00 PM EN07.10.14
Thermal Transport in 2D Materials Using Tersoff Interatomic Potentials Adil Muhammed[1,2], Subramanian Sankaranarayanan[1,2], Aditya Koneru[1,2], Kiran Sasikumar[3] and Partha Sarathi Dutta[1,2]; [1]University of Illinois Chicago, United States; [2]Argonne National Laboratory, United States; [3]Avant-Garde Materials Simulation, Germany

Understanding thermal behavior in two dimensional (2D) materials is important for advancing nanoelectronics and thermoelectric applications, as these materials can exhibit exceptionally tunable thermal conductivities. Especially, emerging 2D materials like Silicene, Arsenene, Bismuthene and Antimonene are necessary as they find applications in a wide range of electronic and thermal devices. In this work we perform molecular dynamic simulations to understand thermal transport of these 2D nanomaterials and their corresponding nanotubes using equilibrium molecular dynamics with the Green-Kubo formalism. We utilize our in-house Tersoff models optimized against different polymorphs across local and global properties. Also, we present the impact of understanding the phonon dispersion predictions made by these models on thermal conductivities. This can greatly aid in optimizing better force-fields which in turn can create accurate surrogate models for inverse design of these thermal materials.

5:00 PM EN07.10.15
Probe Beam Deflection Technique with Liquid Immersion for Rapid Measurement of Thermal Conductance Jinchi Sun and David Cahill; University of Illinois at Urbana-Champaign, United States

Time-domain thermoreflectance (TDTR) and frequency-domain thermoreflectance (FDTR) are well-established techniques for spatially resolved measurements of thermal conductivity and thermal boundary conductance. In these methods, a metal coating serves as a thermometer, generating a thermoreflectance signal. To enhance the signal-to-noise ratio, a frequency-domain probe beam deflection (FD-PBD) was developed, which utilizes the probe beam deflection caused by thermal expansion. FD-PBD is only sensitive to in-plane thermal diffusivity. To introduce sensitivity to through-plane thermal conductance, FD-PBD is adapted by immersing the Al-coated sample in a dielectric liquid. The thermometer now becomes the probe beam deflection which is due to the refractive index gradient in the liquid resulting from temperature changes. This modified approach, named as liquid immersion probe beam deflection (LI-PBD), allows us to measure the thermal conductivity of thin films, thermal boundary conductance, and the thermal conductivity of bulk materials, all without the need for prior knowledge of heat capacities. The measured values agree with reference values within 10%. Rapid mapping of thermal boundary conductance is demonstrated, with the data acquisition time per point required to achieve a noise-induced uncertainty of 1% significantly reduced to 3 milliseconds. Both spatial resolution and maximum probing depth can be adjusted by varying the radius of the focused laser beams. This technique facilitates imaging of defects buried at different depth below the surface.

5:00 PM EN07.10.16
The Role of Deposition Temperature on The In-Plane Thermal Conductivity of Aluminum Scandium Alloys Daniel M. Hirt, Md. Rafiqul Islam, Md Shafkat Bin Hoque, Sara Makarem and Patrick E. Hopkins; University of Virginia, United States

The advancement of modern electronic devices has been limited by a thermal engineering problem existing at the nanoscale: how to reduce the thermal load on critical components of a device. Hillocks, which form due to differences in thermal expansion between a film and its substrate, are a significant limitation to integrated circuit fabrication. Hillocks can cause problems in integrated circuits such as dielectric cracks and interconnection shortages that result in unreliable devices. Aluminum (Al), the current choice for electrical traces in integrated devices due to its low resistivity, is particularly susceptible to hillock formation when heated. Recent advances have shown that alloying scandium with aluminum can help mitigate this issue. Furthermore, the aluminum scandium alloy (Al_3Sc) also has a higher melting point than Al thus making it a potential alternative to Al for high temperature applications. Combining these properties with its low electrical resistivity makes Al_3Sc an excellent choice for the next generation of electrical interconnects. However, a detailed study into the thermal properties of Al_3Sc alloy as well as the scattering mechanisms that contribute to its thermal conductivity is still missing in literature.
In this work we investigate the in-plane thermal conductivity and electron-phonon coupling factor of aluminum scandium alloys deposited at different temperatures with time-domain thermoreflectance (TDTR). For these experiments, we use a $Al_{0.8}Sc_{0.2}$ ($Al_{0.8}Sc_{0.2}$-SiO_2-Si) structure deposited at various temperatures. Our measurements reveal that higher deposition temperatures yields higher in-plane thermal conductivity in aluminum scandium alloys. We attribute this to an increased formation of Al_3Sc crystalline regions for films that were deposited at higher temperatures. In order to investigate the role of electron-phonon scattering on the measured drop in the in-plane thermal conductivity, we performed our TDTR measurements with an infrared probe laser. By measuring the electron-phonon coupling constant at different deposition temperatures we show that the electron-phonon coupling constant remains relatively constant with deposition temperature. This suggests that a reduction in electron-boundary scattering due to increased formation of Al_3Sc is the primary reason for enhanced thermal conductivity at higher deposition temperatures. Our measurements provide insight into the role of different scattering mechanisms on the thermal conductivity of intermetallic alloys.

5:00 PM EN07.10.17
Phonon Thermal Transport in Semiconductors Studied Using a Neural Network Assisted Solution of The Peierls-Boltzmann Equation Navaneetha Krishnan Ravichandran; Indian Institute of Science, India

Unusual thermal transport phenomena such as the hydrodynamic and Poiseuille phonon flow arise out of strong coupling among phonons in certain solid-state crystalline materials, and find applications in thermal cloaking and shielding of semiconductor devices and in the development of low thermal noise detectors. The linearized Peierls-Boltzmann equations (LPBE), which form a set of multi-dimensional and coupled partial differential equations, govern the coupled dynamics, transport and equilibriation of phonons in these systems. Hence, solving the LPBE is a crucial step towards discovering new materials that display these unusual, yet technologically important phenomena.

However, predictive solutions of the LPBE including lowest-order interactions among three phonons and higher-order interactions among four phonons with *ab initio* inputs from density functional theory, which will serve as search tools for new materials, have been computationally intractable until recently [1, 2]. Even considering these recent advances, the computational cost due to the high dimensionality of the LPBE, large number of phonon polarization for the materials with complex crystal geometries and the need to resolve highly localized, temporally evolving interactions among phonons makes these conventional methods unsuitable for the rapid search of new materials that show exceptional hydrodynamic phonon transport.

To overcome this problem, here we develop a neural network scheme to solve the steady-state and the transient LPBE, which enables rapid convergence of the steady-state solution of the LPBE and allows for computationally efficient high temporal resolution of localized interactions among phonons under transient transport conditions, which is particularly important to search for materials with strongly hydrodynamic phonon flow. We show that, for materials with complex crystal structures beyond the cubic geometry such as bulk MoS_2, graphite, w-GaN and hBN, where hydrodynamic transport is possible at cryogenic conditions, the neural network scheme significantly outperforms the conventional iterative solution of the LPBE under both steady-state and transient conditions. Our findings highlight the computational advantages of adopting this new neural network-based first principles solver for the LPBE, which can have significant impact in the research areas of developing robust, efficient computational tools for materials discovery.

Molecular Aspect Ratio Effect on Axial Thermal Transport in Solution-Spun Carbon Nanotube Fibers Yingru Song[1], Michelle D. Chaves[1], Ivan R. Siqueira[1], Ognyan Stefanov[1], Natsumi Komatsu[2], Junichiro Kono[1], Matteo Pasquali[1] and Geoffrey Wehmeyer[1]; [1]Rice University, United States; [2]University of California, Los Angeles, United States

Neat, densely packed, and highly aligned carbon nanotube fibers (CNTF) have appealing room-temperature axial thermal conductivity () and thermal diffusivity (for applications in lightweight axial heat spreading or flexible thermal connections. Although increasing the molecular aspect ratio (i.e., ratio of nanotube length to nanotube diameter) of the constituent single-wall and few-wall carbon nanotubes (CNTs) is expected to improve and by reducing the number of interfaces along the axial direction per unit length, no prior work has quantified the molecular aspect ratio effect on thermal transport for solution-spun CNTF. Here, we perform self-heated steady-state and three-omega thermal measurements at room temperature on suspended CNTF in vacuum. The CNT molecular aspect ratios range from 960 to 5600, as quantified by rheological measurements of liquid crystalline CNT solutions. The thermal measurement results show that increases from to with increasing . The axial electrical conductivity also increases from to with increasing , and the Wiedemann–Franz law predicts the electronic contribution to is for the highest sample. CNTF made with varying volume fraction of constituent high- and low- CNTs generally fall within typical macroscopic rule-of-mixtures bounds for and . The thermal diffusivity scales with , leading to a sample-averaged volumetric heat capacity of 1.5±0.1 . Thus, this work shows that increasing the molecular aspect ratio enhances and of solution-spun CNTF, motivating further investigation into thermal transport mechanisms and applications of carbon nanotube fibers.

5:00 PM EN07.10.19
Bioengineering a Reversible Thermal Conductivity Switch in Tandem Repeat Proteins Emma Tiernan[1], John Tomko[1], Benjamin Allen[2], Melik Demirel[3] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Tandem Repeat Technologies, Inc, United States; [3]The Pennsylvania State University, United States

The reversible regulation of heat transport within a material provides the user the ability to control its temperature as well as that of its surroundings. To achieve this nanoscale regulation, a material must be able to switch between thermally conductive and insulative states. In recent years it has been shown that thin films of certain tandem repeat proteins can achieve this thermal switch by simply hydrating and dehydrating the film. One material that is able to serve as a thermal switch is a synthetic bio-polymer whose sequence is inspired by those found in squid ring teeth (SRT). These SRT bio-polymers consist of repeating amorphous and crystalline domains which rely on hydrogen bonding and other intermolecular forces to retain their folded conformation. The addition and removal of water to these films will enhance or disrupt the intermolecular forces, thus encouraging or inhibiting the transport of heat.

In these experiments, we used time-domain thermoreflectance (TDTR) to monitor the thermal conductivity switch of SRT thin films under varying hydrating conditions. TDTR is an optical pump-probe technique for measuring thermal conductivity of microscale material systems, where a low power “probe” beam monitors the change in reflectivity of a metal transducer on the sample surface in response to a modulated heating “pump” laser. By applying an analytical solution to the heat conduction equation, we calculate thermal conductivity and other thermal properties of the material. We show that by modifying the composition of the hydrating solution, we are able to obtain a thermal conductivity switch ratio of four between ambient and hydrated states.

Anti-Environmental Aging Passive Daytime Radiative Cooling Paint Jianing Song and Xu Deng; University of Electronic Science and Technology of China, China

Passive daytime radiative cooling technology presents a sustainable solution for combating global warming and extreme weather, with great potential for diverse applications. The key characteristics of this cooling technology are the ability to reflect most sunlight and radiate heat through the atmospheric transparency window. However, the required high solar reflectance is easily affected by environmental aging, making the cooling ineffective. We demonstrate a facile strategy to use titanium dioxide nanoparticles, with UV resistance, forming hierarchical porous morphology via evaporation-driven assembly, which guarantees a balanced anti-soiling and high solar reflectance, rendering anti-aging cooling paint (AACP) based coatings. We challenged

the AACP coatings against simulated 3 years of natural soiling and 1 year of natural sunshine, and found that the solar reflectance only declined by 0.4% and 0.5% compared with the un-aged ones, barely affecting the cooling performance. Our AACP is scalable and can be spray coated on desired outdoor architecture and container, presenting durable SDRC, promising for real-world applications.

Physics-Informed Neural Networks for Solving Phonon Boltzmann Transport Equation Tengfei Luo, Jiahang Zhou and Ruiyang Li; University of Notre Dame, United States

The phonon Boltzmann transport equation (pBTE) has been proven to be capable of precisely predicting heat conduction in sub-micron electronic devices. However, numerically solving pBTE is extremely computationally costly due to its high dimensionality, especially when phonon dispersion and time evolution are considered. In this study, we use physics-informed neural networks (PINNs) to solve pBTE for multiscale non-equilibrium thermal transport problems both efficiently and precisely. In particular, a PINN framework is devised to predict phonon energy distribution by minimizing the residuals of governing equations, boundary conditions, and initial conditions without the need for any labeled training data. With phonon energy distribution predicted by the PINN, temperature and heat flux can be obtained thereby. In addition, geometric parameters, such as characteristic length scale, are also considered as a part of the input to PINN, which makes our model capable of predicting heat distribution in different length scales. Furthermore, 1D to 3D heat conduction problems are studied under our PINN framework, and the results show excellent agreement with numerical and FEM solutions. Moreover, our PINN framework has proved to be far more efficient compared to existing pBTE numerical solvers. With superiorly high efficiency and accuracy, the proposed method shows great promise for practical applications, such as thermal design and thermal management of microelectronic devices.
Besides pBTE, we have also extended the applicability of the PINN framework for modeling coupled electron-phonon (e-ph) transport. *e-ph* coupling and transport are ubiquitous in modern electronic devices. The coupled electron and phonon Boltzmann transport equations (BTEs) hold great potential for the simulation of thermal transport in metal and semiconductor systems. However, solving the BTEs is often computationally challenging due to their high dimensional complexity and widespan heat carrier properties, hindering large-scale thermal modeling at the device level. In this work, we present a PINN framework for solving the coupled electron and phonon BTEs. Instead of relying on labeled data, the proposed framework directly learns the spatiotemporal solutions (i.e., the electron and phonon distribution functions) within a parameterized space by enforcing physical laws. The efficacy of this framework is demonstrated through its ability to accurately resolve temperature profiles in low-dimensional thermal transport problems and visualize the ultrafast electron and phonon dynamics in laser heating experiments on thin metal films. The results indicate that our approach can accurately describe non-equilibrium *e-ph* energy transfer with improved efficiency, opening new avenues for the predictive design and optimization of micro- and nanostructures.

Screening Ultralow Thermal Conductivity from 150,000 Crystals by Sub-Trillion-Scale Atomic Data Integrated Deep Learning Approach Ming Hu; University of South Carolina, United States

Existing machine learning potentials for predicting phonon properties of crystals are limited to either small amount of training data or a material-to-material basis, primarily due to the exponential scaling of model parameters with the number of atomic species or elements. This renders high-throughput infeasible when facing large-scale new materials. Unlike previous machine learning models with inherently limited training on small data and global properties, we develop Elemental Spatial Density Neural Network Force Field (Elemental-SDNNFF) with abundant atomic level environments as training data. Benefiting from this innovation, we integrate ~50 million atomic data to train a single deep neural network without increased expensive ab initio simulations. The effectiveness and precision of the Elemental-SDNNFF approach is demonstrated on a set of 150,000 inorganic crystals spanning 63 elements in the periodic table by prediction of complete phonon properties. Our algorithm achieved a competitive force root mean square error of about 40 meV/Å and a speed-up of 3 – 4 orders of magnitude in comparison to first principles. Self-improvement schemes such as active learning and data augmentation techniques are also incorporated allowing human-free refinement of the force accuracy on arbitrary combinations of chemistries. Deep insight into the ultralow lattice thermal conductivity (<1 W/mK) of predicted structures are gained by p-d orbital hybridization analysis and charting the thermal conductivity data in the bonding-antibonding map, which offers a quick approach for future screening of crystals with strong intrinsic phonon anharmonicity. Our model also quantitatively reveals the correlation between off-diagonal coherence and diagonal populations and identifies the distinct crossover from particle-like to wave-like heat conduction. Our algorithm is promising for accelerating discovery of novel phononic crystals for emerging applications, such as heat dissipation in electronics, thermoelectrics, and coherent phonons for quantum information technology.

Advancing Thermal Management in Buildings Globally: Machine Learning-Optimized Dynamic Window Materials Yuan Gao, Jacob Jonsson, Charlie Curcija, Simon Vidanovic and Tianzhen Hong; Lawrence Berkeley National Laboratory, United States

Dynamic window materials represent a significant advancement in energy-efficient building technology, offering a promising approach to intelligent thermal management and energy conversion in architectural applications. Leading areas of interest in dynamic window research include hydrogels, passive radiative cooling materials, dynamic devices based on reversible metal electrodeposition. These cutting-edge materials are capable of dynamically altering their optical and thermal properties in response to external environmental variations, thereby efficiently managing light and heat transfer within buildings. However, dynamic window materials face significant challenges in their development and application. First and foremost, these materials are often optimized based on specific weather conditions rather than a comprehensive, global spectrum. Achieving continuous optimization on a global scale proves to be difficult due to the immense volume of calculations required. This lack of universal optimization may limit their efficiency across diverse climate zones. Furthermore, there is a noticeable gap in the presence of robust indicators to quantify the dynamic performance of these materials. This void in performance metrics poses a challenge, as without clear quantification, it becomes difficult to determine the true value of these windows, especially since their dynamic features may be superfluous in certain climatic conditions.
To address these issues, we proposed novel indicators to evaluate the necessity level of using dynamic windows in buildings for different climates. We use thermochromic (TC) materials as examples to demonstrate this concept for passive dynamic windows. Through an unprecedented global-scale analysis, we executed more than 2.8 million simulations across over two thousand global locations covering most of the Köppen climate classifications in the world. A typical commercial office space, which is adapted from Department of Energy's prototype building model, is used for EnergyPlus simulation in this study. Beyond typical office space, whole commercial and residential buildings are also used for analysis. World heatmaps of indicators for dynamic TC windows

have been obtained by artificial neural networks (ANNs) trained by data from various conditions: differing material properties, window configurations, building and environmental circumstances. The ANN inputs include geographic (latitude) and weather (solar radiation and air temperature) data that can be extracted from weather files and is publicly available as the information in a world-map format. The good linear regressions between target and prediction indicate that the performance indicators can be well predicted from the inputs through ANNs, which are optimized by a hyperparameter tuning process. The heatmaps of indicators obtained from ANNs reveal that TC windows with optimal transition temperatures lack dynamism in most of low-latitude tropical regions, functioning similarly to static windows in terms of energy savings. Seasonal dynamics of TC windows appear more important for energy saving compared with daily fluctuations. Surprisingly, optimal transition temperatures correlate more with clear-state solar transmittance than with dark-state. This insight is unprecedented in existing literature.
To assist researchers in optimizing and evaluating TC materials and windows, we provide an open-source Python tool (https://github.com/LBNL-ETA/PyDynamicWindow, a private repository, will be published soon) to quickly obtain a world heatmap of desired indices or optimal properties within seconds by simply inputting the fixed material properties. Besides thermochromic, other dynamic window materials will also be included in this Python tool in the future. With this powerful tool, researchers can identify climate conditions for dynamic windows and improve their materials and products for target climates.

10:30 AM *EN07.12.01
Atoms to Devices: Predicting Thermal Properties of Materials in Technological Applications Sanghamitra Neogi; University of Colorado Boulder, United States

Recent advances of atomistic modeling techniques have shown remarkable accuracy while predicting heat transport mechanisms in isolated nanoscale systems, such as thin films with confining surfaces, single solid-solid interfaces between materials with different degrees of crystallinity or disorder. Heat is mostly carried by phonons in semiconductors and insulators. When the system size becomes comparable to the characteristic lengths of phonons, heat conduction is affected by phonon confinement and enhancement of scattering due to boundaries, interfaces, and various defects. Phonon confinement results in localization of modes in spatial regions. The effect of scattering mechanisms on phonon transport properties could also be highly varied. The thermal transport properties of nanoscale systems that include multiple confining surfaces, interfaces, and materials with different degrees of crystallinity or disorder, is far from understood. The computational costs of atomistic approaches prohibit us to explore the complete structural parameter space of large systems, that influence phonon transport. The state-of-the-art (SoA) deeply scaled sub-10 nanometers transistors are heterogeneous structures that include nm-scale crystalline semiconductors, disordered dielectric materials and metals, within confining interfaces. The confined geometry results in a net increase of the power density within the structures. The associated self-heating accelerates the defect generation mechanisms leading to decline of performance and reliability issues. The SoA thermal models of microelectronic circuits utilize continuum level models to predict the temperature distribution in the structures, even after 40+ years of being declared outdated. The models also incorporate input from non-continuum models that are better suited to describe the physics at smaller length scales. However, the transistor-level thermal properties are often approximated from the bulk thermal properties or computed using effective models. The effective models include several parameters that need to be calibrated using measurement data. The calibrated parameters may not even accurately represent behavior in dynamic operating conditions. The heat transfer in nm-scale systems can be drastically different from their bulk counterparts. The effective models does not include these details and as a result, cannot explain thermal bottlenecks or runaways or reveal any mitigation strategies. A predictive thermal model must consider the effects of confinement to accurately predict temperatures and identify thermal bottlenecks. In the past decades, algorithmic improvements, and dramatic increase of computing power, have enabled rigorous techniques such as molecular dynamics (MD) simulations to accurately model heat transport in finite systems, with disordered components and interfaces. MD simulations implicitly include the full dynamics of anharmonic interactions and do not make any assumptions about scattering mechanisms. In this talk, I will discuss how we use atomistic modeling approaches combined with machine learning methods to predict thermal properties of sub-10-nm confined geometry field effect transistors and other complex devices.

11:00 AM EN07.12.02
Monte Carlo - Finite Element Mixed Model for Heat Transport on Electronic Devices at The 20 nm Scale F. Xavier Alvarez, Jordi Tur and Albert Beardo Ricol; Universitat Autonoma de Barcelona, Spain

Simulation of the thermal evolution of actual electronic devices is a very challenging topic. Heat transport at the nanoscale does not behave as in the macroscale [1-2]. This is a problem for engineers, as they cannot predict the thermal response of their devices with accuracy.

In the last years, the Kinetic Collective Model (KCM) has been used to develop a finite element tool to describe the thermal evolution of electronic devices with great accuracy using the Guyer and Krumhansl hydrodynamic equation. The results obtained from this approach fit extraodinarily to experiment with characteristic scales up to 400 nm using only ab initio parameters [1-2], but for smaller devices, effective values for the parameters are required. In that situations, some corrections are required in order to predict the experiments.

We present the Higher Order Perturbation (HOPE) an improvement of the KCM-hydrodynamic approach [4-5]. This new method allows to obtain a full predictive finite element model for thermal transport at the 20nm scale. The model is obtained from the split of the Boltzmann Transport Equation (BTE) in two terms, a first one that describes the hydrodynamic behavior and a second one with the residual terms that describes the evolution of the perturbations of higher order. From the solution of the residual term using a Monte Carlo approach we derive a boundary correction term that modifies the hydrodynamic boundary conditions. With this correction, the applicability of our finite element tool is significantly improved. We compare the results obtained from our simulations with experimental data of devices in the 200-20 nm range.

Study of Interfacial Thermal Resistance of Heterostructures Using Machine Learning (ML)-Molecular Dynamics Tianli Feng; University of Utah, United States

Diamond, as an ultra-wide bandgap semiconductor, holds significant potential in many cutting-edge applications from electronics, nanotechnology, biosensors and quantum information processing, owing to its ultra-high thermal conductivity and mobility. The interfacial thermal conductance between diamond and metals is crucial for the thermal management of diamond-based electronic devices and determines the maximum working temperature. However, current knowledge about the metal/diamond thermal interfacial transport is still very limited. There is no reliable interatomic potential between metals and diamond. In this work, we train machine learning interatomic potentials at the interface based on density functional theory (DFT) calculations. The accuracy of the potential is validated against DFT calculations. Using the potentials, we conduct MD simulations and obtain the interfacial thermal conductance. Different surface terminations of diamond have been studied. The results from this research should have significant contribution to improved understanding of interfacial thermal properties, which is key to developing new diamond-based electronics devices.

11:30 AM EN07.12.04
Active Learning Exploration of Thermally Conductive Polymers Under Strain Renzheng Zhang, Jiaxin Xu, Hanfeng Zhang and Tengfei Luo; University of Notre Dame, United States

Finding amorphous polymers with higher thermal conductivity (TC) is technologically important, as they are ubiquitous in a wide range of applications where heat transfer is crucial. While TC is generally low in in amorphous polymers, it can be enhanced by subjecting them to strain since it facilitates the alignment of polymer chains. However, using the conventional Edisonian approach, the discovery of polymers that may have high TC after strain can be time-consuming and lack guarantee of success. In recent years, machine learning approaches have shown promise in the prediction of polymer properties with high accuracy and efficiency. In this work, we employ an active learning scheme to speed up the discovery of amorphous polymers with high TC under strain. Polymers under strain were simulated using molecular dynamics (MD), and their TCs were calculated using the non-equilibrium MD method. A Gaussian Process Regression (GPR) model is then trained using these data. The GPR is used to screen the PoLyInfo database, and the predicted mean TC and uncertainty are used towards an acquisition function to recommend new polymers. The TC results of these selected polymers are then labeled using MD simulations and the obtained data are incorporated into the training set, initiating a new iteration of the active learning cycle. Over a few cycles, we identified more strained polymers with significantly higher TC than the original dataset, and the results offer valuable insights into the structural characteristics that contribute to enhanced energy conduction from a physical perspective.

11:45 AM EN07.12.05
Phonon Diffraction and Interference Konstantinos Termentzidis[1], Paul Desmarchelier[2], Efstatios Nikidis[3], Yoshiaki Nakamura[4], Anne Tanguy[2] and Joseph Kioseoglou[3]; [1]CNRS, France; [2]Université de Lyon, France; [3]Aristotle University of Thessaloniki, Greece; [4]University of Osaka, Japan

We have observed phonons diffraction and interference patterns at the atomic scale, using molecular dynamics simulations in systems containing crystalline silicon and nanometric obstacles as voids or amorphous-inclusions. The diffraction patterns caused by these nano-architectured hybrid systems of the same order as the phonon wavelengths are similar to the ones predicted by a simple Fresnel- Kirchhoff integral. These findings give evidence of the wave nature of phonons, can help to a better comprehension of the interaction of phonons with nanoobjects and at long term can be useful for intelligent thermal management and phonon frequency filtering at the nanoscale.

SESSION EN07.13: Phonon Engineering

1:30 PM *EN07.13.01
Thermal Conductivity and Elastic Modulus in Two-Dimensional Hybrid Metal Halide Perovskites: From a Molecular Engineering Perspective Ankit Negi[1], Liang Yan[2], Cong Yang[1], Yeonju Yu[3], Subhrangsu Mukherjee[1], Andrew Comstock[1], Ziqi Wang[1], Dali Sun[1], Harald Ade[1], Qing Tu[3], Wei You[2] and Jun Liu[1]; [1]North Carolina State University, United States; [2]University of North Carolina at Chapel Hill, United States; [3]Texas A&M University, United States

Device-level implementation of soft materials demands a comprehensive understanding of their thermal conductivity and elastic modulus to mitigate thermo-mechanical challenges and ensure long-term stability. Thermal conductivity and elastic modulus are usually positively correlated in soft materials, such as amorphous macromolecules, which poses a challenge to discover materials that are either soft and thermally conductive or hard and thermally insulative. Here, we show an anomalous correlation of thermal conductivity and elastic modulus in two-dimensional (2D) hybrid organic-inorganic perovskites (HOIP) by engineering the molecular interaction between organic cations. When replacing the organic cation from a softer alkyl ligand to a more rigid aryl ligand, we find that elastic modulus increases but thermal conductivity decreases, which provides a route to engineer thermal conductivity and elastic modulus independently. We further conducted molecular dynamics simulation to understand the molecular interactions and this anomalous

dependence. Introducing chirality into the organic cation induces a unique molecular packing, leading to the same thermal conductivity and elastic modulus regardless of the composition for all half-chiral 2D HOIPs. This finding provides substantial leeway for further investigations in chiral 2D HOIPs to tune opto-electronic properties without affecting the thermal and mechanical stability.

2:00 PM EN07.13.02
Understanding Effects of Gas Molecules on Thermal Transport in Metal–Organic Frameworks Yukyung Moon, Rahil Ukani, Qichen Song, Joy Cho and Jarad A. Mason; Harvard University, United States

Metal–organic frameworks (MOFs)—porous crystals composed of metal nodes and organic linkers—are promising materials for a wide range of applications, notably in gas storage and separations. Despite ultrahigh porosities, large internal surface areas, and highly tunable structures, realizing the full potential of MOFs has been hindered in part by their inadequate thermal properties. MOFs typically possess low thermal conductivities (< 2 W m^{-1} K^{-1}), which can dictate gas adsorption dynamics under practical loading rates. While it has been suggested that the presence of gas molecules within the pore can impact the propagation of phonons, it has been challenging to experimentally examine the effects of interactions at the pore wall. Recent studies have sought to measure the thermal conductivities of various MOFs, and molecular dynamic simulations have been employed to elucidate the factors governing their intrinsic transport properties, but the microscopic mechanisms underlying the effects of adsorbates remain underexplored.
Here, we present experimental investigations of thermal transport in zeolitic imidazole framework-8 (ZIF-8) under systematically varied gas environments. We employ the frequency-domain thermoreflectance (FDTR) technique to probe thermal conductivity in single crystals of ZIF-8 with chemically diverse gas adsorbates. This approach enables us to investigate how the interaction energies between gas molecules and the pore walls influence transport pathways along the porous framework. Our FDTR measurements reveal that gases with higher adsorption capacity, such as CO_2, result in a notable decrease in the thermal conductivity of ZIF-8 compared to adsorbates with a lower adsorption capacity such as N_2. Additionally, variable-temperature FDTR measurements provide insight into the kinetics of gas molecules confined within the pores of ZIF-8. Our research illuminates the dynamic interplay between gas adsorption and the thermal properties of ZIF-8, offering new mechanisms to chemically modulate thermal transport in porous materials systems.

2:15 PM EN07.13.03
Anomalous Thermal Transport of Two-Dimensional Materials in Contact with Metal due to Complex Phonon Scattering Jie Sun, Bin Xu, Rulei Guo and Junichiro Shiomi; Tokyo University, Japan

Heat dissipation is paramount in the realm of modern electronics, encompassing chips and wearable devices, whose typical candidates are the two-dimensional (2D) materials due to their superior intrinsic electrical, optical or phonon properties. However, these materials are seldom found in a freestanding state when integrated into devices, often integrated with crystalline semiconductors, metals, or flexible polymers. Thermal management strategies for such devices typically rely on a macroscopic perspective, which may lack precision. Employing the techniques of machine-learning-based interatomic potentials within DFT-level quality, together with the theory of phonon coherence and scattering from different orders, the heat transport of the 2D materials combined with substrates are investigated. Contrary to conventional expectations of hindered thermal transport, our findings reveal that the thermal conductivity of graphene remains invariant when placed on a substrate. This invariance is attributed to the suppression of four-phonon scattering, a consequence of symmetry-breaking effects. The more intriguing phenomenon is the observed enhancement of thermal conductivity when germanene is placed on the substrate. This outcome defies expectations and can be attributed to the competing mechanisms: increased third-order anharmonicity and decreased fourth-order anharmonicity. Besides, an increase in coherent phonon transport due to the reduced disparities in the frequencies of various phonon modes also accounts for the enhanced thermal transport. In conclusion, our study has unveiled both the invariant and enhanced heat transport in 2D materials when combined with substrates. This investigation, driven by the microscopic phonon transport theorem, offers a fresh perspective on heat dissipation in electronic devices.

2:30 PM EN07.13.04
Unlocking Rayleigh's Law Limit of Phonon Transport for Extremely Low Thermal Conductivity by Materials Informatics Meng An, Wenyang Ding, Jiang Guo and Junichiro Shiomi; The University of Tokyo, Japan

Engineering materials with extremely low thermal conductivity are crucial and desirable for many applications such as thermal management of electronic devices, thermal insulation and thermoelectric conversion. Recently, two-dimensional (2D) materials with heteroatoms from multiple distinct materials blocks show excellent properties and are considered as the promising candidates for constructing integrated circuits and quantum computers. However, Rayleigh's law implies that acoustic phonons, which carry most of the heat, are insensitive to scattering by atomic-scale defects. Therefore, realizing low thermal conductivity of lateral heterostructure with complex composition and diverse arrangement remains challenging due to the high degree of freedom and complex objectives. Herein, we develop a hybrid materials informatics approach which combines the variational autoencoder and Bayesian optimization to design two-dimensional patterned graphene/h-BN lateral heterostructure with extreme low thermal conductivity. With only several hundred training data sets, new structure with extremely low thermal conductivity can be quickly determined in a compressed latent space by calculating far less than 0.0001% of the total candidate structures, which greatly decreases the design period and cost. More interestingly, the thermal conductivity of newly obtained structure is much lower than that of randomly arranged graphene/h-BN lateral heterostructure, where the extracted phonon relaxation time of newly obtained structure from phonon energy spatial density are calculated to demonstrate the validity of Rayleigh's law. Finally, the mode-resolved atomistic Green's function (AGF) method was utilized to calculate the phonon modal transmission of newly obtained structure and analyze the elastic phonon scattering behavior. This study not only can be easily extended to other thermal conduction metamaterials with higher dimensional features but would be beneficial to screening the phonon transport mechanism of two-dimensional heterostructures with multiple thresholds of thermal conductivity.

2:45 PM EN07.13.05
Tailoring Thermal Conductivity Anisotropy Using Ion Beam Modification Marat Khafizov[1], Vinay Chauhan[1], Hao Ma[2], Zilong Hua[3], Azat Abdullaev[4], Shadman S. Priam[1], Saqeeb Adnan[1], Erika Nosal[1], Michael Manley[2], Zhandos Utegulov[4], Lingfeng He[5] and David Hurley[3]; [1]The Ohio State University, United States; [2]Oak Ridge National Laboratory, United States; [3]Idaho National Laboratory, United States; [4]Nazarbayev University, Kazakhstan; [5]North Carolina State University, United States

We demonstrate utilization of energetic particle to introduce few nanometer-sized features in crystalline solids leading to changes in thermal transport. This integrated analysis includes ion irradiation, microstructure characterization using transmission electron microscopy, measurement of thermal conductivity tensor using spatial domain thermoreflectance, and modeling of thermal conductivity accounting for observed nanostructure. In cubic CeO_2 bombarded with 2 MeV energy protons faulted dislocation loops are formed. These loops have long range strain field resulting in significant reduction of thermal conductivity. Aligned ion tracks in Al_2O_3 generated by bombardment with 167 MeV xenon ions modify its thermal conductivity anisotropy, where thermal conductivity along direction perpendicular to ion channels exhibits larger conductivity reduction compared to direction parallel to the channels. Lastly, we show modification of conductivity anisotropy in hexagonal delta-phase U-Zr alloy, caused by formation of platelet nanoprecipitates. For the latter case, the anisotropic modification is also observed in phonon lifetimes measured using inelastic X-ray scattering.

Tuning Thermal Transport and Magnetization Dynamics in Functional Materials Xiaojia Wang; University of Minnesota, Twin Cities, United States

In this talk, I will highlight the ongoing research efforts of our group focused on tailoring thermal transport and magnetization dynamics in functional materials for applications including active thermal control and energy-efficient spintronics. Our research leverages ultrafast laser-based metrology techniques, specifically the basic time-domain thermoreflectance and advanced time-resolved magneto-optical Kerr effect configurations. I will begin by discussing our work in solid-state control of thermal transport in nanoscale perovskite oxides, using lanthanum strontium cobaltite (LSCO) and strontium stannate (SSO) as model systems. We have successfully manipulated thermal transport through structural engineering. Notably, we have demonstrated continuous tuning of LSCO thermal conductivity by a factor of over five. This tuning is achieved via a room-temperature electrolyte-gate-induced non-volatile topotactic phase transformation from perovskite to brownmillerite, accompanied by a metal-insulator transition.

The second part of the talk will feature L10-FePd, a promising material candidate for energy-efficient and non-volatile spintronic devices with large areal densities. We have conducted systematical investigations into the influence of buffer-layer engineering on perpendicular magnetic anisotropy (PMA, crucial for switching speed) and Gilbert damping (related to energy consumption). Additionally, I will delve into the effects of temperature on both PMA and damping to better address the technological viability of L10-FePd for spintronic applications.

4:00 PM EN07.14.02
Reversible and High-Contrast Thermal Conductivity Switching in a Flexible Covalent Organic Framework Possessing Negative Poisson's Ratio Sandip Thakur and Ashutosh Giri; University of Rhode Island, United States

The ability to dynamically and reversibly control thermal transport in solid-state systems can redefine and propel a plethora of technologies including thermal switches, diodes, and rectifiers. Current material systems, however, do not possess the swift and large changes in thermal conductivity required for such practical applications. For instance, stimuli responsive materials, that can reversibly switch between a high thermal conductivity state to a low thermal conductivity state, are mostly limited to thermal switching ratios in the range of 1.5 to 4. Here, we demonstrate reversible thermal conductivity switching with an unprecedented 18× change in thermal transport in a highly flexible covalent organic framework with revolving imine bonds. The pedal motion of the imine bonds are capable of reversible transformations of the framework from an expanded (low thermal conductivity) to a contracted (high thermal conductivity) phase, which can be triggered through external stimuli such as exposure to guest adsorption and desorption or mechanical strain. We also show that the dynamic imine linkages endow the material with a negative Poission's ratio, thus marking a regime of materials design that combines low densities with exceptional thermal and mechanical properties.

4:15 PM EN07.14.03
Thermal Rectification Mediated by Polaritonic Heat Conduction Sichao Li and Sunmi Shin; National University of Singapore, Singapore

The pursuit of advanced thermal management solutions for applications spanning electronics, buildings, and energy conversion/storage has intensified with the exploration of thermal rectification. While previous studies have several approaches using phase-change materials, heterostructures, or mechanical deformation, thermal rectification ratios have consistently lagged behind those observed in electrical or optical transport. This challenge origins from the diffusive nature of heat conduction mediated by classical heat carriers, e.g., phonons and electrons. Here, we leverage surface phonon polaritons (SPhPs), a coupled energy carrier arising from the interaction between optical phonons and photons, to enhance thermal rectification. Theoretical predictions suggest that these distinctive heat carriers exhibit anomalously long propagation length over 100s μm. In our study, various long and thin polar dielectric nanostructures, e.g., SiO_2 nanowalls, were designed and integrated into a suspended thermometry platform to facilitate the probe of polaritonic thermal conductance. To demonstrate the asymmetric heat transfer across forward and reverse directions, we controlled the coupling coefficient of surface-guided waves by incorporating grating structures into one side of the thermometry platform. In this presentation, we will discuss the rationale behind the design of nanostructured heat channels and thermometers, showcasing their critical role in realizing asymmetric transmittance of quasi-ballistic heat transport.

4:30 PM EN07.14.04
Thermal Transistor and Thermal Regulator Devices Utilizing Temperature-Dependent Magnetic Forces Lorenzo Castelli, Ajay Garg, Qing Zhu, Trevor J. Shimokusu, Pooja Sashital and Geoffrey Wehmeyer; Rice University, United States

Switchable and nonlinear thermal devices are enabling technologies for applications ranging from waste heat scavenging to solid-state cooling and battery thermal management. Existing high-performance passive switching devices operating near room temperature rely primarily on thermal expansion to open or close gaps between surfaces; however, many thermal expansion switches have substantial thermal hysteresis and/or require large device thicknesses. Here, we demonstrate passive thermal switching with several devices that use temperature-dependent magnetic forces to make and break mechanical contact between thermally conductive elements. Our devices rely on the reversible paramagnetic/ferromagnetic phase transition of the magnetically soft material gadolinium, which has a convenient Curie temperature near 20ºC for room temperature switching. We use this magnetically-actuated mechanism to construct a thermal regulator,[1] which is a two-terminal device in which the steady-state thermal conductance can be passively tuned between an ON or OFF value by the temperature of the control thermal terminal. We also demonstrate the first reported thermal transistor,[2] which is a three-terminal device in which the temperature at the gate terminal controls the source-drain heat flow in a manner that leads to heat flow switching and amplification.
The thermal regulator displays an average thermal switch ratio of 34 (uncertainty +30,-13) in vacuum with switching temperatures near 20ºC and a 5ºC thermal hysteresis. The magnetic actuation mechanism leads to relatively low thermal hysteresis and smaller thicknesses (<2 cm) as compared to the prior thermal expansion demonstrations. Similarly, the thermal transistor displays an average source-drain thermal switch ratio of 109 (uncertainty +62, -38) in vacuum with switching gate temperatures near 25ºC and a 7ºC thermal hysteresis. The thermal transistor displays measured heat flow amplifications near

30, meaning that a small gate heat flow can drive a larger source-drain heat flow, and has characteristic thermal time constants ranging from 4 to 17 minutes. We quantify the durability and performance of both devices over >1000 cycles and find that the regulator switch ratio decreases by a factor of four after cycling and long-duration (0.5 year) storage. We construct proof-of-concept thermal circuits to demonstrate that these nonlinear thermal devices enable thermal logic operations, passive heat flow routing, and temperature regulation capabilities. Thus, our demonstrations of passive heat switching using a magnetic thermal regulator and thermal transistor will motivate further research implementing nonlinear thermal elements for advanced thermal management.

This work was supported by an Early Career Faculty grant from NASA's Space Technology Research Grants Program (Grant #80NSSC20K0066), by a NASA Space Technology Graduate Research Opportunity (Grant # 80NSSC20K1220), and by a grant from the Welch Foundation (Grant No. C-2023).

Asymmetric Thermal Transport and The Influence of Contact Resistance in Telescopic Nanowires Yashpreet Kaur[1], Saeko Tachikawa[1], Jose Manuel Sojo Gordillo[1], Milo swinkels[1], Matteo Camponovo[1], Anna Fontcuberta i Morral[2], Riccardo Rurali[3] and Ilaria Zardo[1]; [1]University of Basel, Switzerland; [2]EPFL, Switzerland; [3]ICMAB-CSIC, Spain

Heat dissipation has become a critical problem in the performance of electronic devices, thus reducing their lifespans [1]. To cope with this, researchers are using several approaches like thermoelectric generators, coolers, thermal diodes, heat guides, and more [2]. A thermal diode works as a rectifier, allowing the flow of heat preferentially in one direction. In our current research, we have studied telescopic nanowires for their thermal transport and rectification capabilities [3].

A telescopic nanowire is a quasi-one-dimensional structure with a thick and a thin part having diameters of 300 and 90 nm, respectively, with a transition region in between. The GaAs telescopic nanowires are grown by MBE technique using the VLS mechanism [4]. Thermal conductivity measurements of one-dimensional (1D) structures were conducted using thermal bridging technique [5]. Thermal rectification ratios of up to 8% were measured as a function of applied temperature bias.

Further, the temperature jump at the contacts is extracted using Raman thermometry [6] while applying different temperature biases. In numerous instances within the literature, this crucial contact contribution tends to be overlooked despite its substantial influence on the determination of thermal properties. In our case, a thermal contact resistance of $(2.71 \pm 8.43) \times 10^8$K/W was estimated and compared to reference homogeneous nanowires. This enables a corrected estimation of the rectification from the nanostructure. The thermal mapping along the nanowire axis was also done to extract the thermal conductance of the corresponding thick and thin parts.

These results underscore the significance of accounting for thermal contact resistance in accurately characterizing the thermal properties of nanowire-based systems. Moreover, this is the first experimental study on telescopic nanowires indicating rectification and an important contribution towards the development of thermal circuit elements.

Low-Dimensional Heat Conduction in Surface Phonon Polariton Waveguide Yu Pei, Li Chen, Wonjae Jeon, Zhaowei Liu and Renkun Chen; UCSD, United States

Heat conduction in solids is governed by Fourier's law, describing a diffusion process primarily driven by phonons and electrons with short wavelengths and mean free paths. Non-Fourier heat conduction, observed in exotic systems, remains elusive in typical solids. Surface phonon polaritons (SPhP) are evanescent surface waves resulting from the collective oscillation of atoms on the surface of polar dielectric materials. They couple thermal photons and optical phonons, potentially contributing significantly to heat conduction, particularly in nanostructures with diminished volumetric heat conduction by phonons and electrons. Unlike thermal radiation, SPhP waves carry a high energy flux along the solid surface, acting as thermal waveguides. Surface phonon polaritons (SPhP) offer a promising avenue for extraordinary heat transfer due to their longer wavelength and propagation length. However, their low energy flux has hindered direct observation of SPhP-mediated heat conduction.

Here, we demonstrate direct observation of enhanced thermal conductivity mediated by SPhP in SiO2 nanoribbon waveguides. To distinguish SPhP from phonons, the waveguide cross-section must be reduced. However, this introduces challenges related to wave leakage and inefficient coupling with thermal reservoirs. Our study addresses these challenges by designing nanoribbon waveguides of SiO2 with controlled SPhP mode size and efficient coupling to thermal reservoirs using an absorber. We directly observe an increased thermal conductivity in these waveguides, surpassing the limit of phonon thermal conductivity by up to 34%. Moreover, we observe non-Fourier behavior in SPhP thermal conductance over 50-100 μm distances at room and high temperature, indicating the unique characteristics of polaritonic heat conduction. Our work represents the first direct observation of enhanced thermal conductivity mediated by SPhP and provides insights into the potential of manipulating heat conduction beyond traditional limits. These findings open up

new possibilities for engineering thermal transport in various applications.

High Thermal Conductive Liquid Crystal Elastomer Nanofibers Jingxuan Wang[1], Yue Wen[1], Duo Pan[1,2], Shulang Lin[1], Chinnappan Amutha[1], Qiguang He[3], Chuntai Liu[2], Zhiwei Huang[1], Shengqiang Cai[4], Seeram Ramakrishna[1] and Sunmi Shin[1]; [1]National University of Singapore, Singapore; [2]Zhengzhou University, China; [3]The Chinese University of Hong Kong, Hong Kong; [4]University of California, San Diego, United States

Liquid crystal elastomers (LCEs), consisting of polymer networks and liquid crystal mesogens, show reversible phase change induced by thermal stimuli. However, the kinetic behavior is limited by the inherently low thermal conductivity of polymers. Transforming amorphous bulk into fiber-like forms enables us to enhance the thermal conductivity by aligning polymer chains. Rigid networks of crosslinked polymer have challenged to fabricate nanofibers of it while the existence of the crosslinks in LCEs is crucial to shape reversible transformation of the elastomers. In this study, hydrodynamic alignment was employed to orient the LCE domains assisted by controlled in-situ crosslinking. A drag force was applied to a suspended individual single polymer fiber anchored to a micro-thermometry device. This process remarkably cuts down the fiber diameter to sub-microns. We observed the highly enhanced thermal conductivity of LCE nanofibers (<100 nm in diameter) which is one order of magnitude higher than that of bulk counterpart. To further elucidate the size-effect on heat transfer in LCE fibers, temperature-dependent analysis was made with various diameters of LCE fibers.

Nanoscale Thermal Transport in SiC: Effects of Inter-Grain Misorientation, Grain Size and Crystal Anisotropy Omid Farzadian, Yanwei Wang and Zhandos Utegulov; Nazarbayev University, Kazakhstan

Detailed understanding of the thermal transport across grain boundaries (GBs) and nano-size grains in nanocrystalline thermal functional materials is essential for optimizing their performance across variety of advanced energy applications [1,2]. This study aims at elucidating the nature of inter-grain heat transport as well as spatially-resolved thermal conductivity κ inside small grains by controlling the misorientation tilt angles θ, grain sizes D and crystal anisotropy to advance our fundamental insight into thermal transfer in nanocrystalline materials.

For a detailed atomistic treatment of interfacial heat transport across GBs in SiC bi-crystals, non-equilibrium molecular dynamics (NEMD) simulations are employed. We focus on the (hk0)[001] family of symmetrical tilt GBs, where [001] represents the tilt axis, (hk0) signifies the GB plane with tilt angle θ. The primary interest in structural analysis of GBs revolves around uncovering the atomistic configuration that represents the lowest energy state for a specific θ, commonly referred to as the ground-state structure. To discern this equilibrated state for each GB, we employ an optimization procedure involving the conjugate gradient (CG) method [2,3].

To examine the heat propagation behavior across these GBs, a temperature gradient is imposed on both ends of the SiC structure. It is anticipated that κ of nanocrystalline material will be significantly lower than that of the bulk single crystal due to the presence of thermal resistance at the GB interfaces, defined as the Kapitza resistance R. The variation of R with θ across individual GBs is studied with minimized GB energy. Observed asymmetry in R with respect to $\theta = 45$ degrees is due to two dissimilar atoms (Si and C) present in the lattice.

Moreover, we employ perturb MD [3] to compute spatially-resolved anisotropic local thermal conductivities in SiC by varying D and θ. It was explored that the intra-grain κ decreases with the reduction of D and also varies with the rise of θ in the cross-GB and along-GB directions. The κ remains relatively uniform within the grain interiors but decreases near the GB plane. It should be noted that this reduction is more dominant in larger grains than in smaller ones. This observed phenomenon is discussed in terms of the enhanced phonon scattering in the nanoscale vicinity from GBs, phonon mean free paths, interatomic interaction within a diatomic SiC crystalline lattice across the GBs connecting grains misoriented from each other at various tilt angles directly affecting inter- and intra- grain phonon mediated heat transport.

Theory of The Soret Effect in Liquids and Solids Patrick K. Schelling; University of Central Florida, United States

The Soret Effect, also known as thermodiffusion, is the flow of matter in response to externally applied heat sources. This effect is important in a number of applications including crystal growth and analysis interactions between biomolecules, and may present opportunites for guided materials synthesis using temperature gradients. While this effect has been known for some time, predictive models and microscopic understanding have been lacking. We have recently demonstrated that the Soret effect is closely connected to the response of a system to the internal stresses induced by a heat source. In particular, as a system approaches mechanical equilibrium, density gradients develop, and the difference in response to these density gradients is responsible for the observed concentration gradients. Using two-component Lennard-Jones liquids as an example, it is shown that an analysis of the dependence of the partial pressures of the two components on concentrations, namely via second derivatives of the partial pressures, the sign and magnitude of the Soret effect can be established. The results suggest how thermodiffusion in solids either of interstitials or alloys via a vacancy mechanism can be understood.

Wood Waste-Based Thermal Insulation Foam for Building Energy Efficiency Amanda Siciliano[1], Xinpeng Zhao[1], Dr. Jan Kosny[2] and Liangbing Hu[1]; [1]University of Maryland, United States; [2]University of Massachusetts Lowell, United States

Wood, a renewable resource with passive carbon sequestration abilities, has a history of use within construction materials because of its cheap, abundant, and sustainable nature; however, natural wood’s low porosity makes it an unfit candidate for readily producible and highly efficient thermal insulation materials , leading to a high overall thermal conductivity (> 0.1 W/(mK)). Furthermore, the fabrication process of wood-based building insulation materials generally involves chemical- and time-consuming drying methods (e.g., freeze-drying, solvent exchange, overnight curing), resulting in high manufacturing costs. In this work, we illustrate the development and characterization of sustainable wood waste-based thermal insulation foam fabricated through a rapid hot-pressing technique, demonstrating significant product tunability, manufacturing scalability, and time- and cost-efficiency. This method significantly improves the manufacturability of wood-based thermal insulation materials by eliminating solvents from the fabrication process. Performance characterization of wood waste-based thermal insulation foam exhibits a density of 0.2 g/cm^3, thermal conductivity of 0.03 W/(mK), and compressive

strength of ~1 MPa at 10% strain. This example of the quick development of efficient sustainable thermal insulation materials shows promise for addressing complex thermal transport challenges with applications in various sectors including electronics, manufacturing, buildings, and transportation.

Temperature-Vacuum Swing Desorption in Sorbent-Based Atmospheric Water Harvesting Devices: An Approach to Energy Savings Bachir El Fil[1], Chenyang Li[1], Yang Zhong[1], Hyeongyun Cha[1], David Keisar[1], Mengjiao Wu[2], Pasquale Fulvio[2], Jamie Salinger[2], Jay Lin[2] and Krista Walton[2]; [1]Massachusetts Institute of Technology, United States; [2]Georgia Institute of Technology, United States

To meet the increasing global demand for clean and potable water, sorbent-based atmospheric water harvesting (SAWH) is a promising solution. However, challenges remain owing to the complexity of system integration and energy-intensive nature of the regeneration process. The desorption process has long been a bottleneck, directly affecting both the energy efficiency and deployment scalability. Conventionally, the regeneration of sorbents has been dominated by two primary methods: temperature-swing desorption (TSD) and vacuum-swing desorption (VSD). In temperature-swing desorption, heat is typically applied to release the adsorbed water molecules from the sorbent making it prevalent for sorbents with high water capacity but consequently demanding high energy inputs. Conversely, vacuum-swing desorption employs pressure alterations to induce desorption, favored for its operational simplicity, but sometimes limited by its efficacy with certain sorbents. Both methods, while effective, bear significant energy costs, sometimes overshadowing the net water extraction gains and constraining the broad adoption of AWH, especially in regions with limited energy infrastructure. In this work, we delve into the application of a hybrid temperature-vacuum swing desorption (TVSD) as an approach aimed to optimizing the energy consumption in the regeneration of solid sorbents used in AWH devices.
This hybrid approach harnesses the synergistic benefits of both desorption techniques, aiming to minimize the overall energy consumption. To understand this more, we have developed thermo-fluidic models to simulate and optimize the desorption process. Additionally, we conducted experiments under various pressure ranging between 14 to 300 mbar and with desorption temperatures as low as 27°C to 80°C. Preliminary findings indicate that TVSD can achieve energy saving by ~ 33% when compared to conventional temperature swing desorption, for hierarchical silica impregnated with salts. Thereby rendering AWH systems more viable in energy-constrained settings.
In conclusion, TVSD offers a promising avenue for improving the energy efficiency of sorbent regeneration in AWH systems. We continue to optimize this method across various operating conditions, the integration of temperature and vacuum swings stands as a novel solution to enhance the sustainability and accessibility of atmospheric water harvesting.

5:00 PM EN07.15.07
Thermoelectric Properties of Stressed p-Doped Polycrystalline Hollow Nanotubes Jose Manuel Sojo Gordillo[1,2], Yashpreet Kaur[1], Saeko Tachikawa[3], Giulio de Vito[1], Alex Morata[2] and Ilaria Zardo[1]; [1]University of Basel, Switzerland; [2]Catalonia Institute for Energy Research - IREC, Spain; [3]National Institute of Advanced Industrial Science and Technology - AIST, Japan

Thermoelectric generators have the potential to efficiently convert waste heat into valuable electrical power. However, conventional thermoelectric materials face limitations in terms of efficiency, scarcity, high cost, and scalability, impeding their widespread adoption. Nanoengineering techniques have emerged as a promising solution to enhance the thermoelectric properties of abundant and inexpensive materials like silicon. Nevertheless, the integration of these nanostructures on a large scale, necessary for efficient waste heat recovery, remains a significant challenge.
Recently, a novel class of nano-enhanced materials in the form of extensive, paper-like fabrics composed of nanotubes has been developed, offering a cost-effective and scalable approach to thermoelectric power generation [1]. However, the fundamental properties of the building blocks of these fabrics, namely the p-type silicon nanotubes, have not been individually investigated to date.
This study conducts electrothermal measurements using microfabricated suspended nitride membranes to characterize the thermoelectric properties of these nanotubes, including the electrical and thermal conductivity as well as the Seebeck coefficient. Furthermore, Raman thermography is employed in order to accounting for the effects of thermal contact resistance in the thermal conductivity measurement. Raman spectroscopy is also used to examine the residual mechanical stress in the nanotubes and investigate its relationship with the observed thermoelectric properties. A network model is proposed to link the macroscopic thermal properties of the fabrics with those of the nanotubes. Additionally, the study investigates the light absorption within these hollow structures. Finally, the effects of SiGe alloy on the properties of the nanotubes are compared and discussed.
By understanding the interplay between the morphology, structure, and thermoelectric properties of the nanotubes, a pathway can be established for the development of more mechanically stable and efficient fabrics, with the potential for commercializing waste heat recovery through this technology.

Thermal Studies of Au–$BaTiO_3$ Nanoscale Hybrid Metamaterial Haomin Li[1], Benson Tsai[2], Fabian J. Medina[1], Qiyu Chen[1], Haiyan Wang[2] and Qing Hao[1]; [1]The University of Arizona, United States; [2]Purdue University, United States

With embedded periodic vertical nanopillars, oxide-metal nanocomposite thin films hold significant potential for various applications, including magnetic data storage, energy storage, plasmonics, optics, sensors, multiferroics, and spintronics.[1] In these thin films, electron-phonon coupling at the metal-oxide interface plays a crucial role in restricting the in-plane thermal transport. When the corresponding interfacial resistance becomes a critical factor, these thin films become particularly intriguing when compared to extensively studied periodic nanoporous thin films. In general, such periodic structures are used for both photonics and phononics devices, where periodic nanostructures are used to manipulate the wave propagation within the structure by tuning the dispersion relation of photons and phonons. The interplay between optical photons and phonons also leads to important applications such as optomechanical waveguides and resonators.[2]
This study focuses on systematically measuring the in-plane thermal conductivity of Au-$BaTiO_3$ nanocomposite thin films with sub-100 nm feature sizes.[3] The measured samples are fabricated as a metal-coated suspended bridge for 3 omega measurements[4] to extract both the specific heat and in-plane thermal conductivity. Thermal analysis is further carried out to gain a deeper understanding of thermal transport across the metal-oxide interface and within the periodic patterns. Transmission electron microscopy studies are carried out to reveal the defects at the metal-oxide interfaces, which may largely impact the thermal transport.[5] Our study provides important guidance for the thermal management of the related plasmonic or other devices using these composite thin films.[6]

5:00 PM EN07.15.09
Completely Passive Capture of Carbon Dioxide from Air Using Solar Energy Jian Zeng[1], Hsinhan Tsai[2], Ravi Prasher[3], Jeffrey Long[2] and Sean Lubner[4]; [1]The Hong Kong University of Science and Technology (Guangzhou), China; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Boston University, United States

In addition to reducing greenhouse gas emissions, it is now imperative that we implement direct air capture (DAC) of CO_2 from the atmosphere at a scale of hundreds of giga metric tons before the year 2100 to avoid catastrophic climate change. Development of a viable DAC technology is still limited by the high cost and high energy consumption that result from a low adsorbent capture capacity, requirements for expensive, cumbersome infrastructure, and widespread societal acceptance challenges. In this work, we aim to address all three of these challenges and have designed and demonstrated a completely passive DAC device with a projected net CO_2 capture cost as low as 80 \$ t_{CO2}^{-1}, lower than the 'Carbon Negative Shot' 2030 goal (100 \$ t_{CO2}^{-1}) and potentially profitable at 100 \$ t_{CO2}^{-1} with the 45Q carbon tax credit. Our DAC device captures CO_2 passively at night and desorbs CO_2 passively during the day. It uses solar energy as the sole energy source with minimum maintenance requirements. The modular design and passive operation of the system should enable deployment across broad geographic regions far from infrastructure centers, thereby enabling a distributed, self-powered solution to the problem of removing dilute CO_2 from the atmosphere. It further combines low-cost solar-thermal and low-risk photovoltaic technologies, facilitating installation at different scales in any corner of the world with abundant solar resources.

5:00 PM EN07.15.11
Sub-Micron Resolution Mapping of Thermal Properties in CVD and MBE-Grown MoS2 via Nanoscale Thermoreflectance Microscopy Brian M. Foley[1], Patrick E. Hopkins[2,1] and John T. Gaskins[1]; [1]Laser Thermal Inc, United States; [2]University of Virginia, United States

As with most other functional properties of 2D materials, thermal energy transport via phonons can be impacted quite dramatically through their scattering by a variety of material defects. These phonon scattering events in 2D systems arise from the plethora of defects and interfaces that arise from both the growth parameters and post-processing steps that are often required to manipulate the 2D materials functionalities. The thermal transport properties of 2D materials at and around these defect phonon scattering sites, which often have length scales and spacings on the order of a few to 10's of nanometers, are difficult to isolate and measure individually with the thermal measurement techniques available previously. For example, optical based techniques for measuring thermal properties of 2D materials (e.g., Raman, TDTR) are ultimately diffraction limited and thus restricted in-practice to areal spatial resolution on the order of single micrometers. Techniques using lasers coupled with AFM-tips (e.g., Nano-FTIR) have shown promise in achieving sub-diffraction limited areal resolution to qualitatively interrogate optically excited surfaces, but lack the opto-thermal transduction power afforded by thermoreflectance-based methods to ensure accurate measurement of local temperature and thermal wave modulation.

Here, we introduce a novel approach called Nanoscale Thermoreflectance Microscopy (NTM), capable of characterizing the thermal properties of 2D materials with ~10 nm areal spatial resolution. Thermal maps of CVD and MBE-grown molybdenum disulfide (MoS2) are presented, quantifying the impact of the chosen growth method on material quality through direct visualization of how the thermal resistance increases near defects such as wrinkles/boundaries, adlayer nucleation sites, etc. These local increases in resistance are attributed to the impact of the defect in question on phonon transport. As a result, this new capability enables an estimation of the length scales over which various defect structures exert influence over phonon transport in these 2D materials, providing important thermal insight to guide future synthesis, processing and device-integration efforts using this important family of materials.

5:00 PM EN07.15.12
Enhancing Building Thermal Management with Thermochemical Materials-Based Thermal Energy Storage Sumanjeet Kaur, Andrew Martin, Alondra Perez, Drew Lilley and Ravi Prasher; Lawrence Berkeley National Laboratory, United States

Buildings drive energy consumption worldwide, particularly in the United States. Thermal loads, which contribute significantly to CO2 emissions, must be addressed for deeper adoption of renewable energy. On-site Thermal Energy Storage (TES) is vital for reducing peak loads and managing renewable energy intermittency. Thermochemical Materials (TCMs), which consist of reactive pairs of inorganic salts and water vapor, exhibit notable advantages as they have a higher theoretical energy density of approximately 500 kWh/m3 and exhibit minimal self-discharge since energy is stored within chemical bonds. This makes them uniquely suited as compact, stand-alone solutions for daily-seasonal energy storage within buildings. However, TCMs face challenges related to material instabilities at both the salt particle level and reactor level (packed beds of salt). These issues result in poor multi-cycle efficiency and a high levelized cost of storage.

In response to these challenges, this study offers valuable insights into strategies aimed at mitigating chemical instabilities within the salt at both the material and composite levels. Additionally, it explores pathways to enhance heat and mass transport performance at the reactor level, thereby paving the way for more efficient and cost-effective thermal energy storage solutions.

Unveiling High-Order Phonon Physics: High-Pressure Thermal Transport in Extreme Materials Suixuan Li[1], Zihao Qin[1], Huan Wu[1], Man Li[1], Martin Kunz[2], Ahmet Alatas[3], Abby Kavner[1] and Yongjie Hu[1]; [1]University of California, Los Angeles, United States; [2]Advanced Light Source, Lawrence Berkeley National Laboratory, United States; [3]Advanced Photon Source, Argonne National Laboratory, United States

High pressure provides a new dimension for exploring the transport physics and properties of materials. Over the past century, tremendous efforts have been made to study thermal transport under high pressure. However, the first-principles phonon theory for understanding thermal transport under high pressure has been rarely applied. Here, for the first time, we studied high pressure transport and identified high order anharmonic behaviors beyond the classical textbook understanding. We conducted in-situ experiments, incorporating thermal transport, vibrational spectroscopies, and synchrotron X-ray experiments. These measurements were juxtaposed with first-principles calculations, shedding light on the microscopic dynamics underlying heat transfer. Our finding uncovering high-order anharmonic behaviors beyond traditional comprehension based on classical physics. Our development enables new research platforms and provides fundamental insights into thermal transport under extreme conditions. **Reference: S. Li,** Z. Qin, H. Wu, M. Li, M. Kunz, A. Alatas, A. Molecular Dynamics Study of The Heat Transport Mechanism of $Cu_{2-\delta}Se$ Using Machine Learning Potential Tomu Hamakawa and Junichiro Shiomi; The University of Tokyo, Japan

$Cu_{2-\delta}Se$ is a material that exhibits the high thermoelectric performance of zT=1.5 at 1000 K [1]. This high thermoelectric performance is due to its extremely low lattice thermal conductivity at high temperatures. For example, 0.5 W/m/K at 1000 K was reported for Cu_2Se [1]. This value is comparable to that of liquid and amorphous materials. $Cu_{2-\delta}Se$ superionic conduction causes such low lattice thermal conductivity. At high temperatures (>410 K), Cu ions move between the fcc-structured selenium [1,2]. Such a material with liquid-like properties for phonon transport and crystal-like properties for electrons is called "phonon-liquid electron-crystal (PLEC)". It has been explored for candidate thermoelectric materials.
The "liquid-like" nature of Cu ions in PLEC materials makes it hard to treat heat transport in a perturbative manner. Thus, it requires computationally demanding *ab initio* molecular dynamics (AIMD) simulation. On the other hand, the use of machine learning potentials in calculating thermal conductivity has been increasing in recent years [3,4]. Machine learning potentials are developed to approximate interatomic potentials using machine learning. They can reduce the computational cost to the same extent as empirical potentials while maintaining the accuracy of *ab initio* calculations. The Beheler-Parrinello type potential using Neural Networks is one of the machine learning potentials [5].
In this study, we constructed the interatomic potential of $Cu_{2-\delta}Se$ based on Moment Tensor Potential [6] and calculated thermal properties by MD simulations. We tested our potential, and MD trajectories on our potential showed Cu ions' liquid-like properties. We performed the Non-equilibrium Molecular Dynamics (NEMD) method for calculating the lattice thermal conductivity, and we got the calculated thermal conductivity of 0.5 W/m/K at 700 K. Moreover, we derived the relation between thermal conductivity and diffusion coefficient. From this relation, we investigated the contribution of Cu ions transport and found that the hopping transport of Cu ions is dominant in heat transport.

5:00 PM EN07.15.15
Thermal Boundary Conductance at High Temperatures Samreen Khan and Richard B. Wilson; University of California, Riverside, United States

Understanding the physics of thermal boundary conductance is essential for thermal management of semiconductor devices. Thermal boundary conductance between two materials has been shown to depend on atomic scale details like interfacial bonding, interfacial roughness, and interfacial layers. The intrinsic vibrational properties of the materials at the interface also affect thermal boundary conductance[1]. Surprisingly, only a few experimental studies of thermal boundary conductance at high temperatures exist. This prevents testing of theories for how inelastic processes contribute to thermal conductance[2,3]. Inelastic processes at the interface between dissimilar materials are expected to be most important, and more noticeable at high temperatures. In this study, we present results of time domain thermoreflectance (TDTR) measurements of the thermal boundary conductance for nitride-metal/group-IV-semiconductor interfaces between 80 and 800 K. The nitride-metals (TiN and HfN) and group-IV-semiconductors (Ge, Si, SiC, and diamond) have systematic differences in bulk vibrational properties. By comparing the conductance vs. temperature of these systems, we determine the effect of vibrational similarity on inelastic scattering processes. We show that the average probability for interfacial energy transmission increases significantly with temperature by comparing the measured conductance values to theoretical predictions for the elastic and inelastic limits of the constituent materials. In diamond systems, the transmission probability of thermal energy triples from 20% at 300 K to 60% at 900 K. Our findings fill an important gap in the literature for how interfacial conductance evolves at high temperatures, and tests burgeoning theories[2,3] for the role of inelastic processes in interfacial thermal transport.

Strong, Scalable and Anisotropic Wood Composites for High-Performance Thermal Energy Storage in Buildings Bernadette Magalindan[1], Gustavo Felicio-Perruci[1], Yudong Li[2], Kyle Foster[2], Charles Booten[2], Hongbing Lu[2] and Shuang Cui[1,2]; [1]The University of Texas at Dallas, United States; [2]National Renewable Energy Laboratory, United States

Thermoregulation in America's buildings by heating, ventilation, and air conditioning (HVAC) consumes 11% of the nation's total energy use and emits 309 million metric tons of CO_2 in a single year. One promising solution for energy-efficient thermoregulation involves thermal energy storage (TES) through phase change materials (PCMs) integrated into building envelopes. Recent endeavors have explored the encapsulation of solid-to-liquid PCMs in delignified wood; however, the resulting composite is weak due to the removal of lignin, the natural binding agent in wood. Additionally, the scalability of delignification methods is limited by the slow and inhomogeneous permeation kinetics of the chemical treatment. Here, we transform the most commonly used building construction material—wood—into a microporous, anisotropic, strong, and scalable matrix for PCM encapsulation by selectively removing hemicellulose using a chemical-free, pressurized hot water treatment that preserves lignin. Additionally, the exterior of the wood was selectively densified by controlled hot-pressing, enhancing mechanical strength while allowing high PCM loading within the microporous core of the matrix. Following PCM infiltration, the composite exhibits a mechanical strength of 50 megapascals, comparable to that of natural wood, and achieves a latent heat of 55 J/g for TES. The low-carbon fabrication of the composite in addition to the reduced HVAC-associated carbon emissions enabled by TES promotes the sustainability of the built environment.

5:00 PM EN07.15.17
Manipulation of Near-Field Radiative Heat Flow via Mid-Infrared Plasmonic Coupling Saman Zare[1], William D. Hutchins[1], Maxwell Tolchin[2], Angela Cleri[2], Mingze He[3], Joshua D. Caldwell[3], Jon-Paul Maria[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]The Pennsylvania State University, United States; [3]Vanderbilt University, United States

With the continuous reduction in the size of electronic devices to the nanoscale, it becomes imperative to gain a deep understanding of heat transport mechanisms at these levels. In recent years, breakthroughs in nanotechnology and radiative engineering have introduced thermal radiation as a promising mechanism to tailor both the magnitude and direction of heat transfer. The use of metamaterials enhances our capability to manipulate radiative heat flow

in nanoscale systems, particularly in the context of near-field radiation, which can significantly exceed the blackbody limit by multiple orders of magnitude. Heat transport in the near field of metamaterials depends on their geometry, optical properties of the constituent materials, and interfacial properties. By fine-tuning interfaces in or underneath a metamaterial we can manipulate heat flux, and facilitate an augmented flow of radiative heat from specific spectral modes into bulk heat carriers. One proposed way to tune this flow is by capitalizing on the hybridization of resonant modes in plasmonic materials. Highly doped cadmium oxide (CdO) is poised as an exceptional candidate for that purpose as it allows for high electron mobilities while maintaining dielectric properties mechanically. Also, sub-wavelength films of CdO support epsilon-near-zero (ENZ) modes in the mid-infrared range of the spectrum. Most importantly It has been shown that carefully constructed multilayers of CdO with varying carrier densities exhibit tunable hyperbolic plasmonic dispersion properties, allowing for carrying heat across interfaces at a significantly higher rate than conduction.
In this research, we conduct experimental investigations into the interactions between hyperbolic plasmon-polaritons (HPPs) within a layered hyperbolic metamaterial (HMM) and ENZ modes within a doped CdO thin film. Our approach involves employing a unique ultrafast pump-probe technique that enables the precise detection of heat transfer modes with sub-picosecond temporal resolution. This technique relies on a wavelength-tunable mid-infrared probe pulse, allowing us to directly interface with plasmonic heat carriers, thereby providing a direct assessment of polariton dynamics within nanoscale material systems. By utilizing this method, we investigate the ultrafast thermally-induced near-field coupling of HPP and ENZ modes via far-field sensing. Furthermore, we explore the impact of a MgO dielectric gap positioned between the HMM and ENZ layers on the efficiency of near-field coupling between HPP and ENZ modes, and we demonstrate the capability of tuning the near-field radiative heat transfer by introducing a dielectric spacer in an HMM/ENZ structure. Our results provide a new path for novel designs of plasmonic devices with far-reaching applications in tailored thermal emission and thermal management of microelectronics.

5:00 PM EN07.15.19
High Temperature Thermal Conductivity Measurement Using Two-Color Thermal Imaging Hao-Yuan Cheng, Alexander Myers and Jonathan A. Malen; Carnegie Mellon University, United States

This research explores measuring the thermal conductivity of various materials at high temperatures (up to 4000 K). We use the two-color thermal imaging technique with a commercial color camera to measure the temperature distribution on a sample heated by the high-power laser heat source of a Directed Energy Deposition (DED) additive manufacturing machine. The technological requirement to evaluate materials for use in high temperature environments, particularly in the world of additive manufacturing and aerospace, has dramatically increased in recent years. Developing a technique capable of measuring the thermal conductivity of materials up to 4000 K will provide tremendous insights to improve the manufacturing process of different materials. Conventional methods such as the “flash” method have been improved to measure the thermal conductivity of materials up to 3000 K but this approach has challenges including the ability to reach higher temperatures. Electric pulse methods can also reach high temperatures but are applicable only to electrically conductive samples. Using the newly developed two-color thermal imaging method, we are capable of capturing the thermal conductivity of materials with high positional and temporal resolution. This study focuses on developing an apparatus to measure the temperature distribution of a material under a given heat source using the two-color imaging method, then deriving the temperature dependent thermal conductivity using least squares fitting with FEA models. We evaluate the robustness of our proposed method using materials with well-known high temperature thermal conductivity, such as Tungsten, Tungsten Carbide, and Tantalum.

5:00 PM EN07.15.20
Determination of Thermal Conductivity in Metals Under High Temperature and Pressure: A First Principles Study Pravin Karna[1], Oleg Prezhdo[2], Patrick E. Hopkins[3] and Ashutosh Giri[1]; [1]University of Rhode Island, United States; [2]University of Southern California, United States; [3]University of Virginia, United States

Metallic structures find applications across a wide range of challenging environments, including situations involving high temperatures and pressures like nuclear reactors, plasmonics, pressure calibrators, and interconnects. These metals exhibit distinct properties when subjected to extreme conditions, which might not be apparent under ambient conditions. We employ first principles calculations to investigate the interaction between electrons and phonons in these conditions for various metals: free-electron metal (Al), noble metals (Au, Ag, Cu), and a transition metal (W). This analysis reveals how these metals respond to extreme conditions and sheds light on their thermal and electrical characteristics in such environments. Our calculations encompass the thermal conductivity of these metals under extreme conditions, factoring in both electron-phonon and electron-electron interactions. Furthermore, by computing the spectrally resolved electron-phonon coupling parameter at high pressures, we calculate the contribution of different phonon modes in scattering with electrons. This research offers valuable insights into the processes of electron-phonon scattering under high temperatures and pressures, uncovering a new realm of electrical and thermal transport properties in metallic materials.

5:00 PM EN07.15.21
Effect of Interface Curvature at The Axial Junction in Silicon-Germanium (Si-Ge) Nanowires Oreoluwa O. Adesina and Laura de Sousa Oliveira; University of Wyoming, United States

Due to a wide array of potential applications, such as thermal management, thin-film technologies, microelectronics, and semiconductor and optical devices, thermal transport in silicon-germanium (Si-Ge) materials, including nanowires, is an area of continued interest. Thermal transport in small-scale heterogeneous systems is controlled by interfacial thermal resistance but the relative contributions of different transport mechanisms (e.g., elastic and inelastic phonon scattering) remain elusive. Our work is expected to further our understanding of phonon thermal transport and the role of boundary scattering at the interfaces of low-dimensional materials. The curvature and sharpness of the interface at the heterojunctions in Si-Ge nanowires depend on their growth environment. Herein, we evaluate the effect of interfacial curvature at the axial junctions in Si-Ge nanowires. We employ the non-equilibrium molecular dynamics (NEMD) Muller-Plathe method (with the Tersoff potential) to model thermal transport in nanowires with lengths between 100 nm and 1.3 μm and varying interfacial curvatures. Boundary resistance is probed for directional transport between both Si and Ge and Ge and Si. We have observed an overall weak dependence of thermal conductivity on curvature, and that the effect of curvature on thermal transport is dependent on nanowire length. The evolution of the wave-packet kinetic energies during the course of a simulation provides a more comprehensive picture of the wave behavior of phonons across the Si-Ge interface.

5:00 PM EN07.15.22
Unlocking Enhanced Thermal Conductivity in Polymer Blends through Active Learning Jiaxin Xu and Tengfei Luo; University of Notre Dame, United States

Polymers play an integral role in various applications, from everyday use to advanced technologies. In the era of machine learning (ML), polymer informatics promises to become a valuable tool for efficiently designing and developing polymeric materials. However, the focus of polymer informatics has predominantly centered on single-component polymers, leaving the vast chemical space of polymer blends relatively unexplored. This study employs a high-throughput molecular dynamics (MD) simulation approach combined with active learning (AL) to uncover polymer blends with enhanced thermal conductivity (TC) compared to the constituent single-component polymers. Initially, TC values for about 600 amorphous single-component polymers and

approximately 200 amorphous polymer blends with varying blending ratios are determined through MD simulations. The optimal representation method for polymer blends is also identified, which involves a weighted sum approach that extends existing polymer representation from single-component polymers to polymer blends. An AL framework, combining MD simulation and ML models, is employed to explore the TC of an unlabeled dataset comprising approximately 550,000 potential polymer blends. The AL framework proves highly effective in accelerating the discovery of high-performance polymer blends for thermal transport. Additionally, we delve into the relationship between TC, radius of gyration (R_g), and hydrogen bonding, highlighting the roles of inter- and intra-chain interactions in thermal transport in amorphous polymer blends. A significant positive association between TC and R_g improvement and an indirect contribution from H-bond interaction to TC enhancement are revealed through a log-linear model and odd ratio calculation based on the polymer blend dataset, emphasizing the impact of increasing R_g and H-bond interactions on enhancing polymer blend TC.

SESSION EN07.16: Thermoelectrics

Friday Morning, April 26, 2024
Room 327, Level 3, Summit

8:30 AM *EN07.16.01
Si-Based Planar-Type Thermoelectric Generators over 1 μWcm^{-2}K^{-2} Masahiro Nomura; The University of Tokyo, Japan

Thermoelectrics energy harvesting is one of the key technologies for carbon neutrality. This talk introduces recent advances in Si-based thermoelectric generators (TEGs) and we demonstrate a planar-type double-cavity Si TEG with phononic nanostructures based on a phonon-engineered design. The planar-type device was fabricated in an SOI wafer with CMOS and MEMS processes to largely integrate the device. By using phononic nanostructures and three-dimensional thermal design, we achieved over 100 mWcm^{-2} output power density at a temperature difference of lower than 10 K.
We fabricated the Si TEG in an SOI wafer with a 1.1-μm-thick n-type poly-Si device layer and a 1.5-μm-thick BOX layer. The phononic crystal (PnC) structures are an array of circular holes with a period of 300 nm and a neck size between 8 and 100 nm. It was designed to reduce the thermal conductivity of poly-Si by considering the phonon mean free path spectrum. The cap wafer is designed for efficient cooling of the device. This double-cavity thermal design leads to a high-power density of the device. We found that more than 30% of the temperature difference between the upper and bottom of the device was applied in the thermoelectric material thanks to the careful thermal design of the double cavity structure. This thermal design is an important key factor, as well as the ZT of the thermoelectric material. Our TEG showed the output power density of more than 100 μWcm^{-2} at a lower than 10 K temperature difference between the devices (a few Kelvin in thermoelectric material). The obtained normalized performance of over 1 μWcm^{-2}K^{-2} is, to our knowledge, the highest-performing planar-type Si thermoelectric generator reported to date.

9:00 AM *EN07.16.02
Geometric Design and 3D Printing of Thermoelectric Materials and Devices Jae Sung Son[1], Seungjun Choo[1], Jungsoo Lee[2], Seong Eun Yang[2] and Keonkuk Kim[2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Heat is omnipresent in natural and artificial environments, more than 60% of which is dissipated. Thermoelectric (TE) power generation can provide a unique solution to convert this dissipated, wasted heat into useful energy, that is, electricity. The performance of thermoelectric modules, typically composed of cuboid-shaped materials, depends on both the materials' intrinsic properties and the temperature difference created. Despite significant advancements in the development of efficient materials, macroscopic thermal designs capable of accommodating larger temperature differences have been largely underexplored because of the challenges associated with processing bulk thermoelectric materials. At this moment, three-dimensional (3D) printing technology can maximize the flexibility in the design and fabrication of TE modules into more efficient structures. Herein, we present the design strategy for various thermoelectric materials for enhancing power generation performances using a combination of finite element modeling and 3D printing. The macroscopic geometries are designed and realized by the 3D printing processes, leading to significant enhancements in the temperature difference within devices and the resulting output powers. The proposed approach paves the way for designing efficient thermoelectric power generators.

9:30 AM EN07.16.03
All-Silicon Micro-Thermoelectric Generator for IoT Applications Jose Manuel Sojo Gordillo[1,2], Denise Estrada-Wiese[3], Alex Rodriguez-Iglesias[3], Marc Salleras[3], Alex Morata[2], Albert Tarancón[2] and Luis Fonseca[3]; [1]University of Basel, Switzerland; [2]Catalonia Institute for Energy Research, Spain; [3]Institute of Microelectronics of Barcelona, Spain

In the next decade, a new digital revolution will be held over the expansion of the Internet of Things (IoT), involving the deployment of trillions of nodes in multiple locations. The exponential growth of these kind of wireless devices represents a major challenge in terms of their energy supply [1]. Among the available environmental sources, heat can be harvested by means of thermoelectric devices [2]. This work presents a new generation of densely packaged all-silicon microthermoelectric generators (μTEGs) with planar architecture.

Optimized p-doped silicon nanowires with 80 ± 30 nm in diameter are epitaxially integrated as dense arrays into these generators for an improved performance [3]. A procedure to reliably place a heat sink on top of the devices, boosting the fraction of external thermal gradient captured by the thermoelectrically active nanowires, is described. These improvements boosts the generated voltage up to six times with respect to that of a bare μTEG, leading to output powers well within the range of IoT needs (10-100 μW/cm^2). Specifically, the μTEG on top of a heat source above 200°C and under still air convection conditions generates more than 10 μW/cm^2. When exposed to the same temperatures and to an airflow of 1.3 m/s (equivalent to a light breeze) the power density increases above 80 μW/cm^2.

Moreover, a long-term stability study running the device in load matching conditions for a period of 1000 h does not show degradation below 200°C. Finally, the suitability of connecting the μTEG with the current state of the art DC-DC converters is discussed, showing how eventual transients in real operation conditions could allow the device to reach the required cold start-up voltages.

Overall, the results shown here demonstrate the readiness of the presented μTEG as a valid power source for IoT applications at the microscale.

9:45 AM EN07.16.04
Geometric Thermo Electricity (GTE) - Towards "Junction-Less" Unconventional Thermoelectric Devices Oleg V. Kolosov[1], Alexandros El Sachat[2], Charalambos Evangeli[1], Sergio Gonzalez-Munoz[3], Peng Xiao[4], Elisa Castanon[4], Edward McCann[1], Matthew Hamer[4], Johanna Zultak[4], Olga Kazakova[5] and Roman Gorbachev[4]; [1]Lancaster University, United Kingdom; [2]NCSR "Demokritos", Greece; [3]ICN2, Spain; [4]The University of Manchester, United Kingdom; [5]National Physical Laboratory, United Kingdom

Traditionally, thermoelectric (TE) phenomena require junctions between two dissimilar materials to either generate the current when opposing junctions are held at two differing temperatures (Seebeck effect) or to cool and heat the opposing junctions when the external current is applied (Peltier effect). The two materials must have a different thermoelectric (Seebeck) coefficient, *S* (defined as the voltage *V* per temperature difference ΔT) in order to observe either Seebeck or Peltier effect. Nevertheless, the recently discovered phenomenon of "Geometrical Thermoelectricity", GTE [1] indicated that a nanoscale constriction (of the order of 50-200 nm) in the monolayer of two-dimensional material (2DM) graphene on the insulating SiO2/Si substrate acts as de-facto different material with the different Seebeck coefficient, changing the Seebeck coefficient solely by geometrical patterning and allowing to create TE devices out of a single material [2], avoiding the need for another material and a junction between two materials.
Here we investigate the origin of the GTE phenomenon using a well-defined structure of graphene encapsulated between hexagonal boron nitride (hBN) layers with asymmetric constrictions (flat-taper/flat-flat/taper-flat) and under different polarity of the carriers using the back-gating. By using Scanning Thermal Gate Microscopy (STGM) [3] where a heated nanoscale tip of an atomic force microscope is scanned across the material or device surface to produce a map of thermovoltage as a function of tip position, we established that the GTE modification of Seebeck coefficient does not a) depend of the symmetry of the junction nor b) on the polarity of the carriers (electrons or holes) and therefore c) is directly linked solely to the geometrical dimensions of the constriction.
Furthermore, we explored whether GTE can be used for modification of the Seebeck coefficient in the area of 2D material rather than for a single point (nanoscale constriction). We performed the FIB milling of arrays of holes of about 50 nm in diameter in a thick 50 nm layer of 2D material $SnSe_2$ using the varying pitch, density and ordering, showing that it is indeed possible to create multi-μm size areas of material with a very different Seebeck coefficient. By combining STGM with scanning thermal microscopy (SThM) [4] we found that the holes modify the heat transport on the distance of less than 20 nm, whereas the modification of the Seebeck coefficient is extended to the distances larger than 500 nm, suggesting the characteristic TE modification length is linked with the charge carriers.
In summary, we conclusively linked the GTE phenomenon to the geometrical factors and demonstrated that such an effect is present in other 2D materials such as dichalcogenide $SnSe_2$. We also showed the one can create large areas of multilayer 2D material building de-facto a new material with different TE properties while preserving its heat transport performance, paving the way for the much broader applications of GTE effect for the nanoscale and microscale cooling, heat manipulation and TE energy generation.

Unusually Large Anomalous Nernst Effects in Partially-Crystallized Ferromagnetic Metallic Glasses Hyungyu Jin and Hyun-Woo Lee; Pohang University of Science and Technology, Korea (the Republic of)

Nernst effect is a well-established thermoelectric effect where electrons traveling along the direction of a temperature gradient are deflected by the Lorentz force into the transverse direction perpendicular to both temperature gradient and applied magnetic field. As a result, a finite electric field develops along the transverse direction. In magnetic or topological materials, such transversal deflection occurs owing to different mechanisms classified into intrinsic and extrinsic origins, and the phenomenon is called the anomalous Nernst effect (ANE). Recent studies reported that a large ANE arises in materials possessing a large Berry curvature near the Fermi level. Since its origin is intrinsic electronic band topology, such a large ANE is observed in specific crystalline orientations which requires the use of single crystalline materials. Contrary to the growing research interest in discovering new materials with large Berry curvatures, much less attention has been paid to extrinsic aspects of ANE.
In this talk, we show that unusually large ANE can be obtained even in amorphous ferromagnetic metals, when the degree of disorder within the materials is properly controlled. By applying varied heat treatment conditions to initially amorphous materials, we were able to prepare samples with different crystallinity. Intriguingly, samples with partial crystallization show the largest ANEs, comparable to those of the single crystalline state-of-the-art materials. The fact that the ANEs of fully-crystallized samples are far smaller suggests a significant role of extrinsic contribution to the observed large ANEs in partially-crystallized samples. Such large extrinsic contribution is further supported by detailed analysis of anomalous Hall effect, which reveals an unprecedented scaling relation between the longitudinal resistivity and Hall resistivity. Our work sheds new light on disordered materials as promising candidates for large ANE with better mechanical robustness than their single crystalline counterparts.

Advanced Energy Materials and Devices for Low-Grade Heat Harvesting and Flexible Thermal Sensing Dongyan Xu; The Chinese University of Hong Kong, Hong Kong

With the recent advance of the internet of things, wearable technology, and soft robotics, there is a great interest to develop low-cost energy harvesting devices for converting low-grade heat into electricity and flexible sensors for artificial thermal sensation. In this talk, I will share our recent research efforts in these directions through exploring three effects: (1) thermoelectric effect; (2) thermogalvanic effect; and (3) thermodiffusion effect. Specifically, we

developed flexible micro thermoelectric generators (TEGs) with high power density and light weight by integrating pulsed electroplating with microfabrication processes. Compared to traditional electron-based thermoelectric materials, redox couples and ionic thermoelectric (iTE) materials using ions as charge carriers can achieve much larger thermopowers typically on the order of mV/K. Recently, we report polarized electrolytes consisting of I^-/I_3^- redox couple, methylcellulose (MC), and KCl with ultrahigh thermopowers of -8.18 mV/K for n-type and 9.62 mV/K for p-type. Thermoresponsive MC enables polarization switching from n-type to p-type above the gelation temperature, while the giant thermopowers mainly come from the thermogalvanic effect of the I^-/I_3^- redox couple enhanced synergistically by MC and KCl. We also developed an iTE hydrogel with a thermopower of 24.17 mV/K and flexible thermal sensor arrays for human-machine interaction.

11:30 AM EN07.18.06
Thermal Characterization of GeTe PCM based Reconfigurable Devices Zexiao Wang, Xiu Liu, Hyeonggyun Kim and Sheng Shen; Carnegie Mellon University, United States

Nanophotonic devices with adjustable optical response can be achieved through phase change materials (PCMs) such as Germanium Tellurium alloy (GeTe). GeTe can be rapidly melt-quenched or annealed between amorphous and crystalline states with large contrast of electrical and optical properties, making it a good candidate in reconfigurable electromagnetic devices, optical devices, and memory devices. However, challenges exist on the thermal aspect of GeTe PCM, where the cooling rate high as 1 K/ns from the melting point of 1000 K is required for quenching process. The stringent thermal requirements possess high demands on both heating power and heat dissipation ability. Currently several different heating approaches are adopted to achieve phase change in GeTe based nanophotonic devices, including hot plate, pulsed laser, and integrated electrical heater. However, reversible switching of GeTe covering a large area remains difficult, and the device-level understanding of the thermal and electrical properties is still elusive for the GeTe reconfigurable devices.

In this work, device level thermal modelling is conducted for a representative GeTe switching heater device, which includes a Si substrate, an AlN insulation layer, an electrical heater made from tungsten, an Al2O3 separation layer, and the GeTe phase change material on the top. Frequency domain thermoreflectance (FDTR) method is adopted for thermal characterization, where thermal properties of a multi-layered structure can be determined through pump-probe laser heating and curve fitting to an analytical heat conduction model. The most thermally sensitive material parameters, including thermal conductivity and heat capacity of Si, AlN and GeTe layers, as well as the thermal boundary resistance between AlN and tungsten heater, are characterized through FDTR with delicately designed multi-layered samples.

Based on the thermal measurement results, an actual GeTe switching heater device is designed with 8-unit heater layout covering the phase change region of $25\times12.5\ \mu m^2$. A finite element model is established for the heater device to predict the steady state and transient thermal responses. To validate the thermal measurement results and the finite element model, the heater device is also fabricated and experimentally tested. The steady state thermal response is measured through a thermal mapping system; the transient response is reflected through a phase change test with pulse voltage input. Both the steady state temperature profile and the amorphized GeTe region under pulse input show high agreement between simulation and experiment, proving the accuracy of the thermal measurement and the finite element model. This work extends the thermal understanding of the GeTe based reconfigurable devices, and provides a general workflow on comprehensive thermal modelling of nanofabricated heater structures.

1:45 PM *EN07.17.01
Triboelectrics and Tribovoltaics for Energy Harvesting Sang-Woo Kim; Yonsei University, Korea (the Republic of)

Energy harvesting systems based on triboelectric nanomaterials are in great demand, as they can provide routes for the development of self-powered devices which are highly flexible, stretchable, mechanically durable, and can be used in a wide range of applications. Ultrasound was used to deliver mechanical energy through skin and liquids and demonstrated that a thin inplantable vibrating triboelectric nanogenerator is able to effectively harvest it. Secondly the presenter is going to introduce a two-dimensional (2D) materials-based tribotronics for possible future application toward tactile sensors, robots, security, human-machine interfaces, etc. The triboelectric charging behaviors of vaious 2D layered materials including graphene, MoS_2, WS_2, etc were investigated in order to decide the triboelectric position of each 2D material using the concept of a triboelectric nanogenerator, which provides new insights to utilize 2D materials in triboelectric devices, allowing thin and flexible device fabrication. Finally I will introduce a novel tribovoltaic effect, which can generate DC power output through the coupling of tribo exciton and drift by built-in electric field to overcome the limitations of conventional AC power-generating triboelectric nanogenerators. It was found that DC power can be generated at dynamic perovskite/CTL heterojunctions by electrical carrier generation from triboelectrification between two layers, which is different from the electric energy generation by photon excitation in solar cells. The tribovoltaic effect enables a paradigm shift in energy harvesting by enhancing battery charging efficiency based on an innovative working mechanism.

2:15 PM EN07.17.02
Dynamically Tunable Solid-State Thermal Energy Storage Shuang Cui[1,2] and Judith Vidal, Ph.D[2]; [1]The University of Texas at Dallas, United States; [2]National Renewable Energy Laboratory, United States

Thermal energy storage (TES) utilizing phase-change materials (PCMs) holds substantial promise in various applications, such as climate control in buildings and thermal management for batteries and electronics. A critical challenge in PCM-based TES applications is the limited tunability of the operating temperature, especially for the near-ambient applications, as the PCM has a fixed transition temperature as designed. or instance, within buildings, the required operating temperature can significantly fluctuate between summer and winter, and even exhibit notable diurnal variations. This results in suboptimal PCM utilization, often leading to incomplete melting or no phase transition at all. Recent efforts have aimed to enhance the tunability of thermal materials and devices, enabling dynamic changes in their properties and performance. However, most of these endeavors have primarily concentrated on modifying thermal transport properties, such as thermal conductivity, while neglecting thermodynamic characteristics, specifically the transition temperature of materials. Changing the transition temperature using external stimuli like pressure, electric fields, or magnetic fields presents a non-trivial task, as the required magnitude of the stimulus to achieve a sizable change in Tm is typically large, and the enthalpy change at Tm is only moderate for thermal storage applications. Additionally, handling the liquid phase of PCMs during phase transitions (melting) has hindered practical TES implementation. To address these challenges, this work reports a solid-state, tunable TES utilizing shape stabilized PCMs. This innovative tunable TES

achieves an impressive dynamic transition temperature tunability of up to 10°C and enables outstanding shape stability over a month without leakage during melting. Such advancements offer the potential for simplified and safer TES device and system designs. Furthermore, the tunable TES exhibits exceptional cyclability, maintaining TES capacity across more than 100 cycles, thus presenting a promising avenue for practical applications.

Physics-Based Prediction and Design of Absorption Properties of Moisture-Capturing Hydrogels Carlos D. Diaz, Lorenzo Masetti, Miles Roper, Kezia Hector, Yang Zhong, Zhengmao Lu, Gustav Graeber, Jeffrey C. Grossman and Gang Chen; Massachusetts Institute of Technology, United States

Moisture-capturing hydrogels have emerged as promising low-cost sorbent materials for applications including thermal management, thermal energy storage, and atmospheric water harvesting. Despite extensive efforts in the synthesis of novel hydrogels, there is a major knowledge gap between the synthesis variables and the material properties, which hinders the design of properties and system-level optimization. In this work, we develop physics-based models to predict the properties of moisture-capturing hydrogels from their composition. We develop and experimentally validate thermodynamic models that accurately predict the water uptake and absorption enthalpy as a function of humidity as relevant hydrogel synthesis variables are changed. We also develop mass transport models, using a convection-limited transport description, that accurately predict experimental absorption and desorption speeds. This work represents a major step in the design of moisture-capturing hydrogels, enabling application optimization for high performance thermal management of electronics, buildings, and people, heat storage, and atmospheric water production.

2:45 PM EN07.17.05
Hydrogel-Salt Hydrate Composite for Highly Stable Heat Energy Storage with Reduced Supercooling Sung Bum Kang, Youngmun Lee, Wonsik Eom, Wuchen Fu, Mayur S. Prabhudesai, Daniel Hsieh, Sameh Tawfick, Nenad Miljkovic, Sanjiv Sinha and Paul V. Braun; University of Illinois at Urbana-Champaign, United States

Phase change materials (PCM) have potential for use in thermal energy storage in buildings, medical devices, and water heat pumps. Sodium sulfate hydrate (SSD) is appealing due to its high energy storage capability and affordability. However, SSD has issues including high supercooling (> 15°C) and low thermal cyclic stability. In this study, we introduced an ionic molecular nucleating agent that decreases the supercooling temperature to under 2°C. When this SSD was combined with a hydrogel, it maintained its thermal energy storage capacity for over 100 cycles without any decline. The success is attributed to the polymer confining the SSD crystals, preventing large-scale phase separation and the nucleating agent which resulted in nucleation of many small SSD crystals at small undercoolings rather than a small number of larger crystals. As a proof-of-application, we synthesized this composite at a kg scale and demonstrated its properties in a close to real-world demonstration.

3:30 PM EN07.18.01
Ultra Low-Cost Phase Change Hydrogel for Building Thermal Regulation Lyu Zhou, Zainab Faheem and Shuang Cui; University of Texas at Dallas, United States

Energy-efficient thermal management for buildings is one of the keys to our sustainable future, as the demand for thermal comfort has increased swiftly under the impact of extreme weather. Tremendous research endeavors have been reported in recent decades, striving to tackle thermal management tasks using sustainable methods such as radiative cooling, evaporative cooling, and smart window. Thermal energy storage (TES), which utilizes latent heat of phase change materials (PCMs), also received emerged interest for its ability in mitigating temperature fluctuations and sustaining thermal comfort without extra energy input. However, practical implementation of PCMs is constrained by cost, shape stability, and energy density. Here we report an inorganic PCM composite based on sodium sulfate decahydrate (SSD). In contrast to most organic PCM, SSD has an ultralow cost (1.60 $/kWh) and high energy density (254 J/g), making it a promising PCM for building thermal management. To address the intrinsic limitations of SSD in shape stability and phase separation, we introduced another low-cost hydrogel, i.e., poly (acrylamide-co-acrylic acid), to encapsulate SSD through swelling. In particular, we optimized hydrogel composition by exploring the hydrolysis effect, and achieved a swelling ratio of 29.96 g/g in 70 wt% SSD solution. The obtained phase change hydrogel exhibited a melting latent heat of 133.32 J/g with melting temperature of 32.84 °C, while withholding excellent shape stability after 500 hundreds thermal cycles. This demonstrated thermal properties promise a cost-effective PCM for building thermal regulations.

3:45 PM EN07.18.02
Broadband Thermal Management Using Smart Cooling Films Will Chang Liu; Massachusetts Institute of Technology, United States

With the escalating trend of climate change, we are under severe pressure to increase the resilience of commercial and residential buildings and vehicles. Smart lighting and thermal management of windows promise to improve indoor thermal comfort with minimum added carbon footprints. We report a passive smart cooling technology for thermal management throughout the spectrum from visible to mid-infrared regions by using a thermochromic hydrogel network integrated with an optically transparent polymer coating for radiative cooling. We have achieved excellent optical properties, including luminous transmittance of 81.8% and solar transmittance modulation of 74.8%, to intelligently minimize direct solar radiation. Notably, merging the light management of thermochromic hydrogel networks with the thermal management of daytime radiative cooling films enables us to minimize secondary radiation from hot window surfaces, contributing to overall cooling power. To the best of our knowledge, this is the first demonstration of the integration of a thermochromic smart medium and passive radiative cooling film into a single cooling apparatus in a field test. Through this integration, we achieved an indoor temperature drop of up to 5.1°C on summer days with zero energy consumption.
Additionally, our material and device designs offer advances far beyond spectrum tunability and cooling power. The mechanical flexibility and moldability of the hydrogel network promise extensive applications for our technology in buildings, vehicles, and other complex geometric shapes with intelligent cooling needs, distinguishing it from any prior liquid-based counterparts. We believe that the broad thermal management of thermo-responsive hydrogel networks and visually transparent radiative cooling coatings could usher in a new paradigm for extending the scope of space temperature control, bringing tangible benefits to real-world applications aimed at alleviating global cooling needs.

4:00 PM EN07.18.03
On-Demand Modulation of Radiative Cooling Performance with Hygroscopic Salt-Cellulose Fiber for Building Applications Huajie Tang and Dongliang Zhao; School of Energy and Environment, Southeast University, China

Radiative cooling of buildings with low carbon footprints has drawn widespread attention. However, the possible overcooling effect at night may increase building heating energy consumption in transition seasons, especially in mild climates. Herein, we developed a simple, low-cost, and high-performance hygroscopic salt-cellulose fiber to modulate diurnal radiative cooling performance. With the transition of desorption and adsorption of the cooling fiber, the sub-ambient temperature reduction can reach 2.4 °C during the day, and be limited to below 2 °C at night. The daytime cooling performance is dominated by thermal radiation when ambient relative humidity is low, and dominated by evaporation when relative humidity is high. The nighttime adsorption enthalpy is contributed by multiscale mechanisms, including the adsorption of hydrophilic functional groups, capillary condensation, as well as the deliquesce of $CaCl_2$ salt. The profusion of cellulose and hygroscopic salt features desirable cost-effectiveness, and the simple preparation process allows large-scale applications.

4:15 PM EN07.18.04
Cell-Level Mapping of The Thermal Conductivity of Electrode Composites in Lithium-Ion Batteries Juwei Sun and Yee Kan Koh; National University of Singapore, Singapore

In Lithium-ion batteries (LIB), the surface of the active material serves as the primary site for reactions and heat generation. Also, it is the place where the hotspots trend to emerge. Localized high temperatures within the micrometer range can trigger a series of chain reactions, leading to uncontrollable thermal runaway in batteries. Therefore, a detailed understanding of the thermal properties of LIB electrodes is of paramount importance. Previous research has used various methods, for example, laser flash and steady-state measurement, to measure the thermal properties of electrode composite or active materials. However, the previous research typically treats the thermal properties of LIB electrodes as a macroscopic characteristic, failing to provide detailed information about real electrodes. The objective of this study is to produce micrometer-scale resolution mapping for the thermal conductivities of the electrodes.

We adapted TDTR technology, which is a well-established optical pump-probe technique, to perform experiments. In TDTR, the pump laser beam heats the sample surface, and the reflected probe beam is detected to analyze the thermal response of the sample. Before conducting the experiment, we took multiple steps to ensure that the sample would yield a sufficient reflected probe signal. We utilized ion milling techniques to polish the electrode's cross-sectional surface until its Root Mean Square (RMS) roughness within a 10um x 10um area was reduced to less than 50nm. We selected graphite and lithium cobalt oxide (LCO) electrodes, both made from active material particles of approximately 20um in size for the experiment. The local measurement was first conducted under three different conditions: 1) 6um spot size laser at 18.9MHz heating frequency, 2) 3um spot size laser at 9.8MHz heating frequency, and 3)3um spot size at 5.4MHz heating frequency. We fitted the obtained thermal response signal with a thermal model. From this, we derived an isotropic thermal conductivity for LCO, and an anisotropic thermal conductivity for graphite. Finally, we conducted scanning experiments on the electrode within a 30μm x 30μm area. Data was collected at 1 um intervals during the scan. The scanning results clearly indicate the thermal conductivity of each component, with distinct boundaries that align well with the SEM images.

Our study provides detailed thermal properties at high spatial resolution, enabling the calculation of the temperature distribution during battery operation and the prediction of hotspot emergency conditions. This study facilitates the development of thermal management strategies at the electrode level in LIBs, addressing the safety concerns at their root.

4:30 PM EN07.18.05
***In Vivo* Thermal Conductivity Measurement of Blood-Perfused Tissue Accounting for The Effect of Blood Flow** Gimin Park[1], Boksoon Kwon[2], Sang-Kyu Kim[2] and Woochul Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of)

Understanding the thermal properties of human tissue is crucial for evaluating their ability to regulate temperature, assessing the effectiveness of thermotherapy techniques, designing skin-contact medical devices, and optimizing thermal comfort in different environments. Traditional measurement methods primarily conducted on nonliving materials involve modifying the material's geometry and placing the material in a vacuum environment, which is not achievable for living human beings. Moreover, the presence of blood flow and perfusion of tissue introduces advection effects described by Pennes' bioheat equation, and its influence on thermal response at the skin must be considered when measuring thermal conductivity. Previous studies have often been unable to isolate the effect of blood perfusion, resulting in the quantification of effective thermal conductivity, which exhibits a strong temperature dependence due to vasomotion's role in dissipating excess heat or conserving heat in cold conditions. In this study, we employ sinusoidal heating and transient plane source heating to subsequently measure the blood perfusion rate and thermal conductivity exclusively at the skin by controlling the thermal penetration depth. Analytical solution to the transient bioheat equation allows us to separate the influence of blood perfusion when obtaining the thermal conductivity attributed solely to conduction. Tissue temperatures ranging from 30.5°C to 35.5°C yielded tissue thermal conductivity averaged at 0.334 ± 0.035 W/m-K. This value of thermal conductivity agrees well with that of excised human epidermis (0.21 – 0.41 W/m-K) [1]. As expected, the blood perfusion rate increased with increasing tissue temperature from 0.143×10^{-3} to 3.421×10^{-3} $m^3/s/m^3$, which is typical for convective heat transfer coefficients ranging from 5 to 15 W/m^2-K. By measuring the thermal conductivity of blood-perfused skin, we hope to enhance the design and performance of wearable devices, improve the efficacy of thermoregulation techniques, and advance the understanding of various skin-related disorders and conditions. The insights gained from these studies have the potential to revolutionize fields such as biomedical engineering, personalized medicine, and thermal comfort optimization, ultimately benefiting human health and well-being.

High-Powered Superhydrophobic Pyroelectric Generator via Water Droplet Impact Jeonghoon Han[1], Seongjong Shin[2], Seungtae Oh[3], Heejae Hwang[4], Dukhyun Choi[5], Choongyeop Lee[3] and Youngsuk Nam[2]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Kyung Hee University, Korea (the Republic of); [4]Korea Institute of Science and Technology, Korea

(the Republic of); [5]Sungkyunkwan University, Korea (the Republic of)

Recent studies on water-based pyroelectric generators (PyGs), which convert thermal energy to electrical energy, have focused on different operational modes like water evaporation, water stream, and droplet sliding. However, the development of sustainable, high-powered generators and comprehensive theoretical models has been limited. In response, our research introduces a superhydrophobic (SHPo) PyG, exploiting the characteristics of lead magnesium niobate-lead titanate (PMN-PT) coated with titanium dioxide nanoparticles. We analyzed power density by considering the phase transient temperature that maximizes the pyroelectric coefficient of PMN-PT, testing various Weber numbers and droplet diameters within a moderate operating temperature range of 40°C to 80°C. Considering the dynamic characteristics of water droplet on SHPo surfaces, we suggest the peak current model that can accurately predicting the actual peak current. Also, the maximum power density of 54.5 $\mu W/cm^2$ at a droplet diameter of 3.6 mm and a PMN-PT temperature of 80°C, a noteworthy improvement over 3 times higher than previous water-based PyGs. Our results enhance the understanding of the pyroelectric effect coupled with drop impact dynamics and outlines novel strategies for designing high-performance water-based PyGs.

8:15 AM EN07.19.02
Integrating Porous Copper for Supercooling Mitigation in Gallium-Based Phase Change Material Thermal Storage Seokkan Ki[1], Seongjong Shin[1], Sumin Cho[2], Soosik Bang[1], Dongwhi Choi[2] and Youngsuk Nam[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of)

Phase change materials (PCMs) undergo a transition from solid to liquid, absorbing a substantial amount of latent heat, making them suitable for systems that efficiently store and release heat as needed. Research on PCMs is actively pursued in various fields such as energy harvesting, air conditioning, and electronic device thermal management. Paraffin has been extensively utilized in PCM research primarily due to its high specific latent heat (~230 kJ/kg) and cost-effectiveness. Nevertheless, challenges arise when paraffin is applied to systems requiring rapid thermal response, such as electronic devices, due to its low thermal conductivity of approximately 0.2 W/mK.

To address these challenges, researchers have turned to gallium-based liquid metals with an appropriate specific latent heat (80 kJ/kg) and a comparatively high thermal conductivity of approximately 40 W/mK. While gallium may possess a lower specific latent heat per unit mass compared to paraffin-based PCMs, its density exceeds that of paraffin by more than six times. As a result, the specific latent heat per unit volume increases, enabling efficient heat absorption within confined volumes. Furthermore, gallium exhibits high thermal conductivity, enabling rapid system response under conditions of fluctuating thermal load. However, gallium faces a supercooling issue, where it remains in a liquid state after absorbing heat and fails to transition back to a solid state when the temperature drops below its freezing point. In this context, resolving the supercooling problem is imperative for the successful application of gallium in PCM systems.

This study suggests a gallium-porous copper composite to mitigate gallium's supercooling issue. Deoxidized gallium and porous copper were efficiently combined to create the composite material in a low-concentration hydrochloric acid environment. The porous structure increased the surface area, and the intermetallic compound CuGa2 that formed at the interface facilitated heterogeneous nucleation, reducing the supercooling of gallium. The quantitative performance of supercooling mitigation was verified through differential scanning calorimetry and multi-cycle heating and cooling experiments.

8:30 AM EN07.19.03
Assessing Lattice Thermal Conductivity of Topological Insulator Bi_2Se_3 by Temperature-Dependent Raman Spectra Vipin K. E and Prahallad Padhan; Indian Institute Of Technology Madras, India

Topological insulators (TIs) have emerged as a fascinating material class that exhibits unique electronic properties, making them promising candidates for various technological applications. One of the promising areas where TIs hold great potential is thermoelectricity. Unlike conventional materials, TIs possess a non-trivial band gap in their bulk states but harbor conducting surface states due to the presence of robust, spin-polarized, and topologically protected electronic states. The conducting surface states of TIs, known as topological surface states (TSS), have a linear energy-momentum dispersion relationship, which can lead to high electron mobility and improved electrical conductance. This unique electronic structure offers an advantage over conventional thermoelectric materials, where achieving both high electrical conductivity and low thermal conductivity is challenging.
The pursuit of highly efficient thermoelectric (TE) materials hinges on understanding their electrical conductivity (σ), Seebeck coefficient (S), and thermal conductivity (k_L). Among these, thermal conductivity (κ_L) plays a pivotal role and is a critical factor in TE efficiency. This study delves into the reduction of κ_L, focusing on hexagon-shaped nanocrystals cluster of Bi_2Se_3, synthesized via the hot-injection technique employing non-toxic solvents. The nanocrystals' temperature-dependent Raman spectra were analyzed to determine the average Debye temperature (θ_D) and Gruneisen parameter (γ), utilizing the bond order–length–strength correlation theory(BOLS).
At room temperature, κ_L of the Bi_2Se_3 nanocrystals was evaluated as 1.85 $Wm^{-1}K^{-1}$ using θ_D and γ optained from BLOS theory, closer to the simulated values of 1.4 $Wm^{-1}K^{-1}$ in-plane and 0.4 $Wm^{-1}K^{-1}$ out-of-plane direction.
Our theoretical studies adopting 3 phonon process demonstrate that over 54 % of in-plane cumulative κ_L, and around 12 % of out-of-plane cumulative κ_L are contributed by the modes below 2 THz, which are dominated by the Bi atom. The ratio of in-plane cumulative κ_L to out-of-plane cumulative κ_L at 5 THz is ~ 3.58, establishing the anisotropic κ_L of Bi_2Se_3. Further our mean free path (λ) dependent κ_L studies demonstrated the cumulative κ_L in the plane is dominated by the phonons with a mean free path below(λ)~ 15 nm, while along the out-of-plane directions, the phonons with an λ of ~ 5 nm have strong contributions. The Bi_2Se_3 is an anisotropic system, and the cumulative thermal conductivity as a function of the λ displays that a major contribution is arising from the shorter mean free path. This scattering is the main cause of low lattice thermal conductivity in the investigated system.
The introduction of nanostructuring-induced grain boundaries in Bi_2Se_3 obstructs long-mean-free-path phonons. Furthermore, intentional doping can also significantly reduce the phonon mean free path, effectively lowering κ_L. Anisotropic phonon scattering, facilitated by weak Van der Waals forces between quintuple layers in the out-of-plane direction, alongside acoustic-optical phonon scattering and anharmonicity, impeded efficient thermal energy transport in Bi_2Se_3, resulting in reduced k_L.
This research demonstrates a method for determining κ_L from temperature-dependent Raman spectra and sheds light on the potential of intentional nanostructuring and doping to optimize TE materials. These findings are instrumental in advancing the understanding of materials that enhance the TE quality factor and, consequently, the figure of merit, offering a promising avenue for future research in the realm of thermoelectrics.

8:35 AM *EN07.19.04
Plasmon Thermal Conductivity of aThin Metal Film Bong Jae Lee; KAIST, Korea (the Republic of)

The well-known classical size effect causes decreased thermal conductivity of thin films at the nanoscale, which usually results in hot-spot formation and device performance deterioration. Recent research has revealed a novel heat transfer mechanism based on the use of surface electromagnetic waves in a polar dielectric, specifically Zenneck surface modes. Surface plasmon polarations (SPPs) are a type of surface electromagnetic wave that is associate with free electrons within metals and so functions as a heat carrier. Thermally excited SPPs have been used to manipulate the near-field thermal radiation across

a broad spectrum in lossy metals and heavily doped semiconductors. This presentation will discuss our most recent results about the surface-plasmon-enhanced in-plane thermal conductivity of a thin metal film on a glass substrate.

9:05 AM EN07.19.05
Mechanism of Transition Metal-Assisted Healing of Defective Graphene Anbarasan Radhakrishnan and Jae Hyun Park; Gyeongsang National University, Korea (the Republic of)

In graphene synthesis, the emergence of atomic vacancy defects is inevitable. These defects compromise the lattice's capacity to conduct heat, resulting in a diminished thermal transport efficiency for graphene-based devices. The introduction of adatoms to these vacancies termed the healing of defected graphene, has been identified as a method to enhance thermal conductivity. However, the details of the healing process remain unclear. This study delves into the mechanism underlying the healing of mono-vacancy (MV) defected graphene using Pt atoms, employing neural network potential (NNP)-assisted molecular dynamics (MD) simulations. In contrast to the marginal increase in thermal conductivity observed with pure Pt atoms, healing with C-Pt fragments significantly elevates the lattice thermal conductivity of defected graphene as the healing progresses. Upon full healing, the thermal conductivity of defected graphene healed by C-Pt fragments reaches 5.2 times that of the pre-healing state. During the healing process with C-Pt fragments, the fragments dissociate, allowing Pt atoms to move freely on the surface while carbon atoms remain stationary at the vacancies. Subsequently, Pt atoms gather to form a metal cluster, influencing the distribution of phonon density of states and causing a change in lattice thermal conductivity. The study also explores alternative transition metals such as Ni and Pd, with the resulting lattice thermal conductivities for C-Ni, C-Pd, and C-Pt fragment-healed graphene recorded as 382.1 W/m K, 976.9 W/m K, and 1159.7 W/m K, respectively. This variation is attributed to differences in mass and adsorption energy. The findings of this research present the effectiveness of utilizing transition metals as a promising strategy for rectifying defective graphene and controlling lattice thermal conductivity, particularly for applications in thermal management.

This work was supported by the National Research Foundation of Korea funded by the Ministry of Science and ICT under Grant (2022M1A3C2074536, Future Space Education Center) and Grant (2021R1A2C2004207).

9:10 AM EN07.19.06
Solar-Thermal Energy Harvesting to Achieve Water Desalination Taylor Moore[1], Rana Biswas[1,2] and Meng Lu[1]; [1]Iowa State University, United States; [2]Ames Laboratory, United States

Harnessing solar energy to desalinate water is a critical need in many areas of the world where water supplies are scarce, or in regions affected by natural disasters. To address this problem, we developed a novel small-scale solar-thermal energy harvesting scheme to rapidly heat water to boiling, enabling distillation, water desalination, and generation of potable water.
We performed outdoor experiments demonstrating that concentrated solar power can heat water to boiling effectively and achieve desalinate water on a small scale. Using a 1.5 m dish shaped mirror to concentrate solar energy on a flask of water we achieved boiling of water within 1 hour. To accelerate the solar-thermal energy harvesting process we compare the performance of absorbing carbon-black coatings on glass flasks with uncoated flasks. We discuss the use of photonic structures that enhance thermal emission in relevant wavelength windows and describe preliminary measurements with these structures. We measured the conductivity (s) and concentration of total dissolved solids (TDS) in the starting water solution to be 4.32 milli-S/cm and 2.2 ppt respectively and found that these decreased to 20 micro-S/cm and 10 ppm in the distillate achieved with solar-thermal energy conversion, illustrating excellent desalination. To calibrate the outdoor solar-thermal energy conversion results we performed baseline indoor water distillation experiments. We found that the decreases of conductivity and TDS are in outdoor experiments are comparable with those achieved in benchmark indoor distillation experiments. We discuss pathways for scale-up of solar-thermal energy harvesting and water desalination to larger scales. The critical thermal transport processes will be described.
The work was partially supported by Iowa State University through the ECpE FuTure Grant and the ISU Honors program.

Rattling of Three-Fold Coordinated Copper in Sulfides: A Blockade for Hole Carrier Delocalization but a Driving Force for Ultralow Thermal Conductivity Emmanuel Guilmeau; CRISMAT, France

Copper-rich sulfides are attracting a wide attention for energy conversion applications due to their environment compatibility, cost effectiveness and earth abundance. Herein, based on a comparative analysis of the structural and transport properties of state-of-the art Cu-rich sulfides, we highlight the role of the cationic coordination types and networks on the electrical and thermal properties. By combining experiments and theory, we show that the ultralow thermal conductivity originates mainly from the very high anisotropic thermal vibration of copper due to its threefold coordination. Density functional theory (DFT) calculations reveal that these Cu atoms are weakly bonded and, thus, give rise to low-energy, Einstein-like vibrational modes that strongly scatter the heat-carrying acoustic phonons. Importantly, we demonstrate that the three-fold coordination of copper causes a hole blockade. This phenomenon hinders the possibility to optimize the carrier concentration and electronic properties through mixed valency Cu^{+}/Cu^{2+}, differently from tetrahedrite and most other copper-rich chalcogenides, where the main interconnected Cu-S network is built of CuS_4 tetrahedra. The comparison between various copper-rich sulfides demonstrates that seeking for frameworks characterized by the coexistence of tetrahedral and threefold coordinated copper is very attractive for the discovery of efficient thermoelectric copper sulphides. Considering that lattice vibrations and carrier concentration are key factors for engineering and controlling all transport phenomena (electronic, phonon, ionic…) in copper-rich chalcogenides for various types of applications, our findings on the structure/properties relationships can serve as new guidelines for the design of functional materials for the generation of sustainable energy with wide-ranging applications.

9:45 AM EN07.19.08
Strain-Driven Anomalous Lattice Thermal Conductivity in $BaPdS_2$ Xiao X. Yu[1,2], Can Wu[1], Jia W. Hong[2] and Bo Xu[1]; [1]Yanshan University, China; [2]Beijing Institute of Technology, China

Strain engineering is one of the most promising and effective routes toward continuously turning the electronic and optical properties of materials, while thermal property is generally believed to be sensitive and positive with the mechanical compress strain. In this paper, we investigated the lattice thermal conductivity of zigzag chain-like wrinkled structure $BaPdS_2$ with uniaxial compress strain along *c*-axis based on first-principles calculations and phonon Boltzmann transport equation. Unlike the commonly belief that the lattice thermal conductivity increases (or decrease) with compress (or tensile) strain for bulk materials, it is found that the κ_{latt}-*c* was nearly unchanged and κ_{latt}-*a* was increased exceptionally for $BaPdS_2$ with strain imposed in *c*-axis. The unusual strain dependence thermal conductivity in *c*-axis was mainly attributed to the enhanced phonon phase space that neutralized the weakened anharmonicity and the enhanced group velocity. While the abnormal increased κ_{latt}-*a* is attributed to the weak anharmonicity with compress strain perpendicular to *a*-axis, equivalent to uniform biaxial tension strain in *ab* plane. In addition, high thermal conductivity anisotropy was observed because of the large group velocity disparity along *a*- and *c*-axis. The finding discovers materials with unusual thermal conduction mechanism under strain along different directions, as well as provides new material platforms for potential heat-routing or heat-managing devices.

Enhanced Biomechanical Energy Harvesting and Gesture Monitoring: Superhydrophobic, High-Performance Hybrid Piezo-Triboelectric Nanogenerator Using Flexible Nanofibers Sushmitha Veeralingam, Jun S. Choi, Tran D. Khanh, Kampara R. Kishore, Seung B. Jung and Jong W. Kim; Sungkyunkwan University, Korea (the Republic of)

The burgeoning field of nanogenerators presents ongoing challenges in elevating performance through innovative strategies and architectures. This study addresses these challenges by synergistically combining the distinct properties of piezoelectric nanogenerators (PENG) and triboelectric nanogenerators (TENG). It harnesses the bulk polarization effect inherent in PENG and the contact electrification and electrostatic induction in TENG, thereby leveraging their combined strengths. Our focus is the development of a novel hybrid piezo-triboelectric nanogenerator (HPTENG), which employs a multi-layered nanofiber architecture, showing significant promise for applications in flexible electronics and electronic skins. This work introduces composite nanofibers composed of polyvinylidene fluoride (PVDF)-MoS2-MXene (PMMX), capitalizing on the superior piezoelectric effect of MoS2-PVDF and the two-dimensional structure and abundant dangling bonds of MoS2-MXenes. We synthesized MXene (Ti3C2) via chemical etching and MoS2 using the hydrothermal method. The resulting TENG, employing PMMX nanofibers as the negative triboelectric layer and Nylon 6,6 nanofibers as the positive layer, exhibited an open-circuit voltage (Voc) of 25 V and short-circuit current (Isc) of 1.2 µA. The PENG displayed a Voc of 10 V and Isc of 2.0 µA. Notably, the HPTENG demonstrated enhanced performance with a Voc of 100 V and Isc of 6.0 µA. This amplification can be attributed to the synergistic Piezoelectric-Triboelectric (TE-PE) effect, facilitating the conversion of random, low-frequency mechanical energy into electricity by altering the charge density in electrodes under external forces. Our study further emphasizes the necessity of augmenting the electrical performance of PENGs and TENGs to improve energy harvesting efficiency and signal-to-noise ratio. The practicality of HPTENG was validated by attaching it to various human joints, including fingers, elbows, palms, and knees, effectively monitoring real-time motion during activities like bending, running, and walking. Additionally, the need for hydrophobicity in wearable devices, to mitigate the influence of sweat, is addressed through contact angle studies of electrospun PMMX fibers, which demonstrated a significant angle of 117.5 degree, confirming their hydrophobic nature. The promising results of this study highlight the potential of HPTENG as an effective system for human gesture monitoring. The unique material composition and straightforward fabrication strategy presented here pave the way for novel solutions in the realm of advanced energy harvesting.

8:05 AM *EN02/EN08.02
Flexible Self-Charging Power Sources Ruiyuan Liu; Soochow University, China

Flexible power sources are key power solutions towards wireless wearable electronics, untethered soft robotics, and medical care. However, the high power consumption of various components in modern flexible electronics with limited volume raises great challenges for their sustainable operation. A flexible self-charging system that can harvest energy from the working environment and simultaneously charge energy-storage devices to supply power is a promising strategy. Flexible self-charging devices based on solar cells, triboelectric nanogenerators (TENGs), hydrovoltaics, and other emerging energy harvesting technologies hold the advantages of high power density and lightweight. Therefore, they would meet the critical requirements of next-generation soft electronics. In this presentation, the integration of several energy harvesting and storage devices will be introduced, regarding the materials, designs and applications.

Artificial Intelligence Guided Thermoelectric Materials Design and Discovery Guangshuai Han, Na Lu and Yining Feng; Purdue University, United States

Materials discovery from vast repositories of Earth's resources remains a significant impediment to revolutionary technological advancements. The labor-intensive and time-consuming nature of this process hampers the exploration of novel materials. While machine learning techniques have demonstrated their potential in expediting materials discovery, the challenge lies in obtaining effective material feature representations and achieving precise predictions of material properties. This research endeavors to establish an automated framework for material design and discovery, harnessing the power of data-driven AI models. Initially, we have developed a range of diverse material descriptors to enhance the representation and encoding of the distinctive characteristics of materials. This, in turn, leads to improved predictive performance across various molecular properties. As a baseline, we have focused on predicting thermoelectric (TE) properties of materials to demonstrate the framework's effectiveness. Remarkably, our proposed framework attains an accuracy rate exceeding 90% in forecasting TE properties. Moreover, our AI models have identified 6 promising p-type TE materials and 8 promising n-type TE materials. To validate our predictions, we have compared them with Density-functional Theory (DFT) calculations, and they align with the TE properties obtained from experimental results. By harnessing the potential of machine learning, deep learning, and data mining, this endeavor holds the potential to transform the paradigm of high-performance energy harvesting materials design, ushering in a new era of sustainable and efficient energy utilization.

Fabrication of Polyvinylidene Fluoride-Co Hexafluoropropylene (PVDF-HFP) Staple Yarns Using Discrete Electrospun Nano filaments and Evaluation of Their Mechanical and Piezoelectric Properties Adaugo M. Enuka and Vincent Z. Beachley; Rowan University, United States

Textiles fabricated from biocompatible and biodegradable polymers, such as Polyvinylidene fluoride-co hexafluoropropylene (PVDF-HFP), hold immense promise for various biomedical applications, including scaffolds and implants. Electrospinning, a well-established nanofiber fabrication technique, allows for producing nanofibers with exceptional properties at high throughput. One intriguing application of electrospinning is the creation of nano yarns spun from nanofibers. However, the conventional approach employs continuous filaments, limiting the control over filament parameters. An alternative approach involves the fabrication of yarns using discrete filaments, termed "staples," enabling precise tuning of filament parameters as fiber spinning and yarn spinning occur separately. Building upon previous work, this study introduces a high-throughput yarn-spinning device capable of producing staple yarns with repeatable and consistent parameters. By decoupling the electrospinning and yarn-spinning processes, we harness the unique properties of nanofibers and gain control over their parameters, a feat unattainable with current yarn fabrication methods. This advancement will facilitate an in-depth investigation into the impact of tunable fiber parameters on yarn mechanics. PVDF-HFP staple yarns are crafted from electrospun nanofilaments with varying parameters, such as draw ratio, density, segment length, and more, and their effects on yarn mechanical properties are explored.
Methods: Electrospinning and fiber collection are carried out using a Track electrospinning system. A potential difference is applied between the polymer tip (30% w/v PVDF-HFP in a 2:1 DMF: Acetone solution) pumping needle and the collection tracks. Continuous collection of fibers onto a roving track produces discrete filaments. These filaments are then transported to a spinning device that converts them into staple yarns. Mechanical testing and characterization adhere to ASTM D2256 standards.
Textile products created from biocompatible polymers, such as Polyvinylidene fluoride-co hexafluoropropylene (PVDF-HFP), find applications in biomedical technology. Electrospinning, a widely employed nanofabrication technique, enables the production of nanofibers with superior properties at a rapid production rate. One intriguing application of electrospinning is the creation of nano yarns spun from nanofibers. Currently, nano yarns are produced using continuous filaments.
PVDF-HFP exhibits remarkable properties, including excellent chemical resistance, high stability, low dielectric loss, a high dielectric constant, and biocompatibility. When electrospun, PVDF-HFP yields nanofibers with exceptional mechanical strength and an impressive surface area-to-volume ratio. Post-drawing of thin films enhances the β-phase content of these fibers. This copolymer boasts diverse applications, from developing susceptible sensors for measuring blood pressure and joint pressure to transforming mechanical energy from body movements into electrical energy. PVDF-HFP is also well-suited for energy harvesting systems in implantable medical devices. Furthermore, PVDF-HFP is being investigated for actuators and transducers capable of converting electrical energy into mechanical motion and finding applications in medical devices, such as microsurgical tools and drug delivery systems. The ongoing research aims to transform electrospun PVDF-HFP filaments into yarn using a specialized spinning device to assess the piezoelectric responses of the resulting yarns for various biomedical applications. This study presents a significant advancement in developing PVDF-HFP staple yarns, offering a more versatile and tunable approach for biomedical applications. Integrating electrospinning and yarn spinning at distinct stages enables precise control over yarn parameters, expanding the potential for harnessing the remarkable properties of PVDF-HFP in diverse medical devices and systems.

9:05 AM EN02/EN08.05
Macro-Scale Patterning for Hierarchically Designed Thinner Peltier Sheets Norifusa Satoh[1], Jin Kawakita[1] and Junnosuke Murakami[2]; [1]National Institute for Materials Science, Japan; [2]Sekisui Chemical Company, Limited, Japan

Towards the Global Cooling Pledge launched on CoP28 at Dec. 5, 2023, reducing over 60% greenhouse gas emissions from the cooling sector [ref. 1], thermoelectrics (TEs) has a great potential because Peltier human cooling devices directly cool down the body temperature not the entire room temperature to save 10-times energy consumption compared to air conditioners only [ref. 2,3]. To slim the thickness and enhance the contacting body area when using the same amount of TE materials [ref. 3,4], we have been developing thinner Peltier sheets using sticky TE materials [ref. 5,6] based on a hierarchical multi-component strategy turning element composition of TE particles for high Seebeck coefficient at atomic scale [ref. 7], controlling the surface of TE particles for small interfacial electric resistance at nano scale [ref. 7], and minimizing thermal conductivity and absorbing mechanical bending stress by hybridizing organic solvent with the TE particles [ref. 6] and adopting ultra-thin high performance foam at micro-scale [ref. 3]. Instead of the benefits on flexibility and in the rate of heat transfer [ref. 3,4], however, Peltier sheets tend to ruin the cooling performance. Since thinner design requires higher current at the maximum operating point, more Joule heat is generated at the electrodes sandwiching the TE materials to reduce the temperature difference formed within the TE materials based on Peltier effect. Especially, narrow electrode patterns adopted for the TE generation modules to accumulate the thermopower based on Seebeck effect in series and drive booster circuits [ref. 5] generates Joule heat in general. Through surveying various pattern combination between sticky TE materials and electrodes at macro-scale, herein, we propose a different pattering rule than that for TE generation modules.

9:10 AM EN02/EN08.06
Procedure of Failure Analysis on Commercial Available Thermoelectric Modules Karl-Heinz Gresslehner[1], Martin Krenn[1], Patrizia Lerner[2], Lukas Gupfinger[1] and Bernhard Sonderegger[1]; [1]Johannes Kepler University Linz, Austria; [2]University Graz, Austria

In this work, the procedure of a failure analysis on commercial available thermoelectric modules (TE-M) is presented. Due to the research activities in recent years, TE-materials become excellent candidates for power generation devices (TEG) which can be used in the mid- and high-temperature range up to 500 °C on the hot side of the TE-M. Now, in order to bring TE-M from laboratory status to industrial applications, it is very important that the intrinsic positive properties of a TEG, such as no moving parts, easy scalability, etc. can be fully exploited through a high long-term stability / reliability.
To quantify reliability, appropriate stress tests / reliability tests must be performed and defective modules must be analyzed for their failure mode and failure cause / failure location using non destructive (NDE) and destructive evaluation (DE) techniques. Failure analysis is a complex process of collecting and analyzing data to determine the failure mode / failure mechanism and location of the failure in a TE-M (root cause failure analysis). The results of failure analysis now allow the weaknesses of the component to be identified and help to understand the mechanisms and causes of failures, making it possible to undertake corrective measures to optimize the product and guarantee its quality and reliability. In this context, a rough distinction between so-called 'soft' and 'hard' failures is helpful. A soft failure means that the TE-M is working, but is out of specification, generally resulting in an increased internal resistance due to degeneration. A hard failure means that the TE-M is completely inoperable, i. e. no current can flow due to delamination or a gap (e. g. defective soldering or broken leg).
In this work we present the applicability of the NDE methods measuring the internal resistance (for soft and hard failures), IR-thermography (for soft failures), scanning acoustic microscopy (for hard failures) and X-ray computed tomography (mainly for hard failures). After NDE, DE methods of embedding the TE-M, cutting, grinding and polishing the surface where applied, followed by the NDE analysis methods using optical microscopy, SEM and EDS to determine the location of the defect.

Acknowledgments

Defects Engineering in Thermoelectric Copper-Based Sulfides Emmanuel Guilmeau; CRISMAT, France

Among the various possibilities offered by the periodic table, copper-rich sulfides represent a formidable source for the discovery of low cost and environmentally benign thermoelectric materials. Copper-rich sulfides form an important class where univalent copper is the dominant element, giving the possibility of creating hole carriers in the conductive "Cu–S" network for the generation of *p*-type thermoelectrics. During this presentation, recent advances in synthetic minerals and new sulphide compounds will be shown. Some peculiar structural features in connection with atomic and nanoscale order/disorder phenomena and defects engineering were carefully examined to establish rules and correlations between the crystal structures, nano-microstructures, electronic structures, vibrational and thermoelectric properties.

9:30 AM EN02/EN08.08
Effect on Thermoelectric and Mechanical Properties of Interstitial Void Filling by Cu in ZrNiSn HH Alloy Shamma Jain[1,2], Ajay K. Verma[1,2,3], Kishor K. Johari[1,2], Christophe Candolfi[4], Bertrand Lenoir[4] and Bhasker Gahtori[1,2]; [1]CSIR-National Physical Laboratory, India; [2]Academy of Scientific & Innovative Research (AcSIR), India; [3]RMIT University, Australia; [4]Institut Jean Lamour UMR 7198 CNRS - Universite de Lorraine Campus ARTEM, 2 allee Andre Guinier, BP 50840, Nancy 54011, France, France

Widely explored ZrNiSn half-Heusler (HH) alloy has an interpenetrating fcc cubic crystal structure with four vacant positions in the unit cell, where the elemental substitution at these voids by off-stoichiometric composition could play an imperative role in the optimization of electronic transport by tuning the band structure and band gap, as well as it can reduce the phonon transport by interstitial point defect scattering. In the present study, off-stoichiometric compounds are synthesized opting a fast and facile route of arc melting and spark plasma sintering by surplus Cu in ZrNiSn system to fill the available voids at 4d (¾, ¾, ¾,) in the HH unit cell. Here, 0-4% Cu excess was used to easily occupy the vacant site which can improve the thermoelectric properties. The XRD results reflect that up to 2% Cu partially occupied the vacant site. The electronic transport enhances with the Cu excess by increased carrier density due to shifting of fermi level as reflected by reduced chemical potential. Further, this Cu excess of upto 2% significantly reduces the thermal conductivity due to interstitial point defect phonon scattering. The figure-of-merit *ZT* enhances ~ 45% with the peak value 0.81 at 775 K which is the result of interstitial filling of 2% Cu in ZrNiSn. The mechanical properties also improved upto 2% Cu excess, confirming interstitial filling strengthen the mechanical properties.

Materials and Device Strategies for Energy Nanogenerators Pooi See Lee; Nanyang Technological University, Singapore

Tribo- and piezo-electric nanogenerators (TENG and PENG) are deemed as low-cost, and effective distributed energy conversion of mechanical energy to electricity, which allow us to harvest wasted mechanical energy from the environment or human motion. Device design and materials composition are the two important approaches in addressing the challenges in improving the output power of TENG and/or PENG. One of the device engineering involves generation of continuous direct current electricity from dynamic p-n or Schottky junctions to achieve tribovoltaic nanogenerator (TVNG). By incorporating ferroelectricity, we aim to control the interfacial energy band bending to regulate work function for enhanced current output. The materials composition used is a lead-free perovskite-based (3,3 difluorocyclobutylammonium)$_2$CuCl$_4$ ((DF-CBA)$_2$CuCl$_4$) that is coupled with Al metal to form Schottky junction TVNG.[1] The system provides excellent surface charge modulating capacity and high work function regulation via an electrical poling control. On the other hand, in harnessing mechanical bending motion through PENG, an auxetic structure on polymer substrate was fabricated with 3D printing. A synclastic effect of the auxetic structure is harnessed to achieve bending mode flexible energy harvesting of PENG will be introduced.[2] Further work progress on gas-solid interacted TENG will also be introduced.

Electronic Transport Simulations in Thermoelectric Materials beyond The Constant Relaxation Time Approximation Neophytos Neophytou[1], Zhen Li[1] and Patrizio Graziosi[2]; [1]University of Warwick, United Kingdom; [2]CNR, Italy

The large variety of complex electronic structure materials and their alloys offer highly promising directions for improvements in ZT originating from the power factor (PF). The electronic structure of novel materials contains rich features such as many valleys (typically included in machine learning descriptors [1]), warped features, elongated features, anisotropic bands, resonant states, topological states, and more. The transport dynamics also involve complex scattering physics. Many theoretical studies provide very useful direction in identifying and optimizing these materials, most of them, however, based on the constant relaxation time approximation, which brings an arbitrary degree of error, both qualitatively and quantitatively.

Here we describe our advanced electronic Boltzmann transport simulator, *ElecTra* [2], together with a method we developed to obtain accurate scattering rates from ab initio calculations. We demonstrate its capabilities in a series of investigations: i) regarding the importance of including all relevant scattering mechanisms in electronic transport computation [3]; ii) regarding the possibility to obtain ultra-high PF in low bandgap materials with highly asymmetric transport properties between the conduction and valence bands [4, 5]; iii) regarding the influence of the shape of the electronic structure with its elongated features and high band anisotropy on the PF, where we show that 2-3x PF variations are observed based on the band shape complexities alone; iv) regarding the possibility of reliably computing transport properties of complex band materials with low symmetry and large unit cells in realistic time scales entirely from first principles.

The Importance of Electronic Relaxation Times in Complex Fermi Surfaces Øven Andreas Grimenes[1], Ole Martin Løvvik[2] and Kristian Berland[1]; [1]Norwegian University of Life Sciences, Norway; [2]SINTEF Industry, Norway

The difficult task of optimizing the thermoelectric figure of merit (zT) has often been approached by reducing lattice thermal conductivity, such as by nanostructuring or alloying. This strategy has led far, but to engineer even better materials we need to include other strategies. Another popular approach, especially in computational studies, is to engineer band structures that give more favorable electron transport properties. Generally, electron transport is characterized by the transport distribution, that is, the density of states (DOS), where each state is weighted by the square of its group velocity times the relaxation time of that state. A rapidly increasing transport distribution next to the band gap tends to give a higher zT. By aligning bands and valleys, the electronic structure can achieve a higher density of states without a reduction in group velocity. In the commonly used constant relaxation time approximation (CTRA) this band alignment will always be favorable for zT. By more accurate modeling of the scattering rates, we show that moving beyond CTRA is vital to get accurate predictions of zT. The alignment of multiple bands or valleys will generally lead to more electron scattering and lower relaxation times. This effect is especially prominent for materials with complex “extended” Fermi surfaces that result in a large scattering space for electrons.

We use first principle methods to investigate numerous complex semiconductors with unusual band structures and give extra attention to the specific case of the full-Heusler CsK2Sb. This material has an exotic Fermi surface with extended 2D-like features. We also predict a very low predicted lattice thermal conductivity with the Temperature Dependent Effective Potential (TDEP) method. This leads to a very high predicted zT under CTRA. With more accurate modeling of the electric transport properties with scattering rates modeled in AMSET the expected zT is reduced, revealing the shortcomings of the constant relaxation time approximation and the necessity to move beyond it. We also show this trend in several other materials with complex Fermi surfaces.

Finally, we present a counterexample, ZrNiSn. The three-fold degenerate conduction band minimum is not promising under CTRA. However, the simple shape of the Fermi surface and large k-space distance between its Fermi pockets results in relaxation times much longer than the 10 fs often used in CTRA. This increases the n-type zT of ZrNiSn significantly. We conclude that while complex Fermi surfaces indeed can provide very good electronic transport properties, it is essential to include estimations for scattering rates in such materials. These results can help aid the design of future thermoelectric materials with superior properties.

High-Throughput Thermoelectric Materials Screening by Novel Deep Convolutional Neural Network with Fused Orbital Field Matrix and Composition Descriptors Ming Hu; University of South Carolina, United States

Thermoelectric materials assist in generating or harvesting energy through converting waste heat into reusable electricity. Thermoelectric materials are also widely used in real-world applications, such as refrigerators and cooling electronics. However, most popular and known thermoelectric materials to date were proposed and found by intuition, mostly through experiments. Unfortunately, it is extremely time and resource consuming to synthesize and measure the thermoelectric properties through trial and error experiments. Here, we develop a convolutional neural network (CNN) classification model that utilizes the fused orbital field matrix (OFM) and composition descriptors to screen a large pool of materials to discover new thermoelectric candidates with power factor higher than 10 $\mu W/cmK^2$. The model used a few thousand data generated by density functional theory (DFT) coupled with AMSET, a package for calculating electronic transport properties that does not assume constant relaxation time for electrons, thus ensuring more reliable electronic transport properties calculations. The classification model was also compared to traditional machine learning algorithms, such as light gradient boosting and random forest. With the classification model we screened >35,000 structures with non-zero band gap from the Open Quantum Materials Database (OQMD). We identified lots of potential high performance thermoelectric materials with ZT > 1 across wide temperature range for both n- and p-type doping with

different doping concentrations, including quaternary Heuslers, half-Heuslers, and more material families. Insight into the correlation between high power factor and some representative material descriptors was also gained by feature importance analysis and maximal information coefficient, which provides new simple routes for fast screening promising thermoelectrics from large-scale material pool in the future.

Composition Engineering of Thermoelectric Performance of High-Entropy Ge-Te Based Alloys by First Principles Han Meng, Masato Ohnishi and Junichiro Shiomi; The University of Tokyo, Japan

The thermoelectric effect offers a promising pathway for energy harvesting through direct converting waste heat into electricity, however, it is mainly limited by the performance of thermoelectric material evaluated by figure of merit $ZT=S^2\sigma/\kappa$, where S, σ, and κ are Seebeck coefficient, electrical conductivity, and total thermal conductivity, respectively. To pursue good thermoelectric performance, various successful strategies have been proposed to enhance electrical transport properties through the creation of ordered band structure and reduce lattice thermal conductivity by introducing disordered atomic arrangement, following the phonon-glass electron-crystal concept. However, further improvement in thermoelectric performance requires the decoupling of electrical and thermal transport properties and their simultaneous optimization.

High-entropy material, where a stabilized structure coexists with disordered atomic arrangement, hold tremendous potential for enhancing thermoelectric performance. This potential arises from the ability to maintain long-range order in atomic arrangement to support efficient electrical transport, while simultaneously introducing short-range disorder through lattice distortion, which effectively scatter phonons and lead to low thermal conductivity. The GeTe that stabilizes as a rhombohedral lattice at room temperature by distorting high-temperature cubic structure, has been demonstrated to exhibit high thermoelectric performance. Most recently, a significant improvement in ZT, reaching 2.7 at 750 K, has been achieved in high-entropy GeTe-based alloys. This accomplishment was realized in several sample with specific composition by increasing the entropy, which enhanced crystal symmetry to promote delocalization of electron distribution and concurrently localize phonons to effectively hinder the propagation of transverse phonons. However, the high-entropy concept also offers a means to create crystals with an extended chemical composition range, providing ample room for optimizing electronic properties by modulating phase composition and band structure across a wide spectrum of chemical composition.

In this study, we take a significant stride towards engineering the composition for thermoelectric performance of high-entropy GeTe-based alloys. To predict the formation energy, we employed cluster expansion to construct a machine learning model, which was trained and validated using datasets generated from first-principles calculations. Through the Monte Carlo simulation, the configurations with low formation energy were suggested by sampling the structure for various composition, incorporating silver, lead, and antimony atoms as solutes. We designed seven distinct composition-changing paths that involved the alloying of one element, two elements, and all elements, allowing the thorough investigation on the impact of alloying each individual element component as well as their collective influence on ZT. For each composition, the average ZT was calculated from five possible configurations by semi-classical Boltzmann transport theory within relaxation time approximation. The analysis of electrical transport properties through electronic band structure and charge distribution, along with the examination of thermal conductivity via phonon dispersion relations and phonon properties, unveiled the underlying mechanism responsible for the compositional dependence of ZT. This study not only demonstrates the potential for optimizing thermoelectric performance of GeTe-based alloys, but also encourages further exploration of high-entropy alloys in the future.

11:45 AM EN08.01.05
Discovery of Multi-Anion Antiperovskite X_6NFSn_2 (X = Ca, Sr) as Promising Thermoelectric Materials by Computational Screening Dan Han[1,2,3], Bonan Zhu[2], Zenghua Cai[4], Kieran Spooner[2,3], Stefan S. Rudel[1], Wolfgang Schnick[1], Thomas Bein[1], David O. Scanlon[2,3] and Hubert Ebert[1]; [1]University of Munich (LMU), Germany; [2]University College London, United Kingdom; [3]University of Birmingham, United Kingdom; [4]Suzhou University of Science and Technology, China

The thermoelectric performance of existing perovskites lags far behind that of state-of-the-art thermoelectric materials such as SnSe.[1], [2] Despite halide perovskites showing promising thermoelectric properties, namely, high Seebeck coefficients and ultralow thermal conductivities, their thermoelectric performance is significantly restricted by low electrical conductivities. Here, we explore new multi-anion antiperovskites X_6NFSn_2 (X = Ca, Sr and Ba) via B-site anion-mutation in antiperovskite and global structure searches, and demonstrate their phase stability by first-principles calculations. Ca_6NFSn_2 and Sr_6NFSn_2 exhibit decent Seebeck coefficients and ultralow lattice thermal conductivities (< 1 W m^{-1} K^{-1}). Notably, Ca_6NFSn_2 and Sr_6NFSn_2 show remarkably larger electrical conductivities compared to the halide perovskite $CsSnI_3$. The combined superior electrical and thermal properties of Ca_6NFSn_2 and Sr_6NFSn_2 lead to high thermoelectric figure of merit ZT ~ 1.9 and ~ 2.3 at high temperatures. Our exploration of multi-anion antiperovskites X_6NFSn_2 (X = Ca, Sr) realizes the “phonon-glass, electron-crystal" concept within the antiperovskite structure.[3]

Engineering Electronic Properties of Thermoelectric Semiconductors Jeff Snyder; Northwestern University, United States

Engineering Electronic Properties of Thermoelectric Semiconductors

G. Jeffrey SNYDER

Department of Materials Science and Engineering, Northwestern University
jeff.snyder@northwestern.edu
thermoelectrics.matsci.northwestern.edu

Thermoelectric semiconductors often have complex electronic properties yet they can be modeled with a simple effective mass model. Good thermoelectric materials require a high weighted mobility [1] which serves as the electronic component to the thermoelectric quality factor [2] that determines peak zT. Often complex band structures with multi-valley Fermi surfaces are associated with high weighted mobility. This complexity arises from orbital chemistry as well as structure. Band convergence combined with the physics of avoided crossings can also be used to explain the band structures and provide strategies for band engineering Half Heusler materials [6].
Many thermoelectric materials such as Bi2Te3 are topological insulators (TI). The correlation can be understood in that the band inversion that causes TI can lead to band warping that leads to high valley degeneracy and low transport mass. [4]
In some systems the Fermi surface pockets can be anisotropic and even non-ellipsoidal, such as the tubes of Fermi surface found in SrTiO3 and Pb and Ge Chalcogenides [5]. Tubes or sheets of Fermi surface rather than ellipsoidal pockets leads to a density of states like 1D or 2D low dimensional materials. By engineering the orbital chemistry complex behavior and unusual properties can be devised even in 3D materials.

$Zn_{0.5}Ti_{0.5}NiSb$ – A New Aliovalent Half-Heusler Alloy with Intrinsic Low Thermal Conductivity Blair F. Kennedy[1] and Jan-Willem Bos[2]; [1]Heriot-Watt University, United Kingdom; [2]University of St Andrews, United Kingdom

Half Heusler (HH) alloys are leading contenders for thermoelectric power generation and cooling. Traditional XYZ HH materials are characterised by large electronic power factors, $S^2\sigma$, and are limited by high lattice thermal conductivity, κ_{lat}, which limits the achievable figure of merit, zT.[1]

Recently a new class of HH materials has emerged that uses mixtures of aliovalent elements. The archetypal example is the $TiFe_{0.5}Ni_{0.5}Sb$ family, which is a mixture of 17 electron TiFeSb and 19 electron TiNiSb. Hence, an equal mixutre of these ternary systems achieves the required average 18 valence electron count required for semiconducting behaviour. In comparison to regular XYZ materials, these complex compositions are characterized by low κ_{lat} and modest $S^2\sigma$, leading to zT approaching unity.[2] This approach is general, and can also be applied to the X and Z sites, leading to work on $X'_{0.5}X''_{0.5}YZ$ and $XYZ'_{0.5}Z''_{0.5}$ compositions by multiple groups.[3]

As part of this recent new direction of research, this contribution is focused on the aliovalent $Zn_{1-x}Ti_xNiSb$ system, which links 17 electron ZnNiSb with 19 electron TiNiSb. The $x = 0.5$ composition has exactly 18 valence electrons. Samples were prepared between $0.40 \leq x \leq 0.65$; with $x < 0.4$ not accessible under the used conditions, whilst Ti-rich samples can likely be prepared over the full range (to $x = 1$). This difference occurs because TiNiSb forms with Ti vacancies and is close to an 18-electron system, hence removing the electronic driving force for insolubility.
In terms of thermoelectric properties, the samples are characterised by very low $\kappa_{lat,\ 340\ K} = 2.5\ W.m^{-1}.K^{-1}$, comparable for all investigated samples. The electronic response suggests a small bandgap, $E_g = 0.4$ eV, with evidence for bipolar transport. Varying the composition away from $x = 0.5$ leads to a transition towards p- ($x < 0.5$) or n-type ($x > 0.5$) degenerate semiconducting behaviour. The best observed performance is $zT = 0.18$ for p-type $Zn_{0.6}Ti_{0.4}NiSb$ and $zT = 0.33$ for n-type $Zn_{0.4}Ti_{0.6}NiSb$.

The origin for the low κ_{lat} in these materials is not fully resolved. Typically, mass and strain disorder are the main drivers of phonon scattering. However, for the aliovalent HH materials, atomic mass and size differences are typically small, whilst the velocity of sound is only about 10-20% reduced compared to the XYZ materials. We have used synchrotron X-ray total scattering and pair distribution function analysis to probe the local structure of $Zn_{0.5}Ti_{0.5}NiSb$. This confirms that there is not a large source of local lattice strain, e.g. the Ti-Ni and Zn-Ni distances are comparable. Hence, the structure does not substantially deviate from the average unit cell obtained from diffraction. This suggests that differences in bond strength (bond disorder) may play a crucial role in the low κ_{lat} in the aliovalent HH materials.

Thermoelectric Compounds TZnSb, T = Ti to Ni ? Peter F. Rogl[1], Raimund Podloucky[1], Gerda Rogl[1] and Ernst Bauer[2]; [1]Univ Wien, Austria; [2]TU Wien, Austria

We present results of a combined experimental and first-principles study on compounds TZnSb (T=Ti to Ni). Physical properties i.e. electrical resistivity (4.2 - 800 K), Seebeck coefficient (300 - 800 K), specific heat (2 - 110 K), Vickers hardness and elastic moduli (RT) have been defined for the afore mentioned polycrystalline single-phase materials. From X-ray single crystal and Rietveld analyses all these phases, of which TiZnSb and $Cr_{1-x}ZnSb$ are novel representatives, were found to crystallize with the ordered MnAlGe-type (space group $P4/nmm$), whereas NiZnSb is a half Heusler phase. The thermal stability has been investigated by differential thermal analysis.
For the polycrystalline compounds TZnSb (relative densities >90%) the electrical resistivity is gradually changing from typical metallic behaviour (TiZnSb) to semiconductor-like features with resistivities decreasing with rising temperature (T=V,Cr). Specific heat curves Cp vs T and Cp/T vs T^2 of TiZnSb and CrZnSn conform with a simple metal behaviour revealing Sommerfeld coefficients of 6.4 (1) mJ/molK^2 and 12.4 (2) mJ/molK^2 and low-temperature Debye-temperatures of 273(5) K and 245(5) K, respectively.
Rather low Seebeck coefficients ($|S_V|<30$ µV/K), power factors ($pf<0.05$mW/mK^2) and an estimated thermal conductivity of $\lambda<6$ mW/(cmK), yield low thermoelectric figures of merit consistent with the rather metallic behavior of the materials. It should be noted that TiZnSb and VZnSb reveal negative Seebeck values with shallow minima at about 500 K, whereas CrZnSb exhibits a positive Seebeck coefficient which gradually tends towards zero at 800 K. Indentation hardness and elastic moduli of TZnSb were extracted employing the accelerated mechanical property mapping (XPM) mode and were found to be within $5.5\pm1<H_V<6\pm1$ GPa and $E=100\pm10$ GPa for T=Ti, V, but somewhat lower $E=80\pm10$ GPa for CrZnSb. The Poisson ratio in all cases was $\nu=0.24$ (taken from DFT calculations).
A detailed analysis of the structure types TZnSb adopted by the 3d transition elements clearly reveals that electropositive elements T=Ti,V,Cr,Mn,Fe crystallize with the tetragonal MnAlGe-type but with rising electronegativity T=Fe,Co,Ni incline to the cubic half-Heusler structure or to a (2a×2a×2a) superstructure of it. The case of Fe with three modifications constitutes the border range.
A variety of physical properties are derived from first principles such as structural and magnetic structural stabilities, charge transfer and atomic size,

elastic properties, electronic structure (density of states, band structure), electronic transport properties (Seebeck coefficient and resistivity) within Boltzmann's transport theory. All the results are obtained for fully relaxed structural parameters. Concerning magnetic ordering the in-plane antiferromagnetic ordering of T-magnetic moments in the tetragonal MnAlGe-type is dominant. The influence of T- vacancies for VZnSb and $Cr_{1-x}ZnSb$ are investigated and the results emphasize the role of such vacancies.

Mapping The Configuration Space of Intrinsic Properties and Dopability of Half-Heusler Compounds Angela Pak[1], Kamil Ciesielski[2], Eric Toberer[2] and Elif Ertekin[3]; [1]University of Illinois at Urbana Champaign, United States; [2]Colorado School of Mines, United States; [3]University of Illinois at Urbana-Champaign, United States

In this work, we utilize computational approaches to navigate the half-Heusler phase space to identify patterns in how properties relevant to thermoelectric (TE) materials vary with chemistry. Identifying novel TE materials is a challenge due to the unique, and typically disparate, set of intrinsic properties required (thermal and electronic conductivity) together with the need to access high p-type or n-type carrier concentrations. Although half-Heuslers have long been known as candidate TE materials, the hundreds of compositions that have been experimentally realized represent a small proportion of the possible chemistries. Of these possible chemistries, we focus on the 1,126 that are expected to be semiconductors based on the “18 valence electron rule”. In addition to fundamental understanding, design rules that link chemistry to indicators of TE performance such as carrier mobilities, band edge density of states, band edge degeneracy, and thermal conductivity are useful for accelerated materials discovery. Towards identifying these design rules, we evaluate candidate half-Heusler transport properties using first-principles simulations and semi-empirical models. This approach utilizes a filtering scheme that successively eliminates compounds based on their electronic structure, TE performance, stability, dopability, and transport properties. The analysis yields trends across chemical phase space. For instance, Rh and V-containing chemistries consistently have strong n-type TE performance, Ni and Sb-containing chemistries are consistently strong p-type performers, and Ta, or W-containing chemistries are good for both p and n-type performance. Furthermore, good n-type TE is found to arise from chemistries exhibiting high electronic carrier mobility as a result of low band mass, while for p-type performance a high band degeneracy at the valence band edge further enhances performance. Chemistries that exhibit good TE performance for both n and p-type were found to have comparatively low thermal conductivities relative to what is typical for half-Heuslers. This presentation will focus on the key results of the computational analysis and a comparison to experiment, the features of half-Heusler compounds that make them particularly suitable for TE applications, and ongoing work in stochastic assessment of trends using machine learning.

Effect of Magnetic Entropy in The Thermoelectric Properties of Fe-Doped Fe_2VAl Full-Heusler Tarachand Tarachand[1], Naohito Tsujii[1], Takao Mori[1,2], Fabian Garmroudi[3] and Ernst Bauer[3]; [1]National Institute for Materials Science, Japan; [2]Graduate School of Pure and Applied Sciences, University of Tsukuba, Japan; [3]Institute of Solid State Physics, Technische Universität Wien, Austria

Spin entropy is involved in the transport of heat/charge carriers in magnetic materials, and can provide new opportunities to improve the conversion efficiency of thermoelectric materials over that of the conventional case [1-3]. Here, we have explored the effect of magnetic entropy on thermoelectric properties of well-characterized Fe-doped full-Heusler, $Fe_{2+x}VAl_{1-x}$ with x = 0-0.1. These samples are prepared by arc melting, spark plasma sintering and annealing, producing high-density crystalline products. The low-temperature magneto-thermoelectric measurement shows exotic results, including a significantly high power factor near 300 K.
The itinerant weak ferromagnetic behavior of studied samples is confirmed from the magnetization. A systematic increase in magnetic transition temperature (T_c; 40 K to 223 K) and saturation magnetization (M_s; 0.13 to 0.41μ_B/Fe) with increasing Fe doping (x = 0 to 0.1) is observed. Applying a magnetic field causes a clear suppression in the magnitude of thermopower (S) and S/T (entropy term) with a negative magnetoresistance near the T_c for all the samples, demonstrating a clear effect of spin fluctuation [2]. The spin fluctuation leads to an enhancement in S of ~34% than diffusion thermopower and hence a whopping enhancement in thermoelectric power factor of 18% for x=0.1 at the T_C. The temperature-dependent behavior of S ruled out the contribution of magnon drag. Interestingly, Fe doping can shift the T_c towards room temperature and lead to a spin fluctuations induced enhancement in the S, but, it also increases the overall carrier density and hence deteriorates the magnitude of S. Multiparabolic band model fitting reveals the formation of additional spin states with large effective mass near the Fermi level, which can be eliminated/suppressed by applying the magnetic field. Callaway model fitting of thermal conductivity reveals Fe doping increases the number of point defects, causing a significant reduction in lattice thermal conductivity. This study demonstrates the role of spin fluctuation in enhancing the thermopower/ thermoelectric performance of Fe-doped Fe_2VAl and opens a vista for the strategy's applicability for various thermoelectric materials.

Beyond Bismuth Telluride: Magnesium-Based Compounds Redefine Thermoelectric Excellence Pingjun Ying, Heiko Reith, Kornelius Nielsch and Ran He; Leibniz-Institut für Festkörper- und Werkstoffforschung, Germany

Thermoelectric (TE) technology converts heat directly into electricity, and is a promising source of clean electricity. Commercial TE modules are based on Bi2Te3 compounds because of their unrivalled TE properties at low-grade heat-related temperatures (<550 K). However, the scarcity of elemental Te severely limits the applicability of these modules. Here, we present the performance of TE modules assembled from Te-free compounds, including p-type

MgAgSb and n-type Mg3(Sb,Bi)2, using a simple, versatile and therefore scalable processing routine. We demonstrate module-level conversion efficiencies of 3% and 8.5% for temperature differences of 75 K and 260 K, respectively, as well as maximum cooling of 72 K when used as a cooler. These proofs of principle will pave the way for robust, high-performance and sustainable solid-state power generation and cooling to replace the highly rare and toxic Bi2Te3.

4:00 PM *EN08.03.02
Simultaneous Enhancement of Efficiency and Output Power in GeTe/Mg_3Sb_2-Based Thermoelectric Generator Tsutomu Kanno; Panasonic Holdings Corporation, Japan

Recently, there have emerged many reports on thermoelectric generators (TEGs), claiming record-breaking efficiency values. From a viewpoint of practical applications, a problem is the trade-off between the efficiency and the output power in the presence of electrical contact resistance. Thus, high efficiency does not necessarily lead to high cost-performance (W/$).

Here, to break the trade-off, we develop GeTe/Mg_3Sb_2-based TEGs with minimal electrical contact resistance and total thermal resistances. Our TEG allows for simultaneous boost in the efficiency and the output power (10.1% and 1.94 W/cm^2), owing to excellent material performance and high input heat flow [1]. We also discuss a simple and reliable protocol to avoid errors in efficiency measurement [2].

Implication of Alloying The Anionic Framework in Mg_3Sb_2 for *p*-Type Zintl Thermoelectrics Nagendra S. Chauhan and Takao Mori; NIMS, Japan, Japan

Solid solutions of *n*-type Mg_3Sb_2 has garnered growing attention due to its remarkable thermoelectric potential for harnessing low grade waste heat. However, achieving high performing *p*-type conduction around room temperature has remained challenging, fundamentally due to greater degeneracy in conduction band relatively to the valence band. As a Zintl compound, β-Mg_3Sb_2 crystal structure constitutes of an anionic framework of double layer $[Mg_2Sb_2]^{2-}$ wherein Mg^{2+} cations are located between these layers. In this work, we present the implication of (Bi, Sn, Ge, Te) alloying at the anionic framework of Mg_3Sb_2 solid solutions to favorably tune the *p*-type conduction for attaining higher power factors by band engineering. Altering the anionic framework through alloying resulted in modifying the electronic structure to enhance the valley degeneracy at the top of valence bands. Simultaneously, the prospects of enhancing phonon scattering by the distorted lattice, point defects, and nano-precipitates was examined for attaining lower lattice thermal conductivity at near room temperature. The alloyed *p*-type $Mg_3(Sb,Bi,Ge,Sn,Te)_2$ with its tailored properties, shows promising potential as an economical alternative to α-MgAgSb, thereby facilitating the practical realization of Mg_3Sb_2-based thermoelectric power generators for harnessing low-grade heat.

Highly Improved Thermoelectric Performance in Periodically Ablated BiSbTe: WSe_2 Nanostructured Films Karan Giri, Yan-Lin Wang, Ling-Chun Chao, Chuan-Wen Wang, Hung-Shuo Chang, Wen-Chieh Hsieh and Chun-Hua Chen; National Yang Ming Chiao Tung University, Taiwan

An innovative technique has been developed to combine two different layered materials, bismuth antimony telluride (BiSbTe) and tungsten diselenide (WSe_2), which are well-known for their great efficacy in waste heat recovery and extremely low thermal conductivity, respectively. To enhance the thermoelectric properties even more, WSe_2 as a secondary target is encapsulated periodically in the primary target $Bi_{1.5}Sb_{0.5}Te_3$ using a pulse laser deposition technique. The WSe_2, for the first time, is co-ablated with the BiSbTe at four distinct deposition temperatures, resulting in hetero-nanocomposite thin films. Various characterization techniques are employed to determine thermoelectric properties. Both x-ray diffraction (XRD) and Raman spectroscopy validate the existence of WSe_2 and Te as heterogeneous phases. The sharp XRD peaks observed indicate strong crystallinity and evidence that the crystals are grown in a highly c-oriented manner. The electrical transport properties are greatly improved due to the optimized hole concentration, resulting in significantly high electrical conductivity in hundreds to thousands of S cm^{-1} for the samples grown at 573 K and 723 K, respectively. Furthermore, the room temperature and temperature-dependent Seebeck coefficient measurements exhibit highly optimized values, providing evidence of a satisfactory trade-off between the thermoelectric parameters. The overall outcome is a significant increase in the power factor which is computed up to 156 μW cm^{-1} K^{-2}, demonstrating outstanding room temperature thermoelectric performance. In addition to electrical characteristics, the specimens have a low electronic thermal conductivity, k_e. The calculated room temperature k_e values are 0.10 W m^{-1} K^{-1} and 0.87 W m^{-1} K^{-1} for the samples grown at 573 K and 723 K, respectively. Additionally, a qualitative measurement of lattice thermal conductivity was conducted through Raman spectroscopy under different laser power conditions, providing enough room for the highly improved figure of merit value. The enhanced thermoelectric transport characteristics of the periodically encapsulated WSe_2 in the BiSbTe matrix place it among the best thermoelectric materials with excellent performance for thermoelectric conversion, such as solid-state refrigeration and power generation.

Experimental Demonstration of Inverse-Designed Nanostructures with Ultra-Low Thermal Conductivity Giuseppe Romano; Massachusetts Institute of Technology, United States

Tailoring heat transport at the nanoscales is crucial to several applications, such as thermal energy harvesting and heat management. First-principles calculations and mesoscales models, such as the Boltzmann transport equation (BTE), have provided tremendous help in understanding the effect of material composition on thermal transport. However, materials engineering in this space is mostly done with trial. In this talk, we will report numerical

optimization and experimental demonstration of nanopatterned Si membranes with ultra-low thermal conductivity. Shape optimization is performed by density-based topology optimization, a technique commonly employed for elastic materials, and the adjoint mode-resolved BTE [1]. The fabrication of the optimized structures is carried out with Focused Ion Beam, and the effective thermal conductivity is measured with the thermal transient grating technique. Manufacturing constraints, such as minimum length scales, are taken into account by adding suitable constraints to the optimization algorithm. With a patterning resolution of about 70 nm and a film thickness of 50 nm, we record a thermal conductivity as low as 1.7 W/mK. Exploiting a deep synergy between theory and experiments, our work pushes the limits of low-thermal-conductivity materials, opening up novel routes for high-efficiency thermoelectric materials.

8:30 AM *EN08.04.02
Simulations Guiding Phonon Thermal Conductivity Reductions Lucas Lindsay; Oak Ridge National Laboratory, United States

Minimizing lattice thermal conductivity has been a goal for engineering enhanced thermoelectric figures of merit for over a decade, both intrinsically (e.g., material choices) and extrinsically (e.g., defects and nanostructuring). In the context of numerical simulations, we discuss phonon scattering details that underlie thermal resistance in bulk, nanostructured, and alloyed materials. We highlight promising routes for decreasing lattice thermal conductivity, limitations on these, and challenges faced in simulations of realistic materials. We use large-scale mass disorder models, temperature-dependent effective potentials, density functional theory, and Boltzmann and Wigner transport methodologies to understand how alloy disorder, temperature renormalization, correlations, and phonon dispersion features govern thermal transport in materials of potential interest for thermoelectric applications.

Thermoelectric Power Factor Enhancement in Hybrid Solid/Liquid Porous Material Systems: A Simulation Approach Pankaj Priyadarshi, Neophytos Neophytou and Vassilios Vargiamidis; University of Warwick, United Kingdom

Prior experimental work has demonstrated the possibility of large improvements in the thermoelectric (TE) power factor of porous media when intercalated with electrolytes filling their pores [1]. Surprisingly, in many cases both the electrical conductivity and Seebeck coefficient were increased, offering large improvements to the power factor (PF). These improvements were attributed to charge exchange between the solid medium and the electrolyte, with strong dependence on the type of solid and the type of electrolyte used.

In this work we examine theoretically this complex system and provide directions for optimization. For this, we have developed an advanced simulator and theoretical models to accurately describe the TE behavior of a hybrid porous-solid/electrolyte system in the presence of large degree of nanostructuring. We have developed a novel Monte Carlo algorithm specifically designed for large scale thermoelectric simulations in porous nanostructured media [2]. Our code includes may features beyond the state-of-the-art in Monte Carlo simulations, which allow for drastic computational savings of at least an order of magnitude, making large scale simulations feasible. We then developed a model for the addition of the electrolyte within the pores of the solid medium, whose interaction with the solid is computed in a self-consistent manner by solving the Poisson equation. This provides the charge exchange and band variations that the solid thermoelectric material experiences. Once this is achieved, the Monte Carlo simulator provides the thermoelectric coefficients.

We show that it is possible to achieve very high power factor improvements using this solid/liquid hybrid material direction. This happens in two ways: 1) Appropriate choice of an electrolyte can cause favourable band bending in the solid material, resulting in increased carrier density and conductivity, at the levels which optimize the power factor. 2) Rather than relying on intentional doping, we enhance charge density within the material domain by the use of the electrolytes into the pores. This avoids the strong ionized impurity scattering associated with the doping typically required, since now this is achieved electrostatically.

Finally, the simulator we present goes beyond this system, and can be generally used to enable the understanding of transport in highly disordered nanostructured TE materials in a very effective and efficient way.

Thermal Conduction Pathways within Complex Polycrystalline Microstructures Younggil Song, Nick C. Du, Dong-Xia Qu and Tae Wook Heo; Lawrence Livermore National Laboratory, United States

The effective thermal conductivity (TC) of a material is determined by various microstructural factors. Different phases in a material often have distinct thermal conductivities and their geometrical configurations dictate the thermal pathway. In addition, the thermal resistance of the crystalline surface disturbs the thermal transport, while it can be enhanced by the crystalline surface coated by a high conductive material. Due to these various and complicated factors, investigations for effective TCs within polycrystalline microstructures have been limited to the controlled microstructures under selected TC regimes. In this study, we use the numerical method to estimate effective TCs within complex multi-phase systems, which are validated using experimental measurements. For simulations, our comprehensive mesoscale model [1, 2] is used to investigate microstructure-aware effective TC variations within porous materials. The model can compute effective TC within realistic digital microstructures with diffuse interfaces using the FFT method, and the simulation results show quantitative agreement with the experiments [1]. In order to characterize the TC behaviors for porous microstructures, we carried out simulations with wide TC ranges of both the gas and the solid phases. The simulations show two different regimes for the TC variations due to (i) the porosity of a microstructure and (ii) the TC difference between the two phases. We suggest the semi-analytical model by introducing structure and intensification factors to capture the effective TC variations [2]. Additionally, we simulated the effective TCs for a ternary system (Fe, Fe_2O_3, and Air) within porous microstructures, which show reasonable agreement with experiments. Moreover, our simulation method can be extended to evaluate the effective TCs by varying additives and their topological features. We expect our combined experimental, analytical, and numerical approach can shed light on how the effective TC of a complex microstructures can be tailored, allowing for better designing materials microstructures for improved thermal conductivities under the wide range of operation conditions.

From Rattling to Incipient Ionic Conductivity: Neutron Scattering Studies of Tetrahedrite Paz Vaqueiro[1], Sebastian Long[1], Shriparna Mukherjee[1], David Voneshen[2] and Anthony V. Powell[1]; [1]University of Reading, United Kingdom; [2]ISIS Pulsed Neutron and Muon Source, Rutherford Appleton Laboratory, United Kingdom

The thermoelectric performance of tetrahedrites, which are minerals composed predominantly of environmentally-friendly and abundant copper and sulfur, is currently attracting considerable interest. Tetrahedrites, which are *p*-type materials with low lattice thermal conductivities, crystallise in a collapsed sodalite structure in which corner-sharing CuS_4 tetrahedra form cages. Each cage contains an octahedral cluster formed by six trigonal-planar copper cations.
We have exploited a range of neutron scattering techniques to investigate the origin of low thermal conductivity in tetrahedrite, $Cu_{12}Sb_4S_{13}$, which has been previously attributed to the rattling vibrations of the trigonal-planar copper ions and has also been linked to a phonon instability arising from a low-temperature phase transition. Analysis of neutron and synchrotron X-ray diffraction data collected on tetrahedrite shows that copper rattling is a direct consequence of a tetragonal-to-cubic phase transition at 90 K, which results in a sharp increase, by approximately 200%, of the atomic displacement parameters of the trigonal-planar copper cations. This phase transition occurs because of the orbital degeneracy of the highest occupied 3*d* cluster orbitals of the copper clusters found inside the sodalite cages. In the high-temperature cubic phase, the trigonal-planar copper cations form regular octahedral Cu_6^{7+} clusters, which are electronically degenerate. Below 90 K, tetrahedrite contains pentameric Cu_5^{7+} clusters. The Jahn-Teller electronic instability which leads to the formation of "molecular-like" Cu_5^{7+} clusters, suppresses copper rattling vibrations due to the strengthening of direct copper-copper interactions. At temperatures above 200 K, quasielastic neutron scattering (QENS) measurements on tetrahedrite, $Cu_{12}Sb_4S_{13}$, and copper-rich tetrahedrite, $Cu_{14}Sb_4S_{13}$, combined with molecular dynamics simulations, reveal that copper ion diffusion occurs. However, although the copper ions are mobile between 200 and 400 K, they are largely trapped inside the sodalite cages. Analysis of inelastic neutron scattering (INS) data reveals the presence of a low-energy optical mode at 3-4 meV, which can be attributed to the intra-cage diffusion of the trigonal-planar copper ions. This low-energy optical mode, which softens on cooling revealing strong anharmonicity, is capable of strongly scattering the heat-carrying acoustic phonons, and hence lowers the lattice thermal conductivity.

Thermoelectric Enhancement under Hydrodynamic Regime in Interconnected Nanowire Networks F. Xavier Alvarez, Jordi Tur and Albert Beardo Ricol; Universitat Autonoma de Barcelona, Spain

Recent advancements in the field of thermoelectric materials have highlighted the substantial benefits of employing 3D interconnected nanowire scaffoldings. These scaffoldings have demonstrated a significant enhancement in thermoelectric efficiency when compared to 1D nanowires and films grown under similar electrodeposition conditions. A key contributing factor to this improvement is the marked reduction in thermal conductivity (κ) observed in Bi2Te3 3D nanonetworks, while concurrently preserving high electrical conductivity.

Employing a comprehensive approach, we have conducted an in-depth analysis of these structures, employing the Guyer and Krumhansl Equation through in a Finite Element methodology, coupled with ab initio calculations for the transport parameters from the Kinetic Collective Model (KCM). Our findings have revealed that the laplacian (viscous) term in the Guyer and Krumhansl Equation is chiefly responsible for the observed reduction in heat flux within the interconnections. Specifically, the hydrodynamic nature of heat within these interconnected regions has led to a remarkable decrease in the thermal conductivity, as compared to that of the individual nanowires lacking such interconnections.

Through this investigation, we shed light on the critical influence of hydrodynamic effects on heat transport in intricate nanowire networks, offering valuable insights for the development of more efficient thermoelectric materials..

Adventures and Challenges in Computation-Guided Design and Discovery of Thermoelectric Materials -- from Direct Physical Modeling to Language Models Elif Ertekin; University of Illinois at Urbana-Champaign, United States

My presentation will highlight some of our recent attempts to make the computation-experiment handshake applied to the discovery and optimization of thermoelectric materials. We will describe the importance and state-of-the-art of accurate simulations of both intrinsic material properties and dopability in computation-guided search for new materials, focusing on the design space of diamond like semiconductors, ordered vacancy compounds, binary chalcogenides, and half-heuslers. Finally, we'll discuss where computational approaches have success and what aspects are missing and should be realized to enable true computation-guided design and optimization -- focusing on strategies to optimize doping and carrier concentrations, and alloying strategies. Time-permitting, I will depart from direct physical modeling to show some of our recent work in the use of language-based representations in the search for thermoelectric materials and discuss some observations of the merits and possible shortcomings of data-based methodologies.

Investigating The Potential of III-V Type-I Clathrates as Thermoelectrics: A Computational Perspective Alexander Squires and David O. Scanlon; University of Birmingham, United Kingdom

The significant impact of III-V semiconductors on the electronic materials landscape is indisputable, demonstrated by their widespread use in high-profile applications such as integrated circuits, LEDs, and advanced photovoltaics. Innovations in materials discovery have ushered in the synthesis of type-I clathrate structures with a III-V host framework, exhibiting remarkable p-type mobilities [1]. Clathrate structures, consisting of nanometre-sized polyhedral cages encapsulating guest atoms or molecules, have stirred interest as prospective battery electrodes, photovoltaics, but most relevantly as thermoelectrics [2]. The highly electronically conductive framework coupled with weakly bound "rattler" guest atoms leads to fast electron transport and poor thermal transport, thus fulfilling the 'phonon-glass electron crystal' concept and paving the way for exceptional thermoelectric materials. Despite this notable potential, there exist significant discrepancies previous between theoretical predictions and experimental studies of these materials' properties [1], which our research aims to resolve. In our study, we integrate atomistic simulations with data-driven methodologies to screen and characterize both existing and novel clathrates within the III-V compositional space. Employing the SMACT materials informatics tool [3], we efficiently navigate the vast compositional search space of III-V clathrates using economical heuristic tools, refining the search by evaluating the stability of the proposed clathrates using density functional theory. We further utilized spin-orbit coupling corrected hybrid density functional theory to provide a comprehensive first-principles characterization of these materials' electronic structures. Finding that this alone does not reconcile the experimental-theoretical disparities, we explore the strong influences of disorder and off-stoichiometry on their target properties. Our findings present deeper insights into this exciting class of materials, and offers a range of potential new applications.

Advancing Thermoelectric Materials: A CALPHAD Approach to Charged Defects in Semiconductors Adetoye H. Adekoya and Jeff Snyder; Northwestern University, United States

Thermoelectric (TE) devices that offer a route for energy recovery/production often need to be optimized by doping with other elements to improve the thermoelectric figure of merit (zT) which qualifies the efficiency of the device. The solubility of these elements in the bulk system is usually in such dilute concentrations that they can best be described as 0-D defects in an otherwise essentially uniform crystal. However, these defects/dopants are essential to the efficient performance of thermoelectric devices. As a result, an accurate understanding of the solubility limits of these dopants is necessary for the manufacture of high-performing Thermoelectrics. Phase diagrams, which are lines of equilibrium or phase boundaries at specific thermodynamic conditions, can be useful for visualizing the solubility limit. To that end, the method called Computer Coupling of Phase Diagram and Thermochemistry, or alternately Calculation of Phase Diagrams (CALPHAD) is an established technique for visualizing the phase diagram of material systems.
In our previous work, we showed that CALPHAD is a viable tool to both visualize the effects of the dominant defects on the shapes of the phase diagram as well as provide an estimate of the defect concentration. We further extend those principles into describing charged defects in semiconductors. The CALPHAD technique has been used extensively as a thermodynamic framework to optimize the manufacture of alloys by modeling the Processing, structure, properties, and performance relationship. By developing a formalism for describing these charged defects in a CALPHAD framework, we set the stage for a more complete integration of CALPHAD with thermoelectric materials and semiconductors in general

11:30 AM EN08.05.04
Multi-Objective Optimization of Thermoelectric (TE) Performance in Binary Chalcogenides through Computational Assessment of Extrinsic Dopants Ferdaushi A. Bipasha and Elif Ertekin; University of Illinois at Urbana-Champaign, United States

We demonstrate a computational approach to optimize the dopant profile of a thermoelectric material, accounting for the effect of the dopant on multiple interrelated indicators of performance. While most computational studies of dopants in TE materials primarily focus on optimization of carrier concentrations with the assumption that bulk/intrinsic properties of the material remain unchanged, in cases of high concentrations doping can affect other aspects of performance through modifications to carrier mobilities, thermal conductivity, and density of states. These competing effects often make it challenging to identify optimal doping concentrations. In this work, we use the example of Ga and Sb co-doping as a case study for the multi-objective optimization of n-type achievable TE performance in the group IV-VI binary chalcogenides with AB stoichiometry. Although recent reports show improved performance in n-type PbS based on co-doping with Ga and Sb, a predictive model that describes doping effects on multiple properties would reveal ultimate performance achievable and the carrier concentrations at which it occurs. We present models to assess how co-doping with Ga and Sb affect carrier mobilities, thermal conductivity, electronic density of states, and carrier concentrations in PbS and PbSe. The density of states analysis on PbS and PbSe show increased dos curvature after Ga, Sb co-doping. The defect properties show the stability of the co-doped system over a single dopant, which shows the stability of co-doped Ga-Sb defect would be stable over single point defect Ga and Sb. Our analysis reveals opportunities for multi-objective optimization of TE properties through understanding the change in effective mass, mobility, thermal conductivity, and optimized carrier concentration.

11:45 AM EN08.05.05
Micro Thermoelectric Devices: From Thermal Management to Powering the Internet of Things Heiko Reith[1], Nithin Pulumati[1], Aditya Dutt[1] and Kornelius Nielsch[1,2,3]; [1]IFW Dresden, Germany; [2]Institute of Applied Physics, TUD, Germany; [3]Institute of Materials Science, TUD, Germany

Micro-thermoelectric devices (µTEDs) hold significant potential for various applications in the biomedical field, powering internet-of-things devices, and thermal management. To enable their use in such applications, robust packaging is crucial, allowing direct thermal contact between the µTEDs and the target heat sink and source. However, conventional packaging techniques designed for larger modules are unsuitable for µTEDs due to excessive thermal resistance between the capping material and the device, which hampers performance. In this study, we present the fabrication of µTEDs using optimized geometry and contact resistance, coupled with a novel packaging technique that seamlessly integrates with on-chip systems. Our fabrication process involves the creation of micro thermoelectric coolers (µTECs) with vertically free-standing leg pairs, eliminating the need for a top plate. To meet real-world requirements, we embed these free-standing devices to form a flat surface at the top level, ensuring direct thermal contact with the heat sink. This embedding not only enhances mechanical stability but also provides chemical stability. We employ photoresist as the filling material due to its low thermal conductivity and excellent processability. By characterizing the µTECs with and without photoresist using a thermoreflectance thermal imaging technique, we analyze the devices' cooling efficiency and the impact of the photoresist matrix on their performance. The fabrication process of the µTEC involves a combination of photolithographic patterning and electrochemical deposition of Bi2(TexSe1-x)3 and Te, which serve as the n-type and p-type thermoelectric materials, respectively. Through optimization of the geometry and contact resistance of the µTECs, we achieved a maximum cooling effect of approximately 10.8 K at an applied electrical current of 235 mA. Furthermore, our reliability studies demonstrated a rapid response time of 700 µs and over 100 million cooling cycles without device failure. We also conducted finite element analysis to investigate the impact of geometry and contact

resistance on the cooling power density and net cooling temperature, offering valuable guidelines for fabricating thermoelectric coolers with optimal performance. In the case of embedded μTECs, the photoresist matrix acts as a thermal shortcut that results in additional thermal loss, leading to a slight reduction of the maximum cooling from 10.8 K to 9.6 K. This decrease can be attributed to thermal loss through the polymer. Nevertheless, the embedded devices exhibit a rapid cooling response time of 721 μs and demonstrate only a slight reduction in cycling reliability, with a lifespan of 85 million cycles. These embedded, optimized, stable, and easily scalable μTEDs present exciting opportunities for widespread applications in the biomedical field, powering internet-of-things devices, and localized heat management.

Thermoelectric–Photoelectrochemical Water Splitting under Concentrated Solar Irradiation Virgil Andrei; University of Cambridge, United Kingdom

Photoelectrochemical (PEC) systems utilize sunlight to directly convert water and carbon dioxide into useful chemicals like hydrogen, synthesis gas, or ethanol. Such devices may lower the costs of sustainable fuel production by integrating light harvesting and catalysis in one compact device.[1] However, light absorption suffers losses from thermalization and the inability to use low-energy photons, which limits the overall solar-to-chemical conversion efficiency.[2,3] Here, we demonstrate that PEC reactors can utilize this waste heat by integrating thermoelectric modules, which provide additional voltage under concentrated light irradiation.[3] While most single semiconductors require external bias, we already accomplish unassisted water splitting under 2 sun irradiation by wiring a $BiVO_4$ photoanode to a thermoelectric element, whereas the photocurrent of a perovskite-$BiVO_4$ tandem system is enhanced 1.7-fold at 5 sun. This strategy is particularly suitable for photoanodes with more positive onset potentials like hematite, with thermoelectric-perovskite-Fe_2O_3 systems achieving a 29.7× overall photocurrent increase at 5 sun over conventional perovskite-Fe_2O_3 devices without light concentration. This thermal management approach provides a universal strategy to facilitate widespread solar fuel production, as light concentration increases output, reduces the reactor size and cost, and may enhance catalysis.[3]
We further reveal the recent success of thermoelectric composites in other material science applications. While thermoelectric pastes consisting of conductive powders in a polymer matrix display limited power factors,[4] their hydrophobicity proves essential for effective moisture protection of PEC devices and solar cells. Accordingly, a graphite epoxy paste encapsulant extends the lifetime of metal halide perovskite photocathodes to 4 days under operation in water,[5] and increases the stability of a BiOI photocathode for H_2 evolution from minutes to months.[6] This material allows the manufacturing of flexible, lightweight devices, which float on water similar to lotus leaves.[7] Those devices are compatible with large-scale, automated fabrication processes, which present the most potential towards future real-world applications.[8]

1:45 PM EN08.06.02
Kirigami-Inspired Organic and Inorganic Film-Based Flexible Thermoelectric Devices with Built-In Heat Sink Chongyang Zeng and Emiliano Bilotti; Imperial College London, United Kingdom

Thermoelectric (TE) technology presents a unique opportunity to convert waste heat directly into electricity, offering a promising solution to address energy harvesting and sustainability challenges. However, conventional TE devices with π-type structures always need a heat sink to thermally link to the air during operation which remains a significant limitation for their practical applications.
Herein, we report a new configuration of a TE device that has a built-in heat sink for the first time. Furthermore, the device modified with shape-memory polymer films can be self-folded into a hexagonal structure via heating above its glass transition temperature. We demonstrate the feasibility of our design through experimental characterization and modelling. The device with built-in fins exhibits superior thermoelectric performance with both organic (carbon nanotube veils) and inorganic (bismuth telluride, Bi_2Te_3) TE materials. The maximum power output of the Bi_2Te_3-based device can reach 180 μW, which is 4.4 times higher than that of the carbon-based device (41 μW) when the temperature difference is 43 K and airflow is 1.5 m s^{-1}. Bi_2Te_3-based devices show better TE performance but less stability compared to carbon-based devices. Moreover, carbon-based devices can be self-folded via external temperature stimulus and keep resistance no change (95 Ω) while Bi_2Te_3-based devices cannot.
This work provides a path to optimize the thermoelectric performance of TE devices by designing rational structures. This approach has the potential to reduce the cost, mass, and volume of TE devices, making them more attractive for a wide range of applications, such as waste heat recovery, energy harvesting, and thermal management.

Thermoelectric Transport with Metamaterials Lilia Woods; University of South Florida, United States

Thermoelectricity is a basic transport phenomenon encompassing thermodynamically reversible heat-to-electricity conversion. Much of the current research in this area has been focused on the electronic, phonon, and transport properties of materials as a viable route to optimize existing and engineer new compositions for better practical devices. Here I would like to explore a macroscopic perspective that helps us think differently of controlling

thermoelectricity. Using thermodynamics, circuit theory, and transformation optics an efficient approach is offered for the design of thermoelectric metamaterials with targeted functionalities. For example, thermoelectric cloaks and rotators can be achieved by enforcing preservation of the invariance of the governing and constitutive thermodynamic equations. Using basic relations for in-parallel and in-series connected components, the independent control of the coupled via Seebeck coefficient thermal and heat currents can also be achieved. Our pathways for constructing metamaterials capable of achieving such functions is especially exciting for the construction of actual devices.

Process-Structure-Property Relationships for Laser Additive Manufacturing of Thermoelectric Materials for Low and High Temperature Applications Saniya LeBlanc; The George Washington University, United States

Thermoelectric materials enable direct, solid-state conversion of heat to electricity and vice versa, so they offer functional power generation and heat pumping capabilities. Additive manufacturing offers the potential to structure thermoelectric materials and devices at multiple length scales, thus improving both intrinsic properties, overall system performance, and application integration. We report on experimental and computational investigation of process-structure-property relationships for laser powder bed fusion of thermoelectric materials including bismuth telluride (for applications near 100°C) and silicon germanium (for applications near 1000°C). Strategies for non-spherical powders were developed, and the process parameters that lead to conduction mode melting were determined. The process has been demonstrated on multiple tools, both custom setups and commercial tools. The structure of both single melt tracks and bulk parts were characterized at nano-, micro-, and meso-scales for varying process parameters such as laser power, scan speed, and powder layer thickness. Finite element modeling of laser energy deposition and heat diffusion within the powder bed resulted in simulations of spatial and temporal temperature gradients during laser processing of thermoelectric material. These simulations were compared to in situ, long wavelength infrared sensor data collected during processing experiments. The ratio of temperature gradient and solidification rate was used to predict the transition between equiaxed and columnar grains and compare the prediction to the experimentally observed grain morphology. A kinetic Monte Carlo simulation was used to simulate the formation of grain structure during solidification. Thermoelectric properties (Seebeck coefficient, electrical conductivity, and thermal conductivity) were measured on fabricated bulk samples, and structure and property characterization results indicate a link between the process-dependent nanostructure and the Seebeck coefficient, including a transition between n- and p-type behavior and graded Seebeck coefficient. These results indicate functional grading of thermoelectric properties during the additive manufacturing process may be possible. Finally, the power generation performance impact of unique device shapes (e.g., layered, hourglass, and hollow shapes) enabled by additive manufacturing was modeled for high and low temperature and heat flux boundary conditions, and selected promising shapes were fabricated. This work provides knowledge about how rapid melting and solidification of thermoelectric materials during laser additive manufacturing impacts the material structure and properties. The results show how variations in process parameters can be leveraged to enable functional grading of thermoelectric properties within the material by manipulating the material at the nano and micro-scales. The additive manufacturing technique enables fabrication of unique shapes at the mesoscale that show improvements for system-level performance of thermoelectric devices.

4:00 PM EN08.07.02
3D Ink Printing and Casting of $Nb_{0.8}Ti_{0.2}FeSb$ and Half-Heusler Thermoelectric Couples Alexander Proschel, Duncan Zavanelli, Jeff Snyder and David C. Dunand; Northwestern University, United States

Current manufacturing processes for inexpensive, mechanically stable, high performing p-type half-Heusler $Nb_{0.8}Ti_{0.2}FeSb$ such as ball milling and hot pressing are unsuitable for continuous processing, geometrically limited, and require subsequent slicing and assembly steps to fabricate thermoelectric couples. Additionally, current assembly of half-Heusler couples typically relies on brazing or soldering, both of which are unsustainable for long-term use. Thus, new additive manufacturing synthesis of $Nb_{0.8}Ti_{0.2}FeSb$ and half-Heusler couples is necessary to improve utility and eliminate the costly slicing and assembly steps. This talk will present a new procedure for ink casting of bulk $Nb_{0.8}Ti_{0.2}FeSb$ with subsequent half-Heusler couple assembly as well as direct 3D ink printing of a complete half-Heusler thermoelectric couple. This synthesis approach utilizes polymer-based inks loaded with elemental metallic precursor powders which can be co-printed or cast at ambient temperature to produce thermoelectric legs or complete half-Heusler couples.

4:15 PM EN08.07.03
Flexible, Scalable and Reliable Fully Screen-Printed Thermoelectric Generators Irene Brunetti[1,2], Federico Ferrari[3], Nathan James Pataki[4], Sina Abdolhosseinzadeh[5], Lambert Jan Anton Koster[3], Jakob Heier[5], Ulrich Lemmer[2], Martijn Kemerink[6] and Mario Caironi[4]; [1]InnovationLab, Germany; [2]Karlsruhe Institute of Technology (KIT), Germany; [3]University of Groningen, Netherlands; [4]Istituto Italiano di Tecnologia (IIT), Italy; [5]Swiss Federal Laboratories for Materials Science and Technology (Empa), Switzerland; [6]Heidelberg University, Germany

Global energy demand is expected to increase by almost 50% in the next 20 years. Currently, traditional energy sources such as oil, gas, and coal have played a significant role in global energy production. However, they are also responsible for the increase in pollution and are harmful to human health. New energy sources are necessary to support this high demand, in a sustainable way. The thermal energy can be converted into electrical energy in a completely eco-friendly way thanks to thermoelectric generators (TEGs). Due to their flexibility, lightness, affordability, and natural abundance, organic thermoelectric materials are the perfect competitors for making flexible TEGs that can readily conform to complex surfaces. However, up to now, the research has primarily focused on making simple proof-of-concept devices not application-oriented, to highlight the thermoelectric performance of the organic materials. Moreover, demonstrator-devices typically show performance that is far below what one would expect based on the figures of merit of the constituent materials.
Here, we present a new fabrication method to make vertical, fully printed, large-area, flexible, monolithic TEG with a high-density of thermocouples scalable up to m^2, compatible with all the screen-printable inks with performance that matched the expectations based on the figures of merit of the constituent materials.
The TEGs were made screen printing five layers on top of each other on a 25 µm thick Kapton substrate, recreating the Π-shape structure, where device legs are oriented perpendicular to the heat flows. A silver bottom contact necessary for the electrical connection was screen printed, followed by an insulator layer with cavities designed to create a mask for the vertical thermocouples. Successively, the p-type layer and the silver layer were screen-printed

to fill alternatively the cavities, thereby creating the vertical thermocouples. Finally, the top silver contact was screen printed to electrically complete the circuit.
We demonstrated the scalability of the process employing as p-type the well-known and commercially available poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) to make vertical TEGs composed of 4 and 8 thermocouples, with a surface area of 0.5 cm^2 and 1 cm^2, respectively. The devices exhibited an ideal behaviour perfectly scalable in accordance with numerical simulations. After the validation of the fabrication method, we utilized a recently reported additive-free graphene, not previously assessed for thermoelectric applications, as p-type material to make a vertical TEG composed of 8 thermocouples. The power output at a $\Delta T = 25°C$ provided by the additive-free graphene device was over five times higher than that of the PEDOT:PSS TEG. Additionally, the measures were once again in accordance with numerical simulation. The additive-free graphene TEG provides a remarkable, among the organic thermoelectric TEG, power density of 15 nW/cm^2 at $\Delta T = 29,5$ °C.
Scaling this device to a 100 cm^2 large TEG will result in a power output of 1.5 µW, sufficient to power low-energy electronic devices such as sensors, wearables, and wireless communication systems.
The fully screen-printable large-area TEGs presented are also extremely lightweight and flexible. Specifically, the additive-free graphene TEG provides an estimated power output of 1 µW/g, and its internal device resistance remained constant even when the device was rolled into a cylinder with a bending radius of 1 cm.
Future work for this technology will involve making larger devices on thinner substrates to considerably increase the power output. Using a 5 µm substrate the power output of a 100 cm^2 additive-free graphene TEG will increase by an order of magnitude. Furthermore, due to the versatility and reliability of the process, it will also be possible to use inorganic materials as active inks with enhanced thermoelectric performance to further increase the power output.

4:30 PM EN08.07.04
Laser Powder Bed Fusion of Bismuth Telluride on Plastic Foil as a Simple Route for The Scalable Fabrication of Flexible and Large-Area Thermoelectric Generators Isidro Florenciano, Francisco Molina-Lopez, Yuan Tian and Heyi Xia; KU Leuven, Belgium

Thermoelectric generators (TEGs) are solid-state devices that convert waste heat into electrical energy. Conventional manufacturing methods struggle to meet the requirements of scalability and compatibility with unconventional form factors required for emerging applications such as wearables and large-area electronics. In contrast, additive manufacturing techniques offer scalability, reduced material waste, and the ability to conform to various shapes, expanding their potential applications. In particular, Laser Powder Bed Fusion has shown tremendous potential to manufacture high-performing pellets with laser-tunable nanostructure. However, the compatibility with flexible substrate and large-area patterning remains to be demonstrated.
Our work demonstrated the additive manufacturing of high-performing inorganic flexible TEGs by laser powder bed fusion directly onto flexible polyimide foil. We achieve maskless and large-area patterning of thick films of Bi2Te3-based materials deposited from a slurry. By reusing the unexposed powder we minimize material waste. Mechanical interlocking enables simultaneous patterning, sintering, and attachment of films to the flexible substrate, enabling the creation of a highly flexible device adaptable to different shapes.
Moreover, the material structure and chemical composition, and the associated performance, can be precisely tuned by the laser power and scanning speed. For instance the unique microstructure of the laser-printed material imparts remarkable flexibility to the typically brittle Bi2Te3 thick films. Samples can withstand extreme bending with a radius of curvature as small as 0.75 mm while experiencing minimal changes in performance over a 10 mm bending radius. Additionally, we can simultaneously modify the stoichiometry of the material to optimize its power factor. This innovative approach holds promise for the advancement of flexible TEGs and their diverse applications.

4:45 PM EN08.07.05
Flexible Thermoelectric Generators based on Template- Assisted Electrodeposition of Bismuth Telluride inside Commercial Filters Olga Caballero-Calero, Pablo Cerviño Solana, M. Jesús Ramirez Peral, Miguel Angel Tenaguillo Arrese and Marisol Martín-González; IMN-CNM, Spain

Miniaturized thermoelectric generators utilizing bismuth telluride (n-type) and tellurium (p-type) semiconductors have been fabricated within commercial polyester filters. Employing electrochemistry for fabrication for both the electrical contacts and the active thermoelectric material, we create an intricate network of nanostructured bismuth telluride or tellurium, which is electrically connected to the top and bottom electrodes. The control over the electrochemical process allows us to maintain the flexibility of the commercial filter in the final device. It is mandatory to be flexible in applications such as harvesters of body heat to power wearable devices, where adaptability to human skin is essential.

Electrochemical deposition is a cost-effective and scalable fabrication method, that does not use high vacuum or expensive facilities, but has the advantage of allowing conformal growth of the material when a template is used. Given that the commercial filters have hollow structures in the order of tens to hundreds of nanometers in diameter and microns in length, the obtained material will be nanostructured with those dimensions. Our work demonstrates enhanced thermoelectric performance compared to electrodeposited thin films due to the nanostructure [1]. Also, with the control of the different parameters during the electrochemical deposit (temperature, applied voltage, etc.), the stoichiometry, morphology, and crystallographic orientation can be tailored. Once the samples were grown, scanning electron microscopy images, X-Ray diffraction images, and Raman spectroscopy were used to get complete information on the material and optimize the filling of the template, the material composition (which is crucial in the case of bismuth telluride), and crystal orientation to have the best performing material for applications in the out-of-plane direction, that is, with the temperature gradient applied in the direction of the thickness of the template. Once these first parameters were optimized, and a high filling ratio of nanostructures oriented along the [110] direction with stoichiometric composition was obtained [2], the transport properties were also measured (Seebeck coefficient and electrical conductivity) to fine-tune and optimize the material.
For the final thermoelectric generator, which uses the gold electrode evaporated in one of the faces of the filter to perform template-assisted electrochemical deposition as the bottom electrode, a top electrical contact needs to be implemented. This has been made by electrochemically depositing nickel on top of the previously grown bismuth telluride or tellurium nanostructure. In this way, the electrical contact between the different nanostructures of thermoelectric material and the top electrode is granted, and a macroscopic electrode is formed on the top of the filter, which simplifies the use of the generator.
Finally, the optimization of the geometry of the thermoelectric generators was firstly studied by simulations carried out with COMSOL MULTIPHYSICS and then implemented in actual devices. For the moment, thermoelectric generators consisting of 2 or 4 pairs of legs fabricated inside the commercial filter have been implemented.

Theoretical Investigations of Electronic, Thermodynamic and Thermoelectric Properties of Filled Skutterudites ThFe 4 P 12 and CeFe 4 P 12 Using DFT Calculations Abdelkader Alleg; Laboratory for Physical Sciences, Algeria

The structural, mechanical, electrical, thermodynamic and thermoelectric properties of CeFe4P12 and ThFe4P12employing first-principles calculations together with semi-classical Boltzmann Transport equations are investigated. It has been firmly proved that these materials fall within the category of semiconductors. The existence of band gap energies measuring 0.436 eV and 0.52 eV, respectively, supports the basis for this classification. Both materials are stable in terms of mechanics and dynamics. The Seebeck coefficient for ThFe4P12 is 827 μV/K, while CeFe4P12 is 667 μV/K at ambient temperature. For both materials,. The highest recorded figure of merit values for both materials is 0.96 for ThFe4P12and 0.97 for CeFe4P12at 300 K. Therefore, the theoretical findings provide a strong justification for future experimental investigations. Keyword: Thermoelectric; Skutterudites;ThFe4P12 ;CeFe4P12

5:00 PM EN08.08.02
An Efficient High-Throughput Approach for Investigating Anharmonic Lattice Dynamics Hrushikesh P. Sahasrabuddhe[1,2], Zhuoying Zhu[2], Junsoo Park[2,3], Alex M. Ganose[2,4], Rees Chang[2,5], John W. Lawson[3] and Anubhav Jain[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]NASA Ames Research Center, United States; [4]Imperial College London, United Kingdom; [5]University of Illinois at Urbana-Champaign, United States

This work introduces a high-throughput framework specifically designed for anharmonic phonon calculations. The method is based on the efficient fitting of the force constant (FC) matrix implemented in the hiPhive [1] framework and subsequent calculation of harmonic and anharmonic properties. In particular, we determined the set of optimal parameters: FC fitting methods, cutoffs, supercell size for finite displacement DFT calculations, the magnitude of atomic displacements, and the number of perturbed supercells. Our workflow can calculate phonon band structure, phonon DOS, finite temperature free energy, heat capacity, coefficient of thermal expansion (��), and lattice thermal conductivity (). A temperature-induced anharmonic phonon renormalization (APRN) [2] scheme to tackle dynamical instability is also included in the workflow, which is shown to predict the finite temperature stability of cubic GeTe [3] and ZrO_2 [4] phases.

Our workflow exhibits an impressive 100 to 1000X speedup compared to conventional approaches when calculating anharmonic vibrational properties. We conduct a rigorous benchmarking process against experimental measurements, encompassing ��, , and computationally calculated phonon DOS. The �� and obtained from the workflow agree well with the experimentally reported values with a Pearson correlation coefficient of 0.94 and 0.99, respectively. The Pearson correlation coefficient of phonon DOS varies from 0.63 in CdSe to 0.96 in BP.

In this workflow, we integrate lattice dynamic packages like hiPhive with the Materials Project (MP) [5] tech stack using Atomate2. We aim to use this workflow to curate a high-quality dataset of materials with finite temperature phase diagrams and anharmonic vibrational properties in a high-throughput way. This dataset will make it possible to identify novel thermoelectric materials, solid-state ionic conductors for solid-state batteries, photovoltaic absorber materials, and solar cells. It will also aid in the predictive synthesis of solid-state reactions.

5:00 PM EN08.08.03
Developments in Thermal Transport Property Measurement of Thermoelectric Thin Films and Determination of Interfacial Thermal Resistance by Thermo-Reflectance Method Takahiro Baba[1], Tetsuya Baba[1] and Takao Mori[1,2]; [1]National Institute of Materials Science (NIMS), Japan; [2]University of Tsukuba, Japan

Thermo-reflectance method, also called time domain thermo-reflectance (TD-TR) method can measure thermal transport properties in the cross-plane direction of thin films, which is important for evaluation of thermoelectric thin films. Recently the method achieved notable developments. The rise of electrical delay technique has enabled the method to observe temperature response in longer timescale than pulse interval of pump beam, which demonstrate periodic nature of thermo-reflectance signals. In our recent study, we developed an analytical approach based on Fourier analysis, which can consider the periodicity of thermo-reflectance signal into consideration and improved robustness and reliability of the determination of thermal properties. To evaluate thermal transport in thermoelectric thin films, it is also important to consider the transport across interfaces between materials, which is generally called interfacial thermal resistance. Picosecond thermo-reflectance method is suitable to measure the interfacial thermal resistance which has very short characteristic time. Thanks to our approach based on Fourier analysis, we could consider the contribution from interfacial thermal resistance between thin film and substrate by extending the mathematical model in frequency domain. We could finally achieve quantitative evaluation of interfacial thermal resistances by measuring only one sample, whereas a conventional approach to evaluate interfacial thermal resistances needs to prepare thin films with different thickness. In the conventional approach, each thin film should be sandwiched between two metallic films with the same thickness. This approach has some ambiguity because it is difficult to confirm that thin films with different thickness have the identical characteristics. We have measured actual thermoelectric thin films by picosecond thermos-reflectance method. In TDTR method, a sample is generally measured under front heat - front detect (FF) configuration, but we has utilized a thermo-reflectance method under rear heat - front detect (RF) configuration as well. The thermo-reflectance method under RF configuration, sometimes called ultrafast laser flash method, has smaller uncertainty compared to the method under FF configuration. This time we are going to introduce recent developments in thermo-reflectance method and share some notable results of thermal transport property measurements of thermoelectric thin films.

Controlling Defects in Epitaxial Thin Film Growth of $Mg_2Sn_{1-x}Ge_x$ by Modulating Mg Flux Rate in MBE Kenneth M. Senados[1,2], Takashi Aizawa[2], Isao Ohkubo[2], Takahiro Baba[1,2], Akira Uedono[1], Takeaki Sakurai[1] and Takao Mori[1,2]; [1]University of Tsukuba, Japan; [2]National Institute for Materials Science, Japan

Defects manipulation in thermoelectrics is emerging as a key in optimizing their performance. However, because thin film processes differ from bulk synthesis methods, the manipulation of defects in thin films vary significantly from their bulk counterparts. We explore in this study how Mg flux rate modulation in molecular beam epitaxy (MBE) growth affects the defects formation of $Mg_2Sn_{1-x}Ge_x$ (x = 0.05 and 0.12) epitaxial films. Mg flux rates were varied in the range of Mg : Sn(Ge) = 3.9-9.1, while Sn and Ge flux rates were fixed at 1.65 atoms×$s^{-1}$$nm^{-2}$. Although the relative Mg supply rate largely exceeded 2, the obtained films consisted of Mg_2Sn phase as a main component, because the excess Mg can easily evaporate at the growth temperature of 380°C. However, the Mg flux rate can impact the film growth dynamics.

Higher Mg flux rates substantially enhance carrier mobility, Seebeck coefficient and eventually the power factor, which is linked to the reduction of vacancy-type defects detected in the positron annihilation spectroscopy measurements. Simultaneously, the films' X-ray diffraction (XRD) indicated higher crystallinity at higher Mg flux rates. Cross-sectional transmission electron micrographs of films reveal Moiré patterns. EDS measurements at the Moiré patterns for the low Mg flux rate film show Mg-poor regions, suggesting Mg vacancies (V_{Mg}). On the other hand, at the high Mg rate, the presence of Mg interstitials (I_{Mg}) is hinted within the Moiré patterns. The formation of Moiré patterns can be associated with strain relaxation, and their increased occurrence at higher Mg flux rates could be attributed to the role of Mg in altering strain distributions and controlling the defects. Structural analysis through XRD pole figures also unveiled the presence of stacking faults in the films. The total thermal conductivity measured at room temperature of the thin films tends to decrease with an increasing Mg flux rate. These findings suggest a delicate balance between improved overall crystal structure and the presence of localized structural variations that may contribute to the decrease in thermal conductivity and total improvement of the thermoelectric properties of Mg-based thin films.

5:00 PM EN08.08.05
Role of Spin-Orbit Coupling in Determining The Transport Properties of NbFe (As, Sb, Bi) Half - Heusler Compounds Sara Shivalingam Goud[1], Amrita Bhattacharya[1] and Ashok Arya[2]; [1]Indian Institute of Technology Bombay, India; [2]Bhabha Atomic Research Centre, India

Half – Heusler (HH) alloys have proven to be promising materials for thermoelectric (TE) energy conversion due to their remarkable electronic transport properties and good mechanical stability. However, relatively large lattice thermal conductivity (κ_L) limits their performance. For the past two decades, lowering κ_L in these materials without reducing their power factor (PF = $S^2\sigma$; S - Seebeck coefficient, σ - electrical conductivity) using various microstructural engineering techniques has been the primary interest of research. *R*FeSb (R = V, Nb, Ta), a class of Fe – based HH compounds have emerged as high-performing *p–type* thermoelectric materials. Major theoretical works on these compounds are focussed on understating the band structure related transport properties under the rigid band (RB) and constant relaxation time approximations (CTR). The effect of spin–orbit coupling (SOC), which has a significant influence on the band structure due to the presence of heavy elements has not been investigated thoroughly. This study mainly focuses on investigating the role of SOC on transport properties of NbFe*X* (*X* = As, Sb, Bi) alloys using density functional theory (DFT) based electronic structure calculations. Electronic band structure calculations revealed that the splitting in the energy levels has increased as the element gets heavier (As Sb Bi) and the band degeneracy at the valence band maximum (VBM) which occurs at L point in the Brillouin zone for NbFeBi is broken. Due to the different magnitudes of splitting at different chemical potentials, opposing trends in transport properties (S and σ) are observed at lower and higher chemical potentials. The varying trends are mainly due to the change in the number of bands available for conduction and their topology at the extrema for different doping concentrations when SOC is included in the calculation. Lattice thermal conductivity calculations are performed to get a comprehensive insight into the thermoelectric performance of these compounds and the calculations revealed that NbFeBi has the lowest κ_L when compared to NbFeAs and NbFeSb with a phonon band gap due to the suppression of the acoustic modes as Bi is relatively heavier than As and Sb. With a large reduction in the lattice thermal conductivity and a favorable splitting of energy levels due to SOC, NbFeBi is found to best-performing *p–type* TE material when compared to NbFeSb and NbFeAs, with the highest figure of merit (zT) of 1.6 at 1100 K emphasizing the importance of SOC in thermoelectric transport.

5:00 PM EN08.08.06
Impact of Excess Cu on Phase Separation and Thermoelectric Properties of Arc Melted $Ti_{0.5}Zr_{0.5}NiCu_ySn$ Blair F. Kennedy[1] and Jan-Willem Bos[2]; [1]Heriot-Watt University, United Kingdom; [2]University of St Andrews, United Kingdom

Alloys based on XNiSn (X = Ti, Zr or Hf) are leading n-type half-Heusler thermoelectrics.[1] They have large power factors $S^2\sigma$, but are limited by an inherently high lattice thermal conductivity, κ_{lat}. Alloying Ti, Zr and Hf on the X-site in the crystal structure affords significant reductions of κ_{lat}. However, Ti and Zr/Hf mix poorly during materials synthesis, typically resulting in the presence of multiple HH phases in the final product.[2, 3] The presence of multiple HH phases has been attributed to phase segregation, and has been linked to low κ_{lat}, below values expected from alloying.
In this contribution, the impact of excess Cu on the HH phase distribution of $Ti_{0.5}Zr_{0.5}NiCu_ySn$ (y = 0.025, 0.1) is discussed. Structural characterisation of samples treated at varying temperatures reveals minimal impact on the phase distribution for y = 0.025, compared to not having Cu. By contrast, samples with y = 0.1 show improved homogeneity and can be made single phase at high temperature. The homogeneous y = 0.1 sample has the lowest κ_{lat} of all samples, confirming that alloying is the dominant phonon scattering effect. A highest zT = 0.7 is found for multiphase $Ti_{0.5}Zr_{0.5}NiCu_{0.025}Sn$, with a lower zT = 0.5 observed for single phase $Ti_{0.5}Zr_{0.5}NiCu_{0.1}Sn$. This lower value is due to over-doping and a compromised $S^2\sigma$.

This work demonstrates that (1) the poor mixing of Ti and Zr/Hf in XNiSn alloys is predominantly a kinetic effect and not driven by thermodynamic phase segregation. (2) That there is no evidence that multiphase behaviour leads to significant reductions of κ_{lat} in our samples.

Alloying-Induced Structural Transition in The Promising Thermoelectric Compound CaAgSb A K M Ashiquzzaman Shawon[1], Weeam Guetari[1], Kamil Ciesielski[2], Rachel Orenstein[2], Jiaxing Qu[3], Elif Ertekin[3], Eric Toberer[2] and Alexandra Zevalkink[1]; [1]Michigan State University, United States; [2]Colorado School of Mines, United States; [3]University of Illinois at Urbana-Champaign, United States

AMX Zintl compounds, crystallizing in several closely related layered structures, have recently garnered attention due to their exciting thermoelectric properties. In this study, we show that the orthorhombic CaAgSb can be alloyed with hexagonal CaAgBi to achieve a solid solution with a structural transformation at $x \sim 0.8$. This transition can be seen as a switch from 3D to 2D covalent bonding, in which the interlayer *M-X* bond distances expand while the in-plane *M-X* distances contract. Measurements of the elastic moduli reveal that $CaAgSb_{1-x}Bi_x$ becomes softer with increasing Bi content, with the

exception of a step-like 10% stiffening observed at the 3D-to-2D phase transition. Thermoelectric transport measurements reveal promising Hall mobility and a peak *zT* of 0.47 at 620 K for intrinsic CaAgSb, which is higher than previous reports for unmodified CaAgSb. However, alloying with Bi was found to increase the hole concentration beyond the optimal value, effectively lowering the *zT*. Interestingly, analysis of the thermal conductivity and electrical conductivity suggests that the Bi-rich alloys are low Lorenz-number (*L*) materials, with estimated values of *L* well below the non-degenerate limit of $L = 1.5 \times 10^{-8}$ $W.\Omega.K^{-2}$, in spite of the metallic-like transport properties. A low Lorenz number decouples electrical and electronic thermal conductivity, providing greater flexibility for enhancing thermoelectric properties.

Thermal and Electrical Transport Properties of Novel Metal $Ln_2M_2O_5Ch_2$ Compounds for Thermoelectrics Kieran B. Spooner[1], Joe Willis[2], Katarina Brlec[2] and David O. Scanlon[1]; [1]University of Birmingham, United Kingdom; [2]University College London, United Kingdom

Heat loss wastes 50 % of global energy production,[1] making its reduction or utilisation essential in controlling and meeting our ever-increasing energy demand with renewable energy and reducing the effects of global heating. Thermoelectric materials, which convert heat into electricity, are the ideal candidates for this task, however the highest efficiency materials tend to contain rare or toxic elements such as Pb, limiting their potential uses. Therefore, the discovery of efficient, earth-abundant and non-toxic thermoelectrics is of great importance.

The recent analysis of $Y_2Ti_2O_5S_2$ as a thermoelectric[2] has revealed $Ln_2M_2O_5Ch_2$ to be a promising family for further investigation as thermoelectric materials. Here, we study $Ln_2M_2O_5Ch_2$, (Ln = Sc, Y, La; M = Ti, Zr, Hf and Ch = S, Se, Te), first finding the kinetically and thermodynamically stable structures, before identifying their n-type preference via band alignment. Finally, we explicitly calculate the electronic and phononic scattering rates in order to calculate their thermoelectric performance, quantified by the dimensionless figure of merit, ZT.

Exploring Electronic and Thermal Conduction in Lanthanum Diselenide Christopher Savory[1,2]; [1]University of Birmingham, United Kingdom; [2]University College London, United Kingdom

Thermoelectric materials, converting heat into electricity, represent a key part of the energy generation economy, particularly when used for waste heat collection from other industrial processes. Many of the highest performing materials have issues with sustainability, in containing less abundant elements such as Te, or toxic elements such as Pb. Efforts to explore and develop new thermoelectrics are important to improve the diversity of materials – not only to drive for more sustainable compounds but also to tackle different optimal temperature ranges for specific waste heat applications.[1]
$LaSe_2$ has seen recent investigation as a p-type transport material with intrinsic carrier concentrations beyond 10^{19} cm^{-3},[2] although with limited exploration for the microscopic origin of its favourable electronic behaviour. In this study, we examine $LaSe_2$ using multiple computational techniques to explain its electronic and thermal transport properties. Initially, we establish the key role of Se-Se dimerization in the structure of the compound in engineering valence band dispersion using a combination of hybrid Density Functional Theory and GW calculations.[3] We move on to calculate electronic transport properties beyond the relaxation time approximation within the recently-developed AMSET code, allowing the calculation of individual scattering mechanisms, and establish the likely limits to carrier mobilities.[4] Finally, we calculate the thermal transport properties of $LaSe_2$, with comparison between the hiphive and ALAMODE packages[5, 6] to establish the suitability of $LaSe_2$ as a p-type thermoelectric, and the possibility for more earth abundant polychalcogenides.

Ultra Low Thermal Conductivity and Enhanced Thermoelectric Properties of High Entropy Half Heusler Ankit Kumar, S.S Vishak, Prasenjit Ghosh and Surjeet Singh; Indian Institute of Science Education and Research, India

We have witnessed a dramatic reduction of lattice thermal conductivity and improved thermoelectric performance by increasing configurational entropy and tunning carriers of half Heusler (hH) systems. Lattice thermal conductivity is a major player in the thermoelectric performance. κ_L of double hH $Ti_2FeNiSb_2$ is less compared to conventional hH like TiCoSb because of Fe and Ni occupying same site. By increasing the number of component at same site, κ_L can be reduced. In this report we show an unexplored double hH $Hf_2FeNiSb_2$ and some high entropy (HE) hH alloys created by adding more components at Hf and Fe/Ni site. We have further engineered the bands to increase the band gap in order to counter bipolarity. The carriers were optimized by tuning Fe/Ni concentration in the synthesized HE $TiHf(FeCoNi)_{0.667}Sb_2$. κ_L of 0.88 $Wm^{-1}K^{-1}$ was obtained for $TiHf(Fe_{0.5}CoNi_{1.5})_{0.667}Sb_2$ with maximum zT of 0.46 at 973 K. In the p-type region the maximum zT of 0.32 was obtained. This work demonstrates the effectiveness of the high entropy strategy in double hH compounds and the potential of the new concept of high entropy hH compounds as high-performance thermoelectric materials.

5:00 PM EN08.08.12
Favourable Interface Contacts for Thermoelectric Devices Ajay K. Verma[1,2,3], S. R. Dhakate[2,3], Sumeet Walia[1] and Bhasker Gahtori[2,3]; [1]RMIT University, Australia; [2]CSIR- National Physical Laboratory, India; [3]Academy of Scientific & Innovative Research (AcSIR), India

A solid-state thermoelectric device directly transforms the waste heat into useful electricity. Although the practical applications of TE devices are confined owing to their low efficiency. The efficiency of TE devices depends on several parameters such as performance and compatibility of both p- and n-type thermoelectric materials, as well as compatibility of contact material. Further, a crucial aspect of enhancing thermoelectric performance lies in the engineering of contact interfaces within these devices. Various aspects of interface engineering, including contact material selection, surface passivation, and interface morphology control will be discussed here. Along with that will focus on the strategies to tailor interface properties to maximize charge carrier transport while minimizing thermal conduction, with low thermomechanical stresses. Therefore, understanding the key issue of unfavorable contact interfaces in TE devices and its possible solutions could hasten the development of several practical applications.

5:00 PM EN08.08.13

Oxide Thermoelectric Materials for Green Energy Generation Kriti Tyagi, Rohit Yadav and S. R. Dhakate; CSIR-National Physical Laboratory, India

BiCuSeO oxy-chalcogenides are considered promising thermoelectric materials due to high Seebeck coefficient values combined with intrinsically low thermal conductivity. BiCuSeO showcases properties of a semiconductor and possess low electrical conductivity values. The two essential step that must be taken in sequence to create test materials for use in thermoelectric modules are the calcination of the mixed precursors (BiCuSeO) and subsequent consolidation into precisely dense pellets by spark plasma sintering (SPS) technique. By tracking the evolution of structural and morphological measurements, the current work optimizes the processing times for ball milling and calcination on the phase formation of polycrystalline BiCuSeO powder. The work also focus on designing different synthesis routes and their comparison to find out the most suitable route for synthesizing pristine BiCuSeO.

5:00 PM EN08.08.14
Computational Design of SiGeSn Alloys for Thermoelectric Applications Li-Wen Lin and Szu-Chia Chien; National Central University, Taiwan

Owing to the increasing demand for sustainable energy, significant effort has been made towards the development of energy-related materials. Among various candidates, thermoelectric materials have drawn considerable attention. Si-Ge alloys have a long history as effective thermoelectric materials for waste heat recovery. More importantly, recent studies have shown that Si-Ge alloys with the Ge content of 20% possess excellent materials properties as thermoelectric materials [1]. By introducing Sn into Si-Ge alloys, the thermal conductivity can be reduced with a small impact on electrical conductivity, thus making SiGeSn alloys promising thermoelectric candidates. However, challenges in precise composition control and complex synthesis methods in experiments may limit their studies and applications [2]. To this end, this work seeks to employ computational methods to help search for the optimal composition ratios of SiGeSn alloys with the aim of facilitating the development of SiGeSn thermoelectric materials.

In this work, the Alloy Theoretic Automated Toolkit (ATAT), utilizing special quasi-random structure (SQS) modeling, is employed to create random $Si_xGe_ySn_z$ alloys with various Si, Ge, and Sn content. The electronic structure characteristics are calculated using density functional theory (DFT) as implemented in the Vienna *Ab-initio* Simulation Package (VASP) [3], whereas their thermoelectric properties are assessed by BoltzTraP2 software, which applies the Boltzmann Transport Equation (BTE) for obtaining key thermoelectric parameters such as the Seebeck coefficient, electronic conductivity, electronic thermal conductivity, and power factor [4]. Our result shows that with the composition of $Si_4Ge_1Sn_1$, the highest figure of merit of around 0.8 can be achieved. By integrating these computational tools, this work offers comprehensive insights into the intricate correlation between composition ratios and the thermoelectric properties in SiGeSn alloys. It is anticipated that the findings from this work can offer insights into the design of high-performance thermoelectric materials.

Drastic Lowering of Lattice Thermal Conductivity induced by Aliovalent Substitution of TiCoSb-Based Half-Heusler Compound Dipanwita Bhattacharjee[1], Nagendra S. Chauhan[2], Tanmoy Maiti[3], Yury V. Kolen'ko[4], Yuzuru Miyazaki[5] and Amrita Bhattacharya[1]; [1]Indian Institute of Technology Bombay, India; [2]National Institute for Materials Science, Japan; [3]Indian Institute of Technology Kanpir, India; [4]International Iberian Nanotechnology Laboratory, Portugal; [5]Tohoku University, Japan

The performance of the state-of-the-art ternary half-Heusler (HH) compounds is limited by their intrinsically high lattice thermal conductivity (κ_L). In this study, we present a stable n-type biphasic-quaternary (Ti,V)CoSb HH alloy that is equivalent to previously reported nanostructured HH alloys in terms of lattice thermal conductivity (κ_L~ 2 W/mK) within a temperature range of 300-800 K. Aliovalent substitution of TiCoSb, resulting in an effective 18.5 valence electron count ($Ti_{0.5}V_{0.5}CoSb$), results in a significant reduction in κ_L and synergistic enhancement of the power factor with a peak zT of 0.4 (± 0.05) at 873 K. The lowering of κ_L in $Ti_{0.5}V_{0.5}CoSb$ HH alloy is attributed to an enhancement in phonon scattering driven by spinodal decomposition upon annealing. First-principles DFT calculations are performed to investigate the structure, stability, electronic structure, and transport properties of the synthesised alloy, which accredits the decrease in lattice thermal conductivity to the alloy's increased anharmonicity. The changing electronic band-structure upon substitution and an increase in carrier concentration have a good correlation with the observed electrical characteristics. Hence, new prospects for discovering biphasic-quaternary HH compositions with intrinsically lower κ for potential thermoelectric applications are supported by this study.

5:00 PM EN08.08.17
Defect Engineering in Bi_2SeO_2 by Tuning Synthesis Conditions - A Combined Experimental and Theoretical Study Michael Toriyama[1], Andrei Novitskii[2], Illia Serhiienko[2,3], Takao Mori[2,3], Jeff Snyder[1] and Prashun Gorai[4]; [1]Northwestern University, United States; [2]National Institute for Materials Science, Japan; [3]University of Tsukuba, Japan; [4]Colorado School of Mines, United States

Recently, Bi_2SeO_2 has emerged as a promising *n*-type counterpart to *p*-type BiCuSeO in thermoelectric (TE) devices. However, there are significant variations in the reported charge carrier concentration of Bi_2SeO_2 spanning several orders of magnitude, resulting in diverging reports of TE properties. These predominantly arise from the disparate synthesis routes used, which in turn affect the defect thermodynamics in the system. In this study, we employ a combined experimental and theoretical approach to demonstrate how defect engineering controlled by synthesis conditions can be used to tailor the transport properties of *n*-type Bi_2SeO_2. Through first-principles calculations, we identify the dominant native defect in Bi_2SeO_2 as the donor-like selenium vacancy (V_{Se}). We predict that increasing the synthesis temperature (T_{SSR}) of nominally undoped Bi_2SeO_2 will lead to an increase in V_{Se} and, consequently, electron concentration. We observe a rise in carrier concentration by nearly two orders of magnitude between samples synthesized at T_{SSR} = 773 K and T_{SSR} = 1173 K. This results in the enhancement in both the quality factor and the TE performance with a remarkable zT value of 0.25 at 773 K achieved for self-doped Bi_2SeO_2. Our findings underscore a noteworthy relationship between processing conditions and the transport properties of Bi_2SeO_2 rooted in defect engineering.

Side-Chain Engineered p or n-Type Nonaqueous Polymeric Ionic Gels for Sustainable Ionic Thermoelectrics Sungryong Kim, Seyeong Lim and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)

Although ionic hydrogels have been developed recently for innovative wearable electronics, they necessitate high humidity to diffuse ions in water and fast self-healing, which negatively impacts their performance and stability in ambient conditions (e.g., dry environments). In this study, a series of p- and n-type polymeric ionic gels (PIGs) with different ratios of ionic side chains are synthesized to allow only single-type ions to pass through them. The results

demonstrate that our repeatedly stretchable PIGs are transparent, thermally robust up to 125 °C, and self-healing. Among the series of PIGs, p- and n-type PIGs with 75% ion moieties (P75 and N75) exhibit the optimum ionic conductivity (σ_i) (4.1×10^{-4} and 2.7×10^{-4} S cm^{-1}) and ionic Seebeck coefficients (S_i) (5.84, and -4.18 mV K^{-1}) under ambient conditions (25 °C and relative humidity (RH) of 30%), resulting in ZT_i values of 1.87×10^{-3} and 1.18×10^{-3}. Moreover, the σ_i and S_i of PIGs were almost consistent under extremely low RH 10%. Accordingly, P(([EMIM$^+$][SPA])$_{0.75}$-r-MA$_{0.25}$) (P75) and P(([APTA][TFSI$^-$])$_{0.75}$-r-MA$_{0.25}$) (N75) are used to achieve stretchable ionic thermoelectrics (iTEs) with stable operability under ambient conditions (RH of 30%), satisfying all of the requirements. The iTEs with five pairs of p/n couples exhibit a thermovoltage of up to ~0.8 V.

Engineering Thermoelectric Transport in Transparent Conducting Oxides Vinayak B. Kamble, Soumya Biswas, Saptak Majumder and E. Jagadeswara Reddy; Indian Institute of Science Education and Research (IISER) Thiruvananthapuram, India

A number of oxides, including ZnO, ITO, $SrTiO_3$ and cobalt oxides are promising candidate as environment friendly thermoelectric (TE) materials[1-3]. However, high thermal conductivity is the primary factor which hinders their application and leads to poor TE figure of merit (zT). Here we demonstrate that microstructure engineering through Al doping and reduced graphene oxide /graphite additives leads to selective enhancement in phonon scattering in ZnO thereby increasing its TE efficiency[4]. The incorporation of trace Al doping with 1.5 wt% RGO into ZnO (AGZO) has been found to show significant improvement in zT (=0.52 at 1100 K) which is an order of magnitude larger compared to that of bare undoped ZnO. Tunneling spectroscopy performed on bare as well as composite particles reveals that the band gap of ~ 3.4 eV for bare ZnO reduces effectively to ~ 0.5 eV upon RGO encapsulation, facilitating charge transport. The Al doping, defect engineering and RGO encapsulation synergistically brings about drastic reduction of thermal conductivity, through enhanced interfacial and point defect-phonon scatterings. These opposing effects on electrical and thermal conductivities leads to enhancement in the power factors as well as the zT value[5]. Our subsequent efforts with highly ITO oxides will be presented in the later half.

Sustainable Metal Phosphide Thermoelectrics with Promising Performance Robert Quinn[1], Rajan Biswas[2] and Jan-Willem Bos[2]; [1]Heriot-Watt University, United Kingdom; [2]University of St. Andrews, United Kingdom

There is a continued need for discovery of new thermoelectric materials. Metal phosphides are an emerging class of thermoelectrics with promising figures of merit, approaching zT = 1 in n-types and zT = 0.5-0.8 in p-types.[1]

Despite the low atomic mass of phosphorous, structural complexity leads to low thermal conductivities across a range of materials and the main challenge is to embed better electrical properties.[1] Phosphorous has a range of possible oxidation states, affording diverse chemical bonding and a wide range of available structures for exploration.

We have investigated a series of ternary metal phosphides and have discovered promising thermoelectric performance in MgCuP, CaCuP and CaAgP.[2,3,4] In all cases, metal deficiency leads to degenerate p-type conduction and the figures of merit fall between zT = 0.4-0.5 at 660-773 K. CaCuP in particular is promising as this composition has the best electronic properties amongst all reported metal phosphides.[2,3] Modelling shows CaCuP can reach zT = 1 in alloyed compositions if control of doping can be achieved. MgCuP has a lower symmetry structure and achieves a similar zT on account of a lower thermal conductivity.[2] CaAgP has been considered as a candidate topological nodal line semimetal. However, our work shows that CaAgP forms with high concentrations of Ag vacancies, and the stable phase $CaAg_{0.9}P$ behaves like a regular highly doped semiconductor.[4]

This contribution will summarise our recent metal phosphide work, including phase boundary mapping and alloying in the CaCuP system and discuss some of the general conclusions from our recent review.[1]

Enhanced Density of States Mass in Cu Containing XNiSn Half-Heusler Alloys – A New Route Towards High Thermoelectric Performance Robert Quinn[1], Sonia Barczak[1] and Jan-Willem Bos[2]; [1]Heriot-Watt University, United Kingdom; [2]University of St. Andrews, United Kingdom

Half-Heusler alloys are leading contenders for application in commercial thermoelectric generators. They combine strong performance with good engineering properties and thermal stability.[1] There has been great progress in p-type half-Heusler alloys in the past decade, with zT = 1.5 achieved in NbFeSb and ZrCoBi. There have been fewer developments in n-type Heusler alloys with the best performance in compositions based on ZrNiSn, with peak zT = 1.2-1.3.

We have investigated the use of interstitial Cu in the XNiSn half-Heusler alloys. This cheap base metal is an alternative to the usual n-type dopant Sb. In addition to being an efficient n-type donor, its use leads to a suppression of thermal conductivity and a more homogeneous microstructure.[2-4] Our latest work reveals an enhanced density of states effective mass, $m_{DoS}^* \sim 4.1\ m_e$, for Cu-doped XNiSn half-Heusler samples rich in X = Ti. This enhancement over typical values of 3 m_e occurs without substantial drop in electron mobility. This enables improved power factors and peak zT = 1 at 773 K in TiNiSn-based samples with interstitial Cu used as a mineraliser, dopant and to suppress thermal transport.[5] Bandstructure calculations show the emergence of a second band at the conduction band minimum. This brings the performance of TiNiSn-based compositions close to the leading n-types based on Sb-doped ZrNiSn and is a significant development.

This contribution will summarise our current understanding of the impact of interstitial Cu in the XNiSn Heuslers, which goes beyond carrier doping and affects underlying electronic properties and microstructure of these materials.

***Ab Initio* Investigation of Thermoelectric Properties of Two-Dimensional MOFs** Masoumeh Mahmoudi Gahrouei, Emmanuel Odogwu, Nikiphoros Loki Vlastos and Laura de Sousa Oliveira; University of Wyoming, United States

Recent studies have shown that metal–organic frameworks (MOFs) have potential as thermoelectric materials, and the topic has received increasing attention. The main motivation for this project is to further our knowledge of thermoelectric properties in MOFs and find which available density functional based tight-binding method can accurately predict (at least trends in) the electronic and thermoelectric properties of MOFs at a lower computational cost than standard density functional theory. In this work, the monolayer, AA, and AB-stacked $Zn_3C_6O_6$, Zn-NH-MOF and $Ni_3(HITP)_2$ MOF structures have been investigated. Our results indicate that tight-binding density functional theory, especially GFN-xTB, a less computationally expensive first principles-based approach, can be used reliably to speed up predictions of the MOFs' electronic, phonon and thermoelectric properties. Phonon dispersion calculations of the $Zn_3C_6O_6$ and Zn-NH MOFs show that AB-stacking results in the most stable structure whereas for $Ni_3(HITP)_2$ both AA and AA slipped stacking are dynamically stable. To estimate the figure of merit, for the aforementioned MOF geometries, the electrical conductivity and Seebeck coefficient are computed (with a constant carrier relaxation time) along with the lattice thermal conductivity (using third-order force constants). We report on these results, including how the thickness and doping are expected to affect the thermoelectric properties of semiconducting MOFs.

A Computational Investigation of Bi_2MO_4Cl (M = Y, La and Bi) as Thermoelectric Materials Shipeng Bi[1] and David O. Scanlon[2]; [1]University College London, United Kingdom; [2]University of Birmingham, United Kingdom

In the process of primary energy consumption, a large amount of waste heat is generated. Thermoelectric materials (TEs) can convert waste heat energy into electric energy, which is crucial to solving the current energy crisis and mitigating global warming. In general, the performance of TEs can be determined by the dimensionless figure of merit, *ZT*, that is evaluated from its electronic and thermal properties. However, it is difficult to maximise *ZT* due to the interaction between different parameters.

In recent years, mixed anionic oxides have shown great potential in the field of TEs.[1-3] Recently, the mixed anionic oxides Bi_2MO_4Cl (M = Y, La and Bi) was shown to exhibit excellent stability in photocatalytic water oxidation reactions,[4] but their thermoelectric properties have not been explored. We postulated that this quaternary structure with heavy elements will lead to a low lattice thermal conductivity, and they can be synthesised at a relatively high temperature, thus can maintain stability at high temperatures, so we performed density functional theory (DFT) calculations to study the thermoelectric performance of Bi_2MO_4Cl (M = Y, La and Bi). Our results showed that Bi_2MO_4Cl (M = Y, La and Bi) belongs to p-type TEs and exhibits an average ZT of about 1 at 1000 K.

Thermoelectric Enhancement of Thin Si Films by means of Block Copolymer Driven Nanostructuration Alex Rodriguez-Iglesias[1], Iñigo Martín-Fernández[1], Francesc Pérez-Murano[1], Joaquín Santander[1], F. Xavier Alvarez[2], Aitor F. Lopeandia[2], Luis Fonseca[1], Llibertat Abad[1], Marc Salleras[1] and Marta Fernández-Regúlez[1]; [1]Instituto de Microelectrónica de Barcelona (IMB-CNM, CSIC), Spain; [2]Universitat Autònoma de Barcelona, Spain

Thermoelectricity explains the conversion of heat into electricity and vice versa, and a plethora of applications are available nowadays for thermoelectric systems in the fields of cooling, power generation and sensing. Traditionally, the most used thermoelectric materials have been based on chalcogenides, as the main reason that has driven the material choice has been the maximization of the thermoelectric figure of merit (ZT). This figure of merit indicates the performance capabilities of a material as a thermoelectric, and depends on its Seebeck coefficient and its electrical and thermal conductivities. Nevertheless, these widely used materials are based on alloys of scarce, expensive, and toxic elements (Bi, Te, etc.) that are difficult to integrate within the semiconductor industry. On the contrary, silicon (Si) is a poor thermoelectric material when in its bulk form but it has been shown to improve around 100 times its thermoelectric performance when it is nanostructured in two- or one-dimensional structures, then becoming a competitive alternative [1]. This improvement is mainly justified by the effective reduction of the phononic thermal conductance in the nanostructured material.
In this contribution, we present the study of suspended Si ultra-thin films as thermoelectric material, which are much easier to integrate into semiconductor technologies. Although the enhancement in thermoelectric performance of thin films is modest when compared to one-dimensional structures, this is compensated and enhanced by introducing surface nanostructuration with the aim to reach thermoelectric figures of merit similar to the best reported values in the literature for Si structures. These structures are based on rough surface Si nanowires (NWs), whose large-scale fabrication remains unsolved as the synthesis of high density and uniform Si NW arrays with homogeneous nanoscopic surface morphology is a challenging process. Here, we present a cost-effective and scalable approach for the fabrication of the membranes by block copolymer (BCP) nanopatterning. BCP based technologies present manufacturing advantages, as it is a technology easy to scale up for high-volume manufacturing, very cost-effective and capable of achieving sub-10 nm resolution [2].
Nanostructured Si membranes are fabricated on the device layer of a Silicon on Insulator (SOI) wafer with ultrathin device layer (30 – 50 nm). A thin film BCP is self-assembled perpendicularly oriented to the Si surface. The BCP used for surface nanostructuration is polystyrene-block-polymethylmethacrylate (PS-b-PMMA) with cylindrical or lamellar morphology and a period between 28 and 80 nm. After self-assembly, the PMMA block is selectively removed, and PS features are transferred into the Si underneath by reactive ion etching (RIE). As a result, we obtain a nanostructured surface with a hexagonal distribution of holes when a BCP with cylindrical morphology is used as a mask, and a fingerprint-type nanostructuration when a lamellar BCP is used as a mask. The period of such structures is controlled by properly blending BCPs of different molecular weights and the depth and the shape of the walls are tuned by the RIE conditions. The final structures are doped by spin-on dopant to achieve an optimal doping concentration, 10^{19}-10^{20} cm^{-3}, for thermoelectric applications. This method has been chosen because it's a low cost, wafer scale compatible and non-destructive process, and the

characterization of the doping values obtained has been done with the 4-probe method on the thin films.
We will study the effect of surface nanostructuration on the thermoelectric performance. The thermal conductivity of the membranes will be evaluated using the *3w Völklein* approach on an appropriate test structure, in order to find the most optimal nanostructuration conditions for thermoelectricity.

8:30 AM *EN08.09.01
Structure and Property Relationship in GeTe based Thermoelectric Materials Yong Yu, Wu Wang, Lin Xie and Jiaqing He; Southern University of Science and Technology, China

The performance of thermoelectric materials is mainly governed by the materials' electrical and thermal conductivity properties and a number of new materials and structures have been exploited in order to optimize the energy conversion efficiency. Especially, nanostructure engineering via dopants, precipitates or phase/twin/grain boundaries is found to be effective in increasing the conversion efficiency by reducing the thermal conductivity. However, a direct correlation of these nanostructures to the material's property is yet to be elucidated. Nowadays, with the rapid development of aberration-corrected transmission electron microscopy (TEM), the resolution of electron microscopes takes a leap forward to sub-angstrom and sub-eV, which allows a direct access to a material's structure and chemical composition at an atomic scale.
The presentation will start with a brief and realistic coverage of the emerging and maturing themes in the context of energy sources, efficiency, charge storage and distribution. It will illustrate GeTe as one example of emerging excitements in nanostructured materials and systems for thermoelectric materials. It will highlight the role of advanced and classical electron microscopy in unravelling the structure of the constituents and their intimate interplay in governing key phenomena in thermoelectric materials.

9:00 AM EN08.09.02
Defect-Driven Thermoelectric Performance in Disordered Cd-Doped $AgSbTe_2$ Sabrine Hachmioune[1,2], Chenguang Zhang[3], Jose R. Gomez[3], Maheswar Repaka[2], Kedar Hippalgaonkar[2,3], Michael B. Sullivan[2] and David O. Scanlon[4]; [1]UCL, United Kingdom; [2]Agency for Science, Technology and Research, Singapore; [3]Nanyang Technological University, Singapore; [4]University of Birmingham, United Kingdom

With an increasing demand for efficient and environmentally friendly energy conversion technologies, thermoelectric materials play a pivotal role in harnessing waste heat for power generation. In this work, we focus on enhancing the thermoelectric performance of $AgSbTe_2$, a well-known high-performance material that has garnered significant attention for its exceptional performance in mid-temperature range applications.[1] Previous works showed the high ZT could be further improved by Cd-doping to achieve a maximum ZT of 2.6 at 573 K.[2] This improvement in performance was attributed to cationic ordering and tuning of the disorder in the material. This study presents a comprehensive experimental and theoretical investigation of the thermoelectric properties of cadmium-doped silver antimony telluride (Cd-doped AST).

Single-phase Cd-doped AST samples were successfully synthesised, exhibiting notably high-power factor values. Remarkably, a peak power factor of ~ 20 $\mu Wcm^{-1}K^{-2}$ was achieved, demonstrating the material's exceptional electrical conductivity. Furthermore, thermal conductivities as low as 0.5 $Wm^{-1}K^{-1}$ were observed at 330 K. This research also investigates the influence of growing under silver and tellurium poor conditions.

Employing first-principles hybrid-density functional theory (DFT) calculations, we systematically analyse the defect landscape within $AgSbTe_2$. By quantifying the concentration and distribution of defects, we unveil their effect on the crystal lattice structure and electronic band structure. The impact of Cd-doping on the electronic band structure was analysed to understand the underlying mechanisms responsible for the observed changes in thermoelectric performance.

By understanding the interplay between disorder-induced defects and thermoelectric performance, we aim to pave the way for the design and optimisation of advanced thermoelectric materials for efficient energy conversion applications. The combined experimental and theoretical approach offers a robust framework for the design and optimisation of thermoelectric materials contributing to the advancement of sustainable energy technologies.

9:15 AM EN08.09.03
Micro/Nano-Scale Structural and Thermoelectric Characterization of Magnesium Silicide-Based Composite Materials: Investigating Self-Diffusion of Constituent Elements, Band Alignment and Transport Properties Sanyukta Ghosh[1], Harshita Naithani[1], Mohamed Abdelbaky[2], Eleonora Isotta[3], Byungki Ryu[4], Wolfgang Mertin[2], Gregor Oppitz[1], Eckhard Müller[1] and Johannes de Boor[1]; [1]German Aerospace Center (DLR), Germany; [2]University of Duisburg-Essen, Germany; [3]Northwestern University, United States; [4]Korea Electrotechnology Research Institute, Korea (the Republic of)

The ability of thermoelectric (TE) materials to produce electrical power from otherwise wasted thermal energy has propelled this field into the spotlight, with immense potential for addressing critical issues such as energy efficiency, sustainable power generation, and environmental conservation. The effectiveness of a TE generator is intricately linked to the performance of its constituent TE materials, which, in turn, is constrained within uniform bulk materials by the interplay of three fundamental TE transport properties: the Seebeck coefficient, electrical conductivity, and thermal conductivity. The precise manipulation of the electronic band alignment at the micro/nanoscale can serve to disentangle these TE properties by selectively filtering out detrimental spectral fractions of the charge carriers. Among the diverse array of TE materials, magnesium silicide-based materials are the preferred choice for this purpose due to their spontaneous formation of nanostructured composites comprising distinct phases with varying band gaps dependent on the Si:Sn ratio, driven by a miscibility gap in the solid solution series. Furthermore, these materials are emerging as compelling candidates due to their potential to serve as cost-effective and environmentally friendly components, showcasing exceptional TE properties within the mid-temperature range of

500-800 K. However, the conventional bulk property measurements often lack the sensitivity required to detect the subtle effects of charge carrier filtering, necessitating micro/nano-scale characterizations of TE properties (Seebeck coefficient and thermal conductivity) of multi-phase materials. In our research, we have integrated several locally resolved experimental techniques with electronic transport modeling. The transient Seebeck microprobe, with its micron-scale resolution, allows us to map the distribution of the Seebeck coefficient. Combining the Seebeck coefficient map and the compositional map, obtained by establishing a simple correlation between the grey value in backscattered electron (BSE) images and the chemical composition from EDX point analysis, enables a local correlation between the Seebeck coefficient and the phase composition in multiphase materials. Moreover, employing transport modeling offers insights into the local distribution of the reduced Fermi level and the alignment of valence and conduction bands, enabling the generation of a micro-scale carrier concentration map. Furthermore, utilizing Kelvin probe force microscopy with nano-scale spatial resolution can provide the value of the Fermi level position with respect to the vacuum level, enabling generation of the same carrier concentration map at the nano-scale. Our work also demonstrates the potential of selective doping, using Bi as a dopant, to precisely modify the band positions of individual phases, a prerequisite for material enhancement by energy filtering. This localized characterization technique also aids our understanding of the inter-diffusion of Mg, Si, and Sn from one phase to another, resulting in distinct changes in the thermoelectric properties of each phase. This knowledge is vital for optimizing thermoelectric properties, as it can either amplify or attenuate the effects of selective doping. Hence, this integrated approach represents a crucial step towards optimizing composite materials through effective energy filtering.

New Members of The $Ca_{14}AlSb_{11}$ Structure Type: Structure and Thermoelectric Properties Susan M. Kauzlarich; University of California, Davis, United States

Compounds of the $Ca_{14}AlSb_{11}$ structure type show some of the highest *zT*s at high temperatures for p-type compounds. We have shown that preparing these phases with binary precursors of the appropriate composition provides a high-fidelity route to phase pure powders. This allows for broad exploration of this structure type and the resulting thermoelectric properties. We have initiated an investigation of the Eu- and As-containing compounds. In principle, for $Eu_{14}MAs_{11}$, the following compounds should be possible with *M* = Mn, Zn, Cd, Mg, Fe. I will present the synthesis of these phases, and the thermoelectric properties and compare them with other compounds of this structure type.

10:30 AM EN08.09.05
Cu_2SiSe_3 as a Self-Doped Thermoelectric Adair Nicolson[1] and David O. Scanlon[2]; [1]University College London, United Kingdom; [2]University of Birmingham, United Kingdom

Thermoelectric materials can convert thermal energy into electrical energy, taking advantage of the waste heat generated during many industrial processes. Currently, some of the best performing materials are chalcogenides containing toxic elements such as PbSe and PbTe.[1] Therefore, there is a need for research into new thermoelectric materials, which contain earth-abundant and non-toxic elements.

Kesterites, for example CuZnSnS (CZTS), have been shown to have lattice thermal conductivity lower than PbTe, and equivalent to PbSe, showing that a low lattice thermal conductivity can be achieved without the inclusion of heavy atoms by increasing the structural complexity of the material.[2] However, generating sufficient charge carriers through doping is a challenge, due to the complex quaternary defect chemistry. Taking inspiration from the kesterites, we have computationally investigated the ternary Cu_2SiSe_3 as a potential thermoelectric, as it has been previously shown to be intrinsically p-type due to the high concentrations of copper vacancies.[3] There is also a large dopability window to increase the concentration of charge carriers further.

In this work we use the AMSET[4] code to calculate the electronic transport properties using the momentum relaxation time approximation and which when combined with lattice thermal conductivities calculated using Phono3py[5], with force-constants fitted using the hiphive package[6], enabling the calculation of the thermoelectric figure of merit, zT. A zT of 0.91 is predicted in a self-doped crystal at 800 K, increasing to > 1.5 at higher carrier concentrations.

Changes in Physical Properties for HPT-Processed p-Type Skutterudite $DD_{0.7}Fe_3CoSb_{12}$ Gerda Rogl[1], Vilma Bursikova[2], Kunio Yubuta[3] and Peter F. Rogl[1]; [1]University of Vienna, Austria; [2]Masaryk University, Czechia; [3]Kyushu University, Japan

To build thermoelectric generators, which can directly convert heat into electricity, materials with a high figure of merit, ZT are essential. Severe plastic deformation (SPD) via high-pressure torsion (HPT) was successfully applied to produce in a fast and energy saving way bulk nanostructured skutterudites directly from powders. SPD introduces many defects into the sample and in parallel the crystallite size is significantly reduced. HPT-processed $DD_{0.7}Fe_3CoSb_{12}$ is a high-quality thermoelectric material with $1.12 < ZT < 1.35$ at 750 K. During measurement-induced heating these defects anneal partially out, and the grains grow. It was observed that while heating HPT processed material from room temperature to about 850 K, changes of the temperature-dependent physical properties, most of all the electrical resistivity, the density, and the thermal expansion occur more or less simultaneously around 600 K. For the first time we have combined *in situ* TEM observations as well as measurements of the elastic modulus and hardness in order to get a deeper insight into the microstructural behavior of a p-type skutterudite, $DD_{0.7}Fe_3CoSb_{12}$ (DD = didymium) during increasing temperature from 300 K to 823 K.

11:00 AM EN08.09.07
$BaCu_{2-x}T_xP_2$ (*T* = Al, Ga, In, Si, or {Si+Zn}): A New Group Semiconducting 'Golden Geese' in The $ThCr_2Si_2$ Family with Ultra-Low Thermal Conductivity and High Seebeck Coefficient Arka Sarkar[1,2], Gayatri Viswanathan[1,2], Stasia Harycki[1], Andrew P. Porter[1], Alexander Gundlach-Graham[1], Aaron Rossini[1] and Kirill Kovnir[1,2]; [1]Iowa State University, United States; [2]Ames Laboratory, United States

$ThCr_2Si_2$-type layered materials are a large family of compounds with applications ranging from thermoelectricity to magnetism, with most of them showing metallic behavior. In this study, we synthesized a variety of new $ThCr_2Si_2$-type materials with the general formula $BaCu_{2-x}T_xP_2$ (*T* = Al, Ga, In, Si, or {Si+Zn}), most being charge balanced semiconductors, a rarity in this family. They all crystallize in the $ThCr_2Si_2$-type tetragonal *I*4/*mmm* space group,

with Cu/*T* jointly occupying the same 4*d* crystallographic site. In the case of $BaCuAlP_2$ and $BaCu_{1.33}Si_{0.67}P_2$, Ba atom occupies a single crystallographic site. However, the introduction of Zn in the $BaCu_{1.33}Si_{0.67}P_2$ system results in the expansion of the unit cell by 4%, splitting the Ba atom along the crystallographic *c*-direction. Similar structural distortions are observed for $BaCuGaP_2$ and $BaCuInP_2$ as well. Such structural disorder of the Ba atoms leads to the occurrence of clathrate-like rattling behavior along the *c*-direction, as observed from heat capacity measurements. This in turn leads to ultra-low thermal conductivity (as low as ~0.4 W/m-K at 550 °C) at high temperatures. All $BaCu_{2-x}T_xP_2$ materials show semiconducting behavior, making them potential solar absorbers. The composition with the lowest Zn-content, $BaCu_{1.3}Zn_{0.2}Si_{0.5}P_2$, exhibits a clear semiconductor-to-metal transition upon heating above 155 K. The materials show high Seebeck coefficients, such as ~300 μV/K at 550 °C for $BaCuAlP_2$, making them promising candidates for thermoelectric applications. Band structure and density-of-states calculations on ordered hypothetical structures reveal clear semiconducting nature for the triel-based materials and semi-metallic nature for the Si-based ones.

11:15 AM EN08.09.08
Exploration of The Effects of $Yb_{11}Sb_{10}$ and $Yb_{10}MnSb_9$ Secondary Phases on The High Performing Zintl Thermoelectric Material $Yb_{14}MnSb_{11}$
Leah E. Borgsmiller and Jeff Snyder; Northwestern University, United States

The high performing Zintl thermoelectric material $Yb_{14}MnSb_{11}$ has been of interest to the thermoelectrics community for years. However, a major challenge with this material is that it exists in a very busy region of phase space, making it susceptible to having considerable amounts of secondary phases. In particular, the $Yb_{11}Sb_{10}$ phase has been repeatedly reported as a negative secondary phase, but there have been discrepancies in the literature regarding the effect of this phase as a secondary phase in 14-1-11. Since the $Yb_{11}Sb_{10}$ material is a poor metal, it would be expected to hinder thermoelectric performance, and yet there have been studies where large amounts of this metallic phase have relatively no effect on transport, and even one case where it seemed like the $Yb_{11}Sb_{10}$ phase contributed to an improvement in the thermoelectric performance. Recently, a related phase, $Yb_{10}MnSb_9$ has been reported and has been shown to have a high Seebeck coefficient and ultralow thermal conductivity making it a decent p-type thermoelectric material. Despite having very different properties, $Yb_{11}Sb_{10}$ and $Yb_{10}MnSb_9$ have extensive crystallographic and stoichiometric similarities, which makes distinguishing between these two phases difficult, especially if they are only present in small amounts as a secondary phases. In this work, we consider the properties of these two possible secondary phases and explore the consequences of these materials as secondary phases in the high performing $Yb_{14}MnSb_{11}$ material.

11:30 AM EN08.09.10
Enhanced Thermoelectric Performance in Hybrid Inorganic-Organic Conducting Polymer Systems
Iris Nandhakumar[1], Pawan Kumar[2], Syed Zulfiqar Hussain Shah[2,1] and Kedar Hippalgaonkar[2,3]; [1]University of Southampton, United Kingdom; [2]IMRE, Singapore; [3]NTU, Singapore

Wearable technologies such as smart watches, smart glasses or even smart pacemakers have caused a paradigm shift in consumer electronics with huge potential in areas such as healthcare, fashion and entertainment (e.g. augmented reality glasses). Currently these devices are still powered by batteries needing frequent replacement or recharging, a key challenge holding back wearable electronics. Thermoelectric generators (TEGs) can provide a potential solution as a wearable power source: they can convert heat into electricity, are safe, long-lasting and maintenance-free with zero-emissions. The Seiko Thermic watch (which generated 60 µW/cm^2 at DT= 5 K[1]) and the recently released Matrix PowerWatch are just some examples of how TEG technology has already been implemented in commercial devices. Current TEGs however are plagued by low efficiencies, high manufacturing costs, and are fabricated onto rigid substrates which makes them difficult to integrate into many applications that require conformal installation. To date most thermoelectric (TE) materials under study have been inorganic chalcogenides such as Bi- or Pb-based compounds (e.g. Bi2Te3 and PbTe, ZT ~ 1), intermetallics (e.g. half-Heusler alloys), and clathrates and skutterudites. Interest in organic conducting polymers (OCPs) is rapidly growing due to their mechanical flexibility, low thermal conductivities, elemental abundance, low cost and toxicity as well as solution processability. The TE performance of OCPs however still lags behind that of conventional inorganic TE materials which remain the state of the art for applications near room temperature. Recently hybrid inorganic-organic TE materials composed of inorganic nanostructures and OCPs have emerged as a promising class of flexible high performance TE materials. The TE hybrid materials use the OCPs as the mechanical binder providing flexibility whilst simultaneously contributing to the thermoelectric properties of the composite. This has demonstrated PFs exceeding those of either constituent. The reason for this enhancement is still under debate, however Kumar et al.demonstrated that the enhancement in the PEDOT:PSS–Te(Cux) systemwas dominated by the effects of polymer morphology at the organic–inorganic interface and interfacial charge transfer and not by energy filtering as has previously been assumed. We present the results of an in-depth study on flexible tellurium nanowire-P3HT hybrid systems with significantly enhanced power factors that can be rationalised in terms of the Kang-Snyder model on charge transport.

SESSION EN08.10: Thermoelectric Modules and Thin Films

Room 336, Level 3, Summit

1:30 PM *EN08.10.01
The Role of Thermoelectric Property Variations Over Time and Temperature in The Life Performance of Radioisotope Thermoelectric Generators
Thierry Caillat; Jet Propulsion Lab, United States

Radioisotope Thermoelectric Generators (RTGs) have been successfully used to power various NASA spacecrafts and rovers. The flight-proven Multi-Mission Radioisotope Thermoelectric Generator (MMRTG) uses PbTe/TAGS thermoelectric materials and is currently used on the Curiosity and Perseverance Mars rovers. The concept of a skutterudite based MMRTG was first proposed in 2013. It is based on retrofitting the flight-proven MMRTG with higher-efficiency thermoelectric couples based on skutterudite materials developed at NASA's Jet Propulsion Laboratory (JPL) while keeping the balance of the system virtually unchanged. The General-Purpose Heat Source (GPHS-RTG) uses SiGe thermoelectric materials and has been used on several NASA missions, including the Voyager spacecrafts. The degradation of the RTG power over time is controlled by several degradation mechanisms, including the changes in thermoelectric properties over time and temperature. The contribution of these changes for several RTG thermoelectric material systems is reviewed and discussed.

2:00 PM EN08.10.02
Macroscopic Thermoelectric Legs Obtained by Encapuslating Forests of Self-Supporting Silicon Nanowires
Dario Narducci, Federico Giulio and Antonio Mazzacua; University of Milano Bicocca, Italy

The application of nanotechnology in the development of novel thermoelectric materials has yielded remarkable advancements in their efficiency. In many

instances, dimensional constraints have resulted in a beneficial decoupling of thermal conductivity and power factor, leading to large increases in the achievable thermoelectric figure of merit (ZT). As a major example, single-crystalline silicon ZT increases by nearly two orders of magnitude when transitioning from bulk single crystals to nanowires. However, the practical implementation of nanostructured materials in thermoelectric devices remains somewhat restricted, not only due to manufacturing complexity and associated costs but also due to the limited power that nanomaterials deliver because of the reduced heat capture section [1]. Metal-assisted chemical etching offers a potential solution to overcome such limitations, enabling the production of dense, cost-effective forests of silicon nanopillars [2]. Nevertheless, use of pillared silicon chips in thermoelectric devices necessitates the non-trivial establishment of low-resistance electrical and thermal contacts atop the Si nanopillars. Furthermore, the residual single-crystalline silicon membrane adds thermal and electrical resistances that degrade the device performances. In this regard, we will present and compare strategies for achieving high-quality contacts through electroplating [3] and by embedding pillars into appropriate electrical and thermal insulators. Additionally, nanowire embedding will be shown to be of use also to encapsulate quasi-ordered millimeter-long nanowire aggregates, named 'nanofelts', that are obtained by fully etching thick silicon chips [4]. This provides a novel path to employ Si nanostructures with enhanced ZT to make thermoelectric legs with macroscopic sizes.

Thermoelectric Modules and Applications: An Industrial Perspective Aniruddha Ray and Maarten den Heijer; RGS Development, Netherlands

Over the past quarter-century, NASA has maintained a cadence of missions utilizing radioisotope power systems (RPS) at a rate of approximately one mission every ten years. At present, the sole flight-qualified RPS in NASA's inventory is the Multi-Mission Radioisotope Thermoelectric Generator (MMRTG), which boasts an initial power output of around 120 watts. Additionally, NASA and the U.S. Department of Energy (DOE) jointly oversee the development of the Next Generation Radioisotope Thermoelectric Generator (NGRTG), expected to provide an initial power output ranging between 250 and 270 watts.

There is currently an unmet need for low-power generators with a projected initial power output of 15 watts. To address this gap, RGS Development and UDRI conducted a concept study to explore the feasibility of low-power RPS based on a single General Purpose Heat Source (GPHS).[1] Thorough thermoelectric calculations were performed to optimize the design of the current generation of RGS Thermagy architecture, which employs an all-silicon-germanium module. This optimization allows for efficient utilization of available heat flux via a suitable heat interface to meet the required power outputs. Furthermore, by concentrating the heat flux on a smaller hot side surface area of the thermoelectric module, a mechanically robust pellet-based next-generation Thermagy module is envisioned.

In terrestrial applications, RGS has undertaken several noteworthy projects focused on power generation through waste heat recovery in various heavy industries, including Tata Steel, Elkem, and ArcelorMittal. These experiences have underscored the need for mid-temperature Thermoelectric Generator (TEG) devices capable of handling high temperatures, reaching up to 600°C. In response to this demand, RGS is advancing the application of nanostructured SiGe materials, known for their higher average ZT values, while concurrently developing telluride-free thermoelectric modules designed to operate at temperatures up to 350°C in a recently funded EU Horizon project.[2]

RGS has developed significant expertise in various areas, including COMSOL simulations, thermo-mechanical engineering, interface engineering, device aging, and testing, positioning the company to offer TEG solutions for both single-stage and cascaded device architectures tailored to a range of source temperatures and heat flux densities.

Optimal Transient Operation in Thermoelectric Cooling and its Relation to Thermoelectric Properties Jaden Lucas, Udit Halder, Lakshmi Amulya Nimmagadda, Prashant Mehta and Sanjiv Sinha; University of Illinois at Urbana-Champaign, United States

It has been well known for many decades that there exists an optimal Peltier current to achieve the best performance in steady-state Peltier cooling. At this constant current, there is a minimum steady-state cold-end temperature that can be achieved across a thermoelectric cooler. However, in a transient operation over a short time window, the temperature drop can be improved with a transient current pulse where the minimum transient temperature depends on the shape of the current pulse [1]. Here, we apply optimal control theory to find for the first time, a temperature minimizing *transient* current pulse. We consider a thermoelectric cooler with a heat load at the cold end, and model it as a discrete control system and use gradient descent to find a cost-minimizing current [2]. The optimal current diminishes the temperature rise due to the low frequency components of the heat loads, and this performance improvement depends strongly on thermal conductivity [3]. We also consider transient cooling of a thermoelectric below the minimum steady-state temperature. We observe that an optimal current pulse holds the temperature below its steady-state value for longer than a comparable constant current pulse. This work provides new insights into the upper li--mit of the transient performance of thermoelectric coolers.

Boron-Mediated Interface Engineering for Enhancing The Thermoelectric Performance of $Bi_2Te_{2.7}Se_{0.3}$ Films Yen-Ling Wang, Karan Giri, Chuan-Wen Wang, Ling-Chun Chao, Hung-Shuo Chang, Wen-Chieh Hsieh and Chun-Hua Chen; National Yang Ming Chiao Tung University, Taiwan

Nanostructuring has become one of the most practically proven and effective strategies in enhancing the thermoelectric figure of merit, which significantly propels thermoelectric materials to the forefront of progress in fundamental research and advanced applications. Accompanied by nanostructuring, heterogenization, which frequently shows excellent synergistic effects with nanostructures, has appeared as an appendable and feasible solution for a

further breakthrough.
Hexagonal boron nitride (h-BN), exhibiting remarkable thermal and chemical stability, is a potential candidate as the heterogeneous additive since the thermal conductivity of a single h-BN is much lower than that of graphene. In this work, to improve the thermoelectric properties of $Bi_2Te_{2.7}Se_{0.3}$ (BTS) thin films, BTS and h-BN were co-deposited on a SiO_2/Si substrate by a dual-beam laser system. The BN addition is expected to synergistically optimize the thermoelectric properties and stability of the BTS films.
According to the x-ray diffraction, the crystal structure of the formed BTS:BN hetero-nanostructured films deposited at a temperature higher than 400 °C shows a preferred orientation of (00*l*), which significantly improves the carrier mobility (~105 $cm^2V^{-1}s^{-1}$). The optimized Seebeck coefficient is −197 μVK^{-1}, and the corresponding power factor is 29 $\mu Wcm^{-1}K^{-2}$. Raman spectroscopy was performed to analyze the thermal transporting of the formed BTS:BN films. A non-local thermal equilibrium phenomenon of Raman signal collapse at lower laser energy was found, indicating that introducing the BN additive can effectively reduce the thermal conduction of the BTS films and, thus, can effectively improve the thermoelectric performance.

Recent Progress on Thermoelectric Materials and Modules Zhifeng Ren; University of Houston, United States

Thermoelectric modules based on thermoelectric materials can either generate cooling/heating using electrical power or electrical power from heat. Thermoelectric property improvement of materials is only the first step for thermoelectric modules for a variety of applications. How to make efficient modules is equally important as the materials improvement. The thermoelectric properties of the traditional materials are not good enough to make efficient modules to compete with the traditional coolers using compressor or steam engines. However, in the past fifteen years, we have been able to not only achieve some good progress on improving the thermoelectric properties of the traditional materials but also discover new materials with better properties and lower cost. At the same time, thermoelectric modules have also been improved for record-breaking cooling and power generation performances due to the advance in module fabrication. In this talk, I will present some of the advances in both the materials and devices.

4:00 PM EN08.10.07
A Path to Sustainable and Scalable Production of High-Performance Thermoelectric Materials Maria Ibáñez[1], Tobias Kleinhanns[1], Francesco Milillo[2], Mariano Calcabrini[1], Christine Fiedler[1], Sharona Horta[1] and Daniel Balazs[1]; [1]ISTA, Austria; [2]UNIBA, Italy

Over the past few years, there has been a significant surge in interest surrounding solution-based techniques due to their cost-effectiveness and scalability in the production of high-performance thermoelectric materials. This approach involves the synthesis of particles in a solution, followed by their purification and thermal processing to yield the desired dense polycrystalline material. In contrast to traditional methods, solution-based syntheses offer the ability to manipulate particle characteristics, including size, shape, crystal structure, composition, and surface chemistry, to an unprecedented degree. This fine-tuned control over powder properties opens up distinct opportunities for crafting thermoelectric materials with meticulously controlled microstructural attributes.
In this presentation, our primary focus will be on Ag_2Se, an important thermoelectric material for harnessing thermoelectricity at or near room temperature, an area where the selection of high-performing materials is currently limited. While Ag_2Se shows great promise, the main problems are the large discrepancy in the reported thermoelectric properties and difficulties in replicating its exceptional performance. These discrepancies often stem from the intricate control of defects within the material, such as vacancies, interstitial atoms, dislocations, grain boundaries, and precipitates.
We will show that our solution-based synthesis method enables precise defect control, especially avoiding fluctuations in stoichiometry. Additionally, we will illustrate how we can fine-tune microstructural defects, including strain, dislocations, and grain boundary density, leveraging the characteristic phase transition of Ag_2Se during the sintering process. Our results will highlight that besides stoichiometry, the microstructure is crucial for tuning Ag_2Se transport properties and how this control can be provided by our novel synthetic route. Furthermore, we will highlight the sustainability and scalability of our approach, where solvents can be recycled and energy consumption minimized, contributing to a more environmentally friendly production process.

4:15 PM EN08.10.08
Optimization of Sb_2Te_3 and Bi_2Te_3 Thermoelectric Films for Infrared Detection and Energy Harvesting Rumana Zahir[1], Robert E. Peale[1,2], Javier Gonzalez[2], Darian Smalley[1], Masahiro Ishigami[1], Akash Hari Bharath[1], Kalpathy Sundaram[1] and Edgar Nino[1]; [1]University of Central Florida, United States; [2]Truventic LLC, United States

We are developing antenna-coupled thermoelectric junctions for infrared detection and energy harvesting. COMSOL Multiphysics simulations identify Sb_2Te_3 and Bi_2Te_3 thermoelectric materials as ideal for the thermocouple junction at the antenna feed. Joule heating at the antenna feed from currents induced by antenna-collected radiation generates thermoelectric voltage and current for detection and energy conversion. In this work, we optimized the properties of RF sputtered telluride films for these applications. We performed a two-level full factorial optimization experiment with three factors: Argon gas pressure, substrate temperature, and RF power. Their low and high values were 7 and 8 mTorr, 175 and 225 deg C, and 15 and 25 W, respectively. The resulting eight depositions were performed using glass substrates in randomized order. A mid-point deposition at 7.5 mTorr, 200 deg C, and 20 W RF power was performed to reveal curvature in the main effects. We found for Sb_2Te_3 a maximum Seebeck coefficient of 149 μV/K, minimum resistivity 88 μΩ-m, and a maximum power factor (squared Seebeck coefficient over resistivity) of 1 $\mu W/cm\text{-}K^2$. Main effect plots, which are the response (power factor) averaged over two of the factors plotted vs the third, reveal that the power factor was most sensitive to changes in substrate temperature and least sensitive to variations in RF power. All main-effect plots show strong negative curvature. The mid-point response was significantly higher than those of the end points. The maximum power factor was achieved on the low-side of the midpoint. Interaction-effect plots are the response averaged over one of the factors plotted vs a second factor, for each value of the third factor. These reveal no significant interaction between gas pressure and RF power and the most significant interaction between RF power and substrate temperature. SEM images reveal a microstructure comprising ellipsoidal grains with half-micron major axis dimension. Similar results for Bi_2Te_3 will be presented. Photolithographically patterned bowtie-antenna-coupled thermocouples demonstrate successful deposition and lift-off. Response of this device to mm-wave radiation from a backward wave oscillator is consistent with COMSOL predictions.

4:30 PM EN08.10.09
Enhancing Thermoelectric Properties of Semicrystalline Conjugated Polymers through Controlled Tie Chain Incorporation Wenjin Zhu and Henning Sirringhaus; University of Cambridge, United Kingdom

Conjugated polymers are promising materials for thermoelectric applications, however, at present few effective and well understood strategies exist to further advance their thermoelectric performance. Here we report a new model system for better understanding the key factors governing their thermoelectric properties: aligned, ribbon-phase poly[2,5-bis(3-dodecylthiophen-2-yl)thieno[3,2-b]thiophene] (PBTTT) doped by ion-exchange doping. Using a range of microstructural and spectroscopic methods we study the effect of controlled incorporation of tie-chains between the crystalline domains through blending of high and low molecular weight chains. The tie chains provide efficient transport pathways between crystalline domains and lead to

significantly enhanced electrical conductivity of 4810.1 S/cm, that is not accompanied by a reduction in Seebeck coefficient nor a large increase in thermal conductivity. We demonstrate respectable power factors of 172.6 μW m^{-1} K^{-2} in this model system. Our approach is generally applicable to a wide range of semicrystalline conjugated polymers and could provide an effective pathway for further enhancing their thermoelectric properties and overcome traditional trade-offs in optimization of thermoelectric performance.

Defect Engineering of Transparent Thermoelectric Copper Iodide through Low Energy Ion Implantation Martin Markwitz[1,2,3], Peter P. Murmu[2], Ben J. Ruck[1,3], Takao Mori[4,5] and John V. Kennedy[2,3]; [1]Victoria University of Wellington, New Zealand; [2]GNS Science, New Zealand; [3]The MacDiarmid Institute for Advanced Materials and Nanotechnology, New Zealand; [4]National Institute for Materials Science (NIMS), Japan; [5]University of Tsukuba, Japan

Copper iodide (CuI) is a non-toxic earth-abundant wide bandgap semiconductor with many potential technological applications in transparent electronics. Transparent conducting p-type semiconductors CuI and $CuAlO_2$ have lower electrical conductivities compared to their doped n-type counterparts In_2O_3:Sn or ZnO:Al. CuI possesses the highest electrical conductivity of its class as a transparent p-type semiconductor ($\sigma \sim 10^2$ Scm^{-1}) due to its high hole mobility ($\mu \sim 10^1$ $cm^2V^{-1}s^{-1}$) and carrier concentration ($p \sim 10^{19}$ cm^{-3}) whilst boasting a large Seebeck coefficient ($\alpha \sim 280$ μVK^{-1}), mainly attributed to p-type doping with copper vacancies (V_{Cu}) [1,2]. Intrinsic doping via controlling deposition conditions and extrinsic doping with chalcogens allows for control over the crystal quality and carrier concentration [3,4,5,6,7]. Sulfur and selenium doping increases the CuI carrier concentration ($p \sim 10^{20}$ cm^{-3}) [4,6]. Optimizing the intrinsic defect structures in undoped CuI is predicted to yield even higher electrical conductivity [8]. Ion implantation, a well-established microfabrication technique, can be used for defect engineering via noble gas implantation, known to also improve thermoelectric properties by reducing lattice conductivity and vacancy doping [9].
In this work, we elucidate the role of intrinsic point defects in low-energy noble gas ion implanted into ion beam sputtered CuI thin films. Ion energies 13, 27, and 70 keV were used to implant neon, argon, and xenon with fluences between 5×10^{14} ions cm^{-2} and 1.92×10^{16} ions cm^{-2}. Microstructural, compositional, and electronic characterization showed stoichiometric γ-CuI. Moderate implantation fluences ($\lesssim 2\times10^{15}$ ions cm^{-2}) led to a 100% increase in carrier concentration ($\sim 1\times10^{20}$ cm^{-3}) without significant loss in Seebeck coefficient (~200 μVK^{-1}) or carrier mobility (~9 $cm^2V^{-1}s^{-1}$). This led to the increase of the power factor by two-fold to $\alpha^2\sigma \sim 540$ $\mu Wm^{-1}K^{-2}$. Transport of Ions in Matter (TRIM) [10] simulations showed that the damage per atom (DPA) ranged between 1.2 and 16. Density functional theory (DFT) calculations showed that Frenkel pairs (low formation energy defect complexes) are likely produced through ion implantation. We will present detailed results discussing the relationship between point defect formation and thermoelectric performance of CuI thin films supported with Monte Carlo simulations and DFT calculations.

5:00 PM EN08.11.02
Transparent and Flexible Graphene-Based Temperature Sensor via p-n Junction Soomook Lim[1], Hyeon-Jong Lee[1] and Ji Won Suk[1,1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

As the demand for wearable devices surges, there is a growing need for flexible and transparent temperature sensors capable of monitoring changes in body and surrounding environments [1]. Among many two-dimensional (2D) materials, graphene has garnered significant attention due to its exceptional electrical properties, flexibility, and transparency, rendering it suitable for a diverse range of applications, including flexible transparent electrodes, sensors, and optoelectronic devices [2]. Thermocouples, based on the thermoelectric effect, offer an alternative way for temperature monitoring in wearable devices because of their self-powering capability and high accuracy. Thermoelectric devices using a combination of p- and n-type graphene have exhibited noteworthy sensitivity to temperature [3]. Achieving p- and n-type properties in graphene typically involves controlling its electrical properties of graphene via charge transfer doping. However, ensuring the stability of n-type graphene generated by the surface doping poses a considerable challenge in the development of graphene-based thermoelectric temperature sensors [4]. In this work, a transparent, flexible graphene-based temperature sensor was developed by chemical doping of graphene and encapsulation with a thin oxide layer. Monolayer graphene was synthesized using chemical vapor deposition (CVD) on copper foil and transferred to a flexible polyethylene terephthalate (PET) film. Half of the monolayer graphene on the PET film was doped by polyethyleneimine (PEI) coating., resulting in the formation of a p-n junction for thermoelectric sensing. The fabricated graphene thermocouple showed high sensitivity suitable for daily use in wearable devices, along with high flexibility and optical transparency. To overcome the inherent air instability of the PEI coating, the sensor was encapsulated with a thin oxide layer using atomic layer deposition (ALD). Aluminum oxide (Al_2O_3) was chosen for encapsulation due to its widespread use as a stable barrier material against air. The thickness of the aluminum oxide layer was controlled to minimize any degradation in sensor performance. This study demonstrates the potential of monolayer graphene as flexible and transparent temperature sensors for wearable devices.

Transverse Seebeck Effect Devices for Heat Flux Sensing in Hot Environments up to 500ºC Kenneth McAfee, Peter Sunderland and Oded Rabin; University of Maryland, United States

Utilizing the Transverse Seebeck Effect (TSE), heat-flux sensing devices were designed, built and tested, demonstrating the linearity of the heat-flux-to-voltage transduction. We introduce new testing protocols that (1) demonstrate that the electrical signal results from the TSE and not from the conventional Seebeck effect, and (2) provide reliable values for the sensitivity of the sensor (i.e. calibration curves) at elevated temperatures. We introduce new materials as practical TSE transducers. Through materials selection and sensor design, the range of temperatures of operation of the heat-flux sensors has been extended up to 500 degrees Celsius, with the potential to exceed 1000 degrees Celsius upon the identification of appropriate adhesives. These heat-flux sensors fill in a technical void that is currently present in thermal systems metrology, superseding the state-of-the-art Schmidt-Boelter heat-flux sensors under extreme environments, due to their simpler and rugged construction. [Funding: US Department of Energy, Award DE-FE0031902].

5:00 PM EN08.11.04
Tuning Solvent Properties for Efficient N-Type Doping of Highly Aligned Wet-Spun CNT Fibers: Achieving High-Performance Wearable Thermoelectrics SungJun Kim, Yong Kim and Woong-Ryeol Yu; Seoul National University, Korea (the Republic of)

The highly oriented structure of wet-spun carbon nanotube (CNT) fibers makes them a promising candidate for high performance wearable thermoelectric fibers. This orientation facilitates remarkable electrical conductivity without increasing carrier concentration, which would otherwise decrease the Seebeck coefficient. However, their highly packed structure hinders the infiltration of chemical dopants, making it more challenging to prepare N-type CNT fibers through conventional wet processes like dipping, brushing, or spraying of chemical dopants. This study investigates the role of solvent properties in enabling efficient N-type doping of highly aligned CNT fibers. Wet-spun CNT fibers with varying winding rates were prepared to explore the impact of their degrees of orientation on the doping process, as highly aligned structure hinders the sufficient N-type doping. Among the various solvent properties, the Hansen solubility parameter, which represents the affinity with CNTs, has a significant influence on the N-type doping process. By optimizing solvent properties, even for the case of highly aligned CNT fiber with high electrical conductivity of ~1.0 MS/m, a desirable N-type Seebeck coefficient of -39 $\mu V/K$ was achieved, leading to power factor of ~1.5 $mW/m\times K^2$.

5:00 PM EN08.11.05
Stretchable Ag_2Se Thermoelectric Fabric without Thermal Treatment for Wearable Sensors Chaebeen Kwon and Taeyoon Lee; Yonsei University, Korea (the Republic of)

With the rapid advancements in the textile-based electronics, smart fibers have emerged as a pivotal component of functional textiles, distinguished by their remarkable responsiveness to a wide array of external stimuli. These smart fibers boast an extensive range of capabilities, including sensory functions and the capability for energy harvesting. This innovation is currently driving the emergence of novel fiber-based wearable electronics, encompassing applications such as electronic skin, health sensor, and interfaces for human-machine interaction. As the field of fiber-based wearable electronics continues to evolve, the integration of thermoelectric (TE) materials into the fibers has become a significant development. TE materials possess the unique ability to efficiently convert temperature gradients into electrical output voltage, and vice versa. This integration introduces a groundbreaking ability to harvest electrical energy from the natural heat generated by the human body. Furthermore, TE fibers enable the detection of temperature variations and changes in posture through the measurement of output voltage and resistance, respectively.
The pursuit of using inorganic TE materials for wearable applications has garnered significant attention in recent research. Among these efforts, silver selenide (Ag_2Se)-based materials have emerged as promising candidates due to their unique TE properties. Incorporating Ag_2Se into fibers has been a cautions endeavor in several studies, primarily due to the rigidity associated with inorganic TE materials. Yang et al. suggested approach to creating a three-dimensional TE generator with biaxial stretchability. By integrating inorganic Ag_2Se film strips into a kint fabric, aligned with the vertical heat flux direction, a stable temperature gradient of 5.2 °C was achieved when in contact with the wrist at room temperature. Research is currently underway to explore TE units in fiber form, rather than in film, to enhance their suitability for wearable electronics applications. Vinodhini et al. reported a one-step solvothermal method to integrate Ag_2Se and Ag_2S with conductive carbon fabric (CF). Ag_2Se CF and Ag_2S CF exhibited power factors of 6.7 $\mu W/mK^2$ and 24 $\mu W/mK^2$, respectively. However, during the material synthesis process, applying heat at 180 °C for 24 hours frequently results in the formation of rigid structures. The only research on non-thermal Ag_2Se fabric has been recently reported. Liu et al. introduced two-step impregnation method for fabricating a three-dimensional TE network. The TE network demonstrates an elongation of over 100%. The resulting network-based TE generator achieves an output power of 4 $\mu W/cm^2$. Nonetheless, the process can become complicated and time-consuming due to multiple steps. For the effective integration of Ag_2Se into wearable electronics, a simple and non-thermal approach is essential.
Herein, we have fabricated a stretchable Ag_2Se TE fabric through simple and non-thermal process. Ag_2Se nanoparticles (NPs) were densely and rapidly formed within the cotton fabric using a chemical reduction method, without the need for thermal treatment. Due to the durable NP networks, the stretchable Ag_2Se TE fabric exhibited remarkable electrical stability under repeated conditions of 20% lateral strain and 16 kPa normal pressure. Remarkably, it maintained its electrical path even under strain of 200%, surpassing thermally treated Ag_2Se TE fabric in both electrical and mechanical performance. Moreover, the TE unit exhibited a power factor of 9.80 $\mu Wm^{-1}K^{-2}$ with an electrical conductivity of 134.45 Scm^{-1} and a Seebeck coefficient of −26.98 μVK^{-1} at 370 K. To demonstrate the practical utility of our work, we developed a haptic sensing glove capable of detecting changes in strain, pressure, and temperature. This glove effectively alerted users to potential hazards related to elevated temperatures and exhibited accurate sensing capabilities for both pressure and tensile forces.

5:00 PM EN08.11.06
Stretchable Thermoelectric Fibers Using CuI Nanoparticle Networks for Multi-Sensing Wearable Electronics Sanghyeon Lee; Yonsei University, Korea (the Republic of)

Recently, the field of biomedical engineering and robotics has witnessed wearable sensor that is able to imitate functions of human skin. Wearable sensor is required the characteristics such as flexibility and stretchability with capacity that converts external stimulate including temperature, pressure, displacement, pulse, electrocardiograph (ECG) signals, tactile sensations, to electrical signals. Recently, thermoelectric materials that transform reversibly the temperature gradient into an electrical output voltage have been applied to detect changes in temperature through output voltage and current.
To applied wearable sensor, there are several strategies as followings: (1) structural innovations of inorganic thermoelectric materials, (2) materials innovations of organic thermoelectric materials. Although inorganic materials have high figure of merit (zT) and high electrical conductivity, inorganic materials are difficult to deform mechanically due to brittleness. To solve the limitation of rigidity, thermoelectric device consisted with inorganic materials designed by kirigami/origami structure. However, this structure not only has limitation of deformation but also is too complicated to integrate in wearable device. In case of organic thermoelectric materials, the thermoelectric performances are poorer than that of inorganic thermoelectric materials. To improve thermoelectric performances, organic materials are chemically doping. However, the efficiency and stability of chemical modification are always unsatisfactory.
Herein, we fabricated stretchable thermoelectric copper iodide nanoparticles (CuINPs) embedded fibers. CuINPs, which is promising and ecofriendly thermoelectric materials, are densely formed inside and outside of the polyurethane (PU) fiber using the chemical reaction methods. This method consists of two steps: (1) the fiber immersed in Cu precursor to absorbed Cu ions in the PU matrix, (2) the absorbed fiber reacted with I precursor to synthesis CuINPs. CuINPs embedded fiber achieves a power factor of 18.31 $\mu Wm^{-1}K^{-2}$ with electrical conductivity of 5.99 S/cm and Seebeck coefficient of 175.8 μVK^{-1} at room temperature. Moreover, the resistance of the fiber increased with increasing tensile strain. The Seebeck coefficient of the fiber constantly

remained with changing strain of fiber. We demonstrated a sensing system that can detect pressure and temperature changes simultaneously. This facile CuINPs embedded fibers will pave the way for applying inorganic TE materials in a stretchable form in wearable electronics.

Enhancing Thermoelectric Efficiency of Bi_2Te_3 Nanoribbons through *In-Situ* F_4-TCNQ and *Ex-Situ* Cr Interfacial Alloying Jun Beom Park, Rijan Karkee and Michael T. Pettes; Los Alamos National Laboratory, United States

Nanostructured Bi_2Te_3 shows promise in enhancing thermoelectric characteristics by theoretical prediction, but its practical performance often falls short of bulk Bi_2Te_3 due to defects, impurities, and surface oxidation. Addressing this, precise control of the nanostructured surface's chemical potential is crucial for achieving long-lasting, high-performance thermoelectric materials and devices. Various techniques, including oxygen plasma treatment, non-oxidizing superacid treatment, and atomic layer deposition (ALD) of Al_2O_3, have been explored to engineer the surface of Bi_2Te_3. Additionally, extrinsic doping by coating metallic or carrier-rich layer has shown promise in modulating carrier concentration and chemical potential.
In this presentation, we introduce two distinct strategies to enhance the thermoelectric performance of Bi_2Te_3 nanoribbons through the incorporation of external dopant layers: an *in-situ* F_4-TCNQ layer and an *ex-situ* Cr layer. The in-situ coated F_4-TCNQ layer induces a transformation of the major carrier from *n*-type to *p*-type, resulting in 6-times enhancement of the Seebeck coefficient. Moreover, the core-shell structure effectively shields the core from oxidation, demonstrating the absence of surface oxidation or loss of thermoelectric properties even after one month in ambient air. On the other hand, the surface-coated Cr layer is confirmed to induce a 70% reduction in nanoribbon resistance along with a 24% increase in the Seebeck coefficient, which resulting 2-times enhancement of thermoelectric figure of merit (*zT*). Our findings underscore a promising approach to practically application of nanostructured Bi_2Te_3, surpassing the performance of bulk material.

Low Thermal Conductivity and High Thermoelectric Performance in GeTe-Based Medium-Entropy Thermoelectric Material by Sb-Se Alloying Cheng-Ruei Wu and Chien-Neng Liao; National Tsing Hua University, Taiwan

Germanium telluride (GeTe) is a promising thermoelectric material with great tunability in transport properties, but the rhombohedral-cubic phase transition restricts the applications. A substantial research effort has been dedicated to electronic band modulation and thermal conductivity reduction through partial cation substitution. On the other hand, anion substitution has received much less attention due to limited miscibility. In this study, we synthesize GeTe-based medium-entropy alloys (MEAs) with notable (Se) substitution at Te sites and (Sb) at Ge sites by powder metallurgy to suppress the phase transition and achieve the cubic GeTe. The thermal conductivity of GeSbSeTe-based alloy (GSST-8) is significantly reduced due to severe lattice distortion while maintaining decent thermoelectric power factor. The GSST-8 exhibits an extremely low thermal conductivity of 0.68 W/mK and a high Seebeck coefficient (> 220 μV/K) over a temperature range of 300 – 623 K. As a result, a high zT of ~0.3 at 323 K and ~1.24 at 623 K can be achieved in GSST-8. The transport properties of the pristine GSST-8 have been further improved with optimized carrier concentration and mobility through minor doping element and annealing. The influence of dopant and annealing on the band structure and thermoelectric properties of GSST-8 compounds is studied

5:00 PM EN08.11.09
$Cu_2ZnSiTe_4$: A Potential Thermoelectric Material with Promising Electronic Transport Himanshu Sharma[1], Bhawna Sahni[2], Tanusri Saha-Dasgupta[3] and Aftab Alam[1]; [1]Indian Institute of Technology, Mumbai, India; [2]University of Warwick, United Kingdom; [3]S. N. Bose National Centre for Basic Sciences, Kolkata, India

Transition metal-based quaternary chalcogenides have attracted a lot of interest for a variety of renewable energy applications, especially thermoelectrics (TE). Although this class of compounds have low symmetry and complex structure which contribute to low lattice thermal conductivity, achieving a high figure of merit (ZT), is still a challenge for this class of materials for use in TE applications due to low values of power factor. Here, we used first-principles calculation to study the TE properties of a novel system, $Cu_2ZnSiTe_4$, with promising electronic transport. The heavy chalcogen 'Te' atom, contributes to the comparatively low bandgap of 0.58 eV. This results in a promising power factor of 3.95 (n-type) and 3.06 (p-type) $mWm^{-1}K^{-2}$ at 900 K, together with a favourable electronic band topology. Additionally, 'Te' atoms are responsible for the mixing of the optical and acoustic phonon branches, which at high temperature results in low lattice thermal conductivity (about 0.7 $mWm^{-1}K^{-1}$). The compound yields a promising TE figure of merit (ZT ~2.67 (n-type) and ~2.11 (p-type) at 900 K. We predict $Cu_2ZnSiTe_4$ as a viable option for TE applications. We believe our study will motivate experimentalists to explore this compound for future investigation for TE applications.

5:00 PM EN08.11.10
Investigate $NaGeSbO_5$ as a Transparent Thermoelectric Xiaoyu Jia[1], Joe Willis[1] and David O. Scanlon[1,2]; [1]University College London, United Kingdom; [2]University of Birmingham, United Kingdom

Transparent conducting oxides (TCOs) are a unique class of oxide materials that exhibit both transparency and electronic conductivity simultaneously. Thermoelectrics (TEs) are a class of materials that can directly convert heat and electricity mutually. Their Seebeck effect allow thermoelectric devices to recover waste heat and convert it into electrical power. The discovery of high performance transparent thermoelectric materials can potentially develop novel applications such as smart windows and screens with energy harvesting, cooling, and thermal sensing functionalities.
In this project, $NaGeSbO_5$ was chosen due to its complex crystal structure, which typically leads to low lattice thermal conductivities. The $(n-1)d^{10}ns^0sp^0$ electronic configuration of Ge(IV) and Sb(V) is expected to yield a dispersive conduction band minimum, similar to the known TCOs.
State-of-the-art ab initio calculations were performed using the VASP code to understand its thermoelectric capability. The initial steps involved evaluating the thermodynamic stability versus known compounds within Na-Ge-Sb-O phase space by CPLAP[1] and optimizing the geometry. Following this, we studied the band structure of $NaGeSbO_5$ and found its band gap is wide enough to ensure optical transparency. Subsequently, the band alignment was calculated using SURFAXE[2] to examine the doping preference. AMSET[3] code was then used to assess the charge transport properties, and an exploration of lattice dynamics was undertaken through the utilization of Phonopy[4] and hiPhive[5]. The stability at high temperature up to 1100 K has been experimentally confirmed.[6] The thermoelectric figure of merit (ZT) at this temperature was predicted to reach 1.09 at a specific carrier concentration, indicating the potential for setting a record in thermoelectric performance. In-depth defect engineering will be undertaken with the goal of attaining the optimal ZT.

High Thermoelectric Performance in n-Type PbSe via Embedding Coherent Endotaxial Nanostructure Hyungseok Lee and In Chung; Seoul National University, Korea (the Republic of)

PbSe has been regarded as a potential candidate for replacing state-of-the-art thermoelectric (TE) PbTe-based materials, owing to the scarcity of Te. In contrast to the progress in a p-type counterpart, effective strategies to enhance TE performance of n-type PbSe have been rare until recently. For example, band convergence to decouple Seebeck coefficients and electrical conductivity for higher power factor has not been possible because of a large energy gap between first and second conduction bands in contrast to the case of its p-type version. As a result, TE performance of n-type PbSe has been improved by reducing thermal conductivity.
In this presentation, we report a new high-performance n-type PbSe thermoelectric system embedded with a very low concentration nanoscale, semiconducting alloys. Through atomic-resolved TEM, we observed the formation of coherent interfaces between the surrounding matrix and endotaxial nanostructures. The coherent nanostructure gives additional phonon scattering mechanisms induced by mass fluctuation across the interface, remarkably suppressing a lattice thermal conductivity down to ~0.32 W m^{-1} K^{-1}. Concurrently, incorporating alloys effectively manipulate the electronic band structure, consequently increasing the conduction band effective mass maximum and a magnitude of Seebeck coefficient. Both effects synergistically improve the TE performance, showing a record-high TE figure of merit, ZT, of ~2.0 at 823 K, for all n-type PbSe and PbTe-based materials to date. This result shows that the strategy of designing coherent endotaxial nanostructures could be an effective means of controlling charge and thermal transport properties independently.

Room Temperature Minimum Thermal Conductivity in 3D Weak Topological Insulators Jihui Yang; University of Washington, United States

In contrast to the conventional belief that the consideration for topological insulators (TIs) as potential thermoelectrics is due to their excellent electrical properties benefiting from the topological surface states, our work shows that the 3D weak TIs, formed by alternating stacks of quantum spin Hall layers and normal insulator (NI) layers, can also be decent thermoelectrics because of their thermal transport. We found that the 3D weak TI $Bi_{14}Rh_3I_9$ possesses the minimum thermal conductivity at room temperature, very unusual for a crystalline material. Our work revealed that the topologically “trivial” NI layers play a surprisingly critical role in hindering phonon propagation. The weak bonding in the NI layers gives rise to significantly low sound velocity, and the localized low-frequency vibrations of the NI layers cause strong acoustic–optical interactions and lattice anharmonicity. All these features are favorable for the realization of exceptionally low lattice thermal conductivity, and therefore present remarkable opportunities for developing high-performance thermoelectrics in weak TIs.

9:00 AM *EN08.12.02
Ta_2PdSe_6: A Guide Towards High Performance Thermoelectric Semimetals Akitoshi Nakano and Ichiro Terasaki; Nagoya University, Japan

Thermoelectric materials attract great interest due to their promising application to power generation and Peltier cooling devices. Semiconductor thermoelectrics has been mainstream thus far, since the existence of a bandgap makes a large thermopower (S), and tuning the carrier polarity easy by carrier doping. Semiconductor physics predicts that the carrier concentration of around 10^{19} cm^{-3} is appropriate to achieve high S ~ 200 μV/K, and high conductivity (σ) ~10^3 $\Omega^{-1}cm^{-1}$. Bi_2Te_3, the most representative thermoelectric material thus far, well exemplifies the prediction and shows the best thermoelectricity around 300 K. On the other hand, semimetals, in which electrons and holes necessarily coexist, have been out of range of the searching field for the thermoelectric materials, since the compensation between electrons and holes degrades the net S.
We have recently discovered that a transition-metal chalcogenide Ta_2PdSe_6 exhibits an extraordinary thermoelectric property despite its semimetal character [1][2]. Ta_2PdSe_6 crystalizes in a layered structure, each layer of which consists of quasi-one-dimensional chains formed by prismatic $TaSe_6$ and square-planner $PdSe_4$. The thermoelectric property measured along this direction is highly exotic; an ultra-high σ above 10^6 $\Omega^{-1}cm^{-1}$ is compatible with a substantial S of 40 μVK^{-1} at 20K. As a result, the Peltier conductivity P (= $S\sigma$) is the highest among the thermoelectric materials thus far. The value of 100 $Acm^{-1}K^{-1}$ means that a 1cc sample can generate a current of 100 A when it is put across a temperature difference of 1 K.
Furthermore, we have found that thermal conductivity of Ta_2PdSe_6 is relatively small (100 $Wm^{-1}K^{-1}$) for such good electrical conductor associated with significant violation of the Wiedemann-Franz law. As a result, the thermoelectric figure of merit z (= $S^2\sigma\kappa^{-1}$) of Ta_2PdSe_6 at 13 K becomes as high as 0.04, which is comparable to the value of Bi_2Te_3 at 300 K. Roughly speaking, 60 times larger thermal conductivity is cancelled by 60 times larger power factor (= $S^2\sigma$) in Ta_2PdSe_6 as compared Bi_2Te_3. The comparable z from distinct transport parameters strongly indicates a new design rule of high-performance thermoelectric semimetals. In the presentation, we will discuss the origin of the anomalous transport properties of Ta_2PdSe_6 from the viewpoint of the carrier dynamics.

Are Topological Insulators Promising Thermoelectrics? Michael Toriyama and Jeff Snyder; Northwestern University, United States

Some of the best thermoelectric (TE) materials to date are also topological insulators (TIs). While many studies have investigated the effects of topologically-protected surface states on TE properties, it is still unclear how the bulk band structure of a TI can benefit the TE performance. Here, we perform high-throughput transport calculations using density functional theory (DFT) to reveal that TIs, when properly optimized, tend to outperform normal insulators as TEs. Models based on Boltzmann transport theory show that warping driven by band inversion, a key characteristic of TIs, is beneficial for TE performance because of reduced transport mass and effectively higher valley degeneracy. The model also reveals that the band inversion strength is a critical material property dictating the TE performance, where TIs with strongly inverted bands exhibit higher zT. We suggest potential avenues for tuning the band inversion strength and, as a result, enhancing the TE performance in TIs, such as alloying and strain engineering. The study marks TIs as serious candidates for TE applications owing to band inversion-driven warping.

Seebeck Coefficient Enhancement by Quantum Confinement Effect in Superlattice Nanocomposites Ting Meng and Yang Zhao; University of Science and Technology of China, China

Thermoelectric devices enable the bidirectional conversion between thermal and electrical energy, which has great potential in energy harvest and thermal management, etc. This work proves experimentally that the quantum confinement effect could improve the thermoelectric properties of low-dimensional film materials effectively. The quantum wells formed by embedding ErAs nanoparticles with diameter of around 2 nm in $In_{0.53}Ga_{0.47}As$ matrix lead to drastic changes in the material band structure and convert the semimetal ErAs into a semiconductive state. The size confinement increases the asymmetry in the distribution of the density of electron states near the Fermi level and thus improves the Seebeck coefficient. Here, we report that the Seebeck coefficient and power factor of $In_{0.53}Ga_{0.47}As$ films assembled with ErAs nanoparticles are increased by 2.2 times and 5 times at 516 K, respectively.

Unlocking High-Performance Thermoelectrics: From Phase Engineering to Entropy-Enhanced Materials Mercouri G. Kanatzidis; Northwestern University, United States

In the rapidly evolving field of thermoelectric materials, significant strides have been made to improve material properties and energy conversion efficiency. This talk will traverse multiple avenues of cutting-edge research to showcase advancements in our group in thermoelectric materials and applications. We will present our efforts on Ga-doped n-type PbTe thermoelectric materials that undergo dynamic phase conversion through Cu2Se alloying. The addition of Cu2Se enhances electrical transport properties while reducing lattice thermal conductivity. At elevated temperatures, the material undergoes dynamic changes in its phase compositions, achieving a promising ZT for n-type systems of ~1.63 at 823 K for intermediate-temperature applications. Transitioning to p-type lead chalcogenides, these materials exhibit superior thermoelectric performance due to valence band convergence. Improvements on n-type materials are more difficult because of the absence of easy electronic band convergence. However, introducing GaSb doping into their n-type counterparts has led to significant improvements as well. This intervention causes conduction band convergence and increases the average power factor, culminating in a high ZT of across a wide temperature range. Building on our previous results, we have also explored the fascinating realm of entropy-engineered materials, using the PbGeSnCdxTe3+x family as a case study. The high-entropy effect from alloying not only stabilizes the material's cubic phase but also significantly improves thermoelectric properties to a maximum ZT of 1.63 at 875 K. PbS-based compounds are less well-developed by can become key players in this arena. By alloying PbS with GeS, we achieved a multi-tiered optimization of its electrical and thermal transport properties, involving Ge2+ substitution, the formation of a secondary phase of Pb5Ge5S12, and enhanced electron mobility. The resultant 14% GeS-alloyed samples yield a ZT of 1.32 at 923 K, outperforming standard Sb-doped PbS by approximately 55% and setting a new benchmark for n-type PbS-based thermoelectric systems. This presentation aims to provide new insights and spark interdisciplinary discussions on optimizing thermoelectric materials for a sustainable energy future.

11:00 AM EN08.13.02
Optimized Thermoelectric Performance and Plasticity of Ductile Semiconductor $Ag_2S_{0.5}Se_{0.5}$ via Dual-Phase Engineering Hao Wu; Nanjing Tech University, China

Inorganic semiconductor Ag_2S with excellent plasticity is highly desired in flexible and wearable thermoelectrics. However, the compromise between plasticity and thermoelectric performance limits the advances in Ag_2S-based thermoelectric materials and their devices. Here, a 0.5 mol.% Ag_2Te-alloyed $Ag_2S_{0.5}Se_{0.5}$ bulk material is designed, which has a competitively high near-room-temperature figure of merit of ≈0.43 at 323 K and an ultra-high bending strain of ≈32.5% without cracks. Introducing Ag_2Te can optimize the carrier concentration and mobility of the $Ag_2S_{0.5}Se_{0.5}$ matrix due to its metal-like conducting features, leading to a maximum power factor of ≈6 μW cm^{-1} K^{-2}. Simultaneously, Ag_2Te induces Ag-poor amorphous phase boundaries, serving as buffer layers to enhance the overall plasticity. Moreover, such amorphous phase boundaries combined with multiscale phonon scattering sources can significantly suppress the lattice thermal conductivity to ≈0.28 W m^{-1} K^{-1} at 323 K, leading to a high figure of merit. This study demonstrates an innovative route to simultaneously boost the thermoelectric performance and plasticity of ductile semiconductors.

11:15 AM EN08.13.03
Zigzag Ag_2Se Nanorod Arrays with Ultrahigh Room Temperature Thermoelectric Performance and Superior Mechanical Properties Jamal A. Khan and Jitendra P. Singh; Indian Institute of Technology Delhi, India

Ag_2Se is an intriguing material for room temperature energy harvesting. Herein, we report the fabrication of zigzag Ag_2Se nanorod arrays by Glancing angle deposition technique (GLAD) followed by simple selenization in a two-zone furnace. The thermoelectric performance was investigated by varying the number of zigzag arms. The novel Ag_2Se zigzag nanorod arrays with four arms shows an excellent zT= 1.42 ± 0.15 and power factor of 3202.21 ± 105.23 μW/m-K^2, respectively at 300 K. The superior thermoelectric performance of four arm zigzag Ag_2Se nanorod arrays compared to one arm Ag_2Se nanorods could be ascribed to the unique nanocolumnar architecture that not only offers a preferential path for carrier transport but also enhanced the scattering of phonons at the tilted rough boundaries and interfaces. The synergetic dependence between the tilt structure and the thermoelectric properties opens a new avenue to fabricate scalable nanostructure thin films for practical applications in next-generation thermoelectric devices.

11:30 AM EN08.13.05
High-Performance Ionic Thermoelectric Materials by Ionic Doping Jianyong Ouyang; National University of Singapore, Singapore

Ionic thermoelectric materials have been attracting more and more attention mainly because of their high thermopower. Their thermopower can be tens mV/K, higher than that of electronic thermoelectric materials by 2-3 orders in magnitude. The thermopower of ionic thermoelectric materials arises from the accumulations of cations and anions at the two ends of a sample under temperature gradient. We found that ionic doping can greatly increase the difference in the mobilities of cations and anions and thus improve the thermopower. By ionic doping, we observed high thermoelectric performance on

both p-type and n-type thermoelectric materials. The ZTi value can be higher than 6 at room temperature.

Understanding The Impact of Microstructure and Interdiffusion in Mg_2Si-Based Thermoelectric Materials by Integral and Locally Resolved Measurements Johannes de Boor[1,2], Amandine Duparchy[1], Sanyukta Ghosh[1], Aryan Sankhla[1], Harshita Naithani[1], Gregor Oppitz[1], Mohamed Abdelbaky[2], Wolfgang Mertin[2], Byungki Ryu[3], Sungjin Park[3], Sudong Park[3] and Eckhard Müller[1]; [1]German Aerospace Center, Germany; [2]University of Duisburg-Essen, Germany; [3]Korea Electrotechnology Research Institute, Korea (the Republic of)

Alternative thermoelectric materials that can substitute the commercially dominant bismuth telluride technology are highly desirable for heat conversion and thermal management applications. Alternative thermoelectric materials that can substitute the commercially dominant bismuth telluride technology are highly desirable for heat conversion and thermal management applications. Magnesium silicide based solid solutions Mg_2X (X = Si, Ge, Sn) are among the most promising thermoelectric (TE) materials due to very good thermoelectric properties, low cost of raw materials and environmental compatibility. We have demonstrated technological maturity with prototypes of p- and n-type Mg2X and p-MgAgSb/n-Mg_2X, the latter reaching conversion efficiencies > 6.5% (T_c = 25 °C; T_h = 300 °C) and power densities of ~1 W/cm^2, comparable to commercial bismuth telluride modules.
However, stable thermoelectric properties are of utmost importance for successful large-scale application. Intrinsic defects like Mg interstitials and Mg vacancies affect the properties of Mg2X significantly, therefore Mg diffusion is a potential concern here. Annealing experiments and in-situ measurements at high temperature show that degradation of Mg2X is a two-step process, where in the first step loosely bound excess Mg sublimates from the surface, reducing the charge carrier concentration, and only in the second step, after the solubility limit of Mg vacancies has been reached, Mg2X decomposes into other phases. Variation of the annealing temperature allows us to develop a kinetic model which can be used to predict material stability at different application temperatures, we also find indications that this process can be decelerated by sealing of the surfaces.
Furthermore, we find that diffusion phenomena are relevant even at room temperature, changing the thermoelectric properties on a scale of months to years if stored under laboratory atmosphere. Microstructural investigations by SEM, EDX and AFM indicate that the observed changes are related to Mg diffusion inside the material, in line with conclusions from high temperature experiments. They furthermore show that the diffusion constant is highly selective on the Si:Sn ratio of the material, with diffusion being much faster in Sn-rich material. Comparison of different microscopic mechanisms of bulk diffusion by first-principles calculations reveals that Mg transport via Mg vacancies is the most relevant mechanism. We can furthermore show that the drift kinetics of the thermoelectric properties is related to the amount of excess Mg added during synthesis and that high-performance samples with improved stability can be synthesized by omitting excess Mg.
The chemical and structural complexity of this material class allows for employing advanced material improvement strategies, in particular selective scattering of charge carriers on (self-assembling) nanostructures (“energy filtering”). This can be achieved by a locally varying electronic band structure, feasible in Mg2Si1-xSnx by changing the band gap via the Sn content x and energetically adjusting the band edges in grains of different compositions by selective doping. To test selective doping strategies, a local charge carrier concentration measurement is highly useful. We will show that transient microprobe measurements of the Seebeck coefficient can be used to that purpose with a local resolution down to ~5 µm. For carrier concentration determination with sub-µm resolution we employ a combin¬ation of the AFM-based Kelvin Probe Force Microscopy for work function measurements, SEM for determination of the composition, first-principles calculations for band offset predictions and modelling based on the Boltzmann transport equation. Our results reveal an inhomogeneous distribution of the dopant Bi among several observed Mg2Si1-xSnx phases and confirm the feasibility to tune the local carrier concentration to control the electronic band structure alignment.

2:00 PM EN08.14.02
Optimization Study of ($Ta_{0.4}Nb_{0.4}Ti_{0.2}$)–Fe–Sb Half-Heusler Thin Films Using Combinatorial Synthesis, High-Throughput Power Factor Mapping and Thermoreflectance Thermal Property Measurements Dylan J. Kirsch[1], Joshua Martin[1], Nathan Johnson[2], Suchismita Sarker[3], Rohit Pant[4], Ronald Warzoha[5], Apurva Mehta[6] and Ichiro Takeuchi[4]; [1]National Institute of Standards and Technology, United States; [2]Carl Zeiss Research Microscopy Solutions, United States; [3]Cornell University, United States; [4]University of Maryland, United States; [5]U.S. Naval Academy, United States; [6]SLAC National Accelerator Laboratory, United States

Half-Heusler (hH) thermoelectric (TE) intermetallic alloys are promising candidates for commercial modules, but their conversion efficiency can be limited due to high thermal conductivity. One method to improve hH alloy performance is to decrease the lattice contribution to the thermal conductivity through solid-solution alloying. Several publications reported p-type NbFeSb hH alloys can accommodate off-stoichiometry on the Fe- and Sb-sites, which could positively impact the both the electrical properties and the thermal properties, similar to the lattice thermal conductivity decrease observed via Ta-alloying. Combinatorial approaches are an ideal method to explore hH alloy properties and phase stability with the advantage of rapid sample fabrication and characterization of a wide range of compositions. This approach can provide insights into materials systems that could be missed using conventional approaches but requires unique and custom synthesis and transport property measurement instrumentation. Both continuous-spread composition gradient and homogeneous discrete co-sputtered combinatorial thin film synthesis methodologies were leveraged to produce maps of the composition-structure-property relationships as a function of Fe- and Sb-content in ($Ta_{0.40}Nb_{0.40}Ti_{0.20}$)-Fe-Sb hH alloys for the first time. The Seebeck coefficient and electrical resistivity were measured using our custom-built high-throughput scanning probe. Thermal conductivity and heat capacity were measured on our discrete combinatorial hH thin films using a custom-built, automated Frequency Domain Thermoreflectance (FDTR) instrument. Maximum TE figure-of-merit zT values at room temperature are calculated to be ≈ 0.08 for compositions $(Nb_{0.41}Ta_{0.33}Ti_{0.26})_{28.5}Fe_{40.3}Sb_{31.2}$ and $(Nb_{0.42}Ta_{0.33}Ti_{0.25})_{35.0}Fe_{31.7}Sb_{33.3}$ having thermal conductivity values ≈ 2.25 ± 0.27 W m^{-1} K^{-1}. Our custom suite of high-throughput combinatorial instruments can now measure all of the properties needed to calculate the zT of any promising and unoptimized TE material system.

2:15 PM EN08.14.03
Microscale Imaging of Thermal Conductivity Suppression at Grain Boundaries Eleonora Isotta[1], Shizhou Jiang[1], Alexandra Zevalkink[2], Jeff Snyder[1] and Oluwaseyi Balogun[1]; [1]Northwestern University, United States; [2]Michigan State University, United States

Grain boundaries have a central importance in materials science. They can critically control thermal and elactrical transport, determining the performance of energy and electronic materials. In thermoelectric materials, grain boundaries can be leveraged to suppress the thermal conductivity, but can also detrimentally suppress the carrier mobility. Grain boundaries are not all equal: they are associated to several degrees of freedom, and can come in multiple

orientations, symmetries, and chemistries. Recent evidence suggests that some types of grain boundaries could be more beneficial than others for the thermoelectric performance. Despite the importance, we lack a clear understanding of how grain boundaries modify the microscale transport owing to the scarcity of local investigations. Usually the role of grain boundaries is inferred from bulk, effective measurements. However, understanding how grain boundaries impact transport locally is a crucial perspective to enable grain-boundary engineering for the next generation of high-performance thermoelectrics.

In this work, we image the thermal conductivity of individual grain boundaries via spatially-resolved frequency-domain thermoreflectance. Measurements with microscale resolution reveal a suppression in thermal conductivity at grain boundaries both in thermoelectric SnTe and multicrystalline silicon. In contrast to conventional thermal modeling, which assumes that all boundaries are perfect scatterers and lead to uniformly suppressed thermal conductivity, we observe a non-uniform suppression localized within a few microns of a boundary. Furthermore, not all grain boundaries behave the same: misorientation angle, symmetry, and morphology are found to strongly correlate with the effective thermal boundary resistance. Extracting transport properties from microscale imaging can provide comprehensive understanding of how microstructure works. This development can improve our understanding of carrier-defect interactions, advancing the engineering of materials for thermoelectrics.

2:30 PM EN08.14.04
Using Bulk Thermoelectric Measurements to Identify Grain Boundary Transitions in NbFeSb Duncan Zavanelli[1], Ruben Bueno Villoro[2], Ran He[3] and Jeff Snyder[1]; [1]Northwestern University, United States; [2]Max-Planck-Institut für Eisenforschung GmbH, Germany; [3]Leibniz Institute for Solid State and Materials Research Dresden, Germany

Grain boundaries have seen much recent interest for improving the performance of thermoelectrics, with their capacity to reduce thermal conductivity. Thermally activated charge carrier scattering from grain boundaries is detrimental to performance, far outweighing the benefits to thermal conductivity in many materials. If charge scattering of grain boundaries could be reduced or eliminated, then reducing grain size could be used to improve the thermal properties of many thermoelectrics. In half-Heusler materials, experimental observations have shown that compositional changes at the grain boundary from dopant segregation are correlated to a reduction in the detrimental scattering from boundaries. However, there is currently no good method to identify this behavior based on bulk thermoelectric measurements. In this presentation, we propose a method to model the behavior of grain boundaries such that transitions in grain boundary properties can be identified. This enables the identification of changes in chemistry or structure of grain boundaries prior to in depth characterization of individual grain boundaries in the material.

2:45 PM EN08.14.05
Enhanced Thermoelectric Performance in Sputtered Epitaxial Fe_2VAl Thin Films via Crystal Orientation Selection Jose María Domínguez-Vázquez, Olga Caballero-Calero, Alfonso Cebollada, Andres Conca and Marisol Martín-González; Instituto de Micro y Nanotecnología, IMN-CNM, CSIC (CEI UAM+ CSIC), Spain

Heusler intermetallic compounds present a wide variety of compositions that fulfill the requirement of avoiding toxic or scarce elements. The Fe_2VAl family of Heusler alloys shows a large potential and versatility for thermoelectric thin films with tunable properties via doping with additional elements such as Ti, Ta, Si, W, and others [1-3]. The doping allows the fabrication of p- and n-type alloys in the same family, which simplifies future thermoelectric device fabrication. While the undoped alloy Fe_2VAl is a p-type material, the introduction of W, Si, or Ta results in a n-type one. P-type alloys are obtained with Ti and Zr, both with an increase in Seebeck values compared to the undoped case. The addition of these materials can also be performed in an off-stoichiometric manner [4,5].
Sputter deposition is a well-established, inexpensive, and very versatile technique for the fabrication of a wide variety of material systems. The chemical composition can be highly controlled by the simultaneous use of several magnetrons with different elements (codeposition) to achieve the desired film content or doping concentration, which is needed to optimize the thermoelectric properties [6].
From a fundamental point of view, the possibility to explore the influence of crystal orientation on thermoelectric performance is very appealing, offering a perfect scope for experiment versus theory comparison. In this sense, physical vapor deposition techniques are excellent tools for obtaining thin films with desired orientations through the use of adequate substrates in terms of crystal symmetry and lattice match. In this contribution, we present results on Fe_2VAl thin films fabricated by magnetron dc sputtering. Two different sample series have been prepared with varying deposition temperatures (RT-950°C) and with two different substrates and, consequently, two crystalline orientations owing to the different epitaxial relations. Films grown on MgO (100) are (100)-oriented, while Al_2O_3 (11-20) substrates induce a (110) orientation. In both cases, the (111) diffraction peak Fe_2VAl corresponding to the L21 fully ordered phase can be observed in asymmetric configuration diffraction measurements.
The results of the characterization of the thin films with X-Ray Diffraction and SEM imaging are shown, proving epitaxial growth for both series. The electric conductivity, Seebeck parameter, and power factor are reported. We observe a large difference in the thermoelectric performance depending on the growth orientation of the films.
With these results, we prove the large potential of sputtering to produce high-quality Fe_2VAl films ready for further desired compositional variation and tuned doping via codeposition.

Heat Conduction in a Printed Thermoelectric Film Koji Miyazaki; Kyushu University, Japan

We have developed printed thermoelectric thin films using inorganic materials such as Bismuth Telluride. The process involved crushing the material into fine powders and mixing it with polyamic acid in an organic solvent. The resulting viscous solution was screen-printed onto a substrate and annealed in an Argon atmosphere. The heated polyamic acid transformed into polyamide at 400°C, acting as an adhesive between the thermoelectric powders. However, we found that the electrical conductivity of the resulting film was very low due to the low packing density. To address this issue, we decided to create a composite material by incorporating printable materials. We chose the lead-free halide perovskite, $CsSnI_3$, which displayed relatively good thermoelectric properties as a printable material. We mixed the Halide perovskite into the Bismuth Telluride solutions and printed them onto the substrate. After heating the film on a hotplate, the halide perovskite precipitated in the pores, resulting in a composite film of $Bi_2Te_3/CsSnI_3$. This composite film displayed improved electrical conductivity and low thermal conductivity, while the Seebeck coefficient slightly decreased. We also found that the thermal conductivities of both Bismuth telluride and Halide perovskite were low, and the high interfacial thermal resistance between them was measured to be in the order of $10^{-7}K/(m^2\bullet W)$ using the differential 3omega method. This high interfacial thermal resistance explained the low thermal conductivity of the composite film, following a conventional model with interfacial thermal resistance. Ab initio calculations helped us understand the mechanisms behind the high interfacial thermal resistance. We believe that our printing process can be applied to other thermoelectric materials, allowing us to create film-shaped thermoelectric generators. Then, we applied the present printing technique to Cobalt antimonide Skutterudite. The Cobalt antimonide shows a high power factor at room temperature although thermal conductivity is also high. The effective thermal conductivity of the printed film is low, as well as keeping a relatively high power factor at room temperature. The packing density should be increased to improve the electrical conductivity of the printed Cobalt antimonide Skutterudite. This method can be applied to make thermoelectric energy harvester for room temperature use.

An Organic Thermoelectric Generator by Local Doping of Highly-Aligned Polymer Films Nathan James Pataki[1,2], Shubhradip Guchait[3], Martin Brinkmann[3] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Centre National de la Recherche Scientifique (CNRS), France

The growing number of distributed microelectronics in the Internet of Things (IoT) requires versatile, scalable and affordable power sources. Heat-harvesting organic thermoelectric generators (TEGs) are regarded as a potential key component of the future energy landscape. Research surrounding the structure-property relationships in organic thermoelectric materials has led to extraordinary advances in the power factors of preferentially aligned polymer films [1-2], yet there has been little effort to actually leverage these advances and transfer aligned polymer films into a functional TEG. In this work, a previously reported shear-force method is used to induce in-plane orientation of regioregular poly(3-hexylthiophene) (P3HT) and poly[bis(thiophen-2-yl)thieno[3,2,b]thiophene (PBTTT) films which are then floated onto ultrathin parylene substrates. A scalable inkjet printing method along with an ink formulation of the p-type dopant tris(4-bromophenyl)ammoniumyl hexachloroantimonate), known as magic blue (MB), enabled high-precision local doping of the oriented polymer films to pattern a conductive TEG architecture. This novel fabrication method was used to scale the oriented TEGs up to 10 thermocouple pairs resulting in a maximum power output of 1.1 nW and an open circuit voltage of 6.6mV at ΔT=50K. This work represents the first example of an oriented organic TEG and demonstrates the value of local doping as a precise and scalable fabrication method for future TEGs.

4:15 PM EN08.15.03
2D/3D-Printed Bismuth Telluride-Based Flexible Thermoelectrics for Low-Scale Energy Harvesting Francisco Molina-Lopez; KU Leuven, Belgium

The swift development of the Internet of Things (IoT) and wearable electronics is urgently demanding innovative power solutions. Batteries alone can barely satisfy this demand for two main reasons: Firstly, battery replacement limits the implementation of some scenarios of the IoT in which nodes might be highly distributed in difficult access locations; Secondly, batteries are often too bulky and rigid to be seamlessly integrated on thin and soft wearable electronics, or small IoT nodes. Thermoelectric generators (TEGs) refer to renewable power sources able to assist -or even replace- batteries by generating electricity from the abundant waste heat in the environment. Conveniently, it has been suggested that for low-power applications, TEs can surpass other thermal engines in terms of efficiency.[1] Furthermore, TEs are also capable of on-demand cooling and heating. However, to meet the form factor required by the IoT and wearables (namely repeated bendability/stretchability, conformability to curved surfaces, and large areas), important advancements must be made on traditional TEGs, which are rigid, and hard to scale up to large-area devices.[2]

My group is working towards the development of high-performance thermoelectric materials that can be directly 2D- or 3D-printed on flexible substrates. In particular, I will describe our progress in the formulation of bismuth telluride powder as a printable paste/ink, and the process of selective laser sintering and the direct ink writing (DIW) to form in-plane and through-plane TEGs, respectively. Printing techniques can potentially reduce the material waste and cost of TEGs. Moreover, in combination with a flexible substrate, printing enables innovative device architectures, such as large-area and flexible devices that can be easily integrated on the skin/smart textiles to power wearables using the heat emitted by the human body, as well as adapt to hot curved surfaces, like hot pipes or engines, to power IoT nodes. Because we target energy harvesting around room temperature, bismuth telluride is used as a benchmark material to showcase our processes and device architectures. However, our technology is likewise compatible with emerging polymeric materials, which will be also presented for comparison. If successful, this line of research will holistically tackle the main bottlenecks of TEGs, paving the way to their broad implementation in wearables and other low-power energy harvesting applications.

Electrodeposited Silver Selenide Films: From Pourbaix Diagram to a Flexible Thermoelectric Module Cristina V. Manzano, Cristina Llorente del Olmo, Olga Caballero-Calero and Marisol Martín-González; Institute of Micro and Nanotechnology, Spain

In the last few years, the exploration of new thermoelectric materials with low-toxicity, earth-abundance, and high-efficiency has become essential. Following this trend, sustainable, easily scalable, and cost-effective fabrication methods, such as electrochemical deposition, are also desirable. In this work, the Pourbaix diagram of silver–selenium–water was developed to find an adequate pH and reduction potential for the electrodeposition of stable silver selenide. Based on this diagram, a solution without the incorporation of additives was developed. Silver selenide films were electrodeposited at different reduction potentials, and after the deposition, the compositional, morphological, and structural characterizations of the silver selenide thin films were analysed. The thermoelectric properties of the electrodeposited silver selenide films were measured at room temperature. The maximum power factor was found for the films grown at 0.071 V with a value of 3421 ± 705 mW/mK^2 and a thermal conductivity of 0.56 ± 0.06 W/mK. Even better, when it can be done by employing a technique that is easily scalable to an industrial level and allows large areas to be obtained, such as electrodeposition. Finally, films with similar properties were deposited on a flexible Kapton substrate (see Figure 1). A unileg thermoelectric power generator was produced with maximum output powers of 14.7, 29.4, and 37 mW under temperature differences of 10, 15, and 19 K, respectively; and maximum power densities of 55.1, 110.1, and 138.6 mW/m^2 under temperature differences of 10, 15, and 19 K, respectively.

Advances in Soft and Wearable Energy Harvesters Using Stretchable Thermoelectrics Mason Zadan, Dinesh K. Patel, Anthony Wertz and Carmel Majidi; Carnegie Mellon University, United States

To improve operational lifetimes of wearable electronics, energy harvesting solutions must be introduced to offset the limitations of current battery technologies. These solutions must both have energy harvesting performance metrics that can meaningfully extend the operational lifetime of wearable health monitoring systems, along with being biocompatible. Soft and deformable materials must be introduced to replace the rigid components of these systems to allow for these energy harvesters to not impede movement. Currently, various wearable energy harvesting solutions have been introduced including piezoelectric, triboelectric, dielectric elastomer, and thermoelectric generators. While these systems have been developed to be deformable and stretchable, the energy densities still must be improved to meaningfully increase power output while not sacrificing mechanical performance. Thermoelectrics, in particular, have the advantage of operating off of temperature differentials and not requiring biomechanical movement. When a temperature difference is applied across oppositely doped thermoelectric semiconductor junctions, a voltage is generated through the Seebeck effect. Conversely, when a current is driven across the semiconductor junctions, a temperature potential can be generated through the Peltier effect.

In this talk I will discuss recent work on the creation of soft and stretchable thermoelectric generators along with their introduction as a power source for wearable electronic devices. To replace rigid materials such as ceramic thermal interfaces and copper interconnects, we introduce 3D printed elastomers and eutectic gallium indium liquid metals as material replacements for the device substrate and conductive traces. Device packaging and fabrication is discussed for multiple generations of these devices. Seebeck and Peltier characterization along with electromechanical characterization is reported, highlighting performance metrics under strain. Wearable integration is also reported with on-body testing conducted to better understand the relative performance changes during wear. Separately, recent integration of these TEGs into soft robotics is discussed through their combination with liquid crystal elastomer shape memory polymers. These TEGs are introduced as both the heating and cooling element along with energy harvesting capabilities.

Phase Engineering of Nanomaterials (PEN) Hua Zhang[1,2]; [1]City University of Hong Kong, China; [2]City University of Hong Kong Shenzhen Research Institute, China

In this talk, I will summarize the recent research on phase engineering of nanomaterials (PEN) in my group, particularly focusing on the rational design and synthesis of novel nanomaterials with unconventional phases for various promising applications. For example, by using wet-chemical methods, for the first time, we have successfully prepared novel Au nanostructures (*e.g.*, the hexagonal-close packed (*hcp*) 2H-Au nanosheets, 4H-Au nanoribbons, and crystal-phase heterostructured 4H/*fcc* and *fcc*/2H/*fcc* heterophase Au nanorods), epitaxially grown metal nanostructures on the aforementioned unconventional Au nanostructures and 2H-Pd nanoparticles, and amorphous/crystalline heterophase Pd, PdCu, Rh and Rh alloy nanosheets. In addition, by using gas-solid reactions, metastable 1T'-phase group VI transition metal dichalcogenides (TMDs), *e.g.*, WS_2, WSe_2, MoS_2, $MoSe_2$, $WS_{2x}Se_{2(1-x)}$ and $MoS_{2x}Se_{2(1-x)}$, have been prepared. Moreover, the salt-assisted 2H-to-1T' phase transformation of TMDs have been achieved, and the phase transformation of TMDs during our developed electrochemical Li-intercalation process has been observed. Impressively, the lithiation-induced amorphization of $Pd_3P_2S_8$ has been achieved. Currently, my group focuses on the investigation of phase-dependent physicochemical properties and applications in catalysis, (opto-)electronic devices, clean energy, chemical and biosensors, surface enhanced Raman scattering, photothermal therapy, *etc.*, which we believe is quite unique and very important not only in fundamental studies, but also in future practical applications. Importantly, the concepts of phase engineering of nanomaterials (PEN), crystal-phase heterostructures, and heterophase nanomaterials are proposed.

11:00 AM EN09.01.02
Atomic Layer Deposition of Noble Metal Nanoparticles for Catalytic Applications Jan M. Macak[1,2]; [1]University of Pardubice, Czechia; [2]CEITEC, Czechia

Platinum group metals such as Pt, Ru, Pd, Ir, etc., have superior performance for various catalytic applications.[1] Due to their scarcity, efforts were being made to reduce or replace these noble metals. Atomic Layer Deposition (ALD) is one among the best technique to facilitate lowering of loading mass on a support of interest.[2],[3] Furthermore, ALD is the most suitable technology that can decorate high aspect ratio and high surface area substrate architectures.[4] Due to the governing surface energy variations between noble metals and support surfaces, the growth initiates as nanoparticles (NP) and with a further increase in ALD cycles the agglomeration among NP's dominates over the individual NP size increase, thus developing thin films of relatively higher thickness. The surface energy variations are also known to increase the nucleation delay of noble metals especially for Ru considerably. In this regard our efforts were laid to improve the functionality with pretreatments on carbonaceous supports which were shown promising to reduce the nucleation delay of ALD deposited Ru.
For electrocatalytic applications, it is important to choose the right substrates. Among available substrates, carbon papers (CP) and titania nanotube (TNT) layers are best choices considering their physio-chemical properties, availability, vast literature, and low costs incurred using these as support substrates in electrocatalysis and photocatalysis. Several surface modifications for CP's and variations on morphological aspects of TNT layers had received a great attention form applied fields due to their improved surface area, conductivity and stability.[5]–[8] Uniformly decorating these CP's and TNT layers by NPs or thin films of catalysts proved to be highly efficient with no boundaries on applications.[9]
The presentation will introduce and describe the synthesis of different noble metal NPs by ALD on various aspect ratio TNT layers and CP substrates. It will also include the corresponding physical and electrochemical characterization and encouraging results obtained in electrocatalysis.

11:15 AM *EN09.01.03
Nanomaterials for Energy: Controlling Properties through Controlled Synthesis Sophie Cassaignon; Sorbonne University, France

In the realm of applied research for energy, the continuous quest to offer innovative materials with novel properties remains a perpetual challenge. These properties are often tailored to suit specific applications. To approach this challenge effectively, one must master the four fundamental characteristics of a material. The first of these, which dictates its intrinsic properties, is its composition and the crystalline phase it assumes, especially in the case of crystalline solids. The second aspect to consider is the size of the primary objects that constitute the solid. On a larger scale, texturing techniques such as creating porous materials, multi-scale architectures, and superstructures are also used. Finally, the shaping of materials into various forms like films or powders also plays a critical role in determining the material's properties within the final device.
On the side of fundamental research, it is imperative to understand the intricate relationship between a material's structure, morphology, texture, and the specific property we aim to target. The synthesis of the material should not rely on a mere "trial and error" approach; instead, it should be grounded in a profound understanding of the parameters governing reactivity.
Despite the wealth of crystalline phases associated with metals, oxides, carbides, and more, new structures are consistently being discovered, often characterized by unique properties. These structures are frequently beyond the reach of traditional high-temperature synthesis methods. Instead, they can be effectively realized through gentler and more innovative synthesis techniques, such as Sol-Gel chemistry. Operating at lower temperatures, Sol-Gel chemistry facilitates the attainment of metastable states of matter, often emphasizing kinetic control over thermodynamic control. Furthermore, certain phases exist only at extremely small particle sizes, corresponding to the nanoscale. Mastering Sol-Gel chemistry and its key parameters, typically involving concentration, temperature, or pH in the case of aqueous solutions, offers the most suitable means of structuring materials at this scale.
In the presentation, we will explore specific examples of nano-oxides like TiO_2, WO_3, $Na_3V_2(PO_4)_2F_3$… and their applications in the realms of energy and the environment.

11:45 AM EN09.01.04
Magnetic-Field Assisted Synthesis of Transition Metal Aerogels Allows Formation of High Surface Area Electrocatalysts Rosemary L. Calabro[1,2], Garret A. Longstaff[1], Edward Tang[1], Veronika M. Xiao[1], Alexander D. Ciampa[1], Kennedy V. Munz[1], Enoch A. Nagelli[1], Stephen F. Bartolucci[2], Joshua A. Maurer[2] and John Burpo[1]; [1]United States Military Academy, United States; [2]U.S. Army DEVCOM Armaments Center, United States

Transition metal aerogels (TMAs) have emerged as promising electrocatalysts for a variety of reactions due to their lightweight properties, conformability, porous natures, and high surface areas allowing many available sites for charge transfer and catalytic activity. The catalytic properties of the TMAs can be tuned based on the elemental composition, surface environment, and structural properties, allowing opportunities to design a wide range of TMAs that can

catalyze a variety of reactions. An ongoing challenge is that traditional methods to prepare TMAs suffer drawbacks such as aggregation, slow reactant diffusion times, a need for templates which can block catalytic active sites, and formation of a brittle final product. We have developed a magnetic-field assisted synthesis strategy to produce iron aerogels that addresses these limitations. In a typical synthesis, a ferric chloride metal salt solution was placed inside a 150 mT magnetic field. Sodium borohydride was then added as a reducing agent which resulted in immediate formation of a gel. This gel was rinsed and then either supercritically dried into an aerogel or pressed into a thin film. Scanning electron microscopy (SEM) shows that the aerogels consist of iron nanowires that are intertwined with each other, and nitrogen porosimetry confirms that they have high surface areas and porosities. The lack of templates or surfactants in synthesis allows exposed surfaces available for electrocatalysis. The iron nanowire network within the aerogel allows improved mechanical properties relative to TMAs prepared through alternate methods. The aerogels were then used as a sacrificial template for galvanic displacement with platinum which allowed dissolution of the iron and formation of high surface area platinum nanotubes. SEM shows the platinum tubes retain the nanowire network of the iron template, and electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV) indicate high electrochemical accessible surface areas for electrocatalytic applications. This strategy was also applied to cobalt nanowire synthesis with subsequent thermal annealing to Co_3O_4 for pseudocapacitor applications, and for formation of bimetallic iron-nickel aerogels which are promising as electrocatalysts for water splitting.

SESSION EN09.02: Synthesis for (Electro)catalysis II

1:30 PM EN09.02.01
Ordered Metal Nanowire Networks for High Performance Catalytic Electrodes Adam Squires; University of Bath, United Kingdom

We present a new method for the production of ordered 3D metal-nanowire network films using a coating of lipid inverse cubic phase as the template for electrodeposition. We have produced platinum films which show a previously unreported “single diamond” nanoarchitecture with tunable nm-scale pore and wire diameters, and lattice parameters down to below 10 nm. The nanoarchitecture gives high electrocatalytic performance and stability towards fuel cell oxidation reactions; and the production and removal of the template is facile, using mild conditions and green solvents (water, ethanol) in simple half-hour steps, representing an attractive route to high performance nanomaterials.

1:45 PM EN09.02.02
Fast and Facile Microwave Synthesis of Cubic $CuFe_2O_4$ Nanoparticles for Electrochemical CO_2 Reduction Judith Zander and Roland Marschall; University of Bayreuth, Germany

Electrochemical CO_2 reduction is a promising strategy for the sustainable synthesis of carbon-based chemicals or fuels such as CO, or CH_4.[1] Copper-based materials are of special interest due to their broad substrate scope. While copper itself is the first known metal catalyst able to directly yield CH_4, CO, methanol, or C_{2+} products such as ethanol can also be obtained, e.g. from oxide derived catalysts.[2][3] Another interesting copper oxide is the spinel $CuFe_2O_4$, due to its versatile electronic and magnetic properties. Those can be tuned *via* variations in the cation distribution between octahedral and tetrahedral sites.[4] Changes in the cation distribution, or degree of inversion, can additionally lead to a structural transformation between the cubic and tetragonal form, due to the strong Jahn-Teller effect of Cu^{2+}. Both degree of inversion and structure are strongly dependant on the synthesis conditions.[4] In this contribution we introduce a fast microwave-assisted solvothermal synthesis of cubic $CuFe_2O_4$. Very short synthesis times of 1 min and low temperatures of 120 °C in ethylene-glycol/water mixtures could be realised, without a loss of phase-purity and no necessity for subsequent thermal treatment.[5] The degree of inversion was found to decrease with increasing synthesis time, whereas the particle size and crystallinity was almost independent of the synthesis conditions. The influence of the synthesis conditions – and thus material properties – on the activity in electrochemical CO_2 reduction to CO in 0.1 M $KHCO_3$ was investigated. The best activity was obtained for $CuFe_2O_4$ with an intermediate degree of inversion of approx. 0.75, together with a large crystallite size and micro-strain. Since hydrogen was produced as the only site-product, $CuFe_2O_4$ can be an interesting candidate for the production of syngas.

Engineering Stable Mutliscale Electrocalyst Architectures for Efficient Alkaline-Membrane Water Electrolysis Shannon W. Boettcher[1,2]; [1]University of Oregon, United States; [2]University of California, Berkeley, United States

Commercialized membrane electrolyzers use acidic proton exchange membranes (PEMs). These systems offer high performance but require the use of expensive precious-metal catalysts such as IrO_2 and Pt that are nominally stable under the locally acidic conditions. Alkaline-exchange-membrane (AEM) electrolyzers in principle offer the performance of PEM electrolyzers with the ability to use earth-abundant catalysts and inexpensive bipolar plate materials. I will present our work in understanding the chemical and electrochemical processes in earth-abundant water-oxidation catalysts, including the use of integrated reference-electrode device architectures and cross-sectional materials analysis, as well as progress in building high-performance AEM

electrolyzers. Baseline electrolyzers operate at 1 A cm^{-2} in pure water feed at < 1.9 V at a moderate temperature of ~70 °C using either IrO_2 or Co_3O_4 anode catalyst layers, PiperION alkaline ionomers, and stainless-steel porous transport layers. These devices, however, degrade rapidly compared to PEM electrolyzers. The voltage profile corresponding to degradation has initial fast (~10 mV/h) and steady-state slow components (~1 mV/h), which we link to chemical and structural changes in the ionomer-catalyst reactive zone. We further discover that dynamic Fe-based OER catalysts – that have world-record performance in traditional liquid alkaline electrolyzer systems – perform poorly with enhanced degradation rates in alkaline membrane electrolysis, illustrating fundamentally different chemical design principles for OER catalysts. We use these principles to created advanced catalysts with surface and bulk properties tuned for AEM electrolysis applications leading to enhanced performance. I will also highlight promising new chemical strategies to mitigate degradation using novel ionomers and passivated electrolyte-electrode-catalyst compositions and interfacial architectures.

2:30 PM EN09.03.02
Two Dimensional Materials and Their Heterostructures for Ampere-Level Direct Seawater Splitting Suraj Loomba, Muhammad Waqas Khan, Muhammad Haris and Nasir Mahmood; RMIT University, Australia

Green hydrogen has emerged as the potential replacement for fossil fuels; however, more than 20 billion m^3 of water would be required to meet the future demand of 2.3 Gt of hydrogen per year, which is almost equal to the water needs of a country with a population of more than 60 million. Currently, most of the current industrial processes require purified freshwater for the electrolysis process, which is a limited resource, and utilizing freshwater to meet increasing hydrogen demands can lead to a drinking water crisis. Seawater, an almost unlimited resource, can be a potential feedstock for water electrolysis. However, the complex composition and presence of chloride anions in the seawater can interfere with the electrolysis process. Although desalination has been suggested for seawater purification, the economics of scale do not justify the set-up of the plant. Therefore, synthesizing materials that can withstand complex seawater composition and deliver enhanced performance and long-term stability in direct seawater is crucial.
In my previous work, I developed porous sheets of 2-dimensional (2D) N-$NiMo_3P$, which required an overpotential of only 35 mV and 346 mV to acquire 10 mA cm^{-2} for hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) in alkaline seawater, respectively. The presence of Ni and N resulted in enhanced electrical conductivity by assisting in the redistribution of the charge states and the metal-non-metal bond lengths while the pores catered for faster mass transport and increasing active sites. Furthermore, the presence of polyanions (phosphate, nitrate) on the surface safeguarded the catalyst against chlorine chemistry, preventing chlorine evolution reaction at the anode. As a result, the catalyst was stable for over 100 hours of continuous operation. Although the HER performance of the catalyst was exceptional, the long-term operation and anodic performance still needed to be improved to realize the commercial applications.
Learning from my previous work, I have developed a 2D heterostructure catalyst for ampere-level anodic reaction. The as-synthesized catalyst possesses the advantages of its constituent 2D materials while alleviating their disadvantages. The materials are bonded via unique bonds at the heterointerface, which helps in optimizing the surface geometries for selective reactions while also modulating the hydroxyl anions at the interface, which play a crucial role in averting the chlorine chemistry at the anode by repelling the chloride anions. As a result of the unique bonded heterointerface, the material can deliver approximately 10x better performance while also being 65% more economical than commercial IrO_2 for anodic reaction. Furthermore, the catalyst can operate stably for over 1000 h without any current losses. To further confirm the exceptional stability, the working electrode was left idle in the electrochemical system for 5 days and then tested again, where it retained more than 90% of its initial current density after 3 days of continuous operation, making it integrable with renewable power sources. Hence, the interfacial engineering method to obtain a unique bonded heterointerface can be a potential strategy to synthesize a 2D heterostructure catalyst for industrial direct seawater splitting.

2:45 PM EN09.03.03
Electrochemical Water Oxidation over Core/Shell structured Hyperfine β-FeOOH (akaganeite) Crystalline Nanorods coated with Bias-Responsive Amorphous Ni(OH)$_2$ Tomiko M. Suzuki, Takamasa Nonaka, Akihiko Suda, Yoriko Matsuoka, Keita Sekizawa, Yusaku F. Nishimura, Satoru Kosaka, Teppei Nishi, Shunsuke Sato, Takeo Arai and Takeshi Morikawa; Toyota Central R&D Labs, Japan

The water oxidation to extract electrons from water molecules for the oxygen evolution reaction (OER) is essential for the development of a sustainable system to synthesize valuable chemicals such as hydrogen and organic compounds from H_2O and CO_2. The catalysts consisting of earth-abundant elements are required for the system integration with minimized cost and total CO_2 emission in its lifecycle.
We have developed a 10 nm-sized highly crystalline red rust catalyst for OER composed of pure β-phase FeOOH(Cl) hyperfine nanorods (an average diameter of 3 nm and a length of 14 nm) synthesized by a facile one-pot process at room temperature and ambient pressure.[1] This one-pot process yields β-FeOOH(Cl) nanorods sizing more than 10 times smaller than those by conventional methods. The process also enables doping with Ni ions in the crystal lattice (β-FeOOH(Cl):Ni) and simultaneous surface-coating with amorphous a-$Ni(OH)_2$ (a Ni to Fe ratio up to 22 at.%), which forms a core/shell structure.[2] The overpotential for electrochemical OER over anodes stacked with the core/shell β-FeOOH:Ni/a-$Ni(OH)_2$ was 170 mV, and an OER current of 10 mA/cm^2 was obtained at an overpotential of 430 mV in a 0.1 M KOH solution. The high current density at low potential compared with many Fe-rich oxide and (oxy)hydroxide electrodes reported previously.
X-ray absorption fine structure analysis (XAS), Mössbauer spectroscopy, X-ray photoelectron spectroscopy (XPS), field emission scanning electron microscopy (FESEM), X-ray diffraction (XRD), and impedance spectroscopy suggested that surface coating with the a-$Ni(OH)_2$ lowered the OER overpotential of β-FeOOH(Cl), resulting in reduced total impedance in the electrode. Mössbauer spectroscopy suggested interaction between Fe and Ni species [2], and *operando* X-ray absorption spectroscopy (XAS) under biased conditions in the aqueous solution revealed a characteristic behavior that does not occur in Fe-Ni mixed oxide systems.[3] The nearest neighbor structure and valence of Fe^{3+} ions did not change under the OER conditions. In contrast, Ni ions showed second nearest neighbor ordering which was assignable to β-$Ni(OH)_2$, and a fraction of Ni^{2+} ions was partially oxidized to Ni^{3+} at the bias for OER. This is presumably the change at the interface of the β-FeOOH:Ni nanorods and the surface a-$Ni(OH)_2$. This Ni valence change was reversible, following the sweep of the electrical bias. These findings show an essential role of Fe-Ni interactions in the core/shell β-FeOOH:Ni/a-$Ni(OH)_2$, accompanied by Ni species' structural and partial valence change under the electrical bias.
Further, after treatment in an alkaline solution of the β-FeOOH:Ni/ a-$Ni(OH)_2$ stacked electrode operates long-term OER even in a nearly neutral pH solution. The electrode as an anode was series-connected with a Mn-complex catalyst cathode for CO_2 reduction and a Si solar cell in a one-compartment reactor to construct a system mainly consisting of earth-abundant elements.[4] Under a nearly neutral pH solution bubbled with CO_2 (pH 6.9), the system produced CO and achieved solar-to-chemical energy conversion efficiency of 6.6 % in a single electrolyte solution. A long-term OER in the nearly neutral pH solution performed after a specific treatment of β-FeOOH:Ni/ a-$Ni(OH)_2$ will also be presented.

In 2021, the U.S. Department of Energy (DOE) announced its first Energy Earthshot on green hydrogen production, with a cost target of $1/kg within a decade. To put this value in perspective, astonishingly, at least 80% of this cost will be needed to pay for the operating expenditures alone of future utility-scale electricity from photovoltaics. This fact motivates less-expensive means than photovoltaics to generate and collect photogenerated mobile charge carriers, and/or exceedingly low capital cost electrochemical reactors operating at exceptionally low overpotentials. This latter option represents a paradigm shift from state-of-the-art electrolyzers that currently benefit from operation at high current densities, and thus relatively high overpotentials.

Optically thin photosynthetic nanoreactors transmit significant amounts of sunlight, and therefore each operates at a low current density. When combined with the multiplicative output of having many nanoreactors in an ensemble, detailed-balance solar-to-hydrogen energy conversion efficiencies are simulated to exceed those of optically thick photoelectrochemical designs. In efforts to attain these predicted higher efficiencies, Ensembles of Photosynthetic Nanoreactors (EPN) DOE Energy Frontier Research Center (EFRC) is performing detailed studies on the properties of state-of-the-art doped $SrTiO_3$ and $BiVO_4$ photocatalyst nanoparticles.

During my talk, I will share our recent collaborative discoveries in atomic-layer-deposited ultrathin oxide coatings to impart redox selectivity and materials stability, single-photocatalyst-nanoparticle photoelectrochemical behavior and mobile charge carrier properties, and atomic-level information on dopant distributions and materials interfaces obtained from electron microscopies and X-ray spectroscopies. I will also describe a new low-cost reactor design that we are developing. Collectively, our discoveries provide new design guidelines, and motivate additional basic science research pathways, for the development of stable composite materials to serve as active components in cost-effective artificial photosynthetic devices.

Electrolyte-Assisted Polarization in $BiFeO_3$/Nickel Foam for The Enhancement of Electrocatalytic Water Splitting Heng-Jui Liu[1], Yue-Wen Fang[2], Feng-Shuo Li[1], Chih-Yen Chen[3], Sheng-Zhu Ho[4], Ching-Yu Chiang[5] and Yi-Chun Chen[4]; [1]National Chung Hsing University, Taiwan; [2]University of the Basque Country, Spain; [3]Nation Yang Ming Chiao Tung University, Taiwan; [4]National Cheng Kung University, Taiwan; [5]National Synchrotron Radiation Research Center, Taiwan

Efficient and long-lasting electrocatalysts with superior performance are essential for the efficient and sustainable production of green hydrogen, ensuring high yield and minimal energy consumption. Electrocatalysts based on transition metal oxides have a significant advantage due to their abundant natural resources, adjustable physical properties, and their compatibility with various solutions. Among the various oxide catalyst materials, ferroelectrics have received attention for their semiconducting properties and switchable spontaneous polarization, particularly as promising photoelectrodes in solar water splitting. However, their potential as electrocatalysts has been largely overlooked until now. Here we present an effective electrocatalytic electrode composed of a $BiFeO_3$/nickel foam heterostructure. This heterostructure exhibits a lower overpotential and higher current density compared to a bare nickel foam electrode. Additionally, when in contact with an alkaline solution, the interaction between hydroxyls and the $BiFeO_3$ surface induces a significant area of upward self-polarization. This phenomenon reduces the adsorption energy of subsequent adsorbates and enhances the efficiency of the oxygen and hydrogen evolution reactions. Our work illustrates a unique approach, utilizing functional semiconducting materials for the development of highly efficient electrocatalytic electrodes.

Rational Synthesis of PbTe/$Ti_3C_2T_x$ MXene Nanocomposite as Electrocatalyst for Overall Water Splitting Tata Sanjay K. Sharma and Won Mook Choi; University of Ulsan, Korea (the Republic of)

Constructing a pivotal electrocatalyst for electrochemical water splitting is a crucial task to which two-dimensional (2D) lead telluride PbTe is ascribed as a suitable substitution for platinum (Pt). However, due to its limited active sites, sluggish kinetics, and low electrical conductivity a cocatalyst is needed. To overcome this, we fabricated a one-step solvothermal technique in which we combined dual-phase PbTe, with titanium carbide ($Ti_3C_2T_x$) MXene, to attain a wide range of solar absorption and effective charge separation. Several spectroscopical analysis were performed to understand the physiochemical and optoelectronic properties of a prepared electrocatalyst. XRD-Rietveld refinement discloses PbTe as an octahedral crystal system of the Fm3m space group where $Ti_3C_2T_x$ was successfully transformed from Ti_3Al_2C-MAX phase to MXene phase of C2/c space group with orthorhombic structure. The catalytic activities of fabricated electrocatalysts were evaluated using electrochemical HER, and OER to investigate overall water splitting. This facile integration of PbTe with $Ti_3C_2T_x$ not only increased interlayer 2D distance it also suppressed MXene oxidation and restacking enriching catalytic stability and conductivity. Thus, the promoted electrocatalyst emerges to establish further developing prospects in developing feasible catalysts using rational atomic modeling.

4:30 PM EN09.03.07
Chemovoltaic Energy Conversion on Semiconductor Surface Mahdi Alizadeh Kouzeh Rash, Ivan Radevici, Shengyang Li and Jani Oksanen; Aalto University, Finland

The chemovoltaic effect, which involves the generation of electronic excitation through exergonic redox reactions, has emerged as a crucial phenomenon with extensive implications. This effect has been observed on metallic surfaces of Schottky junctions, offering valuable insights into the intricate dynamics of chemically active collisions and having the possibility to open new avenues for energy conversion. One particularly promising application of the chemovoltaic effect is its potential to demonstrate direct chemical energy harvesting by semiconductor solar cells.
This study explores the exciting possibilities of chemovoltaic energy conversion by semiconductors and introduces the concept of an electrolyte-free fuel cell. This novel fuel cell is based on a Gallium Arsenide (GaAs) diode, specially designed to demonstrate electrochemical fuel oxidation and oxidant reduction reactions directly on its conduction and valence bands. The overarching goal is to determine if renewable chemical energy, as well as light, can be used to produce electricity efficiently and sustainably by hybrid cells.
To test the viability of this concept, we developed a thermodynamic charge transfer model to explain the chemovoltaic effect of renewable fuels on semiconductor surfaces, and experimentally demonstrated the electricity generation. Our modelling results indicate that redox reactions occurring between a fuel and an oxidizer on the photovoltaic cell's surface can chemically excite the semiconductor. This excitation, in turn, triggers a splitting of the Fermi

level for both the conduction and valence bands, thereby enabling the direct conversion of chemical energy into electricity. This effect is experimentally observable when the GaAs surface of a specially designed photovoltaic cell is exposed to liquid or vapor-phase methanol in the presence of oxygen or hydrogen peroxide, affirming the potential of the electrolyte-free fuel cell as a new technology in energy conversion. Excitation is also observed for H_2 and O_2 gases which are in-situ generated by splitting of water in KOH (0.05 M) solution in vicinity of the device surface using a separate potentiostat setup. Our findings not only demonstrate the feasibility of chemovoltaic energy conversion with renewable fuels but also suggest a pathway towards practical implementation. A deeper comprehension of the energy conversion process and its potential requires further endeavors in system optimization, cell design enhancement, and the exploration of pertinent materials and catalysts. The chemovoltaic fuel cell offers a unique and versatile platform for capturing energy ideally from a range of renewable chemical sources, potentially providing new solutions for the growing demand for sustainable power generation.

Covalent S-O Bonding Enables Enhanced Photoelectrochemical Performance of Cu2S/Fe2O3 Heterojunction for Water Splitting Artur Braun[1] and Jian Jun Wang[2]; [1]Empa, Switzerland; [2]Shandong University, China

Premature charge recombination and slow kinetic for oxygen evolution reaction have widely limited the application of hematite (α-Fe2O3) for water splitting. We designed [1] a Cu2S/Fe2O3 heterojunction and discovered that the formation of covalent S-O bonds between Cu2S and Fe2O3 can improve the photoelectrochemical performance and stability for water splitting. Compared with bare Fe2O3, the heterostructure of Cu2S/Fe2O3 permits the photoelectrode enhanced charge separation and charge transfer,and an extended range for light absorption, and decreased charge recombination rate. Additionally, due to the thermal properties of Cu2S, the heterostructure exhibits locally a higher temperature under illumination, profitable for increasing the rate of oxygen evolution reaction. Following this slight improvement, the photocurrent density of the heterostructure is enhanced by a factor of almost 2 to around 1.2 mA/cm^2 at 1.23 V versus reversible hydrogen electrode. This work may provide guideline for future in the design and fabrication of highly efficient photoelectrodes for various reactions.

5:00 PM EN09.04.01
Proton Incorporation and Electrical Leakage in $BaZrO_3$ and $BaCeO_3$ Andrew Rowberg[1], Meng Li[2], Tadashi Ogitsu[1] and Joel B. Varley[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Idaho National Laboratory, United States

$BaZrO_3$ (BZO) and $BaCeO_3$ (BCO) are among the best electrolytes for proton-conducting solid-oxide electrolysis cells (p-SOECs). Protons (H_i^+) are introduced via hydration of oxygen vacancies (V_O^{2+}) via the reaction $V_O^{2+} + H_2O \rightarrow 2H_i^+$. This reaction requires acceptor doping with an element such as yttrium (i.e., Y_{Zr}^-) to introduce V_O^{2+}. However, acceptor doping carries an additional consequence of increasing electrical leakage in devices, which can limit their Faradaic efficiency and performance in devices. To understand the factors leading to electrical leakage, we perform first-principles calculations based on density functional theory (DFT) with a hybrid functional. First, we study the properties of hole and electron polarons in BZO and BCO, finding that hole polarons form favorably in both materials, while electron polarons can only be stabilized in BCO and in Ce-containing alloys. In general, doped BZO and BCO will have low electron concentrations, but larger concentrations of hole polarons may be present. To reduce the resultant risk of *p*-type electrical leakage, we find it to be advantageous to avoid extreme O-rich conditions and high dopant concentrations.

In addition, high ionic conductivity in BZO and BCO relies on them having large proton concentrations. We study avenues to achieve this goal by calculating the formation energy of H_i^+ and how the concentration of protons and other relevant defects change under different experimental conditions. Proton concentrations will be highest under wet conditions, with V_O^{2+} becoming more dominant at drier conditions. Our results identify that higher protonation levels correlate with lower concentrations of hole polarons, implying lower electrical leakage with higher hydration levels. In addition to the protonation pathway mediated by V_O^{2+}, we also investigate an alternative mechanism via hydroxyl migration (OH_i^-). However, we find this process to be less favorable than V_O-mediated hydration except at extremely wet conditions.

Additionally, we study migration mechanisms for charge carriers near other defects or impurities as a proxy for grain boundaries, which play an important role in determining device performance. Our results suggest a complex behavior can result for mobile species like H_i, where migration kinetics can be influenced by other defects that may be present (e.g. cation vacancies) and compositional variation due to alloying. Our results provide crucial insights for understanding the complex behavior of these devices *in situ*. Determining how to promote ionic conductivity at the expense of electrical leakage is critical to optimizing their performance in p-SOECs and related devices.

This work was performed under the auspices of the U.S. DOE by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

5:00 PM EN09.04.02
Z-Scheme CBO@MoS_2 System for Enhanced H_2O_2 Photosynthesis with Mechanistic Insights Akshay Tikoo, Nikitha Lohia, S.S.C. Kondeti and Praveen Meduri; Indian Institute of Technology Hyderabad, India

Photocatalysts often have limited light absorption capabilities and suffer from rapid electron hole recombination[1]. This issue can potentially be addressed through suitable band edge line-up of two or more semiconductors, particularly z-scheme systems, which have superior charge separation and light harvesting properties[2]. The present study explores a z-scheme system with CBO (Copper bismuth oxide) and MoS_2 (molybdenum sulfide), which have good light harvesting abilities and efficient charge separation. CBO has a narrow bandgap, good light harvesting capability, and high negative conduction band potential[3]. However, pristine CBO has high charge recombination and unfavourable band edge line-up with the water oxidation reaction. MoS_2, a 2D material is recognized as an excellent co-catalyst for advanced oxidative processes with improved light harvesting, efficient interface charge transfer, and separation[4]. CBO@ MoS_2 is synthesized using two step hydrothermal method. The synthesized catalyst is characterized using several techniques, including XRD, Raman, PL, UV-Vis, and TEM. The catalyst has shown a significantly higher H_2O_2 production rate of 1457 µM h^{-1} and a current density of

-1.6 mA cm^{-2} at 0.2 V, both of which are an order of magnitude higher than the pure components. The improved photocatalytic activity of CBO@ MoS_2 is mainly attributed to the efficient separation of the electron-hole pairs due to staggered band alignment and the z-scheme heterojunction that retains the strong redox ability of both CBO and MoS_2. Mechanistic insight in H_2O_2 production is also provided using mott–schottky analysis, scavenger study and kinetic modelling.

Oxygen Evolution Reaction at Low Overpotential Catalyzed by Nanostructured CuO derived from 2 nm-Sized Colloidal Clusters generated by Laser Ablation at The Air-Liquid Interface Teppei Nishi, Shunsuke Sato, Takeo Arai, Yusuke Akimoto, Kosuke Kitazumi, Satoru Kosaka, Naoko Takahashi, Yusaku F. Nishimura, Yoriko Matsuoka and Takeshi Morikawa; Toyota Central R&D Labs., Inc., Japan

Because oxygen evolution reaction is one of the key factors for artificial photosynthesis of chemicals or fuels from CO_2, a lot of catalysts have been developed. Here, we report CuO catalyst derived from 2 nm-sized Cu based clusters prepared by laser ablation at the air-liquid interface using a colloidal solution as a target[1]. First, colloidal solution was prepared by laser ablation of Cu powder precipitated in a flask filled with pure water. Pulsed laser light was irradiated through the bottom of the flask. After laser irradiation for 1 h, we obtained colloidal solution. Then, laser ablation at the air-liquid interface using a colloidal solution was carried out. After laser ablation at the air-liquid interface, a drastic color change from black to a transparent green was observed. Scanning transmission electron microscopy image revealed monodispersed small cluster formation (ca. 2 nm). Colloidal clusters were stably dispersed in water without any chemical reagents for a few years. To investigate the electrocatalytic activity toward oxygen evolution reaction, colloidal solution was deposited on a carbon paper substrate. After deposition, X-ray diffraction pattern revealed $Cu_2(NO_3)(OH)_3$ formation on carbon paper. After pre-electrolysis in Ar-purged 1.0 M aqueous Na_2CO_3 solution (pH 11.3) at an applied potential of 1.72 V vs RHE for 1h, most of $Cu_2(NO_3)(OH)_3$ was changed into CuO. Tafel slope of 54 mV/dec and overpotential of 540 mV was required for 10 mA/cm^2 in Ar-purged aqueous 1.0M Na2CO3 solution. In addition to 1.0 M Na_2CO_3, electrocatalytic activity in KBi buffer (pH 9.2) was also measured. Tafel slope of 88 mV/dec and overpotential of 570 mV at 1.0 mA/cm^2 was required. In the stability test in both electrolytes for 24h, stable current density were recorded. Scanning electron microscopy images obtained after electrolysis revealed nanostructured CuO formation. Our catalyst exhibited the lowest overpotential for OER rather than those for the previously reported CuO catalyst.

Schiff Bases Complexes prepared from Polyethylene Terephthalate and Amine for Alkaline Water Electrolysis Tzu Hsuan Chiang and Si-Rong Xu; National United University, Taiwan

Alkaline water electrolysis is considered a viable technology for large-scale hydrogen production due to its use of non-precious metal catalysts. This process involves two half-slow-rate electrochemical reactions, the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER). In contrast to non-precious metal electrocatalysts, typically employed for acid-media reactions to enhance slow electrochemical activities, precious metals like Ir/Ru compounds for OER and Pt for HER are used. However, relying on such relatively scarce and precious catalysts is not advisable, as it significantly inflates the cost of hydrogen production and hampers future industrial scalability. Consequently, there is a pressing need to develop high-performance non-precious metal alternatives.

This study investigates metal Schiff base complexes derived from polyethylene terephthalate (PET) and various amines. PET materials have been used for packaging since the 1960s, with global consumption surpassing 24 million tons annually and continuing to rise. While PET's durability is advantageous, its downside is its slow biodegradation rate, taking up to 500 years to decompose in landfills when disposed of as waste. Unfortunately, many developing countries have low PET recycling rates.

PET is a condensation polymer synthesized from terephthalic acid (BDC) and ethylene glycol (EG). The degradation of PET was achieved through a solvent-assisted glycolysis process using EG to obtain BDC. BDC contains carbonyl groups capable of reacting with amine compounds to form Schiff bases. These metal Schiff bases are formed when Schiff base ligands' azomethine groups (–RC=N–) coordinate with metal ions. The study meticulously screened amines' chemical composition and compound ratios to identify those exhibiting optimal electrochemical properties. Furthermore, the study delves into the mechanism and effects of these Schiff bases on OER/HER.

Diverse Schiff bases were synthesized by combining terephthalic acid (TPA) with various amine compounds, including ethylenediamine (EDA), diethylenetriamine (DETA), triethylenetetramine (TETA), tetraethylenepentamine (TEPA), and pentaethylenehexamine (PTHA). In the context of alkaline water electrolysis, the two-electrode cell employing the unheated $Fe_{0.5}Cu_{0.5}Mo_{0.5}$-SB-TEPT @NF couple as both the anode and cathode exhibited higher levels of H_2 and O_2 production compared to the Pt/C and RuO_2 couple at 100 mA/cm^2.

The study expects that metal Schiff bases will demonstrate outstanding electrolysis performance in alkaline water electrolysis, offering innovative applications for PET recycling and contributing to the resolution of the waste PET problem.

5:00 PM EN09.04.05

Laser-Synthesis of Nanostructured Carbides Molybdenum Catalysts for HER/OER Reactions Guillaume Dubois[1], Fabien Grasset[2], Corinne Lagrost[1], Tetsuo Uchikosho[3], Franck Tessier[1], Nathalie Herlin-Boime[4] and Suzy S. Surble[4]; [1]Université de Rennes, France; [2]LINK, IRL3629 CNRS-Saint-Gobain-NIMS, Japan; [3]NIMS, Japan; [4]CEA, France

Platinium doped materials are very efficient for electrocatalytic reaction and H_2 production. However, platinum being a scarce and expensive element, carbides and nitrides could be an interesting alternative to make this technology economically viable. Indeed, transition metal carbides and nitrides demonstrate very interesting electrocatalytic properties, close to those of noble metals.[1,2] In this context, molybdenum (Mo)-based electrocatalysts materials are very promising and are currently attracting a growing interest in the energy field.

We report here the synthesis of molybdenum nitrides and carbides using the laser pyrolysis method for the overall water splitting reactions (hydrogen evolution reaction HER and oxygen evolution reaction OER)[3]. The laser pyrolysis process is a facile, scalable, environmental synthesis of small-sized, highly specific surfaces, well dispersed, and electrochemically accessible. The resulting Mo based materials were characterized with several

complementary techniques (XRD, SBET measurement, SEM, etc.). We also demonstrate that these materials show some electrocatalytic activity for HER reaction.

Sulfur-Doped Activated Carbon derived from Discarded Surgical Masks for High-Performance Supercapacitors Hsiu-Ying Chung and Zhi-Bin Huang; National Sun Yat-sen University, Taiwan

Consumption and discarded face masks are urgently driven by the spread of COVID-19 and the flu epidemic and general medical operations. To reduce the severe environmental pollution, the discarded surgical masks were recycled and subsequently prepared as high-added value supercapacitor electrode materials for energy storage. This study synthesized sulfur-doped activated carbon from the discarded face masks. Additionally, nanoscale manganese oxide was incorporated into sulfur-doped activated carbon to improve the electrochemical properties of supercapacitors. The resulting porous materials were analyzed using SEM, BET and XPS. Due to the synergistic effect of activated carbon and nanomanganese oxide, the capacitance of the hybrid electrode increased by more than 20%, and the capacitance retention rate was approximately 80% after 500 cycles.

5:00 PM EN09.04.07
Mechanistic Insight into Dual-Atom Catalysts for The Oxygen Reduction Reaction Courtney Brea[1] and Guoxiang (Emma) Hu[2]; [1]Queens College (City University of New York), United States; [2]Georgia Institute of Technology, United States

Incorporating a second transition metal to iron-nitrogen-carbon single-atom catalysts (Fe-N-C SACs) to design dual-atom catalysts (DACs) was demonstrated to offer a promising opportunity to enhance the oxygen reduction reaction (ORR). However, it has been challenging to clearly elucidate the structure–property relationship at the atomic level. Here we apply a computational workflow integrating configuration generations, phase diagram constructions, and reaction free energy calculations to provide an insightful understanding of the active site structures and catalytic mechanisms of ORR on DACs. Using Fe-Cu as an example, we generated all possible configurations by tiling the hexagonal lattice and investigate their atomic structures under reaction conditions. We find for a wide range of the electrode potential, the Fe site is covered by an *OH intermediate while the Cu site is not covered by any intermediates. With the OH-ligated structures, we identify the configurations which possess higher catalytic activity than Fe-N-C and Pt(111). We find ORR on Fe−Cu DACs proceeds via the associative pathway, and the desorption of *OH is the rate-determining step. Further analysis reveals a linear correlation between the limiting potential and the magnetic moment on Fe. These mechanistic insights pave the way for the rational design of efficient platinum group metal-free (PGM-free) catalysts for ORR.

5:00 PM EN09.04.08
Electrochemical CO_2 Reduction over Nanoparticles derived from an Oxidized Cu–Ni Intermetallic Alloy Tomiko M. Suzuki, Toshitaka Ishizaki, Satoru Kosaka, Naoko Takahashi, Noritake Isomura, Juntaro Seki, Yoriko Matsuoka, Keiichiro Oh-ishi, Ayako Oshima, Kosuke Kitazumi, Keita Sekizawa and Takeshi Morikawa; Toyota Central R&D Labs., Inc., Japan

Research and development on the electrocatalytic CO_2 reduction reaction (CO_2RR) to valuable hydrocarbons and alcohols has attracted great interest because of the potential to produce sustainable fuels. To date, copper (Cu) and Cu-based compounds are the most studied metal electrocatalysts that have demonstrated the ability to convert CO_2 and CO into large amounts of C2 and C3 molecules [1]. Furthermore, studies of Cu particle catalysts have reported that their particle size, crystalline phase, and morphology are highly correlated with C2 selectivity [2]. As one approach to control C2 selectivity on Cu catalysts, the use of Cu-based bimetallic alloys has been reported [3], especially the combination of Cu with CO-producing metal species such as Ag, Au, Zn, and Pd. On the other hand, combinations of Cu with hydrogen-producing elements such as Fe, Ni, and Pt have been reported to improve the activity and selectivity of hydrogen production compared to pure Cu electrodes, making it difficult to improve C2 and C3 activity with these combinations.
In this study, we demonstrate that Ni species have a positive effect on the formation of C2 compounds in the CO_2RR of Cu-based catalysts. To avoid size-dependent selectivity of copper catalysts, Cu-Ni interatomic alloy NPs (0-83 at% Ni as Ni/(Cu + Ni)) of various compositions with diameters around 10 nm were synthesized by one-pot and two-step synthesis using copper(II) acetylacetonate and nickel(II) chloride [4]. Since these Cu-Ni NPs were easily spontaneously oxidized in air at room temperature, these partially oxidized NPs were loaded onto carbon paper supports and used as electrocatalyst.
The electrochemical CO_2 reduction reaction was evaluated using a three-electrode system in a closed batch single-compartment reactor filled with 0.05 M $KHCO_3$ aqueous solution bubbled with CO_2. Electrolysis was performed at -1.2 V (vs. RHE) using a catalytic electrode as the working electrode, a Pt wire as the counter electrode, and an Ag/AgCl electrode as the reference electrode. The CuNi-NP was driven as a catalyst for hydrogen production in the early stages of the electrolysis, but activated into an excellent CO_2 reduction catalyst in the subsequent electrolysis. The dependence of the C2 selectivity on the Ni content was investigated using various activated Cu–Ni NPs electrodes. Activated Cu–Ni (3–32 at%-Ni) alloy nanoparticles enhance selectivity for ethylene and ethanol formation over oxide-derived Cu nanoparticles by electrochemical CO_2RR in aqueous solution. The Cu–Ni (19 at%) NPs exhibited 35% efficiency for C2 and the suppression of H_2 formation down to 9%. These results demonstrate that the addition of Ni to the Cu NPs facilitates C–C bond formation. The activated catalyst consists of metallic Cu, Cu–O, Ni, and Ni–O species, as confirmed by X-ray absorption spectroscopy measurements [5].
The present research suggests that further investigation is worthwhile to broaden the possibility of an unprecedented oxide-derived Cu–Ni and other CO_2RR catalysts.

Computational Chemistry on Investigating Copper, Nitrogen-Doped Graphene Catalyst for CO_2 Reduction Reactions Youjin Kim and Shiru Lin; Texas Woman's University, United States

With the growing use of fossil fuels, CO_2 emissions are also sharply increasing. This increase directly correlates to the recent global warming issues, affecting the environment, human survival, and development. the CO_2 reduction reaction (CO_2RR) is a potential solution to reducing CO_2 levels by converting CO_2 into fuels and raw materials. CO_2RR will not only be environmentally sustainable but will also be more economically sustainable. A CO_2 reduction reaction is a series of chemical reactions that converts CO_2 into potential products and applications. The products of CO_2RR include C1 products, such as CO, HCOOH, and CH_4, and C2+ products, including C_2H_4, ethanol. However, not all CO_2RR products are of equal importance and have similar

applications. For example, a C1 product, such as CH_4, or methane, is mainly used in natural gas and metal smelting. On the other hand, a different C1 product, CO, carbon monoxide, is used directly as fuel. Therefore, the selectivity of catalysts toward CO_2RR is crucial. Out of various catalysts, Cu stood out from the many catalysts for CO_2RR because of its appreciable CO_2RR catalytic performance. In our project, we use 4N@Cu, 4C@Cu, and 3C@Cu graphene material for CO_2RR by density functional theory (DFT) computations. In our research, we investigate different reaction pathways and products to see their reaction energies and find whether 4N@Cu, 4C@Cu, and 3C@Cu graphene are ideal catalysts for CO_2RR.

Deciphering The Activity of Co-, Fe- Co-Doped NiS supported on Carbon Cloth prepared via a Novel Strategy for Promoted Water Splitting
Ahmed E. Aboubakr, Amr Sabbah, Mahmoud K. Hussien, Kuei-Hsien Chen and Chen-Hsiung Hung; Academia Sinica, Taiwan

Water electrolysis via affordable and efficient electrocatalysts under industrial conditions plays a key role in large-scale green hydrogen production. Since the electrocatalysts may undergo undesired in-situ transformations under high current density, the fabrication of single-phase multi-element sulfides with desired composition is crucial and challenging for the development of sulfide catalysts. In this context, we developed a facile and scalable method to construct Fe and Co co-doped NiS supported on carbon cloth (Fe, Co-NiS-CC). A specific compound of metal sulfide was prepared that can be sprayed on the carbon cloth before being pyrolyzed, resulting in a specific phase of NiS directly attached to the substrate. The presence of dopants and the pyrolysis conditions could control the as-formed phase of NiS. The optimized electrode of Fe, Co-NiS-CC exhibits remarkable performance for industrial water splitting (6 M KOH, 70 °C), achieving a current density of 1000 mA cm^{-2} at a potential of about 1.698 V. The in-situ XAS and Raman measurements and the characterization of the post-electrocatalysts along with the theoretical calculations revealed that the high performance and long-term stability were attributed to the regulation of electronic configuration and the sustained single-phase of doped sulfides, directly grown on carbon cloth. Therefore, high-performance sulfide electrocatalysts can be stabilized by multi-element doping with the formation of polysulfide species that prevent the leaching of the elements and the destruction of the real active catalysts.

Metal Nanoparticles Supported on Hexagonal Boron Nitride Nanosheets as an Efficient Catalysts for Oxygen Evolution Reaction
Conghang Qu, George Bepete, Zhuohang Yu, David Sanchez and Mauricio Terrones; The Pennsylvania State University, United States

The oxygen evolution reaction (OER) is a crucial step in the electrochemical water-splitting process that can be used as a competitive and sustainable method for clean energy production, energy storage, and electrochemical sensing applications. However, due to the commonly sluggish kinetics of the OER steps, newer catalytic materials that can lower the reaction overpotential are pivotal to enhance the overall OER efficiency. In this work, ultrathin hexagonal boron nitride (hBN) nanosheets fabricated by a molten metal assisted intercalation method is used as the supporting structure for metal nanoparticle deposition, then employed as efficient catalyst material for OER in alkaline environments. Different metals and metal combinations including Pt, Pd, Ru, Fe, Ni, NiFe, PtAg, and PdAg are tested in these catalyst systems as dopant materials. Aligning with the goal of using non-precious metal-based catalysts as the alternative to the current benchmarks of Ir and Ru based OER catalysts, our hBN supported Fe nanoparticle sample exhibited competitive electrochemical performance and low overpotential. Additionally, annealing of the hBN supported Fe sample in Ar at 800°C showed further improvements of such catalytic activity and an increased current density. High-resolution transmission electron microscopy (HRTEM) was done to reveal the structural and crystallinity characteristics of the metallic nanoclusters and/or atomically dispersed metal atoms confined on the hBN framework. X-ray photoelectron spectroscopy (XPS) is carried out to characterize the changes of chemical valence state of the dopant metals before and after annealing to offer more insights into the OER reaction mechanism. Electrochemical cycling testing was conducted to evaluate the stability of the metal-doped hBN catalysts that could be applied to hydrogen fuel cells and/or metal-air batteries.

Solvent-Tailored Solvothermal Synthesis of 1T-VS_2 Nanostructured Electrode Materials for Electrochemical Energy Storage Applications
Rahul S. Ingole[1], Minwook Kim[1], Kwangjun Kim[1], Yongtae Kim[1], Snehal L. Kadam[2] and Jong G. Ok[1,1]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

This study explores the electrochemical energy storage properties of 1T-VS_2 nanostructured electrode materials synthesized via a facile solvothermal method using three different solvents: ethylene glycol, ethylenediamine, and N, N-dimethylformamide (DMF). The use of different solvents in solvothermal reactions offers several advantages, including better control over the surface morphology and size of the nanostructures, as well as the ability to synthesize nanomaterials on a variety of substrates. The solvent-mediated synthesized 1T-VS2 nanostructured electrode materials were characterized to explore the structural and morphological properties and composition of electrode materials via different analytical methods such as X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS), field emission scanning/transmission electron microscopy (FESEM/TEM), and Brunauer−Emmett−Teller (BET) for surface area analysis. Furthermore, the electrochemical energy storage performance of 1T-VS_2 electrode materials was investigated systematically in a 6 M KOH electrolyte. The results show the 1T-VS_2 nanostructured electrode synthesized using DMF solvent exhibits the highest specific capacitance of 753.21 F/g with 75.96% columbic efficiency at 20 mA/cm^2 current density compared to the others. The nanostructures also exhibited good long-term cycle stability, retaining over 87% of their initial capacitance after 1000 galvanostatic charge-discharge cycles. The enhanced specific capacitance and capacitance retention over a long cycle life justify the 1T-VS_2 nanostructures as superior electrode materials for electrochemical energy storage applications. For real-life demonstration, a symmetric prototype supercapacitor device has been fabricated using symmetric electrodes and an aqueous electrolyte. The symmetric device shows promising electrochemical energy storage properties.

Synthesized Transition Metal-Based Nanosheet Electrocatalysts for Alkaline Water Electrolyzers
Seunghun Lee[1], In Tae Kim[2], Yoo Sei Park[2] and Yangdo Kim[1]; [1]Pusan National University, Korea (the Republic of); [2]Chungbuk National University, Korea (the Republic of)

Hydrogen is a completely carbon-free energy source with high energy density and conversion efficiency, and it has become a promising alternative to fossil fuels. The best way to produce green hydrogen without carbon emissions is through water electrolysis. Water electrolysis involves two reactions: the oxygen evolution reaction (OER) and the hydrogen evolution reaction (HER). Although HER is produce hydrogen, production efficiency is more directly associated with OER.
The two most famous water electrolysis technologies are alkaline water electrolyzers (AWEs) and proton exchange membrane water electrolyzers (PEMWEs). The recently developed AEM electrolyzer exhibit both the advantage of AWE, PEM electrolyzers mentioned above. This electrolyzer can greatly reduce the ohmic loss using solid ionomer membrane and is operated in alkaline condition, allowing the use of non-precious metals as

electrocatalysts. Although, the cost of hydrogen production can be reduced by using non-precious metal electrocatalysts, the performance of AEM water electrolyzers is still lower than that of PEM electrolyzers due to the sluggish electrocatalyst kinetics for oxygen evolution reaction (OER). To overcome this obstacle, it is strongly necessary to develop high-performance and cost-effective OER elctrocatalysts.
In this study, we developed Cu(OH)2 nanosheets onto ZIF67 for OER electrocatalyst. The obtained material, labeled as CuOH2@ZIF67, improves its conductivity and intrinsic activity. In addition, the AEM electrolyzer equipped with CuOH2@ZIF-100 shows better performance at high current densities than that of RuO2 by reducing the mass transport of the AEM electrolyzer. Our approach is suitable for large-scale hydrogen production as an OER catalyst since it does not require precious metals and enables cost-effective, high-efficiency catalyst production through simple synthesis

Templated Multiwall Polycrystalline MoS_2 Nanotubes with Tunable S-Vacancies for High-Performance H_2 Evolution Reaction Yang Tian; University of Arkansas, United States

As the demand for clean energy intensifies, hydrogen (H_2) emerges as a leading candidate for next-generation energy solutions. Currently, the catalysis for the hydrogen evolution reaction (HER) predominantly relies on noble metals like platinum, which are scarce and economically unsustainable for large-scale applications. Consequently, there's an urgent need for cost-effective, abundant, and efficient catalysts. MoS_2, a low-cost material, has been identified as a potential platinum substitute due to its ability to significantly reduce overpotential in H_2 production. While 2D MoS_2 has demonstrated promising HER results, its synthesis via chemical vapor deposition (CVD) is costly and complex, hindering large-scale production. In this study, we present a novel approach to synthesize templated multiwall polycrystalline MoS_2 nanotubes using hydrothermal methods. Comprehensive characterization using XRD, EDX, and XPS confirmed the successful coating of MoS_2 on Titanate nanofiber surfaces. By controlling sulfur vacancies on the MoS_2 surface, we can modulate the HER performance. Our optimal conditions yielded an overpotential of approximately 280 mV at 10mA cm^{-2} with a MoS_2 coating ratio of 1 wt% when treated at 240°C for 5 days.

SUNER-C: Unlocking The Renewable Energy Future Nathalie Herlin-Boime[1], Nathan Coutard[2], Bert Weckhuysen[2] and Frederic Chandezon[3]; [1]CEA Saclay, France; [2]U Utrecht, Netherlands; [3]CEA - University Grenoble Alpes, France

How can we achieve the EU's goal of becoming the first climate-neutral continent by 20250? SUNER-C is a EU-funded Coordination and Support Action (CSA) aiming to contribute to this objective, targeting the next generation of energy carriers to replace fossil-fuels.
29 EU partners gather to work on building an ecosystem of companies, researchers, societal actors and policymakers, to accelerate the transition of technologies on solar fuels and chemicals, from the laboratory to large-scale industrial applications.
The main objectives of the project are:
Creation of an innovation ecosystem on solar fuels and chemicals
Develop a Strategic Technological Roadmap for the broad implementation in the industry and in society
Prepare a Large-Scale Research and Innovation (LRSI) initiative, ready to be launched after the CSA
Promote communication, dissemination and education of the next generation of Europeans
SUNER-C is an instrument for the SUNERGY community to develop and expand the innovation ecosystem working on the conversion and storage of renewable energy into fossil-free fuels and chemicals, both through indirect processes and direct conversion of solar to chemical and energy products.
The SUNERGY community, formed by +300 supporters, aims at developing a common vision and a technological roadmap for accelerating the scale-up of technologies, focusing on enabling a circular economy through developing closed carbon and nitrogen cycles.

Synthesis of MFI and BEA Type Zeolite Membrane Reactor Abduljelil W. Sabir and Pyung Soo Lee; Chung Ang University, Korea (the Republic of)

Zeolite membranes was found to be an appealing material for separation and catalytic chemical reactions considering suitable pore diameter, catalytic characteristic together with their thermal and chemical stability. This study presents fabrication of MFI type and BEA type single layer and MFI/BEA bilayer membranes. First both zeolite type crystals were prepared by hydrothermal reaction in a self-pressured autoclave reactor. Primary growth was conducted by seeding the zeolite crystals on porous α-alumina support. Thereafter, secondary growth solution was made accompanied by hydrothermal treatment for secondary growth. The manipulation of synthesis time and temperature was conducted in order to achieve a continuous and defect-free membrane, while also attaining the desired optimal thickness range of 5μm-7μm.Membrane morphology and thickness was characterized via FE-SEM. Furthermore, the performance of the membranes evaluated in pervaporation-assisted catalytic esterification of alcohol and carboxylic acid.

Interfacial Polymerization of Covalent Organic Frameworks for The Application of Ammonia Production Chi-Cheng Chen[1], Ming-Chung Wu[2,3] and Tz-Feng Lin[1]; [1]Feng Chia University, Taiwan; [2]Chang Chung University, Taiwan; [3]Chang Gung University, Taiwan

Novel supramolecular structural design, covalent organic frameworks (COFs), was determined by various exact chemical structures such as benzobisthiazole, benzene-1,3,5-tricarbaldehyde, benzene-1,4-diamine, or 2,4,6-Triformylphloroglucinol etc. derivatives. The one-pot synthesis of COFs was achieved from the monomers which was dissolved in the unmixed Brønsted acid and Brønsted base under the Schiff-base reaction system. NMR, TGA, DSC, SEM, PLM, FTIR, contact angle and X-ray scattering (SAXS/WAXS) were used to detect the relationship of effective ammonia production and intermolecular exchange reaction, in order to control the processing conditions. An overall understanding of the physical mechanism of COFs nafion film would be investigated according to the influence of the structural changes on the crystallinity as well as crystal phase morphology. Therefore, our work demonstrates a practical potential for COFs as an ammonia production platform.

On The Interplay of Quantum Capacitance and Pseudocapacitance in rGO with Regulated C/O Ratios Archana Sharma and Alok Shukla; Indian Institute of Technology Bombay, India

Supercapacitors have evolved as mature energy storage devices, utilizing graphene as electrodes to store charge electrostatically. During the process, electric double layers are formed at electrode/electrolyte interface, offering electric double layer capacitance (EDLC). Although large surface area and high conductivity of graphene are favorable for enhanced EDLC, intrinsically low quantum capacitance of graphene limits the overall performance. In recent years, reduced graphene oxide (rGO) has been increasingly gaining favor as an alternative material based on graphene owing to its cost-effective means of production. Experimental characterizations have identified abundant epoxy and hydroxyl functional groups on its basal plane, while hosting relatively fewer carbonyl and carboxyl groups at its edges. Interestingly, these oxygen-containing species on the surface of rGO serve as electrochemically active sites for enhanced pseudocapacitance in aqueous EDLCs. While rGO electrodes have demonstrated superior performance compared to graphene electrodes, the reported capacitances have shown inconsistent responses to different C/O ratio. This highlights the necessity to comprehend the impact of the degree of

reduction on the total capacitance and theoretical simulations can offer valuable insights to decouple the contributions to the total capacitance. Therefore, in this work, density functional theory (DFT) calculations have been employed for studying the capacitive behavior of rGO functionalized with epoxy and hydroxyl functional groups with different coverages on their basal planes. We have considered the cases for low-level, medium-level and high-level oxygen functionalization depending upon the C/O ratio. Under low-level oxygen functionalized graphene (LOFG), rGO with C/O ratios of 8, 6.4 and 5.33 are considered, while for medium-level oxygen functionalized graphene (MOFG) and high-level oxygen functionalized graphene (HOFG), rGO with 4.57, 4, 3.55 and 3.2, 2.9, 2.66 C/O ratios are considered, respectively. We have computed EDLC of rGO subjected to different degrees of reduction using implicit solvent model. The computation of EDLC from this method is validated by first calculating EDLC of graphene (116.52 Fg^{-1}) and compared with the experimental value (125-135 Fg^{-1}). Our calculations show that dispersed coverage of rGO with more of epoxy groups offer relatively higher EDLC than that with more of hydroxyl groups. However, in both the cases, EDLC decreases monotonically for decreasing C/O ratio. Quantum capacitances (C_Q) of LOFG, MOFG and HOFG are directly related to the changes in density of states (DOS) near the Fermi level. LOFG with more epoxy groups have zero bandgap, possessing higher C_Q while MOFG & HOFG with more hydroxyl groups have lower bandgap opening, possessing higher C_Q. As bandgap gets wider, maximum C_Q is obtained at higher voltages. OH-induced enhancement in quantum capacitance (C_Q) tends to be more dramatic with positive polarity because of relatively very low band gap than possessed by graphene with more epoxy functionals. Pseudocapacitance (C_{pseudo}) too exhibits the similar pattern, depicting decreased capacitance with decreasing C/O ratio. Such a behavior is explained by studying the variation in dipole moment and work function change. Maximum total capacitance is offered by rGO at C/O ratio of 5.33, well in accordance with an experimental study. Suppression of EDLC is mitigated by the enhancement in both C_{pseudo} and C_Q for LOFG while only increased C_Q compensates for MOFG. This study motivates future investigations into control and careful optimization of the oxygen content to balance the oxygen induced influences on electrical capacitance and quantum capacitance.

5:00 PM EN09.04.19
Gas Adsorption on Nanoporous Materials for Carbon Capture Applications: A First Principles Study Thomas Sadowski[1,2], Cristian Sayers[1,2], Ericka Barnes[1,2] and Christine Broadbridge[1,2]; [1]Southern Connecticut State University, United States; [2]CSCU Center for Nanotechnology, United States

The world's continued reliance on fossil fuels as the predominant energy source has remained almost unchanged despite significant advancements in renewable and sustainable energy technologies. This persistent dependence necessitates implementing focused initiatives to mitigate carbon dioxide emissions. Traditional carbon capture and storage technologies used in industrial applications rely on chemisorption between CO_2 and a suitable solvent; however, in recent years, physisorbent solids have emerged as an attractive alternative, offering notable energy-efficient benefits. The journey towards fully harnessing the inherent capabilities of these innovative materials is riddled with various obstacles and difficulties, as these materials can be costly to produce and evaluate, possibly limiting their discovery through traditional trial-and-error physical experimentation and observation. Hence, the utilization of computational techniques that possess the capability to forecast material properties effectively has immense value within this domain. The key figure of merit in determining the appropriateness of a specific material for carbon capture is the enthalpy of adsorption, the thermodynamic parameter characterizes the alteration in energy that occurs when a gas molecule adheres to a solid surface. In this study, the enthalpy of adsorption was calculated between the metal-organic framework (MOF) Cu-BTC and the components of ambient air (N_2, O_2, CO_2, and H_2O) within the plane-wave density functional theory (DFT) formalism. Cu-BTC is commercially available and has been intensely investigated for its potential as a sorbent material for post-combustion carbon capture as well as direct air capture applications. A variety of exchange-correlation functionals and van der Waals correction schemes were considered, and the calculated enthalpies were compared with existing experimental results. The goal of this study is the establishment of a computational workflow that can be extended to less well-studied materials such as MIL-100 (Al) and biochar, thereby providing theoretical insight into future experimental studies and increasing the range of materials potentially utilized in carbon capture methods.

5:00 PM EN09.04.20
Development of Vanadium Oxide/Manganese Sellenide Nanocomposite as Robust Bifunctional Electrocatalyst for Oxygen Evolution Reaction and Hydrogen Evolution Reaction Sumaira Manzoor, Safyan Akram khan, Shahid Ali and Muhammad Mansha; Interdisciplinary Research Center for Hydrogen and Energy Storage, King Fahd University of Petroleum, Saudi Arabia

For the expansion of alternative energy structure, it is crucial to develop a bifunctional electrocatalyst for the water splitting process. In this study, we present a novel nanocomposite of Vanadium Oxide and manganese Sellenide ((V_2O_5/MnSe) directly grown on copper foam (CF) using straightforward hydrothermal method, and then characterized via different analytical characteristics. After that the fabricated nanocomposite demonstrates the exceptional electrocatalytic activity for both the hydrogen evolution process (HER) and the oxygen evolution reaction (OER) in a 1.0 M KOH solution. At a current density of 10 $mAcm^{-2}$, V_2O_5/MnSe has exceptionally low overpotentials of 130 mV for HER and 217 mV for OER. Due to the protective properties of the V_2O_5 layers, the catalyst demonstrates exceptional stability of 50 h in alkaline environments. Furthermore, the fabricated nanocomposite V_2O_5/MnSe also shows the tafel slope of 44, and 69 mV/dec for OER and HER, respectively. Hence, the increased catalyst efficacy is a result of the synergistic interaction between the V_2O_5 and MnSe. On the other hand, the presence of MnSe nanoparticles dispersed precisely and inhibit the aggregation process effectively, maximizing active site exposure. In addition, the presence of V_2O_5 shields these exposed metal particles while increasing the material's electrical conductivity. This study reveals a feasible process for the production of bifunctional electrocatalysts with superior performance and stability. These findings introduce novel concepts for advancing the field of water splitting to produce green energy, which will contribute to the ongoing development of electrocatalytic technology.

5:00 PM EN09.04.21
Electrocatalytic Properties of Pulsed Laser-Deposited Titanium Dioxide and Titanium Oxynitride Thin Films Grown on Photo-Adsorbing Single Crystal Substrates with Different Orientations Sheilah Cherono[1], Ikenna Chris-Okoro[1], Swapnil Nalawade[2], Soyoung Kim[3], Jacob Som[4], Dhananjay Kumar[1] and Tanja Cuk[5]; [1]North Carolina Agricultural and Technical State University, United States; [2]Joint School of Nanoscience and Engineering, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Cornell University, United States; [5]University of Colorado at Boulder, United States

The research focuses on the growth of (photo)electrocatalytic titanium dioxide (TiO_2) and Titanium oxynitride (TiON) thin films epitaxially grown on single crystal substrates at different orientations. The films are used as catalysts to examine the eclectrochemical reactions during water-splitting with the aim of producing hydrogen.The films were grown using pulsed laser deposition (PLD), which has many advantages, including fast response time, energetic evaporants, and congruent evaporation. These advantages were used to determine the optimal growth conditions, which, when combined with careful substrate selection, led to oxide and oxynitride films with well-defined strain and well-controlled vacancies. Furthermore, since PLD can transfer the composition of the target having elements with vapor pressures as different as 10^6 from each other, it can enable the incorporation of non-Ti cations into TiO_2 and TiON (photo)electrocatalytic films. Soft X-ray absorption spectroscopy at the Ti L-edge, O K-edge, and N K-edge was collected on the TiON samples to obtain information regarding the electronic structure. This controls afforded by pulsed laser deposition (PLD) allows us to tailor the band edges of semiconductors and to evaluate the creation and evolution of water-splitting intermediates as a function of potential and/or photo triggers. This capability is then used to examine the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) mechanisms on oxide and oxynitride catalysts.

5:00 PM EN09.04.22
4-Electron Oxygen Reduction Reaction via Transition Metal Phthalocyanines Functionalized Three-Dimensional (3D) Fuzzy Graphene Seonghan Jo[1], Lance Kavalsky[2], Venkat Viswanathan[2] and Tzahi Cohen-Karni[1]; [1]Carnegie Mellon University, United States; [2]University of Michigan, United States

Rechargeable metal-air batteries and proton exchange membrane fuel cells are regarded as next-generation energy devices for clean power generation. However, the sluggish rate of the oxygen reduction reaction (ORR), attributed to its complex reaction steps, and the absence of cost-effective and highly stable electrocatalysts seriously restrict energy efficiency and commercialization of these devices. Recently, we reported that nanowire templated 3D fuzzy graphene (NT-3DFG) exhibited remarkable 2-electron ORR performance due to its hierarchical structure composed of exposed single-layer graphene edges that readily functionalized by oxygen in situ under alkaline ORR conditions. Here, we synthesized a highly improved electrocatalyst for 4-electron ORR by modifying the surface of NT-3DFG by iron phthalocyanine (FePc@NT3DFG). FePc@NT3DFG exhibited notable efficiency (half-wave potential of 0.910 ± 0.001 V vs. RHE), low selectivity (3.1 ± 1.0 % H_2O_2), and improved long-term stability (96.0 ± 0.2 % current retention at 30 hours). We attribute this performance to the interaction between Fe active sites and *in-situ* functionalized oxygen groups at the edge of graphene layers, adjusting the electro-configuration of Fe as well as stabilizing the atomic structure during the reactions. Moreover, additional transition metals phthalocyanine displayed the same tendency to favorable for 4-electron ORR. This work provides an increased understanding of tuning electro-configuration from graphene edge-based substrates for 4-electron ORR and offers directions for future electrocatalyst design.

5:00 PM EN09.04.23
Facile Synthesis of Ag_2S Quantum Dots for Energy Storage and Sensing Applications. Sharath S C[1], Naveen Narasimhachar Joshi[2] and M. N. Kalasad[1]; [1]Davangere University, India; [2]Centennial Campus North Carolina State University, United States

Herein, we report the synthesis of Ag_2S Quantum dots by co-precipitation method using the silver, thiol molecules (stabilizing agent) and sulfur (S) S-complex in molarities. The synthesized Ag_2S Quantum dots were characterized by different techniques by using optical absorption, wavelength tunable photoluminescence emissions in the visible range, FTIR, PXRD, TEM, HRTEM, SAED and EDX. From XRD patterns estimated particle sizes are found of 6.50 nm with a monoclinic phase of the Ag_2S quantum dots. The morphological study was made by performing transmission electron microscopy (TEM) images to confirm a spherical shape and the average particle size estimated from the micrographs is 7 nm. The electrochemical measurements as cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS) and Galvanostatic charge/discharge (GCD) and differential pulse voltammetry (DPV) profile in a three-electrode configuration system for prepared nickel mesh electrode. Initially, the CV curves of Ag_2S QDs electrodes were performed at scan rates ranging from 20 to 100 mVs^{-1}. A consistent enhancement in current responsiveness can be observed for 1M KOH electrolyte [27]. The regression values (R^2) of Ag_2S QDs (0.99807) are enhanced. These values signify a reversible and diffusion-controlled redox reaction of the electrodes. The impedance spectra demonstrated that charge transfer resistance (R_{ct}) is enhanced with a low capacitance value of Ag_2S. There is a distinctive depressed semicircle representing the charge transfer resistance in the high-frequency region, along with a slope that is associated with the Warburg impedance observed in the low-frequency range. Nyquist plot of Ag_2S electrode, after and before cycling was carried out [28]. Galvanostatic charge/discharge (GCD) exhibited supercapacitor performances with high specific capacitance at different current density (140 Fg^{-1} at 1 Ag^{-1}) with the potential window 0-4 V and it shows a maximum specific capacity compared to other reported sulfur-based materials. The potential generated in Ag_2S electrode was observed from GCD curves of the first 20 and 200 cycles. After 200 cycles of charge discharge, the coulombic efficiency of was 96% [22,29]. The Differential Pulse Voltammetry (DPV) technique was used to sense the tartaric acid of 0.1M with a linear range of 50 to 1000mM and shows the Limit of Detection about 84.9mM, this shows an extraordinary sensing behaviour of Tartaric acid in the KOH solution with the sensitivity of the sensor about 1.51×10^{-7} A/cm^{-2}, stability (25 days) and the surface coverage area is 7.23×10^{-10} mol cm^{-2}. This Organic acid sensor shows a high selectivity among (Oxalic acid, Citric acid, Mallic acid and Ascorbic acid)[. As a result, Ag_2S Quantum dots, synthesized through co-precipitation, show promise as high-performance supercapacitor electrode materials. They offer high capacitance and efficient charge transfer, making them a compelling alternative to toxic materials. Additionally, they exhibit remarkable sensitivity and selectivity as a tartaric acid sensor. Overall, this research underscores their versatility in energy storage and chemical sensing applications.

The Effective 2D Interlayer Architecture of Cu_2WS_4@N-Doped Graphene Nanocomposite for Oxygen Reduction Reaction and Rechargeable Zn-Air Battery Ranjith Balu[1,2], Debabrata Chanda[1,2], Mikiyas Mekete Meshesha[1,2], Seok Gwon Jang[1,2] and Bee Lyong Yang[1,2]; [1]Kumoh National Institute of Technology, Korea (the Republic of); [2]bGHS (Green H2 System) Co., Ltd., Korea (the Republic of)

A new research trend is exploring highly efficient and prolonged catalysts for oxygen evolution reaction (OER) and oxygen reduction reaction (ORR). Even though, it remains a considerable challenge to understand electrochemical performance enhancement in this field. Herein, we synthesized an interlayered architecture of Cu_2WS_4@NG nanocomposite and are reported as efficient cathode materials for flexible Zinc-Air batteries. Hierarchical porous interlayers create more active sites due to the unique interlayer architecture. As a result of the synergistic interaction between Cu_2WS_4@NG interfaces, the rate of charge transfer is facilitated, the number of active sites is increased, and OER/ORR kinetics is positively influenced in an alkaline environment. Theoretical studies indicate that the interlayered architecture tuning of the electronic structure of Cu_2WS_4@NG nanocomposite, which is significantly increases the electrical conductivity and catalytic activity. The prepared catalyst will be delivers an excellent half-wave potential for ORR and a low overpotential for OER. Furthermore, the quasi-solid state flexible ZACs will be fabricate and testing for commercial purpose.

More than a Matrix: Tailoring Catalytic Sites in Graphitic Carbon Nitride Joel R. Pennings, Mustafa Yavuz and Michael Pope; University of Waterloo, Canada

Graphitic carbon nitride (g-C3N4) is a promising multifunctional 2D material, especially popular as an eco-friendly and accessible catalyst in oxygen reduction reactions (ORR), hydrogen evolution reactions (HER), and fuel cells [1]. However, the application of g-C3N4 is restricted by a natively high e-/h+ recombination rate, poor conductivity, and low surface area, resulting in somewhat sluggish and limited catalytic performance. Research towards ameliorating these limitations has shown that coordinating metals in the lattice gallery space and non-metal substitutional doping are incredibly effective tools for tailoring selective and high-performing catalytic materials [2]. Critically, these tools are often studied in isolation or with sub-optimally prepared g-C3N4, which fails to address the various challenges holistically [3-5]. Our work demonstrates strong improvements in the baseline performance of g-C3N4 due to pre-polymerization supramolecular assembly coupled with extensive exfoliation. We also show that this g-C3N4 synthesis method is highly

compatible for both metals coordinated to the nitrogen lone pairs and substitution covalently bonded dopants. These results show uniquely tailored, catalytically active sites in the material, specifically improving the ORR and HER performance. Specifically, we fabricated exfoliated g-C3N4 nanosheets with transition metals (Fe/Na/Co/Mg/Pd) strongly coordinated to the active sites, which had been secondarily engineered via covalently bonded interstitial dopants (P/S). These materials were subjected to ORR and HER electrochemical assessments and traditional characterization techniques to preliminarily grasp the advantages and limitations of our material preparation procedures. These material variations offer a wide range of selectivity towards catalytic systems and applications while wholistically improving the catalytic performance and preserving the stability, and sustainability of the g-C3N4 system.

Rational Development of Nanostructured Catalyst with Tuneable Electronic Properties towards Electrochemical Ammonia Synthesis Ashmita Biswas and Ramendra Sundar Dey; Institute of Nano Science and Technology, Mohali, India

Ammonia, once a benchmarking element in fertilizer industries has now embarked into the energy sector as a potential carrier of H_2 as a fuel. This has significance to achieve the "NET-ZERO" targets of the society, towards sustainability. It is noteworthy that, the electrochemical ammonia synthesis is capable of reserving green hydrogen that is being sought nation-wide as an alternative of the non-renewable energy sources. Ammonia in itself can act as a fuel or it can be dehydrogenated to extract the H_2 enabling a circular economy. In the current frontier of the world, this holds utmost importance as the storage, handling, transportation and shipping of this green ammonia is comparatively cheaper that liquid hydrogen and hence of potential interest. However, the demand of green ammonia production is although high but the electrochemical methods and components require rigorous optimizations to attain the desired goal.
In this realm, our group works on the development of electrocatalysts and electrode-electrolyte systems capable to overcoming the rate-limiting steps of the electrochemical ammonia synthesis by nitrogen reduction reaction (NRR) at the cost of low energy barrier. Since NRR is a complicated multi-stepped process, we have ventured that the elementary steps and the reaction kinetics heavily depend on the electronic properties of the catalyst impacting the binding strength of the intermediates on the electroactive site. The descriptors include the position of Fermi level and metal d-band center, work function, density of states, charge distribution and polarizability that not only dictate the activation of N_2 (which is very difficult otherwise) and also determine the reaction pathway. In our case-studies, it has been observed that the catalyst designing with hetero-atom doping, interface engineering as well as vacancy engineering has been proven to be efficient in provoking N_2 adsorption over proton adsorption over the active site. A better proton adsorption initiates hydrogen evolution reaction (HER) that lowers the possibility of NRR on catalyst surface with a sacrificial NH_3 yield rate and Faradaic efficiency (FE). With the differential atomic polarizability in our developed systems, we are able to deviate this HER path to adjacent atoms, while preserving the active center for NRR. This is how we tend to improve the NH_3 yield rate and FE upto the industrial scale periphery.
Finally, we have developed an electrolyzer with which we are able to control the overpotential of the NRR. Basically, the electrocatalysts are not strong enough to break the even stronger N≡N. So, a huge power input incurs sufficient energy consumption to produce the value-added ammonia, which ultimately becomes equivalent to that consumed in the Haber-Bosch process. However, with the developed electrolyzer system, we are able to manipulate the kinetics of the NRR-coupled-oxygen evolution reaction and the less overpotential enabled a better electrical to chemical energy conversion efficiency of the system, which has potential to be commercialized and scaled-up to meet the industrial scale demands of ammonia.

Modulating Active Sites in Metal Oxides for Deeper Insights into CO_2 Reduction Amr Sabbah[1], Thang Q. Nguyen[2], Kuei-Hsien Chen[2] and Li-chyong Chen[1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

The pursuit of CO_2 reduction through catalytic processes holds significant promise in addressing climate change. Metal oxide-based catalysts are among the most promising candidates, as they provide invaluable insights into reaction mechanisms and subsequent catalytic enhancements. This presentation delves into the intricate world of active site modulation within metal oxides especially the n-type semiconductor of the Aurivillius oxides family, a pivotal aspect for a deeper comprehension and optimization of CO_2 reduction. Through the systematic manipulation of these active sites, we uncover essential insights into the mechanisms governing CO_2 reduction and its fine-tuning. This study explores a range of modeling approaches, including the manipulation of oxygen vacancies, dopants, heterostructuring, and single atom modifications, each contributing distinct effects to tailor the catalytic properties of metal oxides and enhance their performance in CO_2 reduction. By dissecting these methodologies, our objective is to advance our comprehensive understanding of active site modulation and its pivotal role in the development of efficient and sustainable CO_2 reduction technologies.

Microwave-Assisted Molten Salt Synthesis of Chevrel Phase Chalcogenides Ankita Kumari, Johnathan D. Rivera and Jessica C. Ortiz-Rodriguez; University of California, Davis, United States

The increase in energy demand has brought the challenge of developing efficient energy-conversion technologies. Currently, natural gas reforming is the most common method to generate hydrogen fuel, but this process is energy-consuming and also releases greenhouse gases into the atmosphere. Renewable hydrogen production has long been considered a clean energy carrier and a highly promising alternative to transition away from fossil fuels. Alternatively, electrochemical proton reduction is a sustainable and green method for producing hydrogen gas – a process that leaves virtually no carbon footprint when coupled to renewable sources of electricity. Chevrel phase (CP; $M_xMo_6S_8$; M=alkali, alkaline earth, transition, and post-transition metal), a class of molybdenum chalcogenides are especially attractive due to their tunable composition and lower coordination on their molybdenum moieties which has led to previously observed catalytic activity for oxygen evolution, hydrogen evolution, and CO_2 reduction reactions. Theoretical studies under various reaction conditions agree that proton adsorption interactions in the chevrel phase occur through the undercoordinated chalcogen-molybdenum bridging site. Hence, reducing the size of the CP particles will increase the surface-to-volume ratio exposing a more undercoordinated Mo-S bridging site for proton adsorption. Traditionally CPs were synthesized by high-temperature solid-state reactions which can take several days and require extremely high-energy input. Although some approaches have been made to reduce the preparation time of CPs, the methods either suffer from uncontrolled particle size, high level of agglomeration, presence of MoS_2 impurities, or high energy input. This work presents an efficient route to synthesize size-controlled ternary Chevrel phase chalcogenides ($Cu_2Mo_6S_8$) by a microwave-assisted molten salt approach. This methodology has significantly reduced the reaction times from days to minutes resulting in significant time and energy savings yielding highly crystalline, faceted morphology of CPs. The phase, morphology and surface chemistry of the resultant materials were characterized by X-diffraction (XRD), scanning electron microscopy (SEM), Energy dispersive X-ray Spectroscopy (EDX), and X-ray photoelectron spectroscopy (XPS). The electrochemical reactions were done in a three-electrode cell with Ag/AgCl as the reference electrode, graphite as the counter electrode, and catalyst ink on Toray paper as the working electrode.

Dispersion and Stability Mechanism of Heterogeneous Catalysts Sang-Wook Han[1], Eun-Suk Jeong[1] and In-Hui Hwang[2]; [1]Jeonbuk National University, Korea (the Republic of); [2]Argonne National Laboratory, United States

The dispersion and stability of noble-metal catalysts on transition-metal-oxide supports are considerably important for practical applications of the catalysts. Pt nanoparticles are uniformly and highly dispersed on transition-metal oxides when hydrogen peroxide (H_2O_2) is applied before calcination at 500 ºC**.** The influence of H_2O_2 on the dispersion and the stability of Pt nanoparticles on titania-incorporated fumed silica (Pt/Ti-FS) supports was examined using in-situ X-ray absorption fine structure (XAFS) measurements at the Pt L_3 and Ti K edges as well as density functional theory (DFT) calculations. The local structural and chemical properties around Pt and Ti atoms of Pt/Ti-FS with and without H_2O_2 treatment were monitored using *in-situ* XAFS during heating from room temperature to 500 ºC. XAFS revealed that the Pt nanoparticles of H_2O_2-Pt/Ti-FS are highly stable and that the Ti atoms of H_2O_2-Pt/Ti-FS support form into a distorted-anatase TiO_2. DFT calculations showed that Pt atoms bond more stably to oxidized-TiO_2 surfaces than they do to bare- and reduced-TiO_2 surfaces. XAFS measurements and DFT calculations clarified that the presence of extra oxygen atoms due to the H_2O_2 treatment plays a critical role in the strong bonding of Pt atoms to TiO_2 surfaces.

Enhanced Photocatalytic Reduction of CO_2 to CO Using $Cs_3Bi_2Br_9$/g-C_3N_4 Direct Z-Scheme Heterojunctions Yasmine Baghdadi and Salvador Eslava; Imperial College London, United Kingdom

Lead-free halide perovskite derivative $Cs_3Bi_2Br_9$, has proven to possess optoelectronic characteristics suitable for photocatalytically reducing CO_2 to CO. However, further research is needed to boost the separation of charges in order to improve the overall efficiency of this photocatalyst. This study presents the synthesis of a hybrid heterojunction composed of inorganic and organic materials, combining Cs3Bi2Br9 with g-C_3N_4 at various ratios. This was accomplished by growing $Cs_3Bi_2Br_9$ crystals on the surface of g-C_3N_4 using a straightforward antisolvent crystallization method. The resulting powders demonstrated increased photocatalytic CO_2 reduction in the gas phase with water vapor, producing 14.22 (±1.24) μmol of CO per gram per hour with a 40% $Cs_3Bi_2Br_9$ content, compared to 1.89 (±0.72) and 5.58 (±0.14) μmol CO g^{-1} h^{-1} for pure g-C_3N_4 and $Cs_3Bi_2Br_9$, respectively. Photoelectrochemical measurements revealed enhanced photocurrent in the composite further proving improved charge separation. Additionally, stability tests showed that the heterojunction remained structurally stable even after 15 hours of illumination. Analysis of the band structure alignment and selective metal deposition indicated the formation of a direct Z-scheme heterojunction between the two semiconductors, which led to a significant improvement in charge separation and an overall enhancement in CO_2 reduction.[1]
