Tutorial ASM.01: STEM-in-SEM—From Basic Transmission Imaging to Rigorous Quantitative Analysis
Session Chairs: Jason Holm and Gopal Rao
Saturday Morning, April 17, 2021
ASM

9:00 AM *
STEM-in-SEM—From Basic Transmission Imaging to Rigourous Quantitative Analysis Jason Holm;
National Institute of Standards and Technology, United States

Scanning electron microscopes and solid-state transmission electron detectors are widely available and generally easy to use, making the collection of imaging techniques referred to as Scanning Transmission Electron Microscopy in a Scanning Electron Microscope (STEM-in- SEM) more accessible today than ever before. These techniques are well suited to a host of transmission imaging applications including nanoparticle metrology, imaging beam-sensitive materials, grain texture studies, and defect analyses, for example. In this tutorial, we will describe how to obtain both qualitative and quantitative information from different transmission detectors including secondary electron conversion devices, different solid-state detectors, and a recently-developed programmable STEM (p-STEM) detector.

The first part of the presentation will briefly describe some of the pros and cons of low energy STEM-in-SEM imaging (i.e., with primary electron energies <30 keV). Different transmission imaging modes that can be accessed in a conventional SEM, and the types of information that can be gleaned from those modes will also be described. The importance of acceptance angle control will be emphasized. To that end, and because most commercially available STEM-in- SEM detectors enable only a few acceptance angle options, a straightforward and economical mask/aperture system [5] that can be adapted to most transmission detectors will be described. We briefly demonstrate how this approach can be used with a rudimentary solid-state STEM detector to obtain different imaging modes, and to quantify electron scattering distributions (i.e., diffraction patterns, Fig. 1b) for material systems amenable to this type of signal collection.

The second part of the presentation will emphasize an on-axis, pixelated detector for programmable scanning transmission electron microscopy (p-STEM). The apparatus includes a digital micromirror device (DMD) that enables imaging and diffraction in a single detector by directing different parts of the signal to different sensors. A CMOS digital camera is used to image the diffraction pattern, and a photomultiplier tube (PMT) synchronized with the microscope scanning system is used to generate a real space image by integrating (pixel-by-pixel) a portion of the diffraction pattern defined by the user. In effect, the DMD replaces the objective aperture in a transmission electron microscope (TEM) or an annular detector in a scanning transmission electron microscope (STEM). However, the DMD has the distinct advantage that arbitrary user-definable patterns (i.e., virtual apertures) can be programmed to it in real time, meaning that conventional imaging modes can be used to obtain quantifiable contrast and that non-conventional imaging modes can easily be explored. Detector operation is demonstrated by showing qualitative and quantitative information obtained from diverse samples including conventionally thinned (electropolished) stainless steel, oriented Au and Si films, and 2-dimensional materials. We will also show how the detector can be used to obtain information about the microscope including beam convergence angle and electron column alignment.

The third part of the presentation will present alternative and emerging imaging methods. For example, we will demonstrate how ptychography can be implemented in an SEM, how thermal diffuse scattering can be used as a local temperature probe, and different ways to ascertain sample strain.

Tutorial ASM.02: The Fundamentals of Nanoprobe Analysis
Session Chairs: Randal Mulder and Gopal Rao
Saturday Afternoon, April 17, 2021
ASM

5:00 PM *
The Fundamentals of Nanoprobe Analysis Randal Mulder; Silicon Labs., United States

As semiconductor technologies continue to decrease in size and the number or metallization layers increase, traditional methods for localizing the failure mechanism in failing semiconductor circuits such as micro-probing or light emission are severely limited if not impossible to perform. In response to this situation, nano-probe technologies have been developed to overcome this obstacle. In this tutorial, both AFM based and in-situ beam tool based (FIB/SEM) nano-probe technologies will be reviewed. Techniques for the characterization and identification of common semiconductor defects will be presented. Case studies for several types of defects will also be presented.

Tutorial BI01: Industry's Current Approaches to Sustainable Practices and Strategic Planning for a Sustainable Future
Session Chairs: Tia Benson Tolle, Carolyn Duran, Yvonne Kavanagh, Daniel Steinberg and Jeffrey Whitford
Saturday Morning, April 17, 2021
BI01

9:00 AM *
Intel’s Strategy for Corporate Responsibility—Responsible, Inclusive, Sustainable, Enabling Carolyn Duran; Intel Corporation, United States

Intel Corporation is a recognized leader in corporate responsibility and has a long history in taking action to advance progress in environmental sustainability, supply chain responsibility, diversity and inclusion, and social

impact. In this session we will demonstrate how Intel continues to raise the bar for ourselves in our own operations and supply chain, and the impact this has with our customers and society. This will include a deeper discussion on Intel's key actions in climate and energy, zero waste, and the circular economy. Additionally, we will share strategies around technology industry initiatives to accelerate change and adoption of best practices in responsible minerals, sustainable manufacturing and sustainable chemistry.

10:30 AM BREAK

10:45 AM *
Millipore Sigma and Data Driven Sustainability Planning Jeffrey Whitford; Merck KGaA, Germany

The instructor will discuss the need for quantification and how this is implemented in Merck with the DOZN quantitative analysis tool. He will address the question 'How do you embed quantitative analysis in the academic arena as a key lever for change?' and discuss the following topics:
Making data availability to the masses to encourage informed decision making
Creating and implementing sustainable design principles to drive change
Connecting the dots back to customers to understand the impact and opportunities for change.

12:15 PM BREAK

12:30 PM *
Sustainable Materials and Manufacturing in the Aerospace Industry Tia Benson Tolle and Kelsea Ballantyne; The Boeing Company, United States

Boeing recognizes climate change is a fundamental global challenge, and as we enable people to move freely across the planet we recognize the need to reduce the impact of flying. We are reducing carbon emissions and using resources efficiently through innovative solutions across our product life cycle, in our factories and at work sites. Additive manufacturing, also known as 3D printing, is changing the way we design and build products with fewer raw materials, creating less waste and improving fuel efficiency in our products. Innovative materials and processes are improving product efficiency in several ways. This session will discuss technical challenges and opportunities for sustainability in the aerospace materials and manufacturing industry.

SESSION BI01.01: Innovative Approaches I
Session Chairs: Ivana Aguiar and Daniel Steinberg
Sunday Morning, April 18, 2021
BI01

8:25 AM *BI01.01.02
Incorporating Uncertainty in Materials Industrial Ecology Elsa Olivetti; Massachusetts Institute of Technology, United States

The answer to most questions in environmental assessment for materials choice particularly around materials recovery is, “it depends”. This presentation will focus on sustainability in curriculum within the materials science community and how we enable students to embrace the complexity of sustainability assessment while feeling entirely dissatisfied with the analytical methods used by practitioners. Examples will be drawn from impacts of materials choice on all aspects of the life cycle considering the context in which the material operates and on strategies for addressing and/or mitigating the impact of materials based on industrial ecology principles including dematerialization, substitution, and waste mining. This presentation will focus attention on how one might incorporate variation and uncertainty methodology in course work to account for the context in which the

material operates to understand the appropriateness of a particular mitigation strategy.

8:50 AM *BI01.01.03
Assessing the Contribution of Higher Education Programmes to the UN Sustainable Development Goals (SDGs) Vasiliki Kioupi and Nick Voulvoulis; Imperial College London, United Kingdom

Universities are engines of societal transformation and can nurture future citizens and navigate them towards sustainability through their educational programmes. In this talk, we will present an assessment framework we developed as part of our research at Imperial College London that Higher Education institutions can use to evaluate the contribution of their educational programmes to sustainability by reviewing the alignment of their intended learning outcomes (LOs) to the Sustainable Development Goals (SDGs) and the attainment of those LOs by students. The tool is based on a systemic grouping of the SDGs into eight sustainability attributes, namely, Safe Operating Space, Just Operating Space, Resilient Sustainable Behaviours, Alternative Economic Models, Health and Wellbeing, Collaboration, Diversity and Inclusion, and Transparency and Governance. Application of this tool in forty (40) environment and sustainability related Master's programmes highlighted gaps and areas for further consideration. In addition, we will present results on the application of the tool in a University case study to highlight how it can inform data driven decision-making around interventions to improve the integration of SDGs into curricula and the uptake of sustainability competences by students.

SESSION BI01.02: Online Teaching and Computational Resources
Session Chairs: Ivana Aguiar and Daniel Steinberg
Sunday Morning, April 18, 2021
BI01

10:30 AM *BI01.02.01
Materials Science for Sustainability—From Research Lab to Student Engagement Eva Hemmer; University of Ottawa, Canada

Today's world faces global challenges, such as Societal Health, Environmental and Energy Concerns, that urgently have to be addressed for a sustainable development. While none of these concerns is easy to solve, material scientists are designing the building blocks that are key to sustainable energy and health strategies. Advanced optical materials act as novel optical bioprobes for reliable and early diagnosis of diseases or therapies. Novel optoelectronic/magnetic nanomaterials will increase device efficacy and endow them with yet unseen multifunctionality (photocatalysts, solar, storage devices). Herein, the remarkable optomagnetic properties of the rare-earths (RE) make RE-based materials ideal for biomedical and energy applications. Yet, challenges remain; low emission intensity and efficiency of small nanoparticles (NPs), and reliable and fast synthesis routes. As materials chemists, we are tackling these challenges with new designs of next-generation RE-NPs, accompanied by chemically controlled synthesis, application-oriented surface chemistry, and understanding of structure-property relationships.
While these research activities contribute to sustainability awareness of the small group of students working in our lab, the covid-19 pandemic has triggered a new format of teaching that has the potential to reach larger groups of students, raising their awareness of sustainability. This is the need to transform in-person classes into online courses. While this comes with new challenges, new opportunities arise: Seminar-style lectures for senior undergraduate and graduate students with experts from the fields of energy, environment, chemistry, physics and engineering were found to become popular at the University of Ottawa for students and educators alike. Will this new format of teaching find its permanent place in science curricula?
And how can we reach out further? The MRS Student Engagement Sub-Committee of the Academic Affairs Committee supports student-led activities at MRS events, including networking, science communication, and professional as well as personal development.[1] This presentation will briefly introduce activities and

opportunities to interested students and senior mentors.

10:55 AM *BI01.02.02
Teaching Sustainable Development to Engineering and Materials Students Tatiana Vakhitova, Marc Fry and Mauricio Dwek; Ansys Granta, United Kingdom

The Ansys Granta EduPack has supported undergraduate sustainability related teaching since 2007 with the introduction of an Eco Audit Tool – a teaching focused streamlined Life Cycle Assessment (LCA) Tool. The tool enables the energy and CO2 emissions from each phase of a products life to be visualized, and the costs associated with each stage to be estimated. Based on positive educator and student feedback, in 2013 a new sustainability database was created that contains materials and process data with eco properties, socio-economic data on nations of the world, as well as legislation and regulations related to materials. Further development added data on critical materials and materials risks.
This was followed in 2019 by the creation of a prototype Social Impact Audit Tool, which follows closely UNEP/SETAC guidelines on social life cycle assessment of products.
These existing and new developments aid teaching of courses on sustainable product design, sustainable engineering and many others, providing simple frameworks, tools and data to help students analyze complex sustainability systems and have informed discussion.

11:20 AM BI01.02.03
Materials Science Training Programs for Students and Masters with a Specialization in Electronics and Nanoelectronics Sergey M. Karabanov[1], Irina M. Kuvakova[2] and Yuriy Merkulov[1]; [1]Ryazan State Radio Engineering University, Russian Federation; [2]Social Sciences Institute, Russian Federation

Each stage of the social development creates its own set of intellectual, innovative directions in education. Currently, these areas are: artificial intelligence with the use of digital education (DE); A/B split testing in SEO-DE; video marketing in DE.
The development of materials science largely determines the development of the production of new materials for all areas of human life: medicine, building industry, transport, etc.
Materials science in the education system, especially in the field of electronics and nanoelectronics, ranks high. This is due to both the development of directions in instrument manufacture in the field of electronics and nanoelectronics (MEMS, NEMS, ultracapacitors, etc.), and invention and development of new materials (e.g, graphene). Creation of new methods and equipment for obtaining materials and testing their characteristics is also of great importance.
The paper considers the development of methods and programs for teaching materials science in the field of electronics and nanoelectronics using modern teaching methods (artificial intelligence, split-testing). The acquisition of the information during teaching depends on the initial level of preparation of the trained personnel. Therefore, educational programs correspond to different levels of preparation of the trained personnel: bachelors, masters, students of upgrade training courses. The role of online education, particularly, in teaching materials science is considered.

11:35 AM BI01.02.04
Incorporating Sustainability in Material Science Education—Adapting Computer Aid Programs in Teaching Materials Sustainability Burcu Ozden; The Pennsylvania State University, United States

In the century just ended, engineering recorded its grandest accomplishments. Despite these advances, the human being is face to poses challenges in the upcoming centuries. As the population grows and its needs and desires expand, the problem of sustaining civilization's continuing advancement, while still improving the quality of life, looms more immediate. The world needs engineers who will seek ways to put knowledge into

practice to come over the problem of sustainability. It is of great importance to incorporate concepts of sustainability into material science classes. In this work, I focus on the use of the sustainability component of SolidWorks, a Computer-Aided Design (CAD) tool, in teaching materials sustainability in online classes. The case study presents the virtual model of the product, the software capabilities, and the settings that have to be done for sustainability analysis and the results shown by the software.

11:50 AM BI01.02.05
Practices of Developing Undergraduate Curriculum on Green Engineering—Materials and Environment to Promote Active Learning Kaka Ma; Colorado State University, United States

As sustainability in product development and the relevant environmental impact raised increasing global attentions, it is critical to educate and train future workforce with the principles of green engineering and how to incorporate the principles in a broad context of science and engineering fields. This presentation will focus on development of undergraduate curriculum to incorporate sustainability into materials science education and the relevant pedagogy, including the online course - distanced learning session. I will share the experience of developing an undergraduate course on green engineering – materials and environment as a technical elective for engineering students and the feedback from the students. I will talk about three important aspects: link sustainability to the early design process, address the need of green engineering in the market, and integration of eco audit in CES Edupack in students' projects. Particularly, including some topic options on unrealistic materials in the project, e.g., the "uru metal" for Thor's hammer from Marvel comics, turned out to be an effective pedagogy to motivate the students to look into the sustainability of material selection and processing, as well as to engage active learning.

SESSION BI01.03: Outreach Activities
Session Chairs: William Olson and Daniel Steinberg
Sunday Afternoon, April 18, 2021
BI01

1:00 PM *BI01.03.01
Learning Through Making—Integrating Makerspaces and United Nations Sustainable Development Goals in Science Learning Sara Rodriguez Martinez; ETH Zürich, Switzerland

Science thrives through the making of discoveries, building experiments, developing theories, solving problems. We are driven by all of these actions, but are we always taught that way? The theory of learning through making is not new; constructionism, or the education theory which focuses on how the making of artifacts supports the learner's understanding of science, has been around for decades. Unfortunately, there's little support on how to successfully turn theory into practice. In this talk, we will explore how to integrate learning through making in science learning, applicable to both formal and informal learning situations. We will look into finding support in community-led initiatives such as makerspaces and how to interact with such organizations to make our programs better. Makerspaces or Tinkerlabs are now ubiquitous all around the world, as their project-based nature fosters creativity, confidence and other necessary 21st Century Skills. Finally, we will draw from the United Nations Sustainable Development Goals for topics, projects and demo development, and how to turn them into a common ground for all of your science communication efforts.

1:25 PM BI01.03.02
The Big Compost Experiment—Using Citizen Science to Engage with the Public About Biodegradable Plastics Danielle Purkiss, Ayse Allison, Fabiana Lorencatto, Susan Michie and Mark A. Miodownik; University College London, United Kingdom

In 2018 the UK Plastics Pact set a target to make all plastic packaging 100% recyclable, reusable, or compostable, and to eliminate all unnecessary single-use packaging by 2025 [1]. Including compostable plastics in the target was important for two reasons: firstly, there are some items such as food packaging, wipes, tea bags, coffee pods, sachets, that being small and highly food contaminated are not to suited to recycling or reuse; secondly, food waste is of major environmental importance and compostable liners play an important role in the route out of the home (government target for all UK households by 2023). But there is a fundamental problem. The biodegradable sector is currently the "wild west" of plastic packaging not just in the UK but also internationally. These materials are largely unregulated, the environmental claims around them exaggerated and the identification of them problematic. Nevertheless, these materials are starting to displace recyclable plastics such as PET due to their popularity with the public and brands. The displacement of reusable or recycling products is not the only problem, contamination of other waste streams is another: compostable plastics are currently incompatible with most Anaerobic Digestive, Industrial Composting systems and recycling systems [2]. Plastics Europe estimate the global market for biodegradable plastics is set to grow to 1.3 million tonnes in by 2023 [3] but it could be much greater if small item formats such as compostable snack packets and chocolate wrappers are produced to meet the Plastic Pact target.

The Big Compost Experiment (launched November 2019) [4] uses a citizen science approach to gather qualitative data on UK citizens' opinion and behaviour towards biodegradable plastics and food waste strategies, and quantitative data about the performance of these items under UK home composting conditions. We engaged with more than 8000 citizens and report data from more than 300 home compost experiments from all over the UK [4]. This paper uses an interdisciplinary approach to data collection and analysis, and the evaluation of quantitative statistical and qualitative behavioural experiment data, and fits within a broader context of circular economy research and participatory citizen science.

Our citizen science research shows that 84% of UK households taking part reported that they are more likely to choose products that are marked as "biodegradable" or "compostable" but they are confused about what they are and how to dispose of them. We report on the fate of the biodegradable plastics tested, the majority of which did not fully biodegrade within a home composting environment [4]. We reflect on the role of citizen science in engaging with the public about behaviour change and the materials science of packaging.

1:40 PM DISCUSSION TIME

1:55 PM BI01.03.04

Raising Awareness About Materials Sustainability—Life Cycle Analysis as an Example Ivana Aguiar, Isabel Galain, Romina Keuchkerian, Maia Mombru and Maria Perez Barthaburu; Universidad de la República, Uruguay

When a consumer is faced with the decision of using a product made of a material or another, there are some preconceived ideas and an excess of information. Should I use a plastic or a paper bag? What factors should I consider? We designed and developed an activity for the general public in the University Chapter Udelar framework, which was carried out in different instances like the Heritage Day or the International Day of Women and Girl in Science in Uruguay. The objective was to help the consumers to make these decisions, providing information about life cycle analysis of different products, and explaining its concept and that of sustainability. Considering the COVID-19 pandemic, we had to design an appropriate demonstration which could involve an interaction with the participants, while at the same time complying with the sanitary measures.

We used three typical examples: a paper cup or ceramic mug, a paper or plastic bag, and disposable or cotton diapers. We presented the physical objects and asked the participants to compare the same object but made of different materials, in terms of five of the most common elements taken into account in a Life Cycle Analysis: energy use, water use, water contamination, CO_2 emissions, and solid waste. They have to choose which product was more or less intensive in terms of each category, and use the opportunity to speak with them about the relativity of geographic location and the efficiency improvement in productive processes. For this, we created a magnetic board with the items, which could be sanitized, and allowed participants to interact with the game. This involvement meant that participants would appropriate knowledge in a more organic way. In general, the public showed surprise with the results and claimed that this activity will change their actions in the future. Besides, they showed concern about deciding with the proper information, and demonstrated to us the necessity of disseminating this kind of data, to raise awareness about sustainability in our country and in our region.

2:10 PM BI01.03.05
Impact and Public Outreach of Socially Responsible Strategic Management of a Public Research Institution in the Effective Fight Against SARS-CoV-2 and COVID-19 Ivo Svejkovsky; Institute of Physics of the Czech Academy of Sciences, Czechia

In 2020, the whole world started to struggle with the SARS-CoV-2 pandemic and the coronavirus disease (COVID-19). As part of socially responsible research, the Institute of Physics of the Czech Academy of Sciences, as a public research institution in the Czech Republic, got involved in activities leading to the mitigation of the consequences of SARS-CoV-2 spread.
The main aim of this article is to propose a model of socially responsible management of a public research institution targeted at maximum positive impact for society, improvement of the image of an institution and wide public outreach in the time of the COVID-19 pandemic. Partial aims include the identification of key problems caused by COVID-19 to the inhabitants of the Czech Republic; the description of socially responsible strategic management of the FZU applied for the fight against COVID-19, the specification of the institute corporate culture and communication, the selection, description and evaluation of the most important FZU research projects with the accent on material physics and with a potential to contribute to the mitigation of the negative impact of the coronavirus on society, a set of recommendations for the application of the model to practice and its use in future crises.
For the research, both primary and secondary sources of data and the methods of induction and deduction have been used. The proposed model is based on real FZU strategic management and the functionality of the model has been verified in practical use.
It has been proven by the real use in the crisis time of the pandemic that the proposed model of socially responsible strategic management of a public research institution has brought positive results leading to the decrease in the danger of SARS-CoV-2 and COVID-19 in the Czech Republic. It is assumed that the model will be applicable and effective also when dealing with future crises. The broader issue of socially responsible strategic management of a public research institution in relation to crises has been growing in importance and will be researched further.

SESSION BI01.04: Technical Aspects
Session Chairs: William Olson and Daniel Steinberg
Sunday Afternoon, April 18, 2021
BI01

4:00 PM *BI01.04.01
Creating Sustainable Systems—From Stakeholder Decision-Making to Materials and Supply Chains
Carol Handwerker and Congying Wang; Purdue University, United States

When faculty, students, and even many practicing materials scientists think about sustainability, they frequently focus only on the materials and processes that they believe will lead to a sustainable product, very much a "build it and they will come" approach. University curricula in sustainable materials often mirror this view. In contrast, the NSF-funded Purdue-Tuskegee Integrative Graduate Education and Research Traineeship (IGERT) program "Global Traineeship in Sustainable Electronics" was based on the principle that people, their motivations for making certain decisions, and their ability to form trusted partnerships are central to the creation of sustainable materials, processes, and systems. To that end, the cornerstone of the IGERT program's highly integrated curriculum, international fieldwork experience, and individual research topic mix was Elinor Ostrom's General Framework for Analyzing the Sustainability of Social-Ecological Systems (Science, 2009) for which Ostrom was awarded the 2009 Nobel Prize in Economics. Faculty and three graduate student cohorts from Purdue and Tuskegee in multiple engineering disciplines, anthropology, management, toxicology, chemistry, physics, and mathematics collaborated over 7 years to build the program. In this talk I will present the key program elements and how they have been integrated to prepare students to participate in, and even become leaders in multi-stakeholder sustainable social-ecological systems.

4:25 PM BI01.04.02
En Route toward Sustainable Organic Electronics Clara Santato; Polytechnique Montréal, Canada

Consumer electronics has broadened access to education and information and contributed to improve our quality of life. Unfortunately, the pervasive expansion of electronics is generating an unsustainable growth of waste electrical and electronic equipment (WEEE) that contains toxic substances imposing great pressure on the environment and causing major health concerns (1). The electronics industry requires a paradigm shift: moving away from the planned obsolete strategy that has produced copious amounts of WEEE to an environmentally-responsible circular
approach, placing sustainability alongside performance at the heart of next-gen electronics design and manufacturing. To create this paradigm shift, the Collaborative Research and Training Experience in Sustainable Electronics and Eco-Design (CREATE SEED) initiative (2) trains a new generation of highly qualified personnel with a value-added experience in terms of an interdisciplinary approach, bringing together: chemistry, chemical engineering, engineering
physics, (eco)toxicology, electronic circuit design, hardware engineering, systems analysis, social sciences of the media, environmental economics, sustainable value chains and business models; professional skills in teamwork, communication, management, decision making and leadership. Within the context of CREATE SEED, to alleviate the environmental footprint of electronics and to extend their capabilities in emerging areas focusing on low human- and eco-toxicity, we design
& develop devices based on biodegradable organic electronic materials (3).
We will discuss the case of study of the pigment eumelanin, a bio-sourced candidate for environmentally benign (sustainable) organic electronics. The biodegradation of eumelanin extracted from cuttlefish ink was studied both at 25 °C (mesophilic conditions) and 58 °C (thermophilic conditions) following ASTM D5338 (4) and comparatively evaluated with the biodegradation of two synthetic organic electronic materials, namely copper (II) phthalocyanine (Cu-Pc) and poly(p-phenylensulphide) (PPS). Eumelanin biodegradation reached 4.1% (25 °C)
and 37% (58 °C) in 98 days, and residual material was without phytotoxic effects, while the two synthetic materials, conversely, were not biodegradable. The strikingly different results between bio-sourced and synthetic materials suggest that recurring to organic bio-sourced materials is a viable option to eco-design biodegradable organic electronic materials and devices. 1) Forti V., Baldé C.P., Kuehr R., Bel G. The Global E-waste Monitor 2020: Quantities, flows and the circular economy potential. Council of Canada (NSERC). Clara Santato is the Principal Investigator. 3) Zvezdin A., Di Mauro E., Rho D.,

Santato C., Khalil M., MRS Energy and Sustainability, En route toward sustainable organic electronics, Vol. 7, 2020, E16. 4) Standard Test Method for Determining Aerobic Biodegradation of Plastic Materials Under Controlled Composting Conditions, Incorporating Thermophilic Temperatures. https://www.astm.org/Standards/D5338.htm

4:40 PM BI01.04.03
3D Printing—Research, Training and Outreach in the Sustainability Ecosystem Rigoberto C. Advincula[1,2,3]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]Case Western Reserve University, United States

There is a high interest in using additive manufacturing or 3D printing to demonstrate sustainability, ecosystems in recycling, and biobased materials research. 3D printing to create devices from polymer and composite materials has appended the design functionality for new materials, including uses in biomedical devices, enabling rapid development. It is an important and emerging industrial production method. While 3D printed polymers can be further classified into thermoplastics, thermosets, and elastomers based on their thermo-mechanical properties, there are many desirable physical and chemical properties that can be combined with design. While important for materials research – it is important to integrate this into teaching curricula in materials science and broadcast in the public arena. This talk will demonstrate for the past 8 years: 1) integration in materials research, 2) teaching curricula development, 3) participation in the broad discussion of sustainable materials for affecting the circular economy. We will emphasize high impact factor peer-reviewed research, online and teaching curricula in 3D printing incorporating the circular economy, and participation in conferences to emphasize sustainability and high-performance materials research in 3D printing. The author has demonstrated these activities and paradigms in multi-institutions, multi-collaborations, and internationally.

SESSION BI01.05: How to Engage Materials Scientists and Students to Sustainability?
Session Chairs: Ivana Aguiar and William Olson
Sunday Afternoon, April 18, 2021
BI01

6:30 PM *BI01.05.01
Research and Publishing for the Sustainable Development Goals Ed Gerstner; Springer Nature, United Kingdom

The UN Sustainable Development Goals represent the most urgent, and difficult, challenges facing humanity. Many, such as SDG-13 on Climate Action, represent an existential threat. Meeting these challenges requires the involvement of physicists, chemists, earth scientists, biologists, mathematicians, computer scientists, engineers, clinicians, economists, entrepreneurs, social scientists and policymakers. But although they all share the same goal, and are try to solve the same sets of problems, they rarely attend the same conferences, read the same journals or even speak the same language. In this talk, I'll explore some of the philosophical, cultural and systematic barriers that researchers face, and what governments, funders, research institutions and, in particular, publishers need to do to help them make the world a better place.

6:55 PM *BI01.05.02
Incorporating Sustainability into Materials Science Education—Interest, Requirements and Opportunities Jeremy A. Theil[1,2], Ivana Aguiar[3], Sudheer Bandla[4], Ashley White[5] and Yvonne Kavanagh[6]; [1]Xperi, United States; [2]Mountain View Energy, United States; [3]Universidad de República, Uruguay; [4]Niagara Bottling, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]Institute of Technology Carlow, Ireland

Throughout the Materials Science community (students, employers, faculty) there is interest in incorporating aspects of Sustainability into the educational experience. In order to quantify that interest as well as the needs of the community, interviews and a survey that recorded direct responses from more than 4% of the MRS membership were made. This survey confirmed the strong interest in implementing sustainability teachings from all peer groups, as evidenced by the high response rate. The major barriers to implementation in different regions, as well as the requirements of new educational resources will be discussed, along with guidance of effective educational experiences and resources encountered. Finally, methods to disseminate these materials to the community at large will be presented.

7:20 PM BI01.05.03
Engaging and Promoting Sustainability within Professional Societies Isabel Gessner[1], David Graf[2] and Sanjay Mathur[2]; [1]Massachusetts General Hospital, United States; [2]University of Cologne, Germany

Sustainability encompasses almost all fields of our daily life and has become of increasing importance in the area of material science. While materials for sustainable future-leading technologies are developed, the sustainable production of these materials is likewise important. Professional societies such as the Materials Research Society (MRS) offer a versatile and interactive platform for those interested in engaging more in this topic. The aim of this presentation is to give an insight about MRS Focus on Sustainability Subcommittee, its task force activities and MRS Chapter activities that in many cases go beyond the sustainable development in the field of material science but also include inspirations for everyday life changes. Engagement in societies such as the MRS thereby provides a platform that allows to interact with a broad community of material scientists coming from both academia and industry, and therefore offers optimal conditions to find necessary facilitators and multipliers (refers to the UN Sustainable Development Goal no 17 ‘Partnerships for the Goals’).

7:35 PM BI01.05.04
Materials Chemistry Incorporated into Building Science Identity Mary Sajini Devadas and Ellen Hondrogiannis; Towson University, United States

Science/STEM identity” is the sense of who students are, what they believe they are capable of, and what they want to accomplish with respect to science by interacting with others in the field. This requires intervention to help the “socializers” (i.e., STEM faculty and UGs) better understand the value and purpose of science literacy themselves so as to encourage students to appreciate science, be aware of possible career options in science, and enjoy learning and doing science. The project involves building “*science identity*” via the active involvement of Towson University’s (TU) undergraduate student researchers (UG) in 1) engagement in research with the high school (HS) recruits through the apprenticeship model, 2) outreach activities in local high schools. The findings of this work will be presented.

7:50 PM *BI01.01.01
Sustainability as a Lens for Traditional Material Science Curriculums Gabrielle Gaustad; Alfred University, United States

The theoretical and methodological foundations of the sciences and engineering are essential to the removal of barriers to achieving sustainable systems. The teachings of these concepts still lie in traditional academic disciplines such as engineering, science, and mathematics. This structure can often manifest significant barriers to progress in tackling challenging sustainability issues due to an absence of a multi-faceted, interdisciplinary, systems approach. Material science has a particularly relevant set of foundational courses that lend themselves to interesting sustainability integration. Material selection approaches and software have begun to incorporate both economic and environmental “properties” in the decision analysis, highlighting the tradeoffs made in real applications(Ashby, Shercliff et al. 2013). Thermodynamics and kinetics principles can be illustrated in interesting energy conversion examples for next-generation renewable energy storage and production technologies. Other important contributions exist in fundamentals of mining, processing, alloying, phase equilibria, material flow analysis, etc. A variety of recent research is available with additional innovative

suggestions (Gipson and Prins 2015, Gunister, Ozturk et al. 2015, Mainali, Petrolito et al. 2015). Integration of sustainability issues into material science curriculum promotes nexus thinking. In many engineering curriculums it can be challenging to promote interdisciplinary thinking when the curricular approach is inherently siloed. This can often lead to a reductionist spiral where "solutions" produce unintended consequences or additional problems. Integration of sustainability into traditional disciplinary curriculums also promotes T-shaped or Pi-shaped student competencies. Broad, transversal skills are being emphasized more by employers; it is imperative that today's student leave with not just a disciplinary degree but communication, organization, analysis, and critical thinking skillsets (Faris, Kolker et al. 2011, Connor, Sosa et al. 2017). These approaches also help to improve the translation of theory to practice, another key gap cited by employers. Students often struggle to take academic learning and use it directly for on the job skillsets; ABET has emphasized this need in its accreditation processes (Glasgow and Emmons 2007, Passow 2012). Specific examples will be illustrated for a diverse set of courses and curriculum. Results show such an approach can contribute to improved recruitment and retention number and preliminary results appear to also enhance student learning outcomes measured via traditional assessment methods.

SESSION BI01.06: Sustainability Education into Action I
Session Chairs: Ivana Aguiar and William Olson
Sunday Afternoon, April 18, 2021
BI01

9:00 PM *BI01.06.01
Sustainable Science—Let's Green Our Labs! Rachael Relph; My Green Lab, United States

Recent years have seen the emergence of a green lab movement. Championed by a coalition of scientists, facility managers, engineers, designers, sustainability directors and non-profits, the movement seeks to institutionalize sustainability in laboratories through the adoption of green lab programs. These programs address laboratory sustainability holistically by encouraging scientists to reduce energy, water, waste and hazardous chemical use in the lab.

My Green Lab, a non-profit organization, is at the forefront of the green labs movement. My Green Lab runs several programs around the world for scientists in support of reducing the environmental impact of scientific research, including a Green Lab Certification Program, which uses a global standard for laboratory sustainability, and the ACT Label, which is the industry's first eco-nutrition label for laboratory products.

This presentation will focus on how My Green Lab effectively engages scientists through the Green Lab Certification Program and will look at some examples of ways that materials scientists can incorporate sustainability into their daily work. We will also look at how manufacturers are using the ACT Label to design more sustainable products and how scientists can use it to make more informed purchasing decisions for their lab.

9:25 PM BI01.06.02
Intersecting Materials Science with Sustainability Education—A Single-Use Plastics Module for Undergraduate Curricula Ty Christoff-Tempesta and Noelle E. Selin; Massachusetts Institute of Technology, United States

Foundational principles of materials science and their application to related fields offer a critical toolkit for contextualizing and addressing pressing sustainability challenges. To this end, we developed an adaptable two-class module focused on the single-use plastics crisis for incorporation into undergraduate curricula. Designed for the gateway introduction to sustainability class at the Massachusetts Institute of Technology, "People and

the Planet: Environmental Governance and Science," the module grapples with the proliferation of single-use plastics and their extensive environmental contamination. Students are introduced to a range of materials science principles in the module, including structure-property relationships, environmental interactions of materials, and life cycle analyses. Further, students are afforded the opportunity to consider the single-use plastics crisis through a variety of lenses, including as materials scientists, economists, policymakers, industrial stakeholders, chemists, and more. The module utilizes the Human-Technical-Environmental (HTE) framework and matrix-based approach to analyze the single-use plastics crisis through a pre-module background lecture and briefing paper, an in-class life cycle analysis (LCA) presentation and activity based on the UN Sustainable Development Goals, an in-class negotiation activity, pre- and post-class reflection questions, and readings for each class. The resources for this module are made readily accessible so that educators can incorporate any or all of its parts into their courses.

9:40 PM BI01.06.03
The Joint Undertaking for an African Materials Institute (JUAMI) Life Cycle Assessment Project Brian Iezzi[1], Timothy Tibesigwa[2], Edwin Richard[3], David Maleko[4], Tae Lim[1], Muhammad A. Hashmi[1], Jason Hawes[1], Carlos Biaou[5], Kwasi Amofa[5] and Steve Skerlos[1]; [1]University of Michigan–Ann Arbor, United States; [2]Makerere University, Uganda; [3]Nelson Mandela African Institute of Science and Technology, Tanzania, United Republic of; [4]Sokoine University of Agriculture, Tanzania, United Republic of; [5]University of California, Berkeley, United States

Social, environmental, and economic life cycle assessments (LCA) have become critical decision-making tools in academia, industry, and government the world over. Materials LCA education has similarly become more common and best practices for teaching methodologies are in continuous development. This project is focused on a peer to peer mentorship model for LCA education in which PhD students in East Africa and the United States work together to develop and execute a comprehensive LCA to assess the sustainability of a local product or system. Specifically, the three pilot projects thus far have focused on biodiesel production in Uganda, the dairy industry in Tanzania, and the municipal solid waste system of Arusha, Tanzania. The model relies on vetted learning modules, developed at the Center for Socially-Engaged Design (CSED) at the University of Michigan, that step the students through the process of goal and scope identification, inventory creation, and impact assessment. This is coupled with close mentorship and support from students who have previously conducted LCAs, live and virtual day-long LCA workshops, and access to an open, high computing power server with best in class LCA software as well as critical databases such as EcoInvent and the Social Hotspot Database. This combined approach of peer to peer mentorship, curated educational materials and support, and access to critical computational infrastructure has proven to be successful in the implementation of the above-mentioned projects, with several currently under review for publication. We believe this model of a community-learning based approach to LCA education can be applied in other areas of the world to help train the next generation of global sustainability practitioners and educators. This project is supported by the National Science Foundation Joint Undertaking for an African Materials Institute (JUAMI) as well as the United Nations Environment Program (UNEP) Life Cycle Initiative.

9:55 PM BI01.06.04
Teaching High School Materials Science Through Research Kaci L. Kuntz; Rowland Hall, United States

At this pivotal moment, we are facing climate change, movements to increase diversity and equity in science, and a world-wide pandemic. Educators, researchers, and industry leaders are in the unique position to contribute to valuable and necessary changes. Materials scientists are well-suited to address these changes, particularly through sustainability research. With a strong correlation between mentorship in research, especially by teachers, and success of students in their life-long career in STEM (*Nature* 447, 791–797 (2007), *J. of Coll. Stud. Dev.* 49(4), 285-300 (2008)), we have developed an innovative curriculum to build mentor-mentee relationships in a high school classroom as students perform original materials science research with motivation to advance sustainable technologies for battery applications.

This course curriculum has three major pillars: **motivation**, **community**, and **skill development**. First, students are **motivated** by the broader impacts their research can have on the scientific community. With climate change and the need for improved energy technologies, we are inspiring and challenging the students to work on contributing to this research area. Moreover, to foster and model the culture of sustainability in research, students are first *computationally* investigating structure-property relationships and after identifying compounds with desired properties (e.g. charge/discharge rates, energy storage capacity, nontoxic, renewable, etc), they *experimentally* test the identified materials. On the experimental side, we are employing sustainable lab techniques, such as glove recycling and strategic experimental design to employ reusable equipment. Secondly, a research curriculum in a high school setting allows for **community**, collaboration, inclusivity, and diversity to be intentionally implemented into each class. Success and ideas from each student can be celebrated as a group; collaborations between students, mentor, and other scientists in industry and academic institutions can be fostered, and literature can be intentionally selected to highlight research content, diversity of researchers already in the field, and best sustainable research practices for the lab and industry settings. The aspects of allowing students to have mentors and to be exposed to other scientists with similar scientific identities can increase retention in STEM fields and future careers (*J. of Coll. Stud. Dev.* 49(4), 285-300 (2008)). Thirdly, this course allows students to readily apply their knowledge of math, physics, chemistry, biology, statistics, and engineering knowledge to real science (which is shown to improve retention in STEM (*Int. J. of STEM Edu.* 5(48) (2018)). They are gaining hands on experience and **developing the skills** to
- Perform literature reviews
- Design, engineer, and execute experiments
- Evaluate and interpret data and results
- Form conclusions
- Present findings, both verbally, orally, in writing, and in visual depictions.

The ability to consistently have a group of students gathered and working collaboratively on original materials science research allows for the mentoring and molding of future STEM leaders with a solid skill set foundation, sense of community and self-identity in science, and a motivation to pursue sustainable technologies with broader impacts for the scientific community and the world in this pivotal time.

In this work, we will discuss both the curriculum aspects of the course design and observed results from intentionally providing students with hands-on experience in materials science research in a classroom setting as we foster the growth of the future materials scientists.

SESSION BI01.07: On-demand
Wednesday Morning, April 14, 2021
BI01

8:00 AM *BI01.07.01
Teaching Materials for Mitigating Climate Change Kevin S. Jones; University of Florida, United States

Teaching sustainability is a significant challenge given its broad reaching aspects. In a sustainable world our CO2 levels are stable. Currently this is obviously not the case as the CO2 level has exceeded 420ppm for the first time in human history. In an effort to teach students about the sources of CO2 and ways to mitigate this challenge a new class entitled Materials for Mitigating Climate Change has been developed. The goal of this class is to explore the sources of CO2 and how innovations in materials science are being used to address these challenges. The Environmental Protection Agency has divided up the sources of CO2 into 5 categories including electricity, transportation, industry, commercial/residential and agriculture. The relative contributions of each of these sources to the 17GT of excess CO2 produced each year is reviewed. Then each category is broken down by topic and the historical and recent impact of materials innovations on the CO2 emission process are discussed. It is difficult to use these categories exactly given overlap in the areas. For example,

industrial source of CO2 also involves transportation and buildings etc. In addition to it being difficult to place an exact figure on the relative contributions of each sector to the total CO2 emissions, it is also difficult to place an exact figure on the potential impact of these innovations. Despite these instructional challenges, it is apparent materials innovations are going to play a critical role if we are to address the rising CO2 levels. This talk will review the topics discussed in the class. It was found that asking the students to discover recent innovations external to the class proved to be an excellent method of engaging non-majors in this topic. While such stories can be captivating the challenge is placing numbers on the relative impact of these discoveries remains. This talk will conclude with asking the audience to contribute their ideas on aspects of this challenge that may have been overlooked.

8:20 AM BI01.07.03
Sustainable Polymer Degradation Using Concentrated Solar Energy Miriam Sanchez Pozos; Universidad Autónoma del Estado de México, Mexico

The widespread use of plastic has made plastic waste and its accumulation in the environment a matter of great concern because its natural degradation is very slow. However, there is a wide variety of synthetic polymers that subjected to photo-oxidative reactions produced by UV radiation from sunlight, degrade significantly. And if the wavelength of the UV radiation is adequate according to the type of plastic, for example 300 nm for polyethylene (Ibnelwaleed A, 2007), it is possible to maximize its degradation. Therefore, using solar concentration favoring the appropriate wavelength of UV radiation will allow to accelerate the photodegradation process of these wastes and will favor their rapid incorporation into the environment in a friendly way.

In the Faculty of Engineering of the Autonomous University of the State of Mexico in the Mechanical Engineering Degree program in the Materials Science subject, as well as in the Engineering Science Postgraduate course, (Materials and environmental sustainability), one of the issues addressed is the degradation of polymeric materials. The degradation of polymers is carried out under different schemes such as:

1- Natural weathering method, (CA)
2- QUV Accelerated weathering (Q-Lab), (CI)
3- Accelerated weathering using a solar concentrator, (CS)

With this practice, students learn that a wide variety of synthetic polymers absorb ultraviolet (UV) solar radiation. The Photo-oxidative degradation is the process of decomposition of the material by the action of light, which is considered one of the main sources of damage exerted on polymeric substrates under environmental conditions. Most synthetic polymers are susceptible to degradation initiated by UV visible light.

The methods to carry out the photodegradation practices are the natural weathering method; Outdoor exposure is performed on specimens mounted on test racks, oriented under standard conditions to expose the material to the full radiation spectrum as well as the temperature and humidity at that location. Another technique used is accelerated aging in accelerated weathering chambers that use UV radiation from the brand (Q-LAB). Finally a solar concentration system is used to super-accelerate the polymeric materials degradation . The materials degraded by the three techniques (CA, CI and CS), are analyzed to observe the formation of cracks, the embrittlement of the materials, the disintegration in powder, and the color changes. Finally, the degraded polymers are characterized by means of FTIR, and mechanical testing in order to determine the aging of the material as a function of time and the intensity of the radiation absorbed by them.

In the Faculty of Engineering of the UAEM, they are consolidated the experience about the development of solar concentration devices, with the knowledge and experience on plastics engineering, to develop postgraduate students' projects and laboratory practices of undergraduate, students about the use of solar energy in polymers degradation.

For the accelerated degradation practices, a solar concentrating system (patent MX/a/2015/000346) was designed and built. This solar concentrator was conceived to degrade plastic waste much faster than is done with UV radiation chambers (which only are used at the laboratory level). Therefore, this degradation technology can be considered as ecological, since it can be used with a very low environmental impact because it does not require more energy than from the Sun. This accelerated degradation system is mainly focused on treating plastic waste that is no longer susceptible to being reused or recycled.

With the use of the solar concentration system, students learn the scope of the use of solar energy, to replace the use of conventional equipment that consume too much electrical energy.

In the same way, students understand the effects of UV radiation on the degradation of polymers, and therefore the limited use they must make of them.

8:30 AM BI01.07.05

Late News: Plastics in View of Sustainability—An International Initiative Towards Education and Training of Young Scientists Natalia Tarazona[1], Rainhard Machatschek[1,2], Jinneth L. Castro Mayorga[3], Felipe Salcedo Galán[4] and Andreas Lendlein[1,2]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]University of Potsdam, Germany; [3]Corporación Colombiana de Investigación Agropecuaria, Colombia; [4]Universidad de los Andes, Colombia

In the race between technological progress and education, transformative changes are necessary to prepare a future workforce on sustainable thinking and practice, to act on authentic challenges (eg. ecosystem conservation and global economy) while making responsible use of natural resources. Such development of educational approaches could benefit from a strategic international collaboration, including scientific projects, joint programs and capacity building.
Here, we introduce the Transnational Network for Research and Innovation in Microbial Biodiversity, Enzymes Technology and Polymer Science –MENZYPOL, a team effort to integrate inclusive and equitable quality education into research collaboration projects. The project is jointly funded by the Colombian Administrative Department of Science, Technology and Innovation (Minciencias) and the German ministry of education and research (BMBF).
MENZYPOL aims to create a lasting partnership between Helmholtz Zentrum Geesthacht (HZG) in Germany, Universidad de los Andes (UniAndes) in Colombia and key partners from the Colombian agricultural sector (Agrosavia). The pilot project established in the network concentrates on the exploration of the Colombian biodiversity for the discovery and development of biocatalysts in polymer science. The main focus is to isolate microorganisms with the ability to produce advanced polyesters, and to obtain enzymes that can degrade polyesters from natural and synthetic origin.
Ideally, the DNA and protein sequences of the isolated microorganisms and enzymes, together with their specific activities, will be added to databases to support the identification of other species using predictive analytics. This integrated approach brings together researchers from two different continents aside from requiring a broad range of expertise, from molecular biology all through polymer science and bioinformatics. The participating students and early career researchers not only gain access to sophisticated research infrastructures or the microbial biodiversity of a megadiverse country, but also to scientific approaches that are far out of the scope of traditional scientific education. This is enabled by giving young scientists the opportunity to learn and to be mentored by experienced researchers. The ongoing COVID-19 pandemic presents a challenge by excluding short-term visits, and extended research stays, which can naturally only be offered to very few. Therefore, the lessons learned in the past months in virtualization of science education and exchange will be used to move activities to the digital world, thereby boosting outreach and accessibility.

8:40 AM *BI01.07.06

Low-cost and Recycled Electronics for Sustainable Education, Discovery and International Innovation Stoyan K. Smoukov; Queen Mary University of London, United Kingdom

Low cost and reusable technology is both a sustainable and scalable approach to education. We show examples of low-cost electronics which have resulted in an International Innovation Competition in Africa. Students are able to push the boundaries of what is possible and create new instruments, rather than only reproduce exercisese pre-made for them. www.tinyurl.com/2020Africa
A new direction that grew out of a Trash-to-Treasure workshop - shows the power of up-cycling old electronics for education. Taking apart consumer electronics has long been a staple in materials education. It is a missed opportunity, however, to note how many times such devices fail for a simple reason, and much of them are still functional, capable of re-use in many other contexts, sometimes for even higher value.
The latter is illustrated with the case of dead hard-drives up-cycled to low-cost centrifuges, which have high specs. These can be used to carry out a number of biological tests. Understanding not only the materials but also the interdisciplinary principles of how suc components integrate into a whole, dynamic system allow holistic teaching incorporating materials, electronics, 3D printing, sensing and more.

9:00 AM *BI01.07.07
Individual-Centric Approaches to Accessibility in Materials Science Education Theresa Davey[1] and Rebecca Davenport[2]; [1]Tohoku University, Japan; [2]Max-Born Institute, Germany

A significant part of tackling sustainability in education is promoting access to quality education for all communities. Promoting diversity in university admissions is a vast challenge, involving addressing unconscious biases and perceptions of competence, but it doesn't solve the whole problem. Even if a diverse group of people are accepted to study materials science at university, that doesn't guarantee equal access to education. Time-pressured academics whose institutions undervalue teaching have an understandable overreliance on outdated teaching methods, which can have the unfortunate consequence of magnifying existing inequalities. This talk will present an discipline-based individual-centric approach to higher education teaching that will provide guidelines for working with students to create an inclusive learning environment.

The aim of this approach is to create an environment that promotes student empathy, self-awareness, and confidence in self-advocacy, while balancing competing needs and working within the limitations of a university environment such as large classrooms and non-ideal teaching spaces. The rapid shift to online learning has also revealed potential positive and negative aspects of out-of-classroom teaching, but has also put a significant strain on the mental health of both students and teachers, and exaggerated accessibility issues. Approaches that promote accessibility in the classroom do not always translate directly to online learning environments, but the key idea of individual-focussed education provides a framework for developing best practices for meeting a diversity of student needs and delivering positive student outcomes.

9:20 AM *BI01.07.08
The Repercussions of Gender Bias and Inequalities in Science Knowledge Making Elizabeth Pollitzer; Portia, United Kingdom

Gender equality, diversity, and inclusion have been identified as essential pre-requisites for excellence in science and scholarship, as well as for the socio-economic development of societies. Nevertheless, inequalities and gender gaps persist, e.g. underrepresentation of women and certain social groups in leadership positions. At the same time, previously overlooked issues emerge as critically important, e.g. the widespread occurrence of sexual harassment in academia. New issues also arise, for instance the gaps in knowledge revealed by the COVID pandemic, and the consequences of the pandemic for higher education and for academic and research careers. Another urgent issue is the lack of progress on gender equality in the UN Agenda 2030 and the need for better, more contextualised and gender-bias free approaches to SDGs implementation. Using the latest understanding of gender and diversity issues in science endeavours, complemented by examples pertinent to materials engineering, this presentation will focus on advancing gender equality, diversity and inclusion in the mechanisms of science knowledge making and application to achieve greater societal relevance and trust in science institutions and knowledge.

9:40 AM BI01.07.09
Writing-to-Learn in Introductory Materials Science and Engineering Hongling Lu, Leah Marks, Timothy Chambers, Solaire Finkenstaedt-Quinn, Ginger Shultz, Anne Gere and Rachel Goldman; University of Michigan–Ann Arbor, United States

M-Write is a campus-wide project which aims to transform teaching and learning in gateway courses through enhanced student engagement and transformative learning. In Materials Science and Engineering (MSE), we are implementing Writing to Learn (WTL) assignments and peer review in courses spanning from introductory undergraduate to advanced graduate levels. The WTL assignments enable students to apply content knowledge to "real-world" situations via writing, which promotes deeper thinking and compels students to explain concepts in their own words. The subsequent peer review and revision processes provide additional learning opportunities as the students give and receive feedback on content and critically self-assess their own work. In this project, we are quantifying the influence of WTL assignments on student understanding of key concepts in introductory MSE courses. The project involves evaluation of the effectiveness of the WTL assignments and their impact on student learning. Both quantitative and qualitative research methodologies are utilized, including pre/post assessment surveys and interviews, as well as analysis of writing products. In this presentation, we will discuss our use of WTL in Introductory MSE. For example, we have used WTL to assist student learning of polymer properties, with a prompt that focuses on polymer recycling and its impact on mechanical properties. Our research suggests that the polymer recycling WTL assignment was effective in promoting understanding of stress-strain behavior of polymers, but that further support is needed to help students connect polymer microscopic properties to macroscopic behavior [1]. The effectiveness of WTL assignments associated with other key concepts including the atomic packing in crystals, ductile vs. brittle failure, interpretation of phase diagrams, and corrosion as it relates to the Flint water crisis will also be discussed.

Visualizing ion adsorption and Crystal Growth at Charged Interfaces with Near-Atomic Resolution
Benjamin A. Legg[1,2] and James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Solid-water interfaces can drive complex chemical phenomena, where processes such ion adsorption become tightly coupled to phenomena such as surface charging and crystal growth. In-situ atomic force microscopy (AFM) provides a powerful tool to visualize these phenomena. Here we apply in-situ AFM to directly image individual aluminum ions at a mica-water interface and show how the mica-water interface drives changes in aluminum speciation (favoring the formation of hydrolyzed aluminum species). We subsequently investigate the assembly of these ions into dynamically fluctuating clusters, and the coalescence of these clusters to form 2D epitaxial aluminum hydroxide films with a persistent network of gaps. The cluster populations prior to film-growth reveal an energy landscape that deviates significantly from classical theories of heterogenous nucleation, but these deviations can be explained when we consider the electrostatic energy associated with forming charged clusters at the solid-water interface. Monte Carlo simulations indicate that these charging effects can remove the classical barriers to crystal nucleation and enable a barrierless process of crystal growth by cluster coalescence.

8:15 AM *CT01.01.03
The Duality of Interfacial Water on Crystalline Surfaces—Hydration *vs* Expulsion and Replacement
Ricardo Garcia; CSIC, Spain

Interfacial liquid layers play a central role in a variety of phenomena ranging from friction to molecular recognition. Liquids near a solid surface form an interfacial layer where the molecular structure is different from that of the bulk. Yet the molecular-scale understanding of the interactions of liquid water with solid interfaces is unsatisfactory for the lack of high-spatial resolution methods. The presentation is divided in three sections. The first section is an introduction to the relevance of solid-liquid interfaces. The second section, presents the features and capabilities of 3D-AFM [1-2] to image with atomic resolution the **three-dimensional** interfacial structure of surfaces immersed in aqueous solutions. The third section reports the structure of interfacial water layers on different surfaces from graphene to a few layer MoS_2; from hexagonal boron nitride to pentacene. Those interfaces are characterized by the existence of a 2 nm thick region above the solid surface where the liquid density oscillates (Fig. 1) [3-4]. The distances between adjacent layers for graphene, few-layer MoS_2, h-BN and pentacene are ~0.50 nm. This value is larger than the one predicted and measured for water density oscillations (~0.30 nm). The experiments indicate that on extended hydrophobic surfaces water molecules are expelled from the vicinity of the surface and replaced by several molecular-size hydrophobic layers.

Three-Dimensional Molecular Mapping of Ionic Liquids at Electrified Interfaces Shan Zhou, Kaustubh Panse, Mohammad H. Motevaselian, Narayana R. Aluru and Yingjie Zhang; University of Illinois at Urbana-

Champaign, United States

Electric double layers (EDLs) are key to electrochemical energy conversion and storage applications such as capacitive charging and redox reactions. However, most of the existing spectroscopy and atomistic imaging methods, such as X-ray spectroscopy and electron microscopy, can only probe the binding states and/or the planar distribution of strongly adsorbed species at the electrode interface, therefore the molecular scale structure of EDLs still remains elusive. Based on our recent success on high-speed 3D force mapping [1], here we report a novel technique, electrochemical three-dimensional atomic force microscopy (EC-3D-AFM), and use it to directly image the molecular scale EDL structure of an ionic liquid under different electrode potential. Our technique overcomes the limitations of existing 3D-AFM methods in measuring highly viscous liquids. From the 3D-AFM images, we observe rich 3D molecular distribution profiles and potential-dependent reconfigurations. In combination with molecular dynamics simulations, we are able to gain a molecular level understanding of the capacitive charging effects. We expect this mechanistic understanding to have profound impacts on the rational design of electrode-electrolyte interfaces for supercapacitors and batteries.

8:55 AM CT01.01.05
Probing Electric Double Layers on MoS_2 Using *In situ* Atomic Force Microscopy Kaustubh Panse, Shan Zhou, Haiyi Wu, Narayana R. Aluru and Yingjie Zhang; University of Illinois at Urbana-Champaign, United States

There is an invigorated interest in using operando characterization techniques to analyze the electrode-electrolyte interface in various electrochemical materials systems. Various processes like ion adsorption, intercalation and electric double layer (EDL) charging on the electrode surfaces are responsible for the electrochemical performance, but the precise mechanisms remain unclear. Here we present in-situ electrochemical atomic force microscopy measurements to characterize the EDL structure on MoS_2 surfaces. We have specific interest in using MoS_2 as the electrodes due to their promising applications in batteries and supercapacitors.
We obtain atomic-scale 3D images of the electrode-electrolyte interfaces using a force mapping technique. In the current work, we vary the electrode potential and observe a change of the double layer structure. The observed fine molecular features near the electrode surface are unprecedented and reveal the charge storage mechanism of MoS_2 electrodes.

9:10 AM *CT01.01.06
The Structure of Ionic Liquid Electric Double Layers and Their Functionality Investigated by Atomic Force Microscopy Nina Balke and Wan-Yu Tsai; Oak Ridge National Laboratory, United States

The structure and dynamics of the solid/liquid interface are of fundamental interest for various energy related technologies including energy storage, catalysis, lubrication, and many more. Of particular interest are room temperature ionic liquids (IL) which hold the promise of increasing the electrochemical stability windows for electrochemical capacitors and electrostatic gating of functional oxides. In both cases, the structure of the IL electric double layer (EDL) in three dimensions is the key to understand the device performance. Theories describing the EDL have been proposed showing a layering of cations and anion at solid interfaces. However, a full 3D description is lacking and experimental approaches to measure and understand the EDL's interfacial

structures, dynamics and reactivity are scarce. Due to the characteristic sizes of EDLs, this requires characterization techniques capable of resolving nm length scales. Atomic Force Microscopy (AFM) can investigate such length scales in 3D and has been shown to be suitable to image solid-liquid interfaces.

Here, we demonstrate the use of in-situ AFM techniques to understand processes at the solid/liquid interface and introduce statistical and theory coupled approaches. We will showcase the capabilities for two different systems. First, we will image the EDL of an ionic liquid at a graphite interface and report the direct observation of the structure and properties of topological defects. We will show the existence of structural domains parallel to the solid-liquid interface towards a full picture of the double layer structure and investigate their change with applied bias and shine light on their origin. Then we will apply the technique to IL gated oxide devices where the gating process is explained in terms of the interfacial IL structure. We will show that the transition between both ON and OFF states of the IL-gated amorphous indium gallium zinc oxide transistor is caused by a densification and preferential orientation of counter-ions at the oxide channel surface. This process occurs in three distinct steps, corresponding to regions of different electrical conductivity. In this case, the EDL thickness associated with the flat arrangement of cations at the surface results in extremely high charge density leading to high drain currents.

The work was supported by the Fluid Interface Reactions, Structures and Transport (FIRST), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences. Measurements were performed at the Center for Nanophase Materials Sciences (CNMS), which is sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division, Office of Basic Energy Sciences.

10:30 AM *CT01.02.00
Determining Surface and Interfacial Structures—The Convergence of Computation, Experiments and Machine Learning Maria Chan; Argonne National Laboratory, United States

Determining atomistic structure at surfaces and interfaces is challenging because metastable surfaces/interfaces are likely accessible under realistic conditions, rendering energy-only searches insufficient, and experimental data often give incomplete information. Therefore, neither theory nor experimental data alone is sufficient to determine these structures. In this talk, we will discuss how we use machine learning to combine experimental and theory-based data to determine surface and interface structures.

10:55 AM *CT01.02.01
Interfacial Structure and Electrochemistry of Lithium and Zinc Batteries from Molecular Modeling Oleg Borodin, Travis Pollard and Jenel Vatamanu; U.S. Army Research Laboratory, United States

A molecular scale insight into ion transport and decomposition is important for understanding deficiencies of the currently used aqueous and non-aqueous electrolytes. In this presentation I will summarize progress made towards improving molecular scale understanding of the structure and electrochemistry for a wide range of aqueous and non-aqueous electrolytes. Double layer properties are obtained from classical MD simulations, while modeling of non-aqueous electrolytes will focus on the competitive solvent and salt reduction at the passivated electrochemical interfaces using Born Oppenheimer Molecular Dynamics (BOMD) simulations using DFT functionals. These BOMD simulations included critical factors needed to realistically represent

electrolyte reactivity at electrodes such as explicit description of the substrate – electrolyte interactions; accurate representation of electrolyte structure, ion pairing and aggregation near an electrode; and collection of sufficient statistics from multiple unique simulations that were initiated with differing initial configurations. For example, 20 BOMD simulations starting from different initial conditions using 2.0M $LiPF_6$ in THF tetrahydrofuran/2-methyl tetrahydrofuran showed no solvent decomposition nor HF formation while only LiF formation was observed as a result of $LiPF_6$ salt decomposition.[1] The most frequently observed reduction events included a PF_6^- coordinated to Li^+ cations from the electrolyte and LiF surface that lead to anion defluorination and formation of 3LiF and PF_3 gas. The solvent separated $LiPF_6$ and did not actively participate in reduction. When surface defects in LiF were present near a high population of PF_6^- the anions there was a preference for the $LiPF_6$ reduction and repair the SEI without ether solvent decomposition. Interestingly, a number of fast diffusion events for F^- from the electrolyte | LiF interface to the LiF-lithium metal interface was observed that would be expected to occur during Li stripping indicating that F^- re-arrangement in the thin LiF passivation films should be also considered.[1] Electrolyte reduction at the passivated interfaces from these simulations will be contrasted with other solvents ranging from ethers with mixed salts or carbonates and results from the representative quantum chemistry (QC) calculations performed on the small model electrolyte clusters to estimate oxidation and reduction.

11:20 AM CT01.02.02

First-Principles Modeling of the Kinetics of Electrochemistry at Solid-Water Interface Xunhua Zhao and Yuanyue Liu; The University of Texas at Austin, United States

Kinetic information, such as the activation energy and transition state, is critical to understanding the reaction. However, the kinetic information of electrochemistry at solid-water interface is challenging to obtain from conventional models of density functional theory (DFT), as they often neglect the presence and/or the dynamics of the surface charge [1] and the solvent configuration, which are further coupled. Here we present a new model that accounts for these effects, by combining hybrid solvation, constant-electron-potential, and slow-growth sampling techniques together. We then apply this model to elucidate the active site structure and the mechanism of electrochemical carbon dioxide reduction catalyzed by single-nickel-atom embedded in graphene, which shows high performance in experiments while is not well understood [2].

Computational Study of Ion Binding Mechanisms to Alkali Activated Materials Using Molecular Simulation Ahmed Abdelkawy[1], Mostafa Youssef[1] and Claire White[2]; [1]The American University in Cairo, Egypt; [2]Princeton University, United States

Alkali activated cement (AAC) has proposed as a green alternative to ordinary Portland cement (OPC) due to reduced greenhouse gases emissions compared with the production of OPC powder. Here, we aim at computationally assessing the ability of the AAC binder phase to hinder the diffusivity of corrosive ions and hence protect the reinforcing steel in an AAC-based concrete. We have adopted the tobermorite 14Å crystal structure as a model system for the binder phase because it has Ca/Si ratio similar to sodium-containing calcium-alumino-silicate-hydrate (C-(N)-A-S-H gel that forms during alkali activation of blast furnace slag or class C fly ash. We have also incorporated sodium into the tobermorite structure since the hydration phases tend to be produced using sodium-based activators. To describe the interactions between ions we employed a force field that has been widely used to describe inorganic oxides and relies on representing the polarizability of the oxide ion using a core and a shell connected by a harmonic spring. We believe that this polarizability is needed to accurately describe the tobermorite/water interface. Water molecules have been described by a 3-point flexible model. We validated the transferability of the force field by computing several structural and mechanical properties for tobermorite and compared these with experiments and/or other force fields such as CLAYFF.

In this talk, we will present a detailed analysis of the structure, dynamics, and energetics of Na and Cl ions in bulk water and at the interface between water and tobermorite. We will also examine the effect of introducing and increasing the percentage of sodium as a dopant in tobermorite, with a focus on how this affects the behavior of interfacial ions. In our analysis, we rely on computing a set of time and space correlation functions to explain the mechanisms by which AAC can stop the ingress of corrosive ions such as chloride ions. Our work provides a key step in assessing the durability of reinforced concrete structures produced by AACs.

11:50 AM CT01.02.04
Multi-Stage Bubble Nucleation in Nanoscale Cavities Anirban Chandra, Shekhar Garde and Pawel Keblinski; Rensselaer Polytechnic Institute, United States

Vapor bubble nucleation plays an important role in a variety of evaporation/condensation based thermal transport processes such as evaporative cooling, boiling, etc. In most practical situations nucleation processes are heterogeneous. While homogeneous nucleation has been studied extensively using theory and simulations, heterogeneous nucleation mechanisms are still being actively researched as it is less amenable to standard theoretical/numerical techniques. In this study, we use molecular dynamics simulations to investigate homogeneous and heterogeneous (flat surfaces and cavities) bubble nucleation in water under negative pressures. The maximum negative pressure sustained by the system is used to determine the propensity of bubble nucleation. Our results indicate that trends in calculated nucleation pressures deviate from classical heterogeneous nucleation theory predictions due to the nanoscopic nature of the nucleated bubbles. Furthermore, we show that nanoscale cavities aid the nucleation process when weak interaction exists between the fluid and solid materials. In this weak interaction regime, we show that nucleation is a multistage process and also demonstrate the existence of an optimal groove geometry for heterogeneous nucleation.

***In Situ* Study of the Lubrication Mechanism of Phosphonium Phosphate Ionic Liquid in Nanoscale Single-Asperity Sliding Contacts** Filippo Mangolini[1], Zixuan Li[1], Oscar Morales-Collazo[1], Jerzy Sadowski[2], Hugo Celio[1], Andrei Dolocan[1] and Joan F. Brennecke[1]; [1]The University of Texas at Austin, United States; [2]Brookhaven National Laboratory, United States

Ionic liquids (ILs) have gained considerable attention in the last two decades owing to their unique and tunable physico-chemical properties (*e.g.*, low vapor pressure, high thermal stability), which have made them potentially useful for a range of applications, including batteries, fuel cells, catalysis. Ionic liquids are

particularly attractive in lubrication, since their properties make them suitable for components working under extreme conditions, such as those found in engines, spacecraft, and micro-electromechanical systems. When ILs are used as lubricants, the interface between the IL and the surfaces of the components in relative motion plays a pivotal role in controlling the friction and wear response. Despite the scientific weight of published studies on the tribology of ILs, remarkably little is still known about the underpinning lubrication mechanism of ILs. The development of a fundamental understanding of the mechanism by which ILs reduce friction and/or wear requires shedding light on the processes occurring at nanoscale asperities within macroscale contacts. This constitute a significant challenge since observing and understanding the nanoscale mechanisms at play is inhibited by the hidden nature of the buried interface and the challenge of performing observations at the nanometer scale.

Here, we used atomic force microscopy (AFM) to visualize and quantify the processes occurring at sliding interfaces *in situ*, in single-asperity nanocontacts[1]. The AFM experiments, in which a diamond tip was slid on steel in phosphonium phosphate IL (PP-IL) at high contact pressure (>5 GPa), indicated a significant friction reduction only after the removal of the native surface oxide from steel. Even though the AFM experiments allowed for the identification of changes in topography and friction *in situ* while sliding in PP-IL, they could not provide any information about the composition and structure of the regions scanned by AFM. The analysis of these regions is a challenging surface science problem owing to their limited lateral dimensions and the small thickness of the surface material modified by the mechanical action of AFM tips. To address this challenge and elucidate the origin of the friction reduction observed during AFM experiments, laterally-resolved *ex situ* analyses of the surface chemistry of steel were performed by synchrotron-based X-ray photoemission electron microscopy (X-PEEM), low energy electron microscopy (LEEM), and time-of-flight secondary ion mass spectrometry (ToF-SIMS). The analytical results indicated that the mechanically-induced exposure of metallic iron during AFM tests carried out in PP-IL leads to an increase in surface coverage of adsorbed phosphate anions together with a change in surface potential. These surface modifications are proposed to be caused by a change in surface roughness and adsorption configuration of phosphate anions on metallic iron compared to their configuration on iron oxide, which lead to the formation of a densely packed, lubricious boundary layer only on metallic iron.

The findings of this work[2] not only shed new light on the lubrication mechanism of ILs in general, but also provide guidance for engineering ILs with the aim of tuning their lubricating properties by controlling their interfacial structures with metal and metal oxides. These outcomes can enhance sustainable development through the reduction of the economic (*e.g.*, reduced fuel expenditure) and environmental (*e.g.*, less pollution) impact of tribology, while being a key factor in the attempt of achieving the challenging environmental objective of reducing greenhouse gas emissions.

Recent Advances in Nanoelectrochemical Imaging of Heterogeneous Surfaces Michael Mirkin, Koushik Barman, Tianyu Bo, Rui Jia, Sujoy Sarkar and Xiang Wang; The City University of New York, Queens College, United States

Scanning electrochemical microscopy (SECM) is a powerful tool for nanoscale imaging of heterogeneous surfaces. Emergent applications of this technique in studies of interfacial properties of materials and electrocatalysts require near-atomic scale spatial resolution and the capacity for measuring currents produced by inner-sphere electrochemical processes that typically deactivate nanoelectrode surface. In this paper we present some new approaches to high-resolution electrochemical imaging of surface reactivity and active site characterization. One of them is based on mediated electron transfer at nanoelectrodes that can be used as SECM tips for reactivity mapping and localized kinetic measurements of inner-sphere electrochemical

processes, such as hydrogen evolution reaction and oxygen reduction to hydrogen peroxide. Tunneling mode SECM experiments at flat samples are aimed at establishing the relationship between the electrochemical tunneling signal and local surface properties and developing single entity voltammetry for characterization of individual catalytic nanoflakes. Finally, we discuss SECM experiments in which a TEM finder grid is used as a substrate to enable multi-technique imaging of the same nanoscale portion of the catalytic surface and elucidate the nature of the active sites by correlating the electrochemical reactivity maps with atomic scale structural and bonding information obtained by TEM techniques.

A Comparison of Solid Electrolyte Interphase Evolution on Highly Oriented Pyrolytic and Disordered Graphite Negative Electrodes in Lithium-Ion Batteries Haoyu Zhu[1], Pete Barnes[1], Paul Davis[1], I. Francis Cheng[2], Eric Dufek[3] and Hui (Clair) Xiong[1]; [1]Boise State University, United States; [2]University of Idaho, United States; [3]Idaho National Laboratory, United States

In the early stage of lithium ion batteries (LIBs) cycling, the reaction of negative electrode with electrolyte will result in the formation of a thin film on the electrode surface.[1] This film is referred to solid electrolyte interphase (SEI), the stability of which is essential for practical LIBs. The most used negative electrode material in LIBs is graphite, due to its stability and low working potential.[2] Previous studies indicated that in graphite, the basal to edge plane ratio, particle size, pore size, degree of crystallinity and surface chemical composition affected the formation of SEI and its stability [2-5]. The defects in graphite is also a very important factor for SEI formation but has been rarely studied. Here, we investigated the SEI formation on an almost perfect graphite-HOPG (Highly Oriented Pyrolytic Graphite) and a synthetic defective carbon film - GUITAR (pseudo-Graphite from University Idaho Thermolyzed Asphalt Reaction) through operando electrochemical atomic force microscopy (EC-AFM). It was found that the defects on GUITAR promoted the electrolyte decomposition and SEI formation at a higher potential. Furthermore, the SEI particles evenly formed and densely packed on the GUITAR surface with a particle size of 172 nm ± 83 nm and a thickness of about 50 nm. The SEI thickness on this defective electrode surface is very similar to that on HOPG (about 40-50 nm). It is also noteworthy that on HOPG, the formed SEI only partially covered the electrode surface, along with the graphite layer delamination from the step edge and bulging on the basal plane. This study showed direct evidence of how structural defects affect SEI nucleation and growth upon cycling.

Mapping Alkali-Ion Fluxes at Battery Interfaces: Applications to Understand the Formation of the Solid-Electrolyte Interphase Zachary Gossage, Yunxiong Zeng and Joaquin Rodriguez-Lopez; University of Illinois at Urbana-Champaign, United States

The solid-electrolyte interphase (SEI) is a complex structure that forms on battery anodes as a result of decomposition reactions of solvent and electrolyte prompted by the high electrode polarizations. Understanding the SEI formation and its resulting properties is key to fabricating batteries more effectively, safely, and ensuring their sustained performance. In particular, in-situ analysis of the first stages of SEI formation would

allow us to better understand the ultimate fates of electron transfer and ion transport processes on these important structures. In this study, we explored the first stages of formation of the SEI using versatile redox and ionic probes based on scanning electrochemical microscopy (SECM). Specifically, we were interested in exploring how these new probes could be used to compare the behavior of Li^+ based SEI's to those formed by Na^+ and K^+, which are of great interest for emerging batteries.

For ionic measurements, the principle is based on SECM probes that integrate mercury micro disk-well electrodes on which alkaline ions can be detected by means of fast-scan anodic stripping voltammetry. We unambiguously demonstrated the capability of these probes to detect alkali-ion fluxes at an electrode undergoing SEI formation and subsequent ion intercalation. Surprisingly, reversible Li^+ fluxes were observed on SEI's formed at the edge plane of highly oriented pyrolytic graphite (HOPG), which we ascribe to the presence of reversible redox species on the SEI.[1] Further using a combination of redox imaging using sub-micron sized SECM probes and these new ion-sensitive probes, we elucidated key differences in the reactive evolution of the SEI for the Li^+, Na^+ and K^+ systems. We will describe various correlations observed between the observed fluxes, electron transfer rates, and the presence of organic and inorganic structures observed at the corresponding SEIs. SECM mapping revealed aspects of surface reactivity that are lost during averaging in other electrochemical techniques, and allows a correlation of all reactive species, including ions and electrons, in complex interfacial structures.

2:20 PM *CT01.03.05
Liquid Phase Peak Force Infrared Microscopy for Label-Free Chemical Imaging at Liquid/Solid Interface Xiaoji Xu; Lehigh University, United States

Abbe's diffraction limit prevents traditional optical spectroscopy to directly access the nanoscale structures and phenomena. One way to bypass the optical diffraction limit is through the detection of photothermal expansion from light absorption with atomic force microscopy (AFM). The combination of AFM and infrared excitation provides the ability to perform chemical-sensitive imaging and vibrational spectroscopy nanoscale spatial resolution. The peak force infrared (PFIR) microscopy is one of the emerging AFM-based infrared microscopies with spatial resolutions at sub 10 nm. In this presentation, we will describe the recent development of the PFIR microscopy into the liquid phase to address the needs for *in situ* characterization of materials at the liquid/solid interface. We equip the liquid-phase peak force infared (LiPFIR) microscope with the capability of controlling fluid compositions during the measurement so as to initiate physical transformation and chemical reactions. LiPFIR microscopy is capable of tracking the polymer surface reorganization in fluids and detect the product of click chemical reaction in the aqueous phase. We also measure the hyperbolic phonon polaritons of hexagonal boron nitride submerged in water to reveal its dispersion relations in the fluid phase. As a biological application of the LiPFIR microscopy, the budding site of yeast cell wall particles is imaged in water. The super-resolution, label-free, non-destructive chemical imaging and spectroscopy capabilities of LiPFIR will facilitate investigations of chemical compositions and transformations at the liquid/solid interface.

2:45 PM DISCUSSION TIME

4:00 PM *CT01.04.01
Understanding Electrochemical Interfaces in Batteries via Liquid-Cell/Cryo TEM Reza Shahbazian-Yassar; University of Illinois at Chicago, United States

Electrochemical interfaces play a key role in governing the behavior of lithium batteries. However, access to these interfaces is limited due to the presence of liquid and the need for sealing the battery cells in high vacuum electron microscopes. Advanced in liquid-cell and cryo-holders now enables microscopiests to investigate the local chemical and structural changes in battery interfaces. This presentation encompass the efforts of PI in understanding the role of solid-liquid interfaces in controlling the electrochemical reactions kinetics and thermodynamics in lithium batteries. The first part of this presentation provides an overview on the challenges of
high-energy density rechargeable lithium-oxygen (Li-O_2) batteries due to their potential to surpass conventional lithium ion battery. This system is troubled by sluggish kinetics during the oxygen reduction reaction (ORR) and the oxygen evolution reaction (OER). We investigated the discharge/charge behavior in Li-O_2 batteries using *in situ* liquid-cell transmission electron microscopy (TEM). During ORR, Li_2O_2 particles formation is controlled by Li^+ diffusion in the electrolyte and Li_2O_2 particles nucleate at the carbon electrode-electrolyte interface. Li_2O_2 nucleation and growth were also observed within the electrolyte where there was no direct contact with the carbon electrode. These Li_2O_2 particles exhibit growth following O_2^- diffusion-limited kinetics, which indicate the existence of non-Faradaic disproportionation reaction of intermediate LiO_2 into Li_2O_2. Our in-situ liquid TEM work depicts the ORR/OER fundamentals in Li-O_2 battery system under factors controlling the discharge and charge process. We expect findings here to guide both the electrode design and the electrolyte screening aiming for enhancement of the ORR and OER kinetics in Li-O_2 battery cells. We also show that the use of cryo-TEM can uncover electrochemical interfaces in polymer lithium cells. In particular, we were successful in understanding the composition and structure of SEI as a function of polymer electrolyte and lithium salts.

4:25 PM CT01.04.02
***Operando* Electroanalytical Liquid Cell Microscopy for Energy Applications** Khim Karki[1], Rui Filipe Serra Maia[2], Eric A. Stach[2], Daan Hein Alsem[1] and Norman Salmon[1]; [1]Hummingbird Scientific, United States; [2]University of Pennsylvania, United States

Liquid electroanalytical measurements performed inside the transmission electron microscope (TEM) and X-ray microscope (XRM) are becoming more common and are used to study a wide range of electrochemical reaction-systems at the nanoscale [1-4]. The capability to apply stimuli such as electrical, heating and electrochemical measurements has already started to provide new insights on the dynamics and structural changes during nanoparticles synthesis [1,4], lithium charge and discharge [2], crystal growth [3], and metal corrosion [1]. However, the inability to acquire practical quantitative information in TEM/XRM, mimicking bulk behavior, has prevented researchers from interpreting data accurately and reliably. First, the hardware components are not optimized to perform in the reduced scale environment of the TEM/XRM [5]. Second, the chips configurations such as sizes and aspect ratios of different electrodes suitable for various electroanalytical measurements are poorly designed. Here, we present a newly developed electrochemical *operando* platform to obtain real-world bulk electrochemical analysis during liquid-phase TEM/XRM microscopy.

The *operando* liquid cell platform typically consists of two microfabricated chips sandwiched with electron transparent SiNx membranes for encapsulating liquid and viewing in the microscope. We integrated newly developed bulk-sized electrochemical counter (CE), and reference electrodes (RE) with optimized electrochemistry chips equipped with a specialized working electrode (WE) surfaces with customizable chemical compositions, such as platinum, gold, carbon, and industrially used amorphous oxide films. This new configuration allows true quantitative measurements of electrochemical processes with details resembling the complete cycle of traditional bench-top bulk electrochemistry. To illustrate this capability, we present cyclic

voltammetry (CV) studies of two model electrochemical systems: electrodeposition and stripping of 01.M $CuSO_4$ and redox cycling of 20 mM $K_3Fe(CN)_6$/20 mM $K_4Fe(CN)_6$ in 0.1M KCl solutions. In the former case, the copper deposition and stripping occur at the working electrode at distinct redox peaks in liquid cells. The use of an actual RE such as Ag/AgCl in the newly developed cell avoids using a pseudo-reference electrode (e.g., chip-patterned metal electrode), which is commonly used in traditional liquid cell microscopy. The bulk RE presents an opportunity to replicate data reminiscent of bulk-scale electrochemistry, particularly concerting the drift in the thermodynamic potential that severely affects electrochemical studies using pseudo-reference electrodes [6]. In the latter case, the current-potential (I-V) relationship in the in-situ cell shows similar Tafel slopes at the same potentials to the large electrode setup tests validating the high electrochemical fidelity of the in-situ cell [7]. The electrochemical data from the new liquid electrochemistry cell can be used to correlate the TEM/XRM structural and chemical analysis with the actual bulk behavior of these electrochemical reactions in a true *operando* condition. The work presented here highlights that with a suitable hardware system, the bulk behavior of the electrochemical processes can be observed and measured quantitatively [8].

***In Situ* Study of Electrode-Electrolyte Interfaces Using Liquid Cell Electron Microscopy** Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Liquid cell electron microscopy has attracted a lot of interest and significant process has been made nowadays. In this talk, I will present the recent work in my group on the study of electrode-electrolyte interfaces with electrochemical liquid cell development. It is known that the formation of high quality solid-electrolyte interphase (SEI) is important to limiting lithium dendrite growth. However, how SEI may be modified during lithium deposition is hard to resolve due to challenges in *in-situ* investigation of the SEI with fine details. With electrochemical liquid cell TEM, we were able to directly observe that lithium dendrite growth was suppressed when a poly(diallyldimethylammonium chloride) (PDDA) cationic polymer film was applied on the electrode. Chemical mapping of the deposits provided remarkable details of SEI on individual nanogranules. It showed that lithium fluorides are uniformly distributed within the inner SEI layer, arising from the instantaneous reaction of the deposited lithium with PF_6^- ions accumulated by the cationic polymer film, thus the dendritic growth of lithium was prohibited. The ability to directly measure SEI chemistry at the nanoscale down to the individual grains *in-situ* and unveil its correlation with lithium deposition behavior opens future opportunities to explore unsolved mechanisms in batteries.

4:55 PM *CT01.04.04
***In Situ* and Cryogenic Electron Microscopy for Energy Materials** Yi Cui[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Developing new energy materials for batteries, solar cells, catalysts and gas storage requires understanding their structural evolution across multiple length and time scale. Over the past 15 years, the Cui group has been developing a set of electron microscopy tools to realize this purpose including in-situ electrochemical cell, in-situ gas reaction, in-situ mechanical indentation and cryogenic electron microscopy (cryo-EM). In this presentation, he will discuss how these advanced electron microscopy techniques impact energy materials. 1)

New generation of battery materials are accompanied by large volume and structure change and instability of interphase. He has developed in-situ electrochemical cells and in-situ mechanical deformation as powerful techniques for establishing the relationship of structural change with electrochemical performance, which provides fundamental guidelines for materials design. Cui has demonstrated the most important case on Si anodes: from fundamental understanding, materials design to realizing commercial success of high energy density batteries. 2) Many energy materials are highly sensitive to environment. Studying their reaction in-situ by environmental electron microscopy could provide insights on reaction mechanisms. Li metal reaction with gases as an important case will be presented. 3) Many energy materials are not stable under electron beam. Advanced cryo-EM recently developed in structure biology could be utilized and further developed for materials science. Cui pioneered the cryo-EM towards battery materials and obtained the first atomic resolution images of Li metal and solid electrolyte interphase. With cryo-EM he has answered many important fundamental questions which puzzled the battery field for a long time. He also demonstrated the power of cryo-EM to study a wide range of energy materials including metal-organic frameworks, perovskite and electrocatalysts.

5:20 PM *CT01.04.05
Understanding the Lithium-Electrolyte Interface in Liquid-Electrolyte and Solid-State Batteries Matthew T. McDowell; Georgia Institute of Technology, United States

Understanding how lithium metal behaves in liquid vs. solid electrolytes is key for developing stable, high-energy density lithium-metal batteries. This talk will discuss my group's efforts in understanding the interface of Li metal when in contact with liquid and solid electrolytes. I will first discuss our work in understanding how the lithium/electrolyte interface evolves in liquid-electrolyte batteries at low temperatures. Lithium metal is an attractive anode material for low-temperature batteries since it overcomes sluggish diffusion of Li^+ in graphite. However, most electrolytes exhibit extremely low Coulombic efficiency (CE) for lithium metal cycling at low temperatures. We have developed an ether-based electrolyte system with carbonate additives that substantially improves the CE of lithium metal cycling down to -60 °C. Lithium metal deposited at low temperatures in this and other electrolytes shows a clear reduction in grain size with decreasing temperature, which is correlated with lower CE. Cryo-TEM and X-ray photoelectron spectroscopy investigation of the solid-electrolyte interphase (SEI) shows that this tailored electrolyte allows for greater inorganic content in the SEI at low temperatures, which enables a compact and conducting passivation layer. Next, I will present my group's work using *in situ* methods to understand the evolution of lithium interfaces in solid-state batteries. For NASICON-structured $L_{1+x}Al_xGe_{2-x}(PO4)_3$ (LAGP), electrochemical experiments combined with multi-modal *in situ* investigation of interfacial reactions reveal how the formation of the interphase is linked to electrochemical degradation. *In situ* transmission electron microscopy (TEM) shows that the reaction of LAGP with lithium is similar to a conversion reaction, in which lithium insertion causes amorphization and volume expansion of ~130%. *In situ* X-ray tomography experiments of operating LAGP-based cells reveal that the growth of the interphase causes fracture of the SSE, and quantification of the crack network shows that the extent of fracture with time is directly correlated to impedance increases within the cell. Based on this knowledge, we have found that interphase growth trajectories can be modulated through the deposition of interfacial protection layers, which can extend cycling stability of symmetric cells by almost two orders of magnitude. Finally, *operando* synchrotron X-ray tomography experiments have been developed and used to directly probe lithium/SSE interface dynamics using other SSEs. Together, the insights gained through these studies highlight the similarities and differences between lithium interfaces in liquid- and solid-electrolyte batteries, and building on this knowledge will be key for development of improved lithium metal batteries.

SESSION CT01.05: Optical/Vibrational Spectroscopy
Session Chairs: Feifei Shi and Yingjie Zhang

8:15 PM *CT01.05.01
Using Vibrational Spectroscopy to Understand and Control Electrochemistry for Electrolyzers and Batteries Andrew Gewirth; University of Illinois at Urbana-Champaign, United States

This talk addresses the use of vibrational spectroscopy to evaluate the reactivity associated with CO_2 reduction electroyzers and solid state batteries. In the first área, electrodeposition of CuAg, CuSn, or CuZn alloy films yields high surface area catalysts for the active and selective electroreduction of CO_2 to multi-carbon hydrocarbons and oxygenates. Alloy films containing Ag exhibit the best CO_2 electroreduction performance, with the Faradaic efficiency for C_2H_4 and C_2H_5OH production reaching nearly 60 and 25%, respectively, at a cathode potential of just –0.7 V *vs.* RHE and a total current density of ~–300 mA/cm^2. Alloy films containing Sn exhibit greater efficiency for CO production relative to either Cu along or CuAg at low overpotentials. *In-situ* Raman and electroanalysis studies suggest the origin of the high selectivity towards C_2 products to be a combined effect of the enhanced stabilization of the Cu_2O overlayer and the optimal availability of the CO intermediate due to the Ag or Sn incorporated in the alloy. Sn-containing films exhibit less Cu_2O relative to either the Ag-containing or neat Cu films, likely due to the increased oxophilicity of the admixed Sn. CuZn films exhibit enhanced production of oxygenated products, particularly ethanol. Additionally, modification of the Cu electrode with certain polymers yeilds substantially enhanced reactivity, due in part to control of the Cu_2O layer.
Relevant to batteries, we discuss solid electrolytes (SEs) which have become a practical option for lithium ion and lithium metal batteries due to their improved safety over commercially available ionic liquids. The most promising of the SEs are the thiophosphates whose excellent ionic conductivities at room temperature approach those of commercially-utilized electrolytes. Spectroscopic and structural studies on these materials lead to new formulations exhibiting advantageous properties.

Probing Electrode/Electrolyte Interface Using Plasmon Based Raman Spectroscopy—Recent Progress
Guang Yang, Ilia Ivanov and Jagjit Nanda; Oak Ridge National Laboratory, United States

Plasmonic based Raman spectroscopic methods such as Surface and Tip- Enhanced Raman Spectroscopy (SERS and TERS) are extremely sensitive techniques with high interfacial selectivity.[1-3] However, applying these methods to obtain insights on the underlying interfacial phenomena at the electrode-electrolyte interphase in a functioning battery is challenging. In this regard, we have undertaken a systematic approach by first studying solvation properties of lithium-ion battery electrolytes using gold nanoparticle monolayer as a gap-mode SERS substrate. Specifically, we have chosen Lithium hexafluorophosphate ($LiPF_6$) salt in carbonate solvents -Ethylene Carbonate (EC) and dimethyl- carbonate (DMC). SERS studies shows the solvation shell surrounding Li-cation is different in at the bulk of the electrolyte than at the interface (close to the gold electrode). We have compared SERS results with normal Raman and FT-IR spectroscopy that captures the ensemble average. Insitu time resolved SERS studies showed dynamic changes in the Li-cation coordination close to the interface. Our findings here provide a unique high surface sensitive platform for studying the electrolytes molecules both qualitatively and quantitatively at interface. This work will create further interest in other areas where solid/liquid interface is essential, such as water desalination, heterogeneous catalysis, electrophoresis, corrosion, mass transport across bio membranes,

***In Situ* Raman Spectroscopy of Sulfate Phases in Early-Stage OPC Hydration** Hee Jeong Kim, Hyunchae Loh and Admir Masic; Massachusetts Institute of Technology, United States

Carbon dioxide (CO_2) emissions during cement manufacturing are increasing daily, and the cement industry accounts for 7% of global CO_2 emissions (WBSCD, 2018). Research on cement hydration mechanism is the key for both understanding the physicochemical properties of the cement matrix and designing sustainable and durable construction materials. However, often it is difficult to characterize the initial hydration reactions of cement clinker (tricalcium silicate, dicalcium silicate, tricalcium aluminate, and tetra-calcium aluminate) that take place at the same time. Furthermore, it is difficult to identify the exact phase transformations during the cement hydration processes. Most physicochemical characterization methods applied to cement (BET, MIP, XRD, etc.) are performed on solid-state samples that have been prepared with hydration stoppage, dehydration, or pulverization, which could significantly affect the conditions. Also, the low crystallinity of the major hydrates such as calcium silicate hydrates(C-S-H) poses significant characterization challenges when traditional methods such as XRD are used. In this study, we used in-situ and operando confocal Raman spectroscopy to understand the early stage hydration kinetics of Ordinary Portland cement. In particular, 4% of the $CaCO_3$ powder was added to the mix to accelerate the hydration; we monitored the ettringite formation, which is closely related to the cement paste setting and its rheological properties. We spatially resolved and mapped the sulfate phase transformation with a high spatial (1-micron) resolution and an excellent signal-to-noise ratio.

***In Situ* PM-IRRAS at the Air/Liquid/Solid Interface—Probing the Effects of Cations on Iron Surface Oxidation** Kathryn A. Perrine; Michigan Technological University, United States

Several techniques have been developed to measure *in situ* surface reactions at the gas/solid and liquid/solid interfaces from vacuum to ambient pressure environments. Probing chemical reactions in liquid environments become more complex with the addition of electrolytes, gases, and resulting interface transformations. Surface vibrational spectroscopy measures the effect of adsorbed surface species at the liquid/solid interface that can determine intermediate steps in environmental and electrochemical processes, that involve surface catalytic reactions. Our group has developed a new vibrational technique that simultaneously measures the air/liquid/solid interface using *in situ* polarized modulated infrared reflection absorption spectroscopy (PM-IRRAS). This technique was validated using a well-known system of alkanethiol adsorption on gold at the air/ethanol/gold interface in non-aqueous solutions and applying a model of a three-phase system.
We present our investigation of the *in situ* iron interfacial oxidation from the influence of cations on the formation of inorganic scale, from corrosion. Iron interfaces are ubiquitous in soil, dust, and used as earth-abundant heterogeneous catalysts that undergo spontaneous redox reactions in the presence of oxygen and water, two key reactions in the corrosion mechanism. Chloride ions in electrolytes are found to catalyze the reaction in complex aqueous environments leading to different oxidation rates and results in different mineral

scale growth. In this study, different alkali and alkaline chloride electrolyte solutions were studied on the surface of iron to measure the influence of cations on surface corrosion. The electrolytic solutions are shown to either increase or decrease the rate of oxidation, producing different mineral scale from the reaction with air. These findings are corroborated with X-ray photoelectron spectroscopy and *in situ* liquid atomic force microscopy measurements, connecting oxidation states and surface morphology with surface vibrational signatures. These studies demonstrate how *in situ* PM-IRRAS reveals surface redox mechanisms that impact complex chemistry in the water and mineral cycles, electrochemical catalysis, and material degradation.

Operando Local pH Imaging in CO_2 Reduction Gas Diffusion Electrodes Using Confocal Microscopy
Alex J. Welch, Aidan Q. Fenwick, Ian Sullivan, Chengxiang Xiang and Harry A. Atwater; California Institute of Technology, United States

Here we report a new operando experimental technique to determine the local pH at various depths within an operating CO_2 reduction gas diffusion electrode (GDE). There is currently a lack of experimental data and understanding of the reaction conditions at the catalyst surface in CO_2 reduction GDEs - the thickness of the water layer and the local pH near the catalyst. Being able to observe these conditions *in situ* during GDE operation is important for understanding how the pH and local water quantity effect the selectivity and activity of the device. Measuring these quantities is typically difficult because of the opaque nature of materials used in GDEs and the short relevant length scales. We use a two-color fluorescent pH sensitive dye, DHPDS, with a pK_a of 7.33 and 8.53. The dye is dissolved in the electrolyte and excited by a 458 nm and 488 nm laser consecutively in a confocal microscope. The emission is collected from the two separate excitations and the ratio of the intensity is linearly proportional to the pH. The confocal allows us to excite the dye at specific planes in z, allowing us to see the pH at up to a 40um depth within the porous GDE. As a control we measured what the pH is at the surface of the electrode with no applied potential, and found that the local pH was greater than 9 while the bulk electrolyte (100mM $KHCO_3$ CO_2 saturated) had a pH of 6.8, when a potential -0.5V vs RHE is applied. This increase is due to the fact that protons are consumed during the CO_2 reduction reaction. The next step in the experiments is to characterize the pH at a range of potentials with operando microscopy observation of local reaction conditions in the pores of the electrode and to determine the uniformity of catalytic activity in the lateral direction, within the catalyst layer plane. We will also report results of experiments with several heterogeneous CO_2 reduction catalysts including Ag, Cu and their alloys, supported on different types of GDE materials with various hydrophobicity and structure. We anticipate that this technique will yield insights that inform future GDE design to optimize wetting and that knowledge about local pH will enhance our knowledge of catalytic mechanisms and control of catalytic selectivity and energy efficiency.

10:20 PM CT01.05.07
Fluorophores “Turned-on” by Corrosion Reactions Can Be Detected at the Single-Molecule Level Anuj Saini; Case Western Reserve University, United States

Corrosion is an interfacial process that has a profound impact on society. While the mechanism of iron corrosion has been known for centuries, we haven’t been able to visualize corrosion at the molecular scale due to the spatial and temporal limits of current microscopies and the long time scale of corrosion to develop larger microscale features. We demonstrate that fluorogenic molecules that “turn-on” upon redox reactions can sense the corrosion of iron at the single molecule scale. We first observe the cathodic reduction of non-fluorescent resazurin to fluorescent resorufin in the presence of iron in bulk solution. We show that the fluorescence signal is directly related to the amount of electrons that are available due to corrosion progression and can be used to quantify the catalyzed increase in the rate of corrosion by NaCl. By using modern fluorescence microscopy instrumentation we detect real-time, single-molecule “turn-on” of resazurin by corrosion, overcoming the previous limitations of microscopic fluorescence corrosion detection. Analysis of the total number of individual resorufin molecules shows heterogeneities during the progression of corrosion that are not observed in ensemble measurements.

Probing the Liquid/Surface Interactions on Functionalized Graphene James Carpenter, Hyunchul Kim, Arend van der Zande and Nenad Miljkovic; University of Illinois at Urbana-Champaign, United States

The novel properties of 2D materials, such as graphene, are proposed to enable exciting applications in diverse areas such as sensing, electronics, and mechanics. However, the thinness of 2D materials and their sensitivity to environmental conditions present challenges when examining the fundamental liquid/solid interactions. For instance, it has been shown that the wettability, surface friction, and electrical conductivity of graphene on silicon dioxide can be tuned by adding bond terminations like hydrogen and fluorine to the graphene lattice. However, graphene's wettability, which is typically characterized using contact angle measurements, has also been shown to vary with its supported substrate—a phenomenon known as wetting transparency. This wetting transparency can further be complicated by the adsorption of volatile organic compounds (VOCs) that lower the surface energy of the substrate, raising the contact angle. Thus, to fully leverage the exciting properties of 2D materials for novel applications, we must develop a more rigorous understanding of the interactions between the 2D material, its supporting substrate, and its surroundings.

In this work, we used microgoniometry to examine the wettability of supported bare graphene and its functionalized forms, including fluorinated, hydrogenated, and hydro-fluorinated graphene. The diameter (50 – 100 microns) of the droplets produced using our microgoniometry apparatus eliminates the effects of gravity on the contact angle measurements, leading to high-fidelity results. The graphene samples were functionalized with hydrogen and/or fluorine bond terminations by indirect exposure to hydrogen plasma and xenon difluoride (XeF_2). We examined a range of substrates, including silicon dioxide, sapphire, gold, copper, and Parylene C. A combination of UV/Ozone exposure and plasma cleaning ensured that the graphene and substrates were cleaned properly to minimize the effects of residues from the graphene transfer process and volatile organic compounds. The effect of the cleaning and quality of the graphene was verified using XPS, ToF-SIMS, and Raman spectroscopy. We also systematically examined the effect of VOCs by exposing the samples to ambient conditions for specific amounts of time. The results indicate that the wetting transparency of graphene depends on the specific bond termination, underlying substrate, and exposure to VOCs. Our results offer guidance to those seeking to use graphene in novel applications where the liquid/solid interaction is of paramount importance, such as liquid phase sensors, actuators, and surface modifiers.

(Photo)electrocatalysis at Work—Understanding Chemical Transformations Francesca Maria Toma; Lawrence Berkeley National Laboratory, United States

Artificial photosynthesis is a promising route for efficient conversion of solar energy to chemical fuels. To positively affect the *status quo*, polycrystalline, yet defective and heterogeneous, semiconductor materials are excellent candidates for targeting high efficiency, as well as low production cost, and long lifetimes of the device. However, a typical conundrum in this field is related to the fact that efficient materials are not durable, whereas durable materials show poor efficiency. In this context, characterization of materials transformation and charge transport mechanism is critical to enable design and development of new functional systems. We have established a suite of characterization techniques, including *in situ*/*operando* characterizations to provide insights into the materials chemical transformation in artificial photosynthesis. For instance, we use conductive

and electrochemical atomic force microscopy (AFM) to elucidate functional variations and structural changes at the nanoscale, and we utilize scanning transmission X-ray microscopy (STXM) to provide insights into the electronic structure and chemical composition of functional photoelectrochemical materials. Better understanding of the material behavior during operating conditions can lead to ultimate optimization of fuel cell efficiency.

12:40 PM *CT01.06.04
Nanoscale Probes of Carrier-Selective Catalyst/Semiconductor Contacts in Water-Splitting Photoelectrodes Shannon Boettcher; University of Oregon, United States

Heterogeneous electrochemical processes, including photoelectrochemical water splitting to evolve hydrogen using electrocatalyst-coated semiconductors, are driven by the accumulation of charge carriers and thus the interfacial electrochemical potential gradients that promote charge transfer. Conventional electrochemical techniques measure/control potentials at the conductive substrate or semiconductor ohmic contact, but are unable to isolate processes and electrochemical potentials at the surface during operation. I will present our recent work demonstrating that the nanoelectrode tip of an atomic-force-microscope cantilever can effectively sense the surface electrochemical potential of electrocatalysts coating semiconductor photoelectrodes during operation. This technique allowed us to unambiguously show that metal (oxy)hydroxide layers act as both hole collectors and oxygen-evolution catalysts on metal-oxide photoanodes such as Fe_2O_3 and $BiVO_4$. We also discovered the critical role that heterogeneous interfacial barrier heights, and a related nanoscale pinch-off effect, play in building carrier-selective interfaces in semiconductor photoelectrodes for generating fuel from sunlight.

From Making Disinfectants and Rocket Fuels to Powering Heavy-Duty Vehicles—Single Atom Catalysts for Small Molecule Activation Huolin Xin; University of California, Irvine, United States

The ammonia you use to clean and disinfect your kitchen floor starts off as nitrogen, a gas that makes up almost 80 percent of Earth's atmosphere. But the conversion requires the breaking of a strong chemical bond in a high-heat, high-pressure industrial process known as the Haber-Bosch process. In nature, however, bacteria convert nitrogen gas to ammonia with a nitrogenase enzyme, whose active center is molybdenum, an abundant, nonprecious metal. By mimicking this biological nitrogen fixable process, my group has recently developed a series of new catalysts that can produce ammonia, rocket fuels, and power heavy-duty vehicles in a more sustainable way. The key is anchoring single metal atoms in a nitrogen/oxygen/carbon-coordinated environment to form a so-called single-atom catalyst (SAC). Unlike the Haber-Bosch process, which consumes massive amounts of energy and emits significant quantities of carbon dioxide to the atmosphere, these cheap, single-atom catalysts can be incorporated into modular and compact electrolyzing cells to produce commodities (ammonia, methane, and formate), as well as high-value-added chemicals like pharmaceuticals, with renewable solar or wind power. This emerging technology will not only make the traditional chemical production process greener but can also pave the way for a decentralized chemical industry.

2:40 PM CT01.07.02
Ultrahigh Oxygen Evolution Reaction Activity Achieved Using Ir Single Atoms on Amorphous CoOx Nanosheets Maoyu Wang and Zhenxing Feng; Oregon State University, United States

In the past decades, the renewable energy storage and energy conversion systems, such as fuel cells, water electrolysis, and metal-air batteries, have attract great attention. Oxygen evolution reaction (OER) is a key half reaction of water splitting to produce clean fuels. However, the sluggish kinetics of OER has significantly limited the performance and commercialization of such energy conversion devices. Up to now, the most efficient OER catalysts are still noble metal and metal oxides of Ruthenium (Ru) and Iridium (Ir), which are not cost-effective catalysts and unstable under high potentials. Recently, single atom catalysts have been used to improve the surface-to-volume ratio to increase OER catalytic activity. In our work, Ir single-atom catalysts supported by CoO_x amorphous nanosheets (ANSs) for OER. Experimental results show that Ir single-atoms are anchored by abundant surface-absorbed O in CoO_x ANSs. The Ir single-atom catalysts possess ultrahigh mass activity that is 160-fold of commercial IrO_2. The OER of $IrCoO_x$ ANSs reached a record-low onset overpotential of less than 30 mV. The *in-situ* X-ray absorption spectroscopy reveals that the Ir-O-Co pairs directly boosted the OER efficiency and enhanced the Ir stability.

2:55 PM CT01.07.03
Synthesis of FeCo-N-OLC Catalyst for Oxygen Reduction Reaction Brenda L. Vargas Pérez, Osvaldo E. E. González Sánchez, Yannelly A. Serrano Rosario, Kattia M. Gonzalez Aponte, Fabiola N. Sánchez Fonseca and Lisandro Cunci; Universidad Ana G Méndez, Puerto Rico

The world's main source of energy is fossil fuels, but fossil fuels are finite resources and can also irreparably harm the environment. According to the United States Energy Information Administration, the burning of fossil fuels was responsible for 76 percent of the US greenhouse gas emissions. Fossil fuels not only pollute the environment, but also affect human health. My research focuses on making a catalyst that is economical, efficient and above all friendly to the environment. The oxygen reduction reaction (ORR) is an important reaction for energy conversion systems, such as fuel cells. The fuel cells generate electricity directly by electrochemically reducing oxygen and oxidizing fuel in water as the only by-product. Onion-like carbon (OLC) are used as a catalytic support for fuel cell applications due to their high conductivity and high surface-to-volume ratio. The combination of carbon compounds with conductive polymers results in new materials and devices with possible practical applications. In recent decades, several studies have been conducted on nitrogen doped structures in carbon materials for the ORR. In my research we use nanodiamonds (NDs) to dope them with the polymerization of the aniline monomer. Then, through a pyrolysis process, we convert the ND/PANI particles into N-OLC. These particles are then polymerized using the aniline and pyrrole monomers to dope the OLCs with nitrogen. These particles are characterized using the following techniques, Raman, Fourier-transform infrared spectroscopy (FTIR), Scanning Electron Microscopy (SEM), Energy-dispersive X-ray spectroscopy (EDS) and X-ray Diffraction (XRD). Then the synthesis is carried out with the non-precious metals. The non-precious metals that we use are iron and cobalt. ORR experiments were performed with the FeCo-N-OLC particles. In future work we will characterize these samples using synchrotron techniques.

3:10 PM *CT01.07.04
***In Situ* Characterization of Electrocatalysts for the Oxygen Evolution and the CO_2 Reduction** Alexis Bell; University of California, Berkeley, United States

The electrochemical reduction of CO_2 using electrical energy derived from renewable sources (wind and solar) offers a potentially attractive means for producing carbon-based chemicals and fuels, particularly if the CO_2 can be recovered from the atmosphere. Accomplishment of this goal requires two types of catalysts – an anode catalyst that facilitates the oxidation of water to O_2 and either H^+ or OH^-, depending on the pH of the electrolyte, and a cathode catalyst that facilitates the reduction of CO_2 to hydrocarbons and oxygenated products. Extensive research has found that IrO_2 is the best catalyst for the oxygen evolution reaction (OER) in acidic electrolytes and FeNiOOH is the best catalyst for this reaction in basic electrolytes. On the other hand, Cu is the only metal that promotes the electrochemical reduction of CO_2 to hydrocarbons and oxygenates with high faradaic efficiency. This talk will focus on experimental techniques that have been used to characterize IrO_2, FeNiOOH, and Cu under working conditions, i.e., in situ. The technique that will be discussed include

infrared spectroscopy, X-ray absorption spectroscopy, ambient-pressure X-ray photoelectron spectroscopy, and X-ray diffraction. We will see that use of these in situ techniques enables acquisition of critical information about the composition and structure of the working catalyst and, in some cases, the nature of adsorbed species on its surface under working conditions.

Resolving the Controversy over the Elusive Components in Solid Electrolyte Interphase on Li Metal Anode Enyuan Hu[1], Zulipiya Shadike[1], Hongkyung Lee[2], Xia Cao[2], Jie Xiao[2] and Xiao-Qing Yang[1]; [1]Brookhaven National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States

Lithium metal anode has great advantages such as extremely high theoretical specific capacity (3860 mA h g−1), low density (0.59 g cm−3) and the lowest negative electrochemical potential (−3.040 V vs. the standard hydrogen electrode) and is considered as the ideal anode for rechargeable lithium batteries. Major challenges it faces include lithium dendrite formation and incompatibility with state-of-the-art electrolyte. Solid-electrolyte-interphase (SEI) plays a key role in determining the reversibility of lithium metal anode and engineering of SEI holds great promises for addressing the previously mentioned challenges. Understanding the properties of SEI is of great importance and has been the focus of many research. In this talk, three questions related to this topic will be discussed based on the results obtained from synchrotron-based scattering experiments. 1. Is LiH really an SEI component? 2. How come an ionic insulator like LiF can be considered as a good SEI component? 3. Is it possible to quantify crystalline/amorphous components in SEI? Strengths and limitations of currently available techniques for studying SEI will also be discussed.

Electrochemical Generation of Liquid and Solid Sulfur on Two-Dimensional Layered Materials with Distinct Areal Capacity Ankun Yang[1,2], Guangmin Zhou[1] and Yi Cui[1]; [1]Stanford University, United States; [2]Oakland University, United States

Lithium-sulfur (Li-S) batteries are attractive candidates for energy storage in electric vehicles and grid-scale storage due to their high energy density and low-cost potential. Sulfur, the charge product in Li-S batteries, was believed to be solid, while we recently discovered that sulfur can stay in a super-cooled state as liquid sulfur. However, how the sulfur state (liquid or solid) affects Li-S battery performance is not clear. Here we demonstrate that liquid and solid sulfur provide very different areal capacities through in situ study of electrochemical sulfur generation. We report distinct growth behaviors of sulfur on two-dimensional (2D) layered materials: on the basal plane, only liquid sulfur accumulates; at the edge sites, liquid sulfur accumulates if the thickness of the 2D materials is small, while solid sulfur nucleates if the thickness is large. Based on our understanding of the edge-induced sulfur crystallization, we control the sulfur state (liquid or solid) and demonstrate much larger areal capacities from liquid sulfur compared to solid sulfur in the same charge time period. This work correlates the sulfur states with their electrochemical performance and provides insights on electrode designs for Li-S batteries and the application of 2D materials in Li-S batteries.

6:10 PM *CT01.08.04
Quantifying Capacity Losses Due to Solid-Electrolyte Interface Formation Michael F. Toney; University of Colorado Boulder, United States

Understanding the origins of failure and limited cycle life in lithium-ion batteries (LIBs) requires quantitative linking capacity-fading mechanisms to electrochemical and chemical processes. This is challenging in real systems where capacity is lost during each cycle to both active material loss and solid electrolyte interphase (SEI) evolution. In this talk, I will describe the model system-based approach that we have adopted that combines precision electrochemical measurements of the Coulombic efficiency (CE) and x-ray measurements of the SEI layer and active materials loss. By contrasting these independent quantities, we obtain insight into the SEI growth and evolution. I will discuss how we have used X-ray reflectivity (XRR) to obtain nanoscale insight into solid electrolyte interfaces (SEI) on model anode surfaces that implicate electrochemically formed LiF as playing a major functional role in the SEI. I will also describe how XRR tracks the thickness of a-Si thin films and when this is compared to the CE, we can quantify SEI growth over several cycles. The methodology we are adopting allows to quantitatively track the desirable and undesirable electrochemical processes.

SESSION CT01.09: X-Ray Characterization

CT01

8:15 PM CT01.09.01
Late News: *In Situ* X-Ray Scattering Studies of Organic Electrochemical Transistors Lauren Asselt[1], Nicholas D'Antona[1], Lucas Flagg[1], Tommaso Nicolini[2], Natalie Stingelin-Stutzmann[3], Jonathan W. Onorato[4], Christine Luscombe[4], Chad R. Snyder[1] and Lee Richter[1]; [1]National Institute of Standards and Technology, United States; [2]Université de Bordeaux, France; [3]Georgia Institute of Technology, United States; [4]University of Washington, United States

Organic electrochemical transistors (OECTs) are a novel device architecture, emerging as a potential platform for biosensors and neuromorphic computing. In an OECT, volumetric doping (gating) of the active semiconductor is achieved through ingress of electrolyte ions, under potential control. This opens unique transduction modalities, due to the mixed (ionic and electronic) modes of conduction. This also challenges established paradigms for the operation of traditional, organic field-effect transistors as operation involves the dynamic swelling of the active layer by both solvent and ion. Thus, quantitative understanding of operation (and process-structure-function relationships) requires in-situ measurements of the films under potential control and in contact with electrolyte. Poly(3- (methoxyethoxyethoxymethyl)thiophene) (P3MEEMT) has emerged as an interesting, prototypical OECT material, differing from the classic OFET material, regioregular poly(3-hexyl)thiophene (P3HT), by the replacement of the non-polar alkyl side chains with oligoethylene glycol (OEG).[1] The OEG side chains facilitate ingress of aqueous electrolytes and introduce rich thermal processing behavior. Combining DSC with in-situ thermal GIWAXS we develop a detailed understanding of the thermal processing of P3MEEMT films. Annealing at (115 to 125)° C, above a crystal to liquid crystal transition, results in distinct semicrystalline morphology with predominantly face-on, pi-stacked domains with coherence length, lc, along the lamella (100) direction up to 30 nm. Annealing above the liquid crystal melt results in a nearly isotropic crystal orientation distribution, characterized by significantly shorter lc. The water vapor swelling of the thermally processed films is studied by both in-situ ellipsometry (total film swelling) and GIWAXS (crystalline domain swelling). The volumetric swelling varies with processing and at all times significantly exceeds the swelling of crystalline material, indicating the majority of the water is in the amorphous regions. Volumetric swelling does not exhibit simple Flory-Rehner behavior with a constant χ. Using a novel ‘rolling drop’ electrode, we are able to characterize the electrochemical doping of the films, as a function of both initial

thermal processing and of final water content, from contact with liquid water to equilibration with room relative humidity. The crystalline material exhibits changes similar to those observed for vapor phase doping of P3HT[2]: a small expansion of the (100) lamella separation and a contraction of the π-π separation. The (100) expansion and π-π collapse occur at potentials consistent with the transistor threshold, at doping densities of order 4 10^{20} cm^{-3}.

Investigating Amphiphilic Polymer Surface Chemistry in Conditions from Vacuum to Hydration with Ambient Pressure XPS Mikayla Barry[1], Pinar Aydogan Gokturk[2], Rachel Segalman[1] and Ethan J. Crumlin[2]; [1]University of California, Santa Barbara, United States; [2]Lawrence Berkeley National Laboratory, United States

Marine antifouling coatings represent an environmentally benign solution to the adhesion of marine organisms that markedly reduces fuel efficiency on ships. The success of these coatings is determined by molecular-scale interactions that take place between the polymer surface, water, and marine organisms. Because polymer surfaces restructure in response to the surrounding environment, *in situ* characterization is crucial for providing an accurate understanding of the surface chemistry in ambient conditions. To evaluate the surface chemistry of membrane-relevant polymers and their interactions with interfacial water (i.e. water sorption), we present synchrotron Ambient Pressure XPS (APXPS) studies performed on polymer surfaces in contact with water vapor. Amphiphilic side chains incorporated into these polymers showed surface-directing capabilities in conditions ranging from vacuum to the liquid interface present at 20 Torr water vapor, with side chains contributing more to the surface signal than predicted from the theoretical bulk composition. Depth probing in conditions up to 800 mTorr also indicates that these side chains are saturated at the top surface. Furthermore, substantial water sorption at 20 Torr water vapor suggests a surface with a less well-defined water–polymer interface that may aid the coating's performance as an antifouling material. These findings may be useful in designing and characterizing coatings that leverage favorable interactions with water for marine antifouling applications.

Probing the Role of Polymer Side-Chain Chemistry and Sorbed Counterion on Water Sorption—An *In Situ* APXPS Study Pinar Aydogan Gokturk[1], Mikayla Barry[2], Rachel Segalman[2,3] and Ethan J. Crumlin[1,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Santa Barbara, United States; [3]University of California Santa Barbara, United States

Water interactions with polymer surfaces play an important role in nearly all aspects of life including cellular functions, electrochemistry and water purification. Yet the precise understanding and quantification of such interactions at a molecular level is still incomplete due to difficulty of operating many surface specific techniques under *in situ* conditions. To fill this gap, we use ambient pressure Tender X-ray Photoelectron Spectroscopy (APXPS [1-4]). Tender-APXPS combines the chemical specificity, high surface sensitivity and quantitative analysis of the surface composition of traditional XPS and allow studies at pressures up to 20 Torr. In this study, interaction of water vapor with model styrenic polymer thin film surfaces were investigated *in situ* from UHV up to 100% relative humidity (RH) with APXPS to understand the effect of functional groups, interaction types and counter ions. Our results suggest that the interaction of water with polymer surfaces is mediated by polar and charged functional groups. Additionally, we show that water sorption on polyelectrolytes is highly dependent on the counterion and the fraction of dissociated ionic groups.[5] This talk will also discuss the counterion specific potential developments on the polyelectrolyte/solution interface using the facile advantage of XPS to carry information on local potentials. We believe that these findings will provide direct insight into the critical role of side-chain and counterion chemistry in polymer-water interactions while also demonstrating the potential of APXPS with elemental and potential sensitivity to give valuable information to guide the design and control of future membrane-relevant materials for water and energy applications.

***In Situ* XPS study on Lithiation/Delithiation of a Silicon Electrode for All-Solid-State Lithium-Ion Batteries** Takuya Masuda[1,2]; [1]National Institute for Materials Science, Japan; [2]Hokkaido University, Japan

Silicon is a promising candidate for an anode material of next-generation lithium batteries because of its high abundance, negative redox potential (0.35 V vs Li+/Li), and potentially high capacity density (4200 mAh g−1). However, the details of the lithiation/delithiation reactions of the Si electrode in all-solid-state batteries have remained unclear. Transferring such air-sensitive samples from the battery testing environment to the measurement apparatus may significantly change the structure and chemical state of samples due to undesired side reactions. Furthermore, post-processing ex situ approaches using multiple samples may result in misinterpretation due to the variation of samples. Thus, in situ reaction analysis is essential to clarify the mechanism of lithiation/delithiation processes.

X-ray photoelectron spectroscopy (XPS) enables to determine the elemental composition, oxidation states, and electronic structure of sample surfaces in a vacuum chamber. The reaction process can be tracked in a stepwise manner without any influence of variation and inhomogeneity of samples if XPS can be applied to a certain position of the same battery sample under bias application conditions. Such in situ XPS allows us to assign each spectral feature properly to reaction products and to correlate the effect of reaction products on the reversibility of charge/discharge reactions.
Here, we have developed an in situ XPS apparatus equipped with a bias application system and applied it to the electrochemical lithiation/delithiation reactions of an amorphous Si electrode sputter-deposited on a Li6.6La3Zr1.6Ta0.4O12 (LLZT). Upon the first lithiation, a broad Li peak appears at the Si surface, and peaks corresponding to bulk Si and Si suboxide significantly shift to lower binding energy, showing the formation of lithium-silicide and lithium-silicates due to the lithiation of Si and native oxide. Quantitative analysis of electrochemical response and photoelectron spectra determines the composition of lithium-silicide to be Li3.44Si. Peak fitting of the broad Li peak shows the formation of Li2O and Li2CO3 due to side reactions. After the delithiation, the peak corresponding to Li3.44Si phase shifts to higher binding energy to form Li0.15Si phase, while lithium-silicates, Li2O, and Li2CO3 remains as irreversible species. Thus, electrochemical reactions accompanied with lithiation/delithiation processes are successfully observed.

Platinum Nanocatalyst Degradation During the Oxygen Evolution Reaction Analyzed Through *In Situ* Liquid-Phase Transmission Electron Microscopy Rui Filipe Serra Maia[1], Yijin Kang[2] and Eric A. Stach[1]; [1]University of Pennsylvania, United States; [2]Northwestern University, United States

Photochemical water splitting is very promising because it converts solar energy into chemical energy in the form of molecular hydrogen (H_2), the most energy-rich chemical compound per unit of mass[1]. However, this process is severely affected by catalyst degradation at the anode, where the strong oxidizing environment necessary for the oxygen evolution reaction (OER) causes fast platinum degradation, which is the most active catalyst for this reaction[2]. Currently there are no efficient ways to prevent the catalyst degradation, which results in prohibitive industrial costs and prevents the widespread use of this technology to obtain H_2 and compete with fossil fuels[3]. This happens because it is very difficult to analyze how the chemistry and structure of platinum change at the atomic-scale when subjected to OER electrochemical potential in real-world conditions[4].
We performed *in situ* liquid-phase Transmission Electron Microscopy (TEM) analysis to obtain a time-resolved analysis of platinum nanocatalysts subjected to OER electrochemical stress. The results show that surface Pt_xO_y play a key role in the mobility and dissolution of platinum nanocatalysts during the oxygen evolution reaction. Catalyst degradation involves grain aggregation and growth, followed by Pt_xO_y driven platinum dissolution. The electrochemical stress and degradation effects can be minimized by reducing grain boundary density and through application of intermittent electrochemical stress, which can be achieved by applying a pulsed potential as opposed to a continuous fixed potential. These insights allow correlating the catalyst degradation kinetics to the reaction conditions and catalyst properties, enabling rational optimization of variables such as crystallite size, grain boundary density and the electrochemical protocol for reverting the catalyst degradation and

enabling industrially sustainable hydrogen generation from water splitting.

Insights on Structure-Property Correlations in Hafnia-Based RRAM Devices by *In Situ* TEM Leopoldo Molina-Luna, Robert Eilhardt, Alexander Zintler, Déspina Nasiou, Oscar Recalde, Stefan Petzold and Lambert Alff; TU Darmstadt, Germany

Hafnia based resistive random-access memory (RRAM) devices are promising candidates as next generation non-volatile memories and are appealing because of the compatibility with back-end-of-line processes in the current semiconductor fabrication process. Thus, improving device reliability is crucial for their use in future memory applications. Understanding the influence of the microstructure and the atomistic processes involved will help enhance device performance. As shown in recent work (1), grain boundary engineering the hafnia layer in TiN/HfO_2 /Pt RRAM can yield forming free devices with threading grain boundaries that act as preferential pathways for conductive filament formation (2). The techniques that will be presented provide examples of how to correlate the local structure to the device properties. In situ experiments that involve heating as well as biasing have been carried out on devices mounted on MEMS-based chips by FIB in situ lift-out

techniques (3) and are key towards providing a component specific understanding of the physical/chemical mechanisms involved. Furthermore, we have performed a temperature-dependent study to directly monitor the microstructure evolution of the hafnia layer directly inside the microscope, thus giving a unique insight into the growth mechanism and formation of grain boundaries. The transformation from an amorphous/nanocrystalline to a polycrystalline state lowered forming voltages and device-to-device variability of the memory devices and served as a basis for a direct structure-property correlation. To further analyse the complex texture transfer mechanisms involved, phase-determination 4D-STEM experiments were carried out to locally correlate HfO_2 grain orientations with the underlying TiN electrode. A Machine Learning approach was implemented for analysing the generated 4D-STEM data sets (4).

Late News: Atomic-Scale Friction Between Single-Asperity Contacts Under *In Situ* Transmission Electron Microscopy Xiang Wang and Scott X. Mao; University of Pittsburgh, United States

To date, visualizing the friction process between nanocontacts at an atomic scale is rarely accomplished. Here, through designing the nanocontact and performing controlled motion between asperities under high-resolution transmission electron microscopy (HRTEM), the real-time atomic-friction process is captured. Moreover, the interface dynamics and friction mechanism are illustrated by combining in-situ TEM observation with molecular dynamics simulation. For the first time under in-situ TEM, the atomic-friction between single-asperity nanocontacts is revealed to display a discrete stick-slip behavior and an asynchronous process for the accumulation and dissipation of the strain energy together with the nonuniform motion of interface atoms. This work provides a study approach to realize in-situ atomic-friction research and attains a fundamental understanding of friction phenomena at the atomic-scale.

8:40 AM CT02.01.03
***In Situ* X-Ray Fluorescence Microprobe (XFM) and Electron Energy-Loss Spectroscopy (EELS) to Determine Valence-State Configuration of CoPt Nanoparticles During Chemical Reaction** Alexandre Foucher[1], Nicholas Marcella[2], Ryan V. Tappero[3], Anatoly Frenkel[2] and Eric A. Stach[1]; [1]University of Pennsylvania, United States; [2]Stony Brook University, The State University of New York, United States; [3]Brookhaven National Laboratory, United States

The synthesis of bimetallic CoPt nanoparticles aims to optimize the use of expensive platinum for critical chemical reactions such as the oxygen reduction reaction (ORR). The crystallographic configuration of the intermetallic solution is directly related to its catalytic performance. For instance, the valence state influences the platinum oxygen bond strength, so it is necessary to know and control the crystal's electronic configuration at the atomic level to enhance catalytic properties. Hence, it is crucial to have a precise knowledge of the electronic configuration of Co and Pt and the atomic level to guide the future design of more efficient and active nanostructures.

To that end, we studied carbon-supported CoPt nanoparticles under reaction conditions with *in situ* XFM and *in situ* EELS. The sample was enclosed in an X-ray and electron-transparent closed-cell reactor, capable of providing both elevated temperatures and exposure to O2 and H2. The 1 μm XFM beam is a bulk approach that provides spectroscopic information over a large set of nanoparticles. In contrast, the EELS was performed in scanning transmission electron microscopy (STEM) mode with a probe size lower than 1 Å, allowing us to characterize the sample at the atomic level. This combination of approaches allows us to determine the chemical properties of individual particles and the overall system.

Results showed the progressive change of the oxidation state of cobalt upon reduction or oxidation. The valence state of cobalt could be determined, and we observe that it is spatially heterogeneous. Particle migration and coalescence was observed for a temperature above 400 °C and we determined the temperature where the reduction of cobalt is triggered. We also identified localized segregation of elements within the bimetallic structure, providing crucial information about the nanocatalysts' degradation mechanisms. This combined *in situ* approach can be applied to a large range of nanostructures and opens new opportunities to understand catalysts under reaction conditions.

8:55 AM CT02.01.04
Late News: Mapping the Element Distribution of Changing Materials: EDS for *In Situ* STEM and SEM
Meiken Falke and Igor Nemeth; Bruker, Germany

We discuss challenges and possibilities using energy dispersive X-ray analysis (EDS) in *in-situ*/*operando* experiments. EDS in TEM/STEM, SEM and T-SEM (electron transparent specimen in SEM) is a powerful and fast technique and well suitable for analyzing the whereabouts of particular species, be that static or during processes in liquids or gases, the application of force, changing temperature and involving specimen beam interaction. The time scale for useful EDS results lies in the range of minutes to seconds, depending mainly on spatial resolution (a 2D map or a spectrum of just one atom [1]) and characteristic X-ray yield. The latter again has various dependencies, which include probe current, radiation damage, collection angle, fluorescence yield and detector efficiency.
The dedicated sample holders and reaction cell designs, which are used for *in situ* experiments, often present a challenge for EDS analysis. It is important to understand how the holder design influences the spectroscopic efficiency and quantitative result. We discuss effects, such as spurious signals e.g. from holder materials, absorption e.g. in reaction cell windows, the influence of heat radiation on EDS spectra [2], specimen drift etc. Approaches and tools available so far to keep such effects under control and correct for respective analysis errors are shown. One simple step to take for example, is optimizing the geometry of the holder and EDS detector position. Adjusting the materials of holders and reaction cell windows to increase EDS efficiency and avoid parasitic signals would be a more complex task.
Furthermore, a stream of data from a changing specimen needs specific analysis strategies. Suitable data acquisition and processing tools, not only for EDS, but including complementary techniques, such as diffraction-based analysis options in SEM, are being developed.

9:00 AM *CT02.01.05
Liquid-Phase Electron Microscopy for Soft Matter Science and Biology Niels de Jonge[1,2]; [1]INM – Leibniz Institute for New Materials, Germany; [2]Saarland University, Germany

Innovations in liquid-phase electron microscopy (LP-EM) are discussed that have enabled experiments at the optimized conditions needed to examine soft matter [1]. Soft matter is referred to as a state of condensed matter that undergoes dynamic changes already at low energy, comparable to kT. Examples are polymers, weakly bound self-assembled structures, and biological systems. The main difficulty in such experiments is the occurrence of electron beam radiation effects, and the resulting complex experimental design and data interpretation that is inevitably influenced by those effects. By at least partially resolving the involved experimental difficulties, LP-EM is now capable of providing nanometer spatial resolution and sub-second temporal resolution for quantitative microscopy of soft matter in materials science and biology. This presentation will provide an overview of the different LP-EM systems available including graphene liquid cells, explain how the resolution does not depend much on the electron optical system but rather on the type of material, the available electron dose, and the sample thickness [2, 3]. Strategies for designing experiments are described as well including the usage of quantum dots [4]. An exciting new discovery is the ability to mitigate radiation damage so that the experiments can be carried out at much higher doses than what was previously expected [5]. Two examples will be given of the application of LP-EM, one in cancer research involving the

epidermal growth factor receptor in breast cancer [6], and one in the observation of quasi-crystals self-assembled in liquid from gold nanoparticles [7]. Finally, a perspective of directly imaging dynamic soft matter processes is given including a discussion on sparse imaging and artificial intelligence.

Late News: Visualizing Oxidation Mechanisms in Few-Layered Black Phosphorus via In Situ Transmission Electron Microscopy Piran Ravichandran Kidambi; Vanderbilt University, United States

Layered two-dimensional (2D) black phosphorus (BP) exhibits novel semiconducting properties including a tunable bandgap and high electron mobility. However, the poor stability of BP in ambient environment severely limits potential for application in future electronic and optoelectronic devices. While passivation or encapsulation of BP using inert materials/polymers has emerged as a plausible solution, a detailed fundamental understanding of BP's reaction with oxygen is imperative to rationally advance its use in applications. Here, we use in situ environmental transmission electron microscopy to elucidate atomistic structural changes in mechanically exfoliated few-layered BP during exposure to varying partial pressures of oxygen. An amorphous oxide layer is seen on the actively etching BP edges, and the thickness of this layer increases with increasing oxygen partial pressure, indicating that oxidation proceeds via initial formation of amorphous PxOy species which sublime to result in the etching of the BP crystal. We observe that while fewlayered BP is stable under the 80 kV electron beam (e-beam) in vacuum, the lattice oxidizes and degrades at room temperature in the presence of oxygen only in the region under the e-beam. The oxidative etch rate also increases with increasing e-beam dosage, suggesting the presence of an energy barrier for the oxidation reaction. Preferential oxidative etching along the [0 0 1] and [0 0 1] crystallographic directions is observed, in good agreement with density functional theory calculations showing favorable thermodynamic stability of the oxidized BP (0 0 1) planes compared to the (1 0 0) planes. We expect the atomistic insights and fundamental understanding obtained here to aid in the development of novel approaches to integrate BP in future applications.

9:40 AM CT02.01.07

Late News: Dynamic Observation of Shear-Induced Reversible Low Angle Grain Boundary Formation in Gold Using *In Situ* TEM Shuang Li[1], Nanjun Chen[1], Bharat Gwalani[1], Mathew Olszta[1], Lei Li[1], Ayoub Soulami[1], Peter V. Sushko[1], Aashish Rohatgi[1], Yulan Li[1], Cynthia A. Powell[1], Suveen Mathaudhu[1,2], Arun Devaraj[1], Shenyang Hu[1] and Chongmin Wang[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of California Riverside, United States

Processing pure metals by employing severe shear deformation can result in introduction of defects and thereby microstructural refinement. However, the atomic scale mechanisms of defect evolution and microstructural refinement during extreme shear deformation of pure metals is still at its infancy. Here, we report our observations of dynamic shear-induced low-angle grain boundary(GB) formation processes in nanocrystalline Au via *in-situ* shear deformation inside a high-resolution transmission electron microscopy. It is found that nanotwins nucleate from free surfaces and propagate inwards. This is accompanied by dislocations glide as well. The alignment of the gliding dislocations leads to the formation of low-angle GB. The collaborative

migration of nanotwins and dislocations result in the material being able to accommodate large plastic strain during shear deformation and fully recover under reversed loading with negligible damage accumulation. This nanotwin-mediated dislocation slip mechanism offers new insights for understanding low-angle GB formation during shear deformation of face centered cubic metals.

9:55 AM CT02.01.08
***In Situ* Transmission Electron Microscopy Temperature Measurement and Characterization of High-Temperature Behavior of Nanostructures** Daan Hein Alsem[1], Pawan Kumar[2,2], James Horwath[2], Deep M. Jariwala[2] and Eric A. Stach[1,2]; [1]Hummingbird Scientific, United States; [2]University of Pennsylvania, United States

Using controlled heat to control the structure of materials during processing is the most common *in-situ* transmission electron microscope (TEM) technique, as temperature causes atomic diffusion and thus allows structural re-ordering. Combining this with the high-resolution imaging and spectroscopy ability of the TEM, these experiments can provide detailed insights into what mechanism governs the relation between materials processing and structure.

Thin-film technology and its application to substrates for *in-situ* TEM has allowed heating systems with very localized heating of the specimen in TEM heating holders, enabling more stable imaging during *in-situ* TEM heating experiments. More recently, direct temperature measurements on these thin-film heating systems have made temperature measurements at the sample become closer to becoming a reality. Although double-tilt TEM heating holders have been available, they suffer from some of the same limitations as standard double-tilt TEM holders do, often to a greater extent because of the added electrical connections to operate the on-chip heater and sensor. Specifically, backlash in the tilting mechanism and lack of repeatability of the tilt makes it difficult to get the sample in exactly the right orientation and to know the exact angle of rotation. This work will use an optimized single and double-tilt *in-situ* TEM thin-film heating platform that minimizes mechanical artifacts in the tilting mechanism and provides very stable image performance when heated to temperatures up to 1000°C, where it can be run for more than 150 hours. Outside of standard temperature characterization of these thin-film heating TEM systems using different high resolution optical thermal imaging techniques, we will also report on experiments using melting standards to confirm the on-chip temperature sensor's accurate temperature response. We can identify very local and discrete melting events of samples with known melting points and correlate this to the sensor response, where local melting happens at very discrete moments (typically within a few frames). Surface diffusion occurs in matters of seconds following that. This results in *in-situ* TEM heating specimen holders that allow high-temperature imaging combined with double-tilt sample position control and accurate temperature indication.

This work will present how we used these new *in-situ* TEM sample heating systems to characterize two nanomaterial systems. Starting with gold nanorods to characterize particle motion and stability under the beam and then the phase transformation and (rapid) shape change at the melting point. We will present the rapid frame-to-frame phase transformation process of gold nanorods as we ramp the sample temperature to 1000°C and show that we can use the system to track phenomena in nanostructures over the full temperature range of the TEM heating system with good image stability.

We also show experimental data on few-layer 2D MoS_2 samples that were transferred onto the open viewing area of the heating chip. Depending on the heating rate, heating the MoS_2 sample *in-situ* resulted in either ordered crystalline hexagonal islands (<20 nm) that consist of a mixture of 2H and 3R phases or yielded a mix of nanocrystalline and amorphous regions [1]. Energy-dispersive X-ray spectroscopy (EDS) confirmed the chemical content of each segregated area.

These results illustrate this newly developed *in-situ* TEM double-tilt heating platform's optimized overall mechanical stability and temperature performance.

SESSION CT02.02: Phase Transformation and Structure-Property Correlation
Session Chairs: Biao Jin and Leopoldo Molina-Luna
Sunday Morning, April 18, 2021
CT02

10:30 AM *CT02.02.01
Gas Phase *In Situ* TEM Facilitates Improved Understanding of Nanoscale Processes Rainer Straubinger; Protochips EMEA GmbH, Germany

In situ (scanning) transmission electron microscopy [(S)TEM] in a gas atmosphere has proven to be an outstanding technique for investigating dynamic processes in material structures under high resolution conditions. New innovations in-situ gas handling systems and in-situ software have enabled researchers to re-create complex environmental conditions inside the TEM by precisely controlling temperature, gas pressure, flow, and the introduction of gas and vapor mixtures to the sample during the course of the experiment. These advances have made it possible to investigate dynamic catalytic processes, such as the degradation catalytic material, one example being the strong metal support interaction (SMSI). These studies showed in real-time that an amorphous reduced titania layer is formed at low temperatures, and that the crystallization of the layer into either mono- or bilayer structures is dictated by the reaction environment and in accordance with the theory. Investigation these processes under high resolution conditions further allowed the correlation between the formation of the SMSI and a dramatic reshaping of the metallic surface facets.
Another field were in situ research can help to overcome the current limitations is in the field of semiconductor research. Compound semiconductors are promising candidates for optoelectronic applications on Si. Ga(N,As,P) for example could be capable of overcoming the efficiency limitations of gallium indium arsenide phosphide ((Ga,In)(As,P)) based structures. Unfortunately, the realization of good quality epitaxial layers of highly metastable materials is indeed very challenging. A successful approach to improve the layer quality and therefore increase the optical output of these structures is post-growth annealing. A robust mechanistic understanding cluster formation, desorption processes, and material distribution within the Ga(N,As,P) and Ga(P,Bi) layer due to thermal treatment is desirable, but replicating these experiments under in-situ TEM conditions is complicated due to the handling requirements of the necessary precursor gases. To overcome the issues handling toxic and pyrophoric group III and group V precursor gases, it was necessary to develop an in situ system which fulfills all of the technical- and safety-requirements of a modern MOVPE machine, the results of which will improve our understanding of the factors necessary to optimize the efficiency of semiconductor materials.

10:55 AM CT02.02.02
Atomic Gradient Transitional Structures Induce High Photocatalytic Efficiency Dongsheng Li; Pacific

Northwest National Laboratory, United States

Polymorphs widely exist in nature and synthetic systems and are well known to determine material properties. Understanding phase transformation mechanisms among polymorphs enables the design of structures and tuning of phases to tailor material properties. However, current understanding is limited due to the lack of direct observations of the structural evolution at the atomic scale. Here, integrating (semi) in situ transmission electron microscopy and density functional theory, we report atomic structural evolutions of phase transformation from anatase (A) to rutile (R), brookite (B), R-phase, and TiO. Understanding the atomic structural evolution sheds light on interpreting and controlling TiO_2 polymorphs and interface structures for various applications. Here, we reveal the transitional atomic gradient structures, that form during phase transformation processes, alter electronic structures in 3D across the bulk of the crystals and thus substantially increase the active volume to separate electrons and holes and the resulting photoactivity. These new insights suggest that interphase matter based on gradient structures can be designed to induce new functions not achievable using abrupt interfaces. These findings enable a new materials design paradigm that can potentially be harnessed for a broad range of applications.
We also reveal the anisotropic nature of the electron-beam effect: dependence of crystallographic orientation with respect to electron-beam irradiation direction. The revealed electron-beam effects in our work provide guidance for in situ transmission electron microscopy studies.

11:10 AM BREAK

11:35 AM *CT02.02.05
***In Situ* Observations of Strain Induced Effects on Structure and Properties** Eva M. Olsson; Chalmers University of Technology, Sweden

Strain offers the possibility to tune the structure and properties of materials. The dimensionality of the material structures determines to what degree they can be strained prior to fracture. While bulk semiconductors fracture at 0.5-1.5 % strain and corresponding nanowires fracture at about 3-5 %, 2D structures can withstand up to 10% strain before fracture. This presentation will illustrate how *in situ* electron microscopy can reveal site specific information about the correlation between strain and catalytic activity, electrical, optical and thermal properties. We also show how strain can be introduced in nanostructures during their growth in solution and thereby tune the properties.

We have used high spatial resolution and precision using scanning transmission electron microscopy (STEM) to image the influence of atomic site-specific strain on catalytic activity of supported nanoparticles [1]. The data includes high precision information about the position of individual atoms as well as atom columns with varying number of atoms. We have also used *in situ* STEM to correlate nanoscale strain to electrical transport properties in III-V semiconducting nanowires [2]. The study shows an inhomogeneous strain distribution within nanowires where a uniaxial strain is applied. We have mapped the energy band gap and bulk plasmon as a function of tensile and compressive strain [3] in III-V nanowires. The work illustrates the potential of using combined *in situ* electrical and mechanical experiments where we have developed methods for in situ experiments and illumination with light for both scanning electron microscopes [4] and TEMs. We have performed *in situ* measurements of the resistance and thermal handling capabilities of wrinkled reduced graphene oxide [5].

***In Situ* Transmission Electron Microscopy and Multivariate Analysis of Phase Segregations in Cesium-Lead-Halide Perovskite Nanoparticles** Hannah Funk[1], Alberto Eljarrat[2], Oleksandra Shargaieva[1], Eva Unger[1], Christoph T Koch[2] and Daniel Abou-Ras[1]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Humboldt-Universität zu Berlin, Guernsey

With power conversion efficiencies surpassing 25% in 2019, hybrid organic-inorganic lead-halide perovskites solar cells attract ever more interest in the photovoltaics community. Photo-induced phase separation has been reported for a range of mixed-halide perovskites, which limits the available band-gap energies for photovoltaic applications. An enhanced understanding of the phase separation mechanism is essential to rationalize limitations and design stable perovskite semiconductors. During electron microscope experiments, the electron beam may cause, in the same way as photons when using a laser beam for irradiation, phase transformations in halide perovskites. In the present work, we report about the in-situ monitoring of electron-beam-induced phase segregation in $CsPb(Br,I)_3$ crystallites by means of high-resolution imaging in a transmission electron microscope. The acquired time series were evaluated with multivariate analysis to classify the structural change over time. An algorithm "scans" the TEM image creating a diffractogram for each patch. The diffractogram patterns of all patches of the whole time series are collected into a two-dimensional image stack, which was then classified using principal component and the independent component analysis blind source separation. By this approach, it was possible to directly monitor and provide an atomistic picture of the in-grain phase segregation. The authors will provide insight into the various aspects of this in-situ approach for the study of nanoparticles.

Understanding the Role of Grain Boundaries in Solid Electrolytes for Batteries via *In Situ* Electron Microscopy Miaofang Chi; Oak Ridge National Laboratory, United States

Solid-state batteries are considered to be one of the most promising battery configurations for future energy storage with desirable properties including safety, capacity, and longevity. However, recent studies found that interfaces and grain boundaries in solid state batteries, regardless of the type of solid electrolyte, are the primary feature limiting their commercialization. One major advantage of solid-state batteries over conventional liquid electrolyte-based batteries was expected to be reduced dendrite growth, however, dendritic growth was recently observed and was revealed to be associated to grain boundaries. Interfacial resistances between electrolyte and electrodes are higher than projected and the majority of solid electrolytes are predicted to be unstable to lithium metal. Mitigating these issues can't be achieved without a fundamental understanding of the atomic and electronic structures of these interfaces and, more importantly, how they evolve upon electrochemical cycling. Here, we highlight several recent *in situ* microscopy studies that unveil the interface stability of model solid

electrolytes, e.g. LiPON and ($Li_7La_3Zr_2O_{12}$)LLZO, with lithium metal and compare their responses to different electrochemical cycling conditions. The role of grain boundaries in dendrite nucleation and propagation within LLZO is investigated by combining monochromated EELS with *in situ* microscopy imaging. The root cause of dendrite network formation in polycrystalline solid electrolytes will be discussed. We further provide a perspective as to how these issues, i.e. resistivity and dendrite growth at grain boundaries, could possibly be mitigated by controlling critical steps during synthesis.

Revealing Reaction Dynamics of Battery Electrolyte-Electrode Interfaces via *In Situ* Electrochemical TEM Alex W. Robertson[1], Shengda Pu[1], Chen Gong[1], Xiangwen Gao[1], Ziyang Ning[1], Sixie Yang[1], John-Joseph Marie[1], Boyang Liu[1], Robert House[1], Gareth O. Hartley[1], Jun Luo[2] and Peter Bruce[1]; [1]University of Oxford, United Kingdom; [2]Tianjin University of Technology, China

The critical area for understanding and progressing battery technology is the interface between the electrode and the electrolyte. The electrochemistry occurring at this interface, including the formation and evolution of an intermediate solid-electrolyte interphase (SEI) layer, is notoriously complex. Applying in-situ characterisation techniques to illuminate these dynamics will help with the diagnosis of the specific interfacial processes, and thus facilitate the design of better electrolytes. In this talk I will discuss some of our recent work using in-situ liquid-cell TEM to probe the evolving electrode interface in real time.[1]

Multivalent electrolytes, using chemistries based on Ca or Mg ions, are promising candidates for next-generation batteries. Recent breakthroughs are beginning to overcome the longstanding problem of devising effective multivalent electrolytes, yet a major challenge remains in designing electrolytes that yield a stable SEI that does not inhibit cycling. We performed extensive in-situ TEM characterisation of one of the more promising new electrolytes, a calcium borohydride salt in tetrahydrofuran (THF),[2] capturing the real-time nucleation, growth, and dissolution of calcium under various current density conditions. In-situ TEM imaging demonstrates the existence of a critical current density, beyond which adverse dendritic calcium plating morphologies dominate, and yielding detached isolated calcium deposits on stripping.[3]

Several other next-generation batteries are based on Li ion chemistries, and to attain peak performance desire a lithium metal anode. Yet ensuring that they remain stable over many cycles has proven challenging. One of the most effective avenues to combat this has been tailoring the SEI by adjusting the electrolyte composition with additives. These fluoride-rich interphases significantly improve cycling efficiency, yet diagnosing how they alter the structural dynamics of Li electroplating and stripping is difficult without in-situ imaging. I will discuss how using in-situ TEM can provide unique insights into the distinct morphological changes that occur to Li plated from electrolytes tailored to form a fluoride-rich interphase. Our observations reveal that the fluoride-rich SEI favours the formation of a densely interwoven Li deposit, as opposed to the more dendritic structures formed from standard electrolyte. This denser structure proved more amenable to uniform dissolution, leaving behind fewer isolated dead Li fragments, and thus yielding superior efficiency.

Heaters and Electrode Materials for Expanding the Capabilities of Liquid Cell Electrochemistry Frances M. Ross[1], Shu Fen Tan[1], Kate Reidy[1], Serin Lee[1], Julian Klein[1], Nicholas Schneider[2], Haeyeon Lee[1], Ainsley Pinkowitz[1] and Jeung Hun Park[3]; [1]Massachusetts Institute of Technology, United States; [2]Renata Global, United States; [3]Princeton University, United States

Liquid cell transmission electron microscopy provides exciting opportunities for imaging processes in liquid with good spatial and temporal resolution. The quality and quantification of liquid cell data continue to improve, driven by advances in liquid cell equipment, control of local conditions, and theoretical understanding of electron beam effects. Liquid cell studies that combine imaging with electrochemical measurements have proved particularly useful in studies of energy materials, corrosion processes and crystal growth. The ability to control the temperature is important in extending the capabilities of liquid cell electrochemistry in probing these materials reactions. The electrode material is also important as it determines the reliability and consistency of the electrochemical measurements and can also affect the image resolution. Here, we explore the opportunities for liquid cell electrochemistry that arise from the use of heating as well as new electrode materials, specifically graphene and other two-dimensional (2D) materials. Heating is implemented by patterning electrodes over microfabricated liquid cell chips that already include a Pt resistance heater. 2D electrodes are implemented by transfer onto liquid cells that already include electrical contacts. We will describe the performance of combined heating and biasing chips and evaluate several 2D materials for their properties as electrodes in liquid cell electrochemistry, in comparison with conventional electrode choices such as Pt, Au or carbon. The minimal electron scattering from the 2D layer is especially helpful for preserving image resolution in electrochemical experiments carried out in plan view, where the imaging takes place through the electrode. Of the 2D materials we have tested we will focus on graphene as it appears to be particularly promising. We discuss its mechanical and electrochemical properties within the liquid cell, as well as the negligible voltage drop expected even in large area electrodes tens of micrometers across. We also discuss its stability under electron beam irradiation, even at the higher accelerating voltages often used in liquid cell electron microscopy. To demonstrate the capabilities of heating and graphene electrodes we deposit various metals from acidified electrolytes. Heating changes the kinetics, increasing the deposition rate at regions of elevated temperature. For graphene electrodes, the improved resolution allows us to explore nucleation and growth processes and demonstrate an unexpected coarsening process that occurs during deposition. We finally consider some future opportunities that will be enabled by the use of new chip designs in liquid cell electrochemistry. Particularly exciting are the possibilities of incorporating heating with novel electrode designs, and the performance of 2D materials that show favorable scavenging properties. The use of stacked 2D materials, as well as 2D layers patterned to control nucleation sites, will expand the opportunities further. We anticipate that both temperature control and incorporation of 2D materials into liquid cell design will open up new opportunities for investigating a wide range of problems relevant to energy storage and electrocatalysis as well as fundamentals of electrochemical reactions.

Vaporization and Diffusion of Pt/Pd from Pt/Pd/Al_2O_3 Under Redox Conditions Andrew C. Meng[1], Ke-Bin Low[2], Alexandre Foucher[1], Yuejin Li[2], Ivan Petrovic[2] and Eric A. Stach[1]; [1]University of Pennsylvania, United States; [2]BASF Corporation, United States

Al_2O_3-supported Pt/Pd bimetallic catalysts were studied using *in-situ* atmospheric pressure and *ex-situ* transmission electron microscopy. Significant metal vaporization was observed at temperatures above 600°C, both in pure oxygen and in air. This behavior implies that material transport through the vapor during typical catalyst aging processes for oxidation can play a more significant role in catalyst structural evolution than previously thought. Concomitantly, Pd diffusion away from metallic nanoparticles on the surface of Al_2O_3 can also contribute to the disappearance of metal particles. Electron micrographs from *in-situ* oxidation experiments were mined for data, including particle number, size, and aspect ratio using machine learning image segmentation. Under oxidizing conditions, we observe not only a decrease in the number of metal particles and

an increase in average size but also a decrease in the surface area to volume ratio. Some of the metal that had dissolved into the support can be regenerated and reappear back on the catalyst support surface under reducing conditions. Real-time observation of particles during separate oxidation and reduction processes provides nanometer-scale structural details of supported Pt/Pd particles at intermediate states not observable through typical *ex-situ* experiments. These observations represent a first step towards understanding how rapid cycling between oxidative and reductive catalytic operating conditions affects catalyst structure.

Direct Imaging of Nanoparticle Superlattice Crystallization and Protein Fluctuation at the Nanoscale
Qian Chen; University of Illinois at Urbana-Champaign, United States

I will discuss my group's recent progress on capturing and understanding the intermediates and fluctuation dynamics at the nanometer resolution using liquid-phase TEM. The specific systems concern the nucleation and growth pathways of nanosized colloids into superlattices and moving membrane proteins in their native lipid and liquid environment. We find that prenucleation precursors and a layer-by-layer growth mode exist universally in diverse nanoparticle shapes. Single particle tracking, machine learning and simulations combined unravel the energetic and kinetic characteristics generic to the unexplored nanoscale, enabling advanced crystal engineering. For membrane proteins, we find that they exhibit real-time "fingering" fluctuations, which we attribute to dynamic rearrangement of lipid molecules wrapping the proteins. The conformational coordinates of protein transformation obtained from the real-space movies are used as inputs in our molecular dynamics simulations, to verify the driving force underpinning the function-relevant fluctuation dynamics. This platform invites an emergent theme of structural biophysics as we foresee.

Self-Assembled Nanoparticle Superlattices with Size-Dependent Reconfiguration Chang Qian[1], Binbin Luo[1], Ethan Stanifer[2], Xiaoming Mao[2] and Qian Chen[1,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Michigan–Ann Arbor, United States

We use liquid-phase transmission electron microscopy (TEM) to study the self-assembly of charged gold nanocubes, which showed a unique reconfigurable superlattice. The lattice can adopt two different states with same energy but different orientations, and our analysis showed the size-dependence of this reconfiguration process. Combining interaction modeling with simulation, we revealed the entropic nature of reconfiguration which dampens reconfiguration as the crystal size increases. We expect this tunable reconfiguration behavior to shed light on the design of responsive mechanical metamaterial.

Aqueous Dynamic Molecular and Particular Assembly of Amphiphilic Block Copolymer Visualized by *In Situ* LP-TEM Junho Hwang, Jun Hwa Hwang and Eunji Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

The self-assembly structure of a general amphiphilic block copolymer is carried out by direct dissolution into a selective solvent or through the gradual exchange from common solvents to selective solvent for one block. In this process, the self-assembled structure was either dynamically equilibrated in a solvent to have the lowest free energy or kinetically trapped to exhibit a uniform morphology. In the case of kinetically trapped

assemblies, morphological reconstruction and dynamic deformation occurred, implying the possible Brownian motion-based particle growth by collision and fusion. The self-assembly accompanying the dynamic nanoscale process of these organic molecules has not been directly observed, and basic mechanisms such as fusion, fragmentation, and growth are still subject to much research. The block copolymer self-assembly used in this study is a crew-cut micelle, not a star-shape micelle, and it can be confirmed that the volume fraction due to the ratio of the block length is controlled and the self-assembly structure transitions. Here, using the amphiphilic block copolymer, the self-assembly behavior of nanoparticles in real-time according to the molecular weight of the block in an aqueous solution was to be observed using a transmission electron microscope(TEM) and the dynamic behavior of the nanostructure was quantitatively analyzed by multiple object tracking analysis. This study provides a useful strategy for observing mechanisms of amphiphilic block copolymer self-assembly and the growth behavior of organic molecules based on Brownian motion.

7:20 PM *CT02.04.04
Capture the Moment of Nucleation from a Solution Using a Transmission Electron Microscope Yuki Kimura; Hokkaido University, Japan

Our goal is to clarify what happens immediately before and after a nucleation event and how the nucleation pathway is determined. In the last decade, in situ observations of the crystallization processes in a solution have been performed for several materials and non-classical nucleation pathways have been reported based on a liquid-cell transmission electron microscope (TEM). Examples include oriented attachment growth of nanocrystals [1], and two-step nucleation of calcium carbonate (CaCO3) and lysozyme protein crystals from amorphous/dense liquid particles [2, 3]. The unidirectional formation and growth of particles triggered by electron irradiation has also been observed. However, it is still difficult to directly observe crystals that follows the classical nucleation: grow beyond a certain large critical nucleus after fluctuations due to the competition between attachment and detachment of growth units. The difficulty is originating from their nanometric scale, rapidity, stochastic nature, and less ability to control the solution environment. We may be able to observe a crystallization process in lower magnification condition.
Then, unfortunately, crystalline nuclei cannot be observed separately as well as a conventional optical microscope.
To overcome the difficulties of direct observation, we have tried several approaches based on machine learning. One is a real-time prediction/detection at the moments of nucleation and the other one is enhancing the contrast of live images under very weak electron intensity. Both have been achieved based on machine learning. Real-time prediction allows us to notify a nucleus before growth and, therefore, enable to observe and magnify it from a very beginning of nucleation. Enhances the contrast of TEM images allow us to magnify the nucleus at a constant electron intensity. This does not eliminate the
effect of the beam completely, but it does minimize the change of a solution condition at higher magnification conditions. These have been evaluated by several nucleation and growth experiments. In the presentation, I will introduce more about our recent challenges and resent result of the early stages of crystallization.

Self-Similar Mesocrystals Form via Interface-Driven Nucleation and Assembly Guomin Zhu[1,2], Maria Sushko[2], John Loring[2], Benjamin A. Legg[2], Miao Song[2], Jennifer Solits[2], Kevin Rosso[2] and James J. De Yoreo[1,2]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Crystallization by particle attachment (CPA), which is a common mechanism of colloidal crystallization resulting in hierarchical morphologies, has been both exploited to create nanomaterials with unique, emergent

properties and implicated in the development of complex mineral textures. Oriented attachment (OA), a form of CPA in which crystalline primary particles align and attach along specific crystallographic directions, produces structures — typically referred to as mesocrystals — that diffract like single crystals, even though the constituent particle domains are still discernable. While the existence of mesocrystals has been well documented in a wide range of crystal systems and individual particle attachment events have been directly visualized, the mechanism by which these seemingly random events lead to well-defined, self-similar morphologies remains a mystery, as does the role of organic ligands, which are ubiquitous in nanoparticle systems. Combining *in situ* liquid phase TEM at 80°C with "freeze-and-look" TEM using indexed grids, we tracked formation of hematite (Hm) mesocrystals in the presence of oxalate and interpreted the results using classical density functional theory. The results show that formation of isolated Hm particles rarely occurs. However, once formed, interfacial gradients created by hematite-bound oxalate drive new hematite particles to repeatedly nucleate about 2 nm away from the new interface and then immediately undergo OA. We suspect our discovery reveals a widespread phenomenon with significant implications both for synthesis of materials and for understanding mineralization in natural environments. In addition, our discovery on the phenomenon close to solid interface highlights the complexity of material/solution interface, which lays the grounds for future research on the chemical and structural nature of the material/solution interface.

8:00 PM CT02.04.06

Crystallization Kinetics of Phase Change Materials Using Complementary *In Situ* Microscopic Techniques Victoriea Bird[1], Khalid Hattar[2], David LaVan[3], Izak McGieson[1], Joseph McKeown[4], Bryan W. Reed[5], Feng Yi[3] and Melissa K. Santala[1]; [1]Oregon State University, United States; [2]Sandia National Laboratories, United States; [3]National Institute for Standards and Technology, United States; [4]Lawrence Livermore National Laboratory, United States; [5]Integrated Dynamic Electron Solutions, Inc., United States

Phase change materials (PCMs) are semi-conducting alloys with distinct optical and electrical properties in the amorphous and crystalline phases that make them useful for memory applications. In memory devices, amorphous bits are crystallized in nanoseconds by either laser or Joule heating, but the amorphous phase must also be stable against crystallization for long-term data retention. Crystal growth rates relevant to memory devices span orders of magnitude and fundamental questions regarding PCM crystallization mechanisms remain open, partly due to the difficulty in measuring crystallization kinetics in certain temperature regimes.

Ag-In-doped Sb-Te (AIST) alloys are an important class of PCMs that have been widely studied. Experiments using time-resolved reflectivity [1] and ultra-fast differential scanning calorimetry [2] have broadened the temperature range for which the crystallization kinetics of AIST have been characterized, but these indirect methods of measuring crystal growth have not yet resolved the kinetic behavior just above the glass transition temperature, T_g, which is of especial interest in the characterization of glass-forming materials. Direct methods of measuring crystal growth using microscopic methods which could more completely characterize crystallization behavior have emerged in recent years.

In this presentation, the application of multiple imaging techniques used to directly quantify crystal growth rates in PCMs over a broad range of temperatures will be described, with a focus on recent experiments on an AIST alloy with a nominal composition of $Ag_3In_4Sb_{74}Te_{17}$. The measurable growth rates from the different techniques span from ~10^{-9} to >10 m/s and the *in-situ* imaging techniques applied include optical microscopy, conventional transmission electron microscopy (TEM), and dynamic TEM, a photo-emission TEM technique with nanosecond-scale time resolution [3]. It will be shown that crystal growth just above T_g could be imaged during *in situ* TEM through the use of sub-framing and a high-frame-rate direct electron detection camera [4]. The use of complementary *in situ* experimental techniques allow the crystal growth rates to be mapped over a large temperature range and can give insights into the crystallization kinetics of PCMs. Challenges associated with integrating results from different microscopic techniques, the issues with the determination of temperature during *in situ* TEM experiments, and the incorporation of nanocalorimetry with simultaneous TEM imaging [5,6] during crystallization will be discussed.

***In Situ* and *Operando* Atomic Level Observation of Fluxional Behavior at Surface Sites In Ceria-Based Catalytic Systems** Joshua Vincent, Ramon Manzorro and Peter A. Crozier; Arizona State University, United States

The oxygen exchange and storage capacity of CeO_2 make it a common component in oxidation and reduction catalysts, with a wide range of applications such as automotive three-way catalysts, reforming, and fuel cells. These catalytic systems are typically based on a highly dispersed metal phase supported on CeO_2 nanoparticles, either pure or doped. In many cases, the fundamental catalytic mechanism usually involves reactant activation on the metallic component and oxygen transfer at or near the three-phase boundary that exists between the metal, oxide and gas phases. In the so-called Mars-van Krevelen type process, the reducible oxide support plays a key role by serving as a buffer to store and release oxygen to the reactant intermediates on the surface. The oxygen exchange process involves creation and annihilation of oxygen vacancies on the surface. Modelling with density functional theory suggests that the oxygen vacancy formation energy varies considerably depending on the characteristics of the surface site. To investigate the potential impact of surface heterogeneity during oxygen exchange, we have developed an *in situ* electron microscopy approach that allows us to directly observe the dynamic creation and annihilation of oxygen vacancies on CeO_2 surfaces and structural changes in Pt nanoparticles. We have employed this technique to explore the variation of lattice oxygen exchange with surface structural features such as nanofacets, step sites, adatom location and strain. In metal/oxide systems, the metal-support interface may be destabilized by these oxygen exchange events, giving rise to a surface that is constantly restructuring or fluxional behavior during catalysis. This presentation will discuss TEM based effort to determine in the oxygen exchange rate at different locations on CeO_2 nanoparticle surfaces and also at the metal/oxide interface of Pt/CeO_2 catalysts observed under *operando* conditions.

Time Resolved Reflectometry With Pulsed Laser Melting of Implant Amorphized $Si_{1-x}Ge_x$ Thin Films Jesse A. Johnson[1], Chris Hatem[2], Bruce Adams[2], Xuebin Li[2], David Brown[3,1] and Kevin S. Jones[1]; [1]University of Florida, United States; [2]Applied Materials, Inc., United States; [3]Air Force Research Laboratory, United States

Nanosecond pulsed laser melting using a frequency doubled Nd:YAG laser (l = 532 nm) was performed on implant amorphized Si and $Si_{1-x}Ge_x$ thin films. Undoped pseudomorphic $Si_{1-x}Ge_x$ thin films were grown to a thickness of 40 nm on (100) Si wafers and Ge^+ implants produced ~20 nm amorphous layers. The dynamic evolution of the single pulse laser melt process was probed in detail by using *in situ* time resolved reflectometry

(TRR) covering the sub-melt, partial and full amorphous melt, to full epi-layer melt regimes. TRR spectra were correlated as a function of energy density and Ge concentration with corresponding post-irradiation cross sectional TEM micrographs. It was shown that the resolution of the amorphous to crystalline conversion based on reflectivity differences allowed for the distinction between solid phase and liquid phase epitaxy regimes. Additionally, detection of the melt phase increased in sensitivity with increasing Ge concentration. Recovering the damage of implanted $Si_{1-x}Ge_x$ is a crucial step in CMOS manufacturing, and the metastable microstructures produced by pulsed laser melting of $Si_{1-x}Ge_x$ may be of interest for source/drain contact and channel strain engineering applications.

9:45 PM CT02.05.03
Shining New Light on Perovskite Precursor Inks with Cryo-Electron Microscopy Nikita Dutta, Nakita Noel and Craig Arnold; Princeton University, United States

Lead halide perovskites have attracted great interest in recent years as promising materials for optoelectronics. Their ability to be solution processed is central to this interest, as it is a low-cost, scalable method with considerable flexibility. It has previously been observed that perovskite precursor inks are colloidal in nature, and that ink chemistry affects both the colloid distribution and the morphology of the deposited film. Yet, the mechanisms through which these effects arise are still poorly understood due in large part to the experimental difficulty of characterizing nanoscale colloids in solution. Here we demonstrate how cryo-electron microscopy can be used to overcome this challenge, presenting results from an interdisciplinary suite of methods that includes electron diffraction of vitrified inks and near-atomic resolution single particle averaging. Our results reveal for the first time that colloids in prototypical inks consist of a crystalline precursor phase, distinct from any of the starting materials. This shines light into the black box of perovskite solution processing and will ultimately enable better control of film morphology and optoelectronic properties.

Liquid-Liquid Phase Separation of $CaCO_3$ Revealed by *In Situ* Transmission Electron Microscopy Biao Jin[1], Harley Pyles[2], Ying Chen[1], Benjamin A. Legg[1], David Baker[2] and James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

The nucleation of solids plays an important role in crystallization applications. Various intermediates have been proposed, including a dense liquid phase formed via liquid-liquid phase separation, but little is known about the occurrence of liquid-liquid phase separations at the nanoscale and the evolution of the dense liquid phase into a solid phase. Herein, taking $CaCO_3$ as a model system, our *in situ* liquid cell transmission electron microscopy directly shows that the dense liquid phase first appears from highly supersaturated solution in the presence of proteins as a stabilizer, which has also been demonstrated by *in situ* liquid NMR and ATR-FTIR results. By analyzing the behavior of coalescing droplets, it is found that the dense liquid phase may be a high viscosity fluid. In addition, when highly charged proteins are added, a network of the dense liquid phase forms, reminiscent of spinodal patterns in polymer melts near the interior of a spinodal. Subsequent dehydration of liquid droplets drives the formation of less hydrated amorphous calcium carbonate. This direct observation of dense liquid phase formation dynamics helps provide an in-depth understanding of the liquid-liquid phase separation mediated nucleation model.

Cubic boron arsenide (BAs) is attracting greater attention owing to the recent experimental demonstration of ultrahigh thermal conductivity κ higher than 1000 W/m●K. However, its bandgap has not been settled and a simple yet effective method to probe its crystal quality is missing. Furthermore, traditional κ measurement methods are destructive and time-consuming, thus they cannot meet the urgent demand for fast screening of high κ materials. After we experimentally established 1.82 eV as the indirect bandgap of BAs and observed room-temperature band-edge photoluminescence, we developed two new optical techniques that can provide rapid and non-destructive characterization of κ with little sample preparation: photoluminescence mapping (PL-mapping) and time-domain thermo-photoluminescence (TDTP). PL-mapping provides a nearly real-time image of crystal quality and κ over mm-sized crystal surfaces; while TDTP allows us to pick up any spot on the sample surface and measure its κ using nanosecond laser pulses. These new techniques reveal that the apparent single crystals are not only nonuniform in κ but also are made of domains of very distinct κ. Because PL-mapping and TDTP are based on the band-edge PL and its dependence on temperature, they can be applied to other semiconductors, thus paving the way for rapid identification and development of high-κ semiconducting materials.

Structural and Chemical Analysis of Electrochemical AgAu De-Alloying at the Atomic Scale Through *In Situ* Transmission Electron Microscopy Rui Filipe Serra Maia and Eric A. Stach; University of Pennsylvania, United States

Nanoporous gold obtained through gold-silver dealloying exhibits unparalleled performance in catalysis, sensing, and battery electrodes[1–3]. For example, combining metal oxides with nanoporous gold enables highly reversible cathodic reactions with significantly lower overpotentials than state-of-the-art electrodes for lithium-ion batteries[4]. The functionality and performance of nanoporous gold varies strongly with the synthesis conditions[1]. However, the relationship between synthesis conditions and the final product's structural and morphological properties is still poorly understood. This is because it is difficult to obtain a time-resolved analysis of the dealloying process in real-world conditions[5,6].
We performed *in situ* liquid-phase Scanning/Transmission Electron Microscopy (S/TEM) to obtain a time-resolved analysis of the structure and chemistry of AuAg at the atomic scale during electrochemical dealloying at variable electrochemical and hydrodynamic conditions. The results indicate that pore formation occurs through a priming step of phase separation, where silver and gold form intertwined but separated domains and dealloying then proceeds through silver dissolution. The dealloying process is surface limited, and for that reason, thinner areas de-alloy faster than thicker ones. These results suggest that the previously observed inverse correlation between electrochemical overpotential and pore sizes is caused by an initiation of the second step before phase separation is complete when the separated domains are not fully developed. These insights allow direct correlations between processing parameters and the final properties, enabling rational optimization of properties such as crystallite size, grain boundary density and edge/terrace ratio for various technologic applications.

8:00 AM INTRODUCTORY COMMENTS

8:05 AM *CT03.01.01
***In Situ* Coherent X-Ray Diffraction Imaging During the Catalytic Process** Hyunjung Kim; Sogang University, Korea (the Republic of)

Understanding structural changes in the atomic scale during the catalytic reaction process is crucial for revealing underlying mechanisms. However, it remains challenging to characterize the strain and defect evolution for a single nanocrystal catalyst in situ. Bragg coherent diffraction imaging (BCDI) is a powerful tool for investigating structural changes inside the nanoparticle in-situ in a non-destructive way. In my talk, I show how the atomic level of interaction of reactants affects the nanoparticles as strain-induced and the defect dynamics during the catalytic process by exploiting the merits of BCDI.

***In Situ* Structural Evolution of Model Catalysts Imaged by Bragg Coherent X-Ray Diffraction** Marie-

Ingrid Richard[1,2], Maxime Dupraz[1,2], Ni Li[1,2], Jerome Carnis[3,2,4], L. Wu[2,3], Stephane Labat[3], Steven Leake[2], L. Gao[5], J.P. Hofmann[5], S. Fernández[2,3], M. Sprung[4], A. Resta[6], Tobias Schulli[2], E.J.M. Hensen[5] and Olivier Thomas[3]; [1]Univ. Grenoble Alpes, CEA Grenoble, IRIG/MEM/NRS, France; [2]The European Synchrotron, France; [3]Aix Marseille Université, CNRS, Université de Toulon, France; [4]PETRA III, Deutsches Elektronen-Synchrotron (DESY), Germany; [5]Technische Universiteit Eindhoven, Netherlands; [6]Synchrotron SOLEIL, France

Characterising the structural properties (strain gradients, chemical composition, crystal orientation and defects) inside nanostructures is a grand challenge in materials science. Bragg coherent diffraction imaging (Bragg CDI) can be utilised to address this challenge for crystalline nanostructures. A resolution of the structural properties of less than 10 nm is achieved up-to-date [1,2]. The capabilities of the Bragg CDI technique will be demonstrated on single nanoparticles for enhanced catalysis.

As an example, the Bragg CDI technique [3,4] allows understanding the interplay between shape, size, strain, faceting [5], composition and defects at the nanoscale. We will demonstrate that Bragg CDI on a single particle model catalyst makes it possible to map its local strain/defect field and directly image strain build-up close to the facets. We will also show results obtained during *in situ* [6,7] and *operando* Bragg CDI measurements: it was possible to track a single particle in gas or liquid phase environments to monitor its facet changes and to measure its strain/defect response to reaction.

This technique opens pathways to determine and control the internal structure of nanoparticles to tune and optimise them during catalytic and other chemical reactions. This technique should benefit from a unique opportunity: the ESRF EBS Upgrade. This should revolutionise imaging by making it possible to map evolving physico-chemical processes in a slow-motion movie.

8:55 AM CT03.01.03
Late News: Three-Dimensional Coherent X-Ray Imaging of Ferroelastic Domains in CsPbBr3 Perovskite

Nanoparticles Dmitry Dzhigaev[1], Zhaojun Zhang[1], Lucas Marcal[1], Simone Sala[2], Alexander Björling[2], Anders Mikkelsen[1] and Jesper Wallentin[1]; [1]Lund University, Sweden; [2]MAX IV, Sweden

Halide perovskites attract significant interest due to their remarkable performance in solar cells. However, the gap in understanding of the relationship between their nanoscale structure and properties limits their application towards novel devices. Here we present a direct 3D imaging of twinned ferroelastic domains in single 500-nm $CsPbBr_3$ particles using Bragg Coherent X-ray Diffractive Imaging (BCDI) at sub-60 nm resolution. A preferential double-domain structure is revealed in several identical particles, with one (110)-oriented and one (002)-oriented domain and a similar domain volume ratio of 1:2.5. The domains exhibit a difference in lattice tilt of 0.59 degrees, in excellent agreement with calculations based on the lattice mismatch. The results in this work provide important insights both for the fundamental understanding of these materials and for the performance improvement of perovskite-based devices.

9:10 AM *CT03.01.04
Development of *In Situ* Broadband Laue Microdiffraction for Determination Crystallographic Orientation at the 34-ID-C Bragg Coherent Diffraction Imaging Instrument of the APS Ross Harder; Argonne National Laboratory, United States

Measurement of Bragg coherent diffraction imaging (BCDI) data relies on finding a Bragg diffraction signal from a single nanoscale crystal object. Often the object of interest can have unknown orientation in the sample or be one of many crystallites in a polycrystalline sample. In addition, even when a single Bragg reflection is found, the full crystallographic orientation remains unknown, and thus finding other Bragg reflections from the identical crystal becomes time-consuming or impossible.
In this talk, the commissioning of a movable double-bounce Si (111) monochromator at the 34-ID-C end station of the Advanced Photon Source will be described. The resulting capability aims at delivering multi-reflection BCDI as a standard tool in a single beamline instrument. The upgraded instrument enables, through rapid switching from monochromatic to broadband (pink) beam, the use of Laue diffraction to determine crystal orientation. With a proper orientation matrix determined for the lattice of a specific crystal, one can measure coherent diffraction patterns near multiple Bragg reflections, thus providing enough information to image the full strain tensor in 3D at the nanoscale. The design, concept of operation, the developed procedures for indexing Laue patterns, as well as automated measurement of Bragg coherent diffraction data from multiple reflections of the same nanocrystal will be presented. In addition, recent advances in identifying single grains of interest in a polycrystalline sample will be described.

9:35 AM *CT03.01.05
X-Ray Linear Dichroic Ptychography Jianwei (John) Miao[1], Yuan Hung Lo[1], Jihan Zhou[1], Arjun Rana[1], Drew Morrill[2], Christian Gentry[2], Bjoern Enders[3], Young-Sang Yu[3], Chang-Yu Sun[4], David Shapiro[3], Roger Falcone[3], Henry Kapteyn[2], Margaret Murnane[2] and Pupa Gilbert[4]; [1]University of California, Los Angeles, United States; [2]University of Colorado Boulder, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]University of Wisconsin–Madison, United States

Ptychography, a powerful scanning coherent diffractive imaging technique, has attracted significant attention for its general applicability. Here we experimentally demonstrate x-ray linear dichroic ptychography for the first time and map the *c*-axis orientations of the aragonite ($CaCO_3$) crystal. Linear dichroic phase imaging at the oxygen K-edge energy shows strong polarization-dependent contrast and reveals the presence of both narrow (<35°) and wide (>35°) *c*-axis angular spread in the coral samples. These x-ray ptychography results are corroborated by 4D scanning transmission electron microscopy (STEM) on the same samples. Evidence of co-oriented but disconnected corallite sub-domains indicates jagged crystal boundaries consistent with formation by amorphous nanoparticle attachment. We expect that the combination of x-ray linear dichroic ptychography and 4D STEM could be an important multimodal tool to study nano-crystallites, interfaces, nucleation and mineral growth of optically anisotropic materials at multiple length scales.

CT03

10:30 AM *CT03.02.01
Correlative Multi-Modal 3D Imaging of Topologically Non-Trivial Magnetic Textures Emma M. Cating[1], Arjun Rana[2], Chen-Ting Liao[1], Yuan Hung Lo[2], Charles Bevis[1], Peter Johnsen[1], Sinead Ryan[1], Robert Karl[1], Xingyuan Lu[2], Christian Gentry[1], Michael Tanksalvala[1], Yuka Esashi[1], Bin Wang[1], John Badding[3], Jianwei (John) Miao[2], Henry Kapteyn[1] and Margaret Murnane[1]; [1]University of Colorado Boulder, United States; [2]University of California, Los Angeles, United States; [3]The Pennsylvania State University, United States

Understanding the structure and dynamics of spin textures in magnetic materials on the scale of the magnetic exchange interaction is both a question of fundamental physics and at the forefront of developing quantum technologies. Topologically stabilized magnetic textures such as skyrmions and the direct light-induced manipulation of spins hold promise for spintronics, low-energy data transport, and memory. However, because of their small size and low contrast, intricate nanoscale magnetic textures have proven difficult to image directly in 3D without prior knowledge of the sample.

Correlative multi-modal spectro-microscopy using complementary nanoscale imaging techniques and extreme ultraviolet and x-ray spectroscopies at both tabletop and facility scale provides access to a more complete range of elemental, chemical, electronic, magnetic, and structural and dynamic properties of complex samples. Resonant x-ray magnetic circular dichroism (XMCD) provides element-specific magnetic sensitivity; ptychography yields diffraction-limited images with phase contrast, ideal for low-contrast materials; time-resolved extreme UV (EUV) spectroscopies can capture new light-induced spin excitations; and x-ray reflectometry can image buried layers with sub-nm depth resolution. By combining these techniques, we are able to uncover new materials function and comprehensively characterize complex nanostructured, layered, and heterogeneous samples.

10:55 AM *CT03.02.02
Hyperspectral Imaging with Quick-XAS: Combining Micrometric Spatial- and Second Time-Resolutions with X-Ray Absorption Spectroscopy Camille La Fontaine, Olga Roudenko, Stéphanie Belin, Laurent Barthe and Valérie Briois; SOLEIL Synchrotron, France

X-ray Absorption Spectroscopy (XAS) is among the techniques widely employed to characterize materials providing atomic selective information on the materials structure and chemical speciation. Since the advent of 3rd generation synchrotron radiation facilities, a high photon flux is achieved at XAS beamlines which permits fast measurements and thus time-resolved monitoring of evolutionary processes. A wide range of materials science topics has taken advantage of this breakthrough (e.g. catalysis, energy storage, materials synthesis) through *in situ* and *operando* approaches. In order to access to a deeper and more accurate temporal description of the processes, multivariate data analysis is now commonly employed and provides spectra of the pure chemical species together with their concentration profiles.
Nevertheless, time-resolved XAS data are generally collected as macroscopic information related to the fraction of sample exposed to X-rays. At specialized beamlines, spatial resolution can be achieved using micro- or nano-focused beam while scanning the sample but with increased collection times. Alternatively, full-field sample illumination collected by a 2D detector can provide both spatial and time resolutions. Recent developments have been conducted at the ROCK beamline of SOLEIL synchrotron to allow time-resolved hyperspectral full-field X-ray imaging with XAS information.

ROCK is a XAS beamline tailored for *in situ* and *operando* investigations in the 4 to 40 keV energy range using Quick-EXAFS monochromators to achieve sub-second time resolution for macroscopic measurements. Hyperspectral full-field X-ray imaging experiments are operated at the beamline in transmission by collecting the visible light emitted from a thin scintillator imaging the sample absorption by a pixelated detector (ORCA Flash 4.0 V3 CMOS camera, Hamamatsu). Depending on the objective mounted on the camera, the pixel size and field of view (FoV) range from 0.65 µm to 1.625 µm and 1.3 mm to 3.3 mm, respectively, with a resolution of ca. 5 µm. Images at different energies of the XAS spectrum (typically ~ 600 images) are collected with an exposure time of 5 ms during the Quick-EXAFS monochromator energy scan yielding to one complete hyperspectral dataset every 10 s. XAS spectra can then be reconstructed on individual or binned pixels to improve the signal-to-noise (S/N) ratio when necessary. A specificity of ROCK is its versatile beam size from 0.4 to ~ 4 mm while keeping constant the flux delivered by the optics. Thus the beam size on the sample can be optimized considering the nature and size of the sample, the FoV and the S/N ratio of reconstructed spectra. Selected examples of studies using the methodology implemented at ROCK beamline will be presented in the field of pressure-induced spin transition, regeneration of heterogeneous catalysis, and cycling of Li-ion batteries. These examples illustrate the great potential of time-resolved XAS hyperspectral imaging and the gain obtained in comparison with macroscopic information for identifying potential dynamic heterogeneous behavior of materials.

Acknowledgment: The ROCK beamline construction and operation (2011-2019) were supported by a public grant overseen by the French National Research Agency (ANR) as part of the “Investissements d’Avenir” program (ref: ANR-10-EQPX-45).

11:20 AM CT03.02.03
Nanoscale Crystal Strain and Oxidation State Mapping of Primary $LiNi_{0.33}Mn_{0.33}Co_{0.33}O_2$ Particles
William Judge[1], Jordi Cabana[1], Martin Holt[2], Zhonghou Cai[2] and Brian May[1]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

Global concerns over the consistent consumption of finite fossil fuel stores have called for a transition to renewable energy sources. A significant stepping stone in completing this movement relies on the safety and reliability of energy storage technologies. Revolutionizing the industry John Goodenough, Stan Wittingham, and Akira Yoshinos were all critical of the development in current Lithium-Ion battery energy storage. However, their efforts are not without need of improvements. Sub-optimal reliability is caused by prevalent capacity fade at moderate working potentials. For global adoption in heavy uses cases (EV, power grid storage, etc.) this must be remedied. Degradation of the cathode material is narrowed down to three main categories; structural/chemical strain, electrolyte decomposition, and increase of surface-electrolyte interfaces. Narrowing these options, my focus is on cathode material strain characterization, both structural and chemical, at the nano-scale through the use of multiple techniques.

Well characterized, relevant LiNi0.33Mn0.33Co0.33O2 (LiNMC) material was chosen as an agent for nano-characterization. Ptychographic analysis methods with a resolution of 5 nm has been implemented in mapping transition metal oxidation states of a single particle for various states of charge. Further, lattice strain analysis has been carried out through the application of Scanning X-Ray Diffraction Microscopy. With a resolution of 30 nm, spatially resolving crystallographic spacing's for Pristine, Charged (to 4.75V), Discharged (to 2.7V) material was achieved. It was determined most point defect upon cycling effect primarily the chi regime of the diffraction patterns. Heterogeneities in both regards have given insight into degradation pathways for the LiNMC material.

12:00 PM CT03.02.05
Micro X-Ray Fluorescence Microscopy as a Tool to Study Moisture-Dependent Inorganic Ion Diffusion in Individual Wood Cell Wall Layers Joseph Jakes; USDA Forest Service, Forest Products Laboratory,

United States

The diffusion of chemicals and inorganic ions through wood cell walls is a critical process in nearly all woody biomass applications, including biorefineries, wood-based building materials, green electronics, and even as bioinspiration for new smart materials. Despite the near ubiquitous importance of intra-cell wall diffusion, the poorly understood diffusion mechanisms and rates are hindering progress. In this work, a new experimental methodology utilizing synchrotron-based X-ray fluorescence microscopy (XFM) was developed to study inorganic ion diffusion at submicron length scales in individual wood cell wall layers. Using a custom-built in situ relative humidity (RH) chamber, it was discovered that deposited K, Cu, Zn, and Cl ions only diffuse when the humidity is above 60% RH. Additionally, time-lapse XFM imaging was used to measure the time-dependent concentration profiles of implanted K, Cu, and Cl ions diffusing through cell wall layers. Time-lapse XFM imaging was performed at 70, 75, or 80% RH. Diffusion constants were calculated from the time-dependent concentration profiles using an analytical model developed based on Fick's second law for diffusion. Results revealed that diffusion rates increased with RH, the larger Cu ion diffused slower than the K ion, and the Cl ion diffusion constant was the same as the counter cation, indicating ions diffused together to maintain charge neutrality. The results also improve the understanding of the diffusion mechanisms. It is now understood that diffusion occurs via interconnecting pathways of rubbery amorphous polysaccharides, which contrasts the nearly century-old assumption of intra-cell wall transport occurring through interconnecting water pathways. With these new insights, researchers can now utilize polymer science approaches to engineer the molecular architecture of lignocellulosic biomass to optimize properties for specific end uses.

12:15 PM CT03.02.06
Non-Destructive Characterization of 3D Nanostructures via EUV Coherent Diffractive Imaging Reflectometry—High-Resolution, Chemically Specific, Interface-Sensitive Maps Michael Tanksalvala[1], Christina Porter[1], Yuka Esashi[1], Nicholas W. Jenkins[1], Zhe Zhang[1], Naoto Horiguchi[2], Sadegh Yazdi[1], Jihan Zhou[3], Michael Gerrity[1], Jianwei (John) Miao[3], David Ren[4], Laura Waller[4], Henry Kapteyn[1,5] and Margaret Murnane[1]; [1]University of Colorado Boulder, United States; [2]imec, Belgium; [3]University of California, Los Angeles, United States; [4]University of California, Berkeley, United States; [5]KMLabs Inc., United States

The development and integration of next-generation nano and quantum devices is approaching a significant metrology hurdle. This is because nanoscale functional properties are no longer well-described by macroscopic models and can become almost entirely geometry- or interface-dominated. Moreover, the transport across interfaces (i.e. charge, spin and heat transport) impact various device properties, such as the switching energy of magnetic memory or the coherence time of quantum devices. This transport is difficult to measure and its in-situ measurement in working devices will be critical to further understanding and optimizing their synthesis and integration. Thus, there is a great need for non-destructive, non-contact imaging techniques applicable to general samples.
There exist many techniques for nano-characterization; however, most are destructive to the sample or insensitive to depth or composition. Milling techniques like secondary-ion mass spectroscopy (SIMS) and auger electron spectroscopy (AES) can determine the chemical composition through the sample's depth, but have a spatial resolution limited by the spot size of the milling beam, and destroy the sample in order to measure it. On the other hand, techniques based on transmission electron microscope (TEM) — such as energy-dispersive x-ray spectroscopy (EDS) or high-angle annular dark-field imaging (HAADF) — can measure composition or structure with atomic resolution, but require the sample to be extremely thin, and often require complex and destructive sample preparation (e.g. FIB-excavation). Non-destructive techniques like atomic-force microscopy (AFM) and scanning-electron microscopy (SEM) can do high-resolution imaging, but lack quantitative depth- or chemical-sensitivity.
Photon-based techniques such as x-ray reflectivity (XRR) and x-ray diffraction (XRD) perform non-destructive measurements that are sensitive to composition, layer thicknesses, and interface quality by measuring the reflectivity as a function of incidence angle (aka reflectometry). However, since XRR and XRD use hard x-rays, they must operate within 1deg of grazing-incidence to get sufficient reflectivity, and the resulting on-sample focus size limits their resolution to >1μm.

Extreme ultraviolet light (EUV, wavelength ~10-100nm) has many unique advantages for sample characterization. Many absorption edges lie in this region of the spectrum, providing excellent composition-sensitivity. Unlike x-rays, EUV absorption depths are 10nm-1μm, enhancing the depth-sensitivity of reflectometry. This work combines EUV reflectometry with ptychographic coherent diffractive imaging (CDI) to demonstrate a unique non-destructive microscopy whose resolution approaches the diffraction limit. Furthermore, the quantitative phase information also given by ptychography, which traditional XRR cannot measure, is extremely sensitive to the sample's composition and structure.
We use this technique to investigate a sample fabricated by imec. The sample consists of Si_3N_4 structures on an As-doped Si substrate ($5x10^{20}$ atoms/cm^3). We investigated our technique's sensitivity to composition, layer thickness, interface quality and dopant level and found, for several, it approached or exceeded other techniques, while remaining non-destructive and high-resolution.
This work demonstrates a general nanoimaging technique that promises to fill a current gap in sample metrology. Our technique combines the unique advantages of coherent EUV light with the composition- and interface sensitivity of XRR and XRD and the resolution-enhancement and quantitative phase information of ptychography. This technique enables non-destructive, large-area, quantitative, 3D imaging of nanostructures and their chemical makeup, layer thicknesses, interface quality and dopant levels, without special sample preparation.
This work was financially supported by NSF STROBE STC (DMR-1548924); DARPA STTR (W31P4Q-17-C-0104); DARPA PULSE (W31P4Q-13-1-0015).

12:20 PM CT03.02.07
On-Line Microfluidics XRF and FTIR Spectroscopy for Fast Exploration of Liquid/Liquid Extraction Thermodynamics Ange Maurice[1], Varun Rai[1], Asmae El-maangar[2], Johannes Theisen[2], Thomas Zemb[2] and Jean-Christophe Gabriel[1,3]; [1]Nanyang Technological University, Singapore; [2]ICSM, University Montpellier, France; [3]Université Paris-Saclay, France

Liquid-Liquid extraction can be a complex chemical **purification** process involving many thermodynamic and kinetic parameters. For instance, the **recycling** industry has an incoming waste stream with high variability. Thus, they need to constantly adjust their processes to match the variation in chemical composition. There is a need for fast process development tools to study liquid-liquid extraction. In this regard, downscaling an extraction system in microfluidics can be more accurate, faster and safer due to fluids being more stable and controlled.
We report on newly developed microfluidic devices integrated with Fourier Transform Infrared Spectroscopy (FTIR) and X-ray fluorescence (XRF) [1, 2]. These tools are primarily aimed at studying **liquid/liquid extraction** processes. First, using FTIR characterization of the vapor pressure, we study the **chemical activity** of the solvents [3]. Second, we perform, for the first time, **on-line XRF** quantification of metals to monitor liquid-liquid extraction in **microfluidics[4]**. The measurement is automated and performed for both aqueous and organic phase. This approach allowed us to quickly study the variation of free energies of transfer for the extraction and reverse-extraction of three rare-earth elements at different temperatures. Overall, thanks to a fully automated approach, we show that thermodynamics and kinetics of extraction can be obtained in **less than 12 hours** with a resulting liquid waste of **less than 20mL.**

Nanoscale Materials Characterization Capabilities at NSLS-II Yong S. Chu, Mingyuan Ge, Hanfei Yan, Huang Xiaojing, Xianghui Xiao, Ajith Pattammattel and Lee Wah-Keat; Brookhaven National Laboratory, United States

The NSLS-II has outstanding nanoscale x-ray imaging capabilities in the hard x-ray regime, enabling a broad range of scientific research. The transmission x-ray microscopy (TXM) method, offered at the Full-field X-ray Imaging (FXI) Beamline, has the world-leading morphological and spectroscopic imaging capabilities with spatial resolutions from 20-50 nm. This full-field imaging capability with unprecedented imaging throughput finds excellent application in visualizing 3D chemical transformation in complex materials under in-situ controls [1-2].
With the focus size down to 12 nm, the Hard X-ray Nanoprobe (HXN) offers simultaneous multimodal imaging capabilities, which are ideal for visualizing material heterogeneity or defects with outstanding detection sensitivities. Some of the recent scientific applications include fluorescence tomography [3], high-sensitivity oxidation-state imaging [4], and strain imaging [5]. Significant efforts are directed toward achieving sub-10 nm 3D imaging using ptychography and performing more comprehensive material analysis by utilizing both full-field and scanning imaging modalities. The presentation will describe the latest technical capabilities and their applications for solving scientific problems.

X-Ray Nano-Diffraction of Extremely Bent Single Nanowires Ullrich Pietsch[1], Arman Davtyan[1], Dominik Kriegner[2], Vaclav Holy[3], Ryan Lewis[4] and Julian Müller[1]; [1]University of Siegen, Germany; [2]Technical University of Dresden, Germany; [3]Charles University, Czechia; [4]McMaster University, Canada

Core–shell nanowires (NWs) with asymmetric shells allow for strain engineering of NW properties because of the bending resulting from the lattice mismatch between core and shell material. For this study GaAs core NWs were grown by molecular beam epitaxy (MBE) onto an
Si(111) substrate and $In_xAl_{(1-x)}As$ shells were preferentially grown onto one side of the core only, for example onto the

(1̄-10) plane. Besides electron microscopy the bending of NWs has been observed by X-ray diffraction analysis using a micro- and nanofocused beam. Respective measurements have been performed at beamlines ID1 of ESRF and P23 of PETRA III, respectively. A new scheme of data recording has been developed in order to determine bending radii and strains of NWs with different nominal bending radius. For data analysis a kinematical diffraction theory for highly bent crystals was developed and applied. The homogeneity of the bending and strain was studied along the growth axis of the NWs, and it was found that the lower parts, i.e. close to the substrate/wire interface, are bent less than the parts further up. Extreme bending radii down to about 3 micron did result in strain variation of about 5% in the NW core.

Nano X-Ray Diffraction Imaging of Strain-Engineered $LaSrFeO_3$ Across the Metal-Insulator Transition

Travis D. Frazer, Dina Sheyfer, Tao Zhou, Zhonghou Cai, Jianguo Wen, Yuzi Liu, Deshun Hong, Changjiang Liu, Anand Bhattacharya and Yue Cao; Argonne National Laboratory, United States

Strongly correlated materials exhibit interesting emergent behavior, such as high temperature superconductivity, colossal magnetoresistance and metal-insulator transitions (MIT) [1-3]. For perovskites, these exotic functional properties can be tuned via strain engineering [4,5] due to the strong coupling between the charge, spin, and lattice degrees of freedom. It is still not fully understood how these degrees of freedom interrelate to produce exotic states, and part of the complexity comes from spatial inhomogeneities on the nanometer scale [1]. Moreover, real material systems contain defects that can greatly influence their behavior, such as phase transitions being pinned to and nucleated at point defects. It is thus critical to characterize the electronic and structural evolutions of correlated materials at the nanoscale, through their relevant phase transitions. As part of this effort, we use nano x-ray diffraction (nano-XRD) to image strain and structural changes in $La_{1/3}Sr_{2/3}FeO_3$ (LSFO) across its MIT. LSFO has a concurrent metal-insulator phase transition involving the spin and charge orders, along with a structural component, according to past work [6]. We synthesize LSFO films on $SrTiO_3$ (001) and (111) substrates, where both samples exhibit a MIT, but with onset temperatures that differ by 20 K. Whether these LSFO films are identical to the bulk LSFO, the nature of the MIT, and the role of the lattice strain are not fully understood. Utilizing the 30 nm spatial resolution and 10^{-5} strain sensitivity of nano-XRD, we image the evolution of strain with temperature for LSFO on the (111) substrate. We find that LSFO on STO (111) has a smooth structural response through the MIT, in contrast with the relatively sharp onset of the charge order. This differs from the sample on the (001) substrate, where the exact same charge order parameter cannot be found. Moreover, using nano-XRD, we see evidence of structural heterogeneity and domain formation in the (111) sample that becomes more pronounced 50K below the MIT, without a corresponding change in the charge order. Our results on the strain and lattice changes across the MIT will directly inform first principles calculations of correlated behavior in LSFO on STO. Clarifying the complicated energy balance between the lattice and electronic degrees of freedom in strain-engineered LSFO will have further implications for other MIT materials being investigated for next-generation memory devices. Time permitting, I will also discuss how simple machine learning techniques can enhance nano-XRD data analysis, independently extracting information on the film's local surface normal tilt and lattice plane spacing, in a single measurement.

The sample processing, experimental design, data collection, and development of new analysis methods were supported by the US Department of Energy, Office of Science, Basic Energy Sciences, Materials Science and Engineering Division. Work at the 26-ID-C and 33-ID-D beamlines of the Advanced Photon Source was supported by the US Department of Energy, Office of Science, Basic Energy Sciences, under Contract No. DE-AC02-06CH11357.

Nano-Imaging of Functional Nanomaterials by Spatially Resolved X-Ray Diffraction Tobias Schulli[1], Steven Leake[1], Marie-Ingrid Richard[1,2], Tao Zhou[1,3] and Edoardo Zatterin[1]; [1]ESRF, France; [2]CEA Grenoble, France; [3]Argonne National Laboratory, United States

Unprecedented tools to image crystalline structure distributions in materials have been made possible by recent advances in X-ray sources, X-ray optics and X-ray methods. Nanobeams combined with diffraction have made it possible to image parameters that were traditionally only addressed as ensemble averages. This enables the study of highly heterogeneous materials such as microelectronic devices and opens a new field of material science on the mesoscale. Furthermore, coherent nanobeams offer the opportunity to image nanomaterials in three dimensions with a resolution far smaller than the focused beam size. This has opened up new fields in X-ray diffraction in general and has become one of the main drivers for the enhancement of existing, and the construction of new, large scale scientific infrastructure projects around the world.
As one example, the ID01 beamline has been built to combine Bragg diffraction with imaging techniques to produce a strain and mosaicity microscope for materials in their native or operando state. A scanning probe with nano-focused beams, objective lens-based full-field microscopy and coherent diffraction imaging provide a suite of tools which deliver micrometre to few nanometre spatial resolution combined with the unrivalled strain resolution supplied by X-ray diffraction.
With worldwide efforts in the upgrading or new conception of synchrotron sources, improvements of several orders of magnitude in the throughput of these methods are expected in the next years. Our first results show the relevance of such new tools in complex experimental environments as encountered in nanotechnology and chemistry.
Although many basic principles and processes in what is in a wider sense called nanotechnology are known and exploited since more than a century, their development and improvement is still very much based on a trial and error approach. In the sector of energy materials such as batteries or electrochemical systems for energy conversion, the physiochemical complexity has prevented over decades a clear-cut understanding of processes and reactions at the nanoscale, essentially due to the absence of suited characterization tools. Looking at the example of batteries, and the worldwide implication of research groups on only a few prominent material systems, it becomes clear that rarely any progress in a technology depended so much on characterization and understanding of the complete reaction system. On the other hand, many common characterization techniques cannot assess such electrochemical systems under reaction but rather their constituents once isolated or extracted from the reactive system. Lab and synchrotron based powder X-ray diffraction has been a tool of choice for investigating nanomaterials in complex systems and under reaction. But only very recent developments permit to overcome the absence of spatial resolution of this method. We have developed several diffraction based microscopes that have proven their usefulness in microelectronic samples where high strain resolution needs to be combined with large fields of view and sub micrometer resolution. For typical nanostructures as present in catalytic reactions or batteries, coherent X-ray diffraction imaging tools will allow to zoom into single nanocrystallites with the potential of 3D nanometric imaging. While most published examples of the recent past aimed at high spatial resolution in static samples, current efforts are aiming at the operando assessment at a time resolution of relevance in chemical engineering, while preserving a 3D spatial resolution well below 10 nm. These tools that are today mainly limited to a small expert community are prone to quickly develop into one of the most powerful operando assessment methods; We will present the current state of the art of X-ray diffraction based microscopy with examples for imaging of individual nanostructures.

Local Structure and Switching of Ferroelectric/Ferroelastic Superdomains Probed by Scanning X-Ray NanoDiffraction Edoardo Zatterin[1], Marios Hadjimichael[2], Steven Leake[1] and Pavlo Zubko[3]; [1]European Synchrotron Radiation Facility, France; [2]University of Geneva, Switzerland; [3]University College London,

United Kingdom

Due to novel functionalities recently discovered at domain walls, thin-film ferroelectrics with dense ferroelastic domain structures represent promising candidates for a new generation of nanoelectronic devices [1]. Ferroelastic domain structures form to minimize epitaxial strain in the film, which can be tailored by selecting an appropriate combination of thin film and substrate material [2]. Certain combinations give rise to peculiar hierarchical organizations, whereby ferroelastic domains arrange in distinct "superdomain" bundles [3,4]. Recent studies have demonstrated that interconversion between superdomain states can be induced by the application of an external electric field [5] or stress [6], making these systems attractive for potential applications in reconfigurable electronics.

Little is still known about the superdomain arrangement locally, as well as the exact nature of its response to applied fields in device-like conditions. Studies to date have been confined to surface-limited Piezoresponse Force Microscopy (PFM) imaging or large area X-ray diffraction.

Here we attempt to fill this gap by employing synchrotron Scanning X-ray NanoDiffraction (SXND) [7]. An X-ray beam focused down to 50nm is swept across a ferroelectric thin film displaying a superdomain arrangement, giving local and spatially resolved access to its crystallography – with beam-size resolution. We use PbTiO3 (PTO) // KTaO3 (KTO) thin films as a prototype system for this study due to the rich mixture of both in-plane and out-of-plane domain bundles (the so-called "a_1a_2/c" structure) that PTO exhibits as a result of the moderate epitaxial tensile strain exerted by the KTO substrate.

The superdomain structure revealed by SXND displays a peculiar distribution of PTO tilt and tetragonality gradients [8], especially evident at the boundaries between a_1a_2 and ac bundles. We subsequently track changes in this spatial distribution of tilts as a function of in-plane electric field applied via interdigitated electrodes, observing 90 degree domain wall rotations to accommodate 180 degree switching of the in-plane polarization component as the applied field polarity is inverted. PFM data collected on the same regions corroborates our interpretation, and suggests that the peculiar nature of the superdomain boundaries plays a major role in the switching mechanism.

Recent Commissioning of the Nanoprobe Endstation at the Submicron Resolution X-Ray Spectroscopy (SRX) Beamline at the NSLS-II Andrew Kiss, Evgeny Nazaretski, David S. Coburn, Jun Ma, Huijuan Xu, Mourad Idir, Lei Huang, Weihe Xu, Huang Xiaojing, Yang Yang, Randy Smith and Yong S. Chu; Brookhaven National Laboratory, United States

The Submicron Resolution X-ray (SRX) Spectroscopy beamline at the National Synchrotron Light Source II (NSLS-II) is a hard X-ray scanning-probe imaging and spectroscopy beamline. A focused X-ray beam is rastered over the sample to collect X-ray fluorescence (XRF) maps and spatially-resolved X-ray absorption spectroscopy (XAS) measurements from the sample. These techniques support a wide range of scientific fields including environmental and biological sciences, earth sciences, and material and energy sciences. Recently, a

new nano-endstation was commissioned to provide users with an increased spatial resolution and higher photon flux onto the sample. This nano-endstation is the result of a multiyear program coordinated by an in-house team of scientists and engineers to replace the existing micro-endstation at SRX by filling a gap in imaging spatial resolution at the NSLS-II and providing users with additional imaging capabilities.

The nano-endstation at the SRX was built downstream of the existing micro-endstation and utilizes all new equipment. A pair of fixed-curvature Kirkpatrick-Baez (KB) mirrors focus the incident beam onto the sample. These mirrors are installed in a vacuum chamber designed to provide high stability with a newly designed alignment mechanism and interferometer feedback. The KB mirrors were manufactured with tight tolerances to provide a sub-250 nm focus and have demonstrated a 225 nm focus from a knife-edge scan on a test pattern. The sample is mounted on a new piezo stage stack which uses coarse and fine stages to raster the sample through the focused beam. Additionally, a rotation stage is mounted to allow for tomographic measurements. The rotation stage with slip-ring connectors can be run with continuous rotation for advanced scan strategies. This is also important for operando measurements where an electrical connection is necessary, *e.g.* electrochemical cycling. An interferometer system is installed to monitor the sample position and correct for any potential run out. These enhancements and added capabilities at SRX enable our user community to collect the high-quality elemental maps and spectroscopy for their experiments, as well as collecting more information on their samples by extending from 2D images to 3D volumes.

Nanostructured materials can exhibit exotic properties and behaviors that enrich the landscape of bulk materials, due to the increased influence of dopants, surfaces, geometry, and interfaces. Moreover, at the nanometer length scale, conventional macroscopic models of materials fail to accurately describe their physical behavior. In addition, traditional metrology tools struggle to precisely measure their functional properties. Specifically, heat transport in dielectric and semiconductor materials—which is dominated by phonons—is traditionally considered to follow Fourier's law of diffusion. However, when the relevant length scales of the system approach the scale of the phonon mean free paths, past experiments observed [1] and theories predicted [2] a breakdown of Fourier's law. To date, experimentally probing thermal transport at the nanoscale for general geometries is an outstanding challenge, precluding the development of comprehensive models of heat flow in complex systems. These challenges are a current roadblock for nano- and quantum technologies, including the development of advanced nanoelectronics and efficient thermoelectric devices.
Fortunately, tabletop sources of ultrafast, coherent extreme ultraviolet (EUV) pulses, produced via high harmonic generation, have nanometer wavelengths and femtosecond pulse durations which are well-matched to the intrinsic length- and timescales of energy transport at the nanoscale [3]. Here, we demonstrate that a

dynamic scatterometry technique—based on these coherent EUV beams—is a versatile route for uncovering non-diffusive thermal transport behavior in nanostructured systems, from nanostructures on single crystal silicon to complex metalattices.
Using this new metrology capability, we map non-diffusive thermal transport away from 1D- and 2D-confined nanoscale heat sources on bulk substrates. This allows us to validate the counter-intuitive behavior that heat source periodicity (reduced spacing) can increase thermal dissipation efficiency [4,5]. We probe the full thermal transport landscape by studying varying heat source geometries on a variety of materials with drastically different phonon properties: silicon, silica, and diamond. Moreover, these EUV scatterometry results made it possible to develop and benchmark advanced mesoscopic and microscopic models to form a more general picture of phonon transport. We demonstrate that the kinetic-collective model, a mesosopic model using a hydrodynamic-like transport equation, predicts the full thermomechanical response observed in the experiment—including non-diffusive transport behavior—over a wide range of length- and timescales. We also perform microscopic atomistic calculations to model experimentally relevant geometries and uncover the fundamental physics responsible for the observed counter-intuitive behavior.
Furthermore, we advance this EUV-based technique to probe transport in nanoengineered metalattices [6]. Metalattices are a powerful bottom-up approach to tuning the propagation of high frequency phonons—highly ordered nanoscale opal templates allow for precise control over structure, into which different materials can be infiltrated. Specifically, we explore the interplay between heat source geometry and the nanoscale structure of the metalattices. We observe that metalattices are capable of significantly reducing the thermal conductivity below the prediction of continuum models and support these findings with atomistic calculations. In conclusion, we highlight extensions of this scatterometry technique to novel modalities based on coherent EUV beams to probe behavior in general devices [7].

4:25 PM CT03.04.02
Evaluating the Effects of Cyclic Stresses on the Microstructure of Ferrite—A Microsecond Time Resolved X-Ray Diffraction Based Technique Doriana Vinci[1], Vincent Jacquemain[1], Christophe Cheuleu[1], Olivier Castelnau[1], Vincent Michel[1], Véronique Favier[1], Cristian Mocuta[2] and Nicolas Ranc[1]; [1]Laboratoire PIMM, Arts et Métiers Institute of Technology, CNRS, France; [2]Synchrotron SOLEIL, France

Many mechanical systems are submitted to deformations repeated for a very large number of cycles during their service (e.g. several billion cycles, in what is called the gigacycle fatigue domain or very high cycle fatigue – VHCF - domain) and can break under stress lower than their ultimate tensile stress. This phenomenon, called fatigue of materials, can be encountered in many industrial sectors. Fatigue design is thus crucial in engineering and it requires the accurate characterization of material behavior under cyclic loadings to ensure the safety and reliability of structures throughout their life. The characterization of the fatigue behavior of materials has been largely investigated with fatigue tests requiring long testing time in standard laboratory. To overcome this inconvenient new approaches based on ultrasonic fatigue machines have been developed during the last decades. In particular, the present research focuses on a new method for the fast determination of fatigue behavior by interpreting diffraction patterns with a temporal resolution of ~ 1µs during an ultrasonic fatigue test at loading frequency of about 20kHz.
The present study points the estimation of the XRD peak broadening evolution during sample deformation due to ultrasonic fatigue cyclic loadings. This is a crucial parameter as it is strictly related to the microstructure of a material in term of mean elastic strain distribution and its fluctuation, intragranular strain heterogeneity and dislocation density.

A fully perlitic steel specimen was loaded using a 20kHz ultrasonic fatigue machine mounted on the six-circle diffractometer available at the DiffAbs beamline on the SOLEIL synchrotron facility in France. Since we are interested to investigate the VHCF domain, the amplitudes of the cyclic stresses ranges from 78 to 262 MPa. The diffraction patterns were acquired with a 2D hybrid pixel X-ray detector (XPAD3.2) with a temporal resolution of 1µs.
From the XRD patterns, peaks position and their respective broadening can be estimated. In particular, the evolution of diffraction peak broadening of ferrite (110) and (220) reflections is calculated by fitting the experimental data with an asymmetric Pearson-7 function. The results highlight an increase of the peak broadening with the amplitude of applied stresses. The micromechanical interpretation of these experimental data, based on a homogenization scheme capturing the strain heterogeneity inside the material, will be presented.

4:40 PM *CT03.04.03
Time-Resolved Synchrotron X-Ray Diffraction Studies of the Piezoelectric Response in Ferroelectric Thin Films Thomas W. Cornelius[1], Cristian Mocuta[2], Matthias Rössle[3], Stephanie Escoubas[4], Eudes B. Araujo[5] and Olivier Thomas[4]; [1]CNRS, France; [2]Synchrotron SOLEIL, France; [3]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [4]Aix-Marseille Université, France; [5]University of São Paulo State–UNESP, Brazil

Piezotransducers, based on piezoelectric materials, that convert electrical into mechanical energy (and vice-versa) are widely used in several communication, sensing and energy harvesting applications. Piezoelectric materials are thus used in various devices, including resonators, actuators and sensors, recently as thin films to facilitate their integration into microelectronic devices and for miniaturization purposes (at lowest energy consumption). Among piezoelectric materials it is well established that the piezoelectric coupling coefficients are very large in crystalline materials which are also ferroelectric, i.e. which exhibit a remanent electrical polarization, switchable by applying an external electric field.
Besides the intrinsic piezoelectric effect, extrinsic mechanisms related to the presence of domains contribute to the piezoelectric effect in ferroelectrics. The domains are regions in which the orientations of the polarization vector and the spontaneous strain tensor are uniform. They are separated by domain walls, within which polarization and strain change direction upon passing to an adjacent domain having different orientations of the polarization vector and spontaneous strain. When external fields are applied to the ferroelectric, the domain walls move to minimize the energy of the unfavourably oriented domains, thus contributing to the field-induced changes in polarization and strain. The intinsic and extrinsic mechanisms are interdependent and, consequently, the total macroscopic response of a piezoelectric ceramic emerges from complex interactions of intrinsic and extrinsic mechanisms.
To investigate the physical properties of ferroelectric thin films various techniques, e.g. piezoelectric force microscopy (PFM), interferometry etc. are typically used. We use *in situ* synchrotron X-ray diffraction combined with the application of an electric field during measurements, which provides useful and precise information beyond the usual applications for structural studies [1-5]. It grants strain resolutions of the piezoelectrically-induced strain of better than 10^{-4}. In addition, *time-resolved* X-ray diffraction gives access to the structural dynamics during electrical loading [6]. We present the electric field-dependence of structural dynamics in lead zirconate titanate (PZT) and lanthanum-modified lead zirconate titanate (PLZT) thin films with various La concentrations using *in-situ* and *time-resolved* X-ray diffraction with temporal resolutions down to few tens of nanoseconds. The build-in electric field effects on butterfly curves asymmetry in PZT films and the La-doping effects on the coexistence of nanodomains and coarse domains evolution in PLZT films is shown and discussed.

Transient Lattice Response upon Photoexcitation in $CuInSe_2$ Nanocrystals with Organic or Inorganic Surface Passivation Samantha Harvey; Northwestern University, United States

$CuInSe_2$ nanocrystals offer promise for optoelectronics including thin-film photovoltaics and printed electronics. Additive manufacturing methods such as photonic curing controllably sinter particles into quasi-continuous films and offer improved device performance. To gain understanding of nanocrystal response under such processing conditions, we investigate impacts of photoexcitation on colloidal nanocrystal lattices via time-resolved X-ray diffraction. We probe three sizes of particles and two capping ligands (oleylamine and inorganic S^{2-}) to evaluate resultant crystal lattice temperature, phase stability, and thermal dissipation. Elevated fluences produce heating and loss of crystallinity, the onset of which exhibits particle size dependence. We find size-dependent recrystallization and cooling lifetimes ranging from 90 to 200 ps with additional slower cooling on the nanosecond time scale. Sulfide-capped nanocrystals show faster recrystallization and cooling compared to oleylamine-capped nanocrystals. Using these lifetimes, we find interfacial thermal conductivities from 3 to 28 MW/(m^2 K), demonstrating that ligand identity strongly influences thermal dissipation.

5:20 PM CT03.04.06
Advanced Material Characterization Using Quantitative Full-Field X-Ray Nano-Imaging Mingyuan Ge, Jiayong Zhang, Xianghui Xiao and Lee Wah-Keat; Brookhaven National Laboratory, United States

Transmission X-ray microscopy (TXM) is a full-field imaging technique. By taking advantage of using a synchrotron light source, TXM provides unique capabilities in fast 2D/3D imaging with nano-scale resolution. At the Full-field X-ray Imaging (FXI) Beamline at NSLS-II, we can routine perform 3D x-ray imaging with 1k x 1k x 1k voxels at a sub-50 nm resolution in less than one minute[1]. While morphology characterization is the primary mode of the TXM application for vast samples, quantitative analysis in terms of material composition and oxidation states can be achieved through a TXM XANES method, where the imaging data are collected at multiple x-ray energies across one or more elemental absorption edges allowing spatially-resolved XANES analysis[2]. The high-imaging rate at the FXI Beamline makes it possible to perform three-dimensional TXM XANES imaging under in-situ sample environment. In the presentation, we will report our recent instrument and data analysis development with few examples to describe the quantitative analysis using the data analysis tools we developed in-house[3].

Insight into Biological Structures Using 3D Imaging Techniques Izabela B. Zglobicka[1], Jürgen Gluch[2], Qiong Li[2], Zhongquan Liao[2], Stephan Werner[3], Peter Guttmann[3], Tomasz Plocinski[4], Andrzej Witkowski[5], Ehrenfried Zschech[2] and Krzysztof J. Kurzydlowski[1]; [1]Bialystok University of Technology, Poland; [2]Fraunhofer Institute for Ceramic Technologies and Systems (IKTS), Germany; [3]Helmholtz-Zentrum Berlin (HZB), Germany; [4]Warsaw University of Technology, Poland; [5]University of Szczecin, Poland

Nature is not only a constant source of inspiration and knowledge for modern engineering but also most of all the source of materials with unique complex structures and properties. The structure optimized by millennial evolution can be used as a base for the preparation of advanced engineering materials. An essential requirement for this is the full understanding of the laws endowing the nature-built materials with superb properties. To this end, high resolution imaging techniques are essential for understanding the hierarchical structures formed in self-assembly processes.

Examples of inspirational organisms are diatoms. The particularly extensively studied diatom characteristic is their intricate cell wall structure, called frustule, mainly made of silicon dioxide (opal). These silica shells exhibit large variation in morphology as well as hierarchical architecture (from nano- to micro-metres).

In recent years, scientists have bridged the gap between biology and material science of diatoms by developing techniques for imaging diatom frustule cross-sections, using scanning electron microscopy (SEM) [1,2]. It enables imaging the fine details of the structure. However, an intrinsic limitation of this technique is the need of cross-sectioning of the studied species, e.g. applying Focus Ion Beam (FIB) milling. Recently, a new insight into the structure of diatoms has been provided by non-destructive visualization of interior structures using nano X-ray computed tomography (nano-XCT) [1,3-4].

The advantage of nano-XCT is demonstrated based on high-resolution 3D data sets describing the structure of diatoms non-destructively. These data sets are of particular importance and were complemented by high resolution three-dimensional structure information using soft X-ray nano-tomography (available at Helmholtz Zentrum Berlin HZB) combined with high-resolution transmission electron microscopy.

The associated imaging and composition analysis results from SEM/FIB, nano-XCT and TEM allow to describe the microstructure of frustules on multiple length scale. Those datasets are used to describe complex structure of diatoms frustules and to derive models in aim of fabrication of a self-similar, bio-inspired structure by applying 3D Selective Laser Melting (SLM) [3] as well as simulation to determinate mechanical properties of such shells [4].

***Operando* Tomography of Lead-Based Batteries for Improved Design of Energy Storage Systems** Mark Wolfman, Alan Kastengren, Tiffany Kinnibrugh and Tim Fister; Argonne National Laboratory, United States

Lead-based rechargeable batteries are promising candidates for stationary grid storage due to their low cost, high stability, and fast discharge capabilities compared to other electrochemical energy storage chemistries. However, current lead-based batteries are unable to fully utilize the theoretical storage capacity, and are limited in their charging rates. Changes in particle size and porosity impact ion and electron transport dynamics between the electrolyte, active material, and current collector grid, ultimately affecting charge acceptance and cyclability. During cycling, large volume changes are encountered that strongly influence electrode morphology and hence battery performance. An improved understanding of this relationship is necessary in order to design more efficient batteries capable of meeting future energy storage needs. The strong attenuation of lead presents several challenges for conventional X-ray imaging. This work presents new techniques and tools developed to overcome these challenges including experimental design, instrumentation, and data analysis; then uses these tools to track the evolution of electrode morphology during initial formation and subsequent cycling of lead-acid batteries.

Mechanical Set-Ups in Laboratory X-Ray Microscopy to Study *In Situ* Crack Propagation at Patterned Structures Kristina Kutukova, Jürgen Gluch, André Clausner and Ehrenfried Zschech; Fraunhofer Institute for Ceramic Technologies and Systems, Germany

The combination of high-resolution X-ray imaging with in-situ mechanical testing, particularly the application of specially designed test setups in a transmission X-ray microscope, allows the study of the fracture behaviour in heterogeneous materials, composites and micropatterned devices. A miniaturised micro double-cantilever beam test (micro-DCB) setup is integrated into a laboratory transmission X-ray microscope (TXM) to guide microcracks to the mechanically weakest region of a material, which is determined by the materials-dependent fracture toughness, the size and the shape of defects as well as the local stress, and to achieve stable crack propagation in a controlled way [1]. In-situ mechanical studies in a nano X-ray computed tomography (nano-XCT) system allow a 3D visualization of the micro-crack evolution in materials or in microchips with a spatial resolution of about 100 nm. During the micro-DCB experiment, the load is applied perpendicular to the optical axis of the X-ray microscope while images are collected. A force sensor allows to determine the mechanical load at certain stages of crack propagation. The local energy release rate can be determined quantitatively. The in-situ micro-DCB technique offers several benefits over existing methods and is applicable across a range of disciplines, including materials science (e.g. composites), microelectronics (e.g. interconnect stacks), and life sciences (e.g. tissue, bones).
High-resolution 3D image sequences based on nano-XCT are used to visualize crack opening and propagation in fully integrated multilevel on-chip interconnect structures of integrated circuits. The nondestructive study of the propagation of sub-micron cracks during the in-situ micro-DCB test allows to image cohesive failures in organosilicate glass (so-called low-k materials) or adhesive failure, i.e. delamination along Cu/dielectrics interfaces. Weakest layers and interfaces in the interconnect stack can be identified [2]. The quantitative determination of the energy release rate allows to judge the robustness of Cu/low-k interconnect stacks against process-induced thermomechanical stress and the effectiveness of so-called guard-ring structures. These data provide important input for the guard-ring design and for the selection of materials, particularly the insulating dielectrics. Eventually, the risk of failure of the patterned metal/dielectrics structures can be reduced.

High Throughput Grain Mapping Using Advanced Acquisition Schemes with Laboratory Diffraction Contrast Tomography (LabDCT) Jun Sun[1], Florian Bachmann[1], Jette Oddershede[1], Hrishikesh Bale[2], Will Harris[3] and Erik Lauridsen[1]; [1]Xnovo Technology Aps, Denmark; [2]Carl Zeiss X-ray Microscopy, United States; [3]Carl Zeiss Microscopy, United States

Characterizing the polycrystalline grain microstructure of metals, alloys, ceramics or minerals in three dimensions nondestructively is paramount to better understanding the material properties. Often, such samples demand a larger representative volume/quantity to be statistically relevant or possess characteristic geometry (e.g. high aspect ratio rolling geometry) that is essential to interpret grain structure anisotropy.

Recent advances of Laboratory Diffraction Contrast Tomography (LabDCT) allow to record and reconstruct larger representative volumes seamlessly. We will present and discuss different approaches of data acquisition strategies attacking acquisition problems inherent to a given sample. Combining the 3D grain microstructure, i.e. grain morphology and crystallographic orientation, with traditional absorption contrast tomography gives unprecedented insights on the laboratory scale. Time resolved studies of the response of the material under investigation to external stimuli in- or ex-situ can be conducted.

Late News: Transparent X-Ray Beam Monitoring and Imaging with PIN diamonds Anna M. Zaniewski[1,2], Jesse Brown[2,1], Manpuneet Benipal[2] and Robert J. Nemanich[1,2]; [1]Arizona State University, United States; [2]Advent Diamond, United States

Advanced x-ray beam facilities support a wide range of scientific and technological development of materials. To maximize the value of these experiments, the x-ray beam itself needs to be well understood, with fine control over its position. As x-ray sources become more advanced, they will benefit from better beam monitoring and measurements. Most of the monitoring methods currently in use can only position the beam or measure beam flux before or after experiments; any drift in the beam position or intensity fluctuations that occur during the experiment would go unnoticed. Therefore, there is a need for real-time, direct beam monitoring which can be integrated with beam controls to quickly set up and control beam parameters, and image the beam. Recent advances demonstrate that thin diamond detectors are a viable technology for minimally invasive imaging of x-ray beams. The choice of diamond brings a number of advantages due to diamond's remarkable physical properties, such as large bandgap, semi-transparency to x-rays, extreme thermal properties, and fast electron and hole mobilities. In this work, we will describe our advances in producing a pixelated, thin, transparent x-ray beam monitor based on doped diamond, with a p-type/intrinsic/n-type (PIN) design, and preliminary results of testing the detector and readout system at the National Synchrotron Light Source II at Brookhaven National Lab.

9:50 AM CT03.05.06
Holistic Materials Analysis Through Scale-Bridging 3D X-Ray Microscopy Robin T. White, Tobias Volkenandt, Stephen T. Kelly and Will Harris; Carl Zeiss Research Microscopy Solutions, United States

X-ray Computed Tomography has proven to be a crucial method to properly characterize and understand a huge variety of materials applications. Due to the non-destructive 3D imaging capabilities, this imaging methodology provides unique insight into material properties with comparatively minimal sample processing. One limitation however has been resolution capabilities. Previously, X-ray tomography imaging has utilized the principle of geometric magnification to obtain resolution. This has several limitations, the main impact being the realistic resolution achievable. Recently, the application of using a photon-converting scintillator and objective lenses has enabled much higher resolution imaging. A unique ability of this system architecture is to enable non-destructive, multi-length scale visualization; with an imaging field of view range from tens of millimeters down to tens of micrometers, and resolution capabilities reaching 500 nm in instruments such as the ZEISS Xradia Versa. Alternatively, another X-ray imaging method is to use X-ray lenses such as Fresnel Zone Plates that can

achieve resolutions down to 50 nm and less, utilizing a quasi-monochromatic lab-based X-ray source in instruments such as the ZEISS Xradia Ultra. This system also employs an inline phase ring that enables Zernike phase contrast imaging which can greatly improve imaging contrast.
Due to the restrictions of lab-based equipment, each imaging solution requires its own imaging system. Often, this results in non-correlative imaging workflows – where a similar but different sample or region is imaged in each system to the maximum system resolution capabilities. This poses a number of inherent limitations in obtaining the full understanding of the sample in question: What does the sample look like as a whole and how representative is this region to another? Are there microscale properties that correlate to macroscale features? Additionally, knowing the exact resolution limit required to properly characterize a sample is an important question that can be difficult to answer without observing enhanced resolution of the exact same feature. Combining systems that can achieve different resolutions in a correlative workflow of the same sample also allows for advanced analysis, such as applying properties obtained from high resolution imaging to a large volume obtained from lower resolution imaging. For example, intra- and inter-particle porosity that is not resolved could inherently change simulation results without proper characterization.
We present here results combining two X-ray tomography systems, the Zeiss Xradia Versa and Zeiss Xradia Ultra instruments, into a correlative, multi-length scale analysis workflow through the use of specifically designed hardware and software tools. We demonstrate several applications using this combined approach to enable non-destructive, massively multiscale 3D imaging. Specific examples include combined quantitative studies in nuclear graphite material to facilitate a multiscale porosity and microstructural analysis, battery anode particles with combined machine learning upscaling as well as polymer electrolyte fuel cell device layers.

Structural Analysis of Dot-Core GaN Substrates Using X-Ray Topography Michael E. Liao, Yekan Wang, Kenny Huynh and Mark S. Goorsky; University of California, Los Angeles, United States

A refined systematic method for imaging and analyzing the structural characteristics of dot-core GaN substrates using X-ray topography is presented. Currently, fundamental understanding of the defect nature of dot-core GaN substrates and the impact on device performance is still in its infancy. Work by Raghothamachar et al.,[1] have previously used X-ray topography to catalogue various dislocations in dot-core GaN substrates. However, only rocked images were generated in that study, which are integrated images recorded by exposing a single film along different angular positions along an X-ray diffraction rocking curve. Our method involves generating single exposure images instead – images exposed at various points along the rocking curve with each image recorded on separate pieces of film. Rocked images were also generated for comparison. The measurements were performed at the 1-BM beamline of the Advanced Photon Source, Argonne National Laboratory using an X-ray energy of 8.05000 ± 0.00015 keV and a (111) Si beam expander to measure the (11$\underline{2}$4) GaN reflection in the glancing incidence geometry. Unlike the rocked images, the single exposure images unequivocally preserve all the structural information pertaining to lattice tilt and distortion – both the magnitude of tilts and the spatial locations of tilt boundaries for example. The importance of preserving this structural information is that it enables us to describe quantitatively the distortion of the defects present. In fact, the single exposure images allow us to calculate the lattice curvature on two different scales: (1) globally across the entire dot-core GaN substrate (~tens of mm) and (2) locally across each highly distorted core (~500 μm). One of the dot-core substrates measured had a radius of curvature of ~15 m across the entire substrate, while locally across individual cores the radius was on the order of ~0.2 m to ~0.4 m. This information is lost in rocked image measurements because the integration of images along different parts of the rocking curve loses angular information. Furthermore, the single exposure image method has the freedom of generating a ‘rocked image’ by superimposing each of these single exposure images together. Measured rocked images cannot be accurately deconvoluted into its image components. We demonstrate that a contour tilt map can be generated when superimposing many of these images together – an impossible task to accomplish from a measured rocked image. Lastly, many instances were found where dislocations that appeared in the single exposure image measurements were not present in the rocked image measurements. This is due to spatial overlapping of diffraction areas from recording images from different parts along the rocking curve on the same film when measuring rocked images.

AI-Enabled Phase Retrieval for Transmission and Bragg Ptychography Tao Zhou, Mathew Cherukara and Martin Holt; Argonne National Laboratory, United States

In this work, we demonstrate how machine learning and its related optimization tools can be used to replace conventional phase retrieval methods in X-ray transmission and Bragg ptychography. X-ray transmission ptychography has become a well-established technique for high resolution imaging and phase retrieval. We present PtychoNN, a novel approach to solve the ptychography problem based on deep convolutional neural networks. Once trained, PtychoNN is capable of generating high quality reconstructions up to hundreds of times faster compared to conventional iterative methods, essential for implementing real time phase retrieval. Moreover, by surpassing the numerical constraints of iterative methods, the sampling condition can also be significantly relaxed. The counterpart of transmission ptychography in diffraction condition is known as Bragg ptychography. The technique itself is less mature, as limited by the more complex diffraction geometry and data quality. Here we describe the forward propagation in Bragg ptychography using the Takagi-Taupin Equations (TTE). We show that, when combined with Automatic Differentiation (AD), TTE can be used as a general formalism for 3D phase retrieval, applicable to both Bragg ptychography and Bragg Coherent Diffraction Imaging. Compared to conventional Fourier Transform based methods, our approach accounts for additionally refraction, absorption, interference, dynamical effects, and is applicable to any kind of weakly strained material system. Artificial Intelligence for Efficient Analytical Processing of X-Ray Diffraction Data Alex Ulyanenkov[1] and Alexander Mikhalychev[2]; [1]Atomicus LLC, United States; [2]Atomicus OOO, Belarus

Artificial intelligence methods attract significant interest nowadays due to the general tendency of automating analysis procedures. Computer-based techniques are not only much faster and less demanding for expert knowledge of operators than manual techniques, but also provide reliability and reproducibility of the analysis results due to much lesser vulnerability to accidental errors. In this contribution, we focus on those two aspects of X-ray diffraction experiments: namely, we demonstrate how artificial intelligence can help in choosing the optimal measurement configuration and in data interpretation (both in powder and high-resolution X-ray diffraction). The approaches, discussed in our contribution are based on combining fundamental physical ideas with the two efficient mathematical tools: Bayes' theorem and Fisher information, which are quite often

overlooked by physicists.

Fisher information [1] quantifies the sensitivity of the measured data to the parameters of interest and, therefore, gives us a hint on choosing the most suitable way of data acquisition. Cramer-Rao bound [2] connects Fisher information to the reliability of the obtained results and the possible correlations between the model features. We demonstrate that fully automatic analysis of Fisher information is suitable for choosing the most informative reflections and measurement geometries when panning high-resolution X-ray diffraction (HRXRD) measurements. The decision is made adaptively, by rating all possible sets of scans and reciprocal-space maps, as well as diffractometer configurations, on the base of the amount of their information on the investigated sample. Also, analysis of the Fisher information structure (namely, detection of a banded diagonal shape of the inverse Fisher matrix) helps to reconstruct the sample parameters in a more efficient way: a problem with locally correlated parameters can be solved by iterative consideration of only a subset of parameters to be reconstructed at each step [3,4]. We apply this technique to the problem of automatic decomposition of an X-ray spectrum, consisting of a large number of strongly overlapping peaks, into contributions of individual peaks.

Bayes' theorem describes the update of our knowledge about the investigated sample by the obtained measurement results. It represents an efficient tool for quantitative ranking of models in the pattern recognition problems [3,5]. We apply a Bayesian approach to quantitative analysis of X-ray powder diffraction data (identification of phases from a measured X-ray spectrum), to peak indexing in HRXRD spectra (finding the correspondence between each measured peak with an expected Bragg peak, a layer thickness oscillation fringe or a superlattice fringe), and to the problem of decomposing strongly overlapping peaks (for power XRD data). The initial information about the investigated sample or dataset is encoded in prior probabilities for the models. The expected experimental inaccuracies caused by statistical and systematic noise are characterized by the likelihood function. Finally, models of the spectrum decomposition (peak identification, etc.) are ranked according to the estimated posterior probability. The approach is quite universal and can be easily adjusted to a particular physical problem: for example, additional systematic errors can be efficiently detected and corrected by introducing them into the analyzed model during powder phase identification. For all the mentioned tasks, the designed algorithms succeeded in automated solving of the problems.

Machine Learning Aided Image Reconstruction in X-Ray Tomography Jiayong Zhang, Thomas Flynn and Mingyuan Ge; Brookhaven National Laboratory, United States

Computer tomography has found broad application in material science and medical imaging, providing a versatile approach to visualize the internal structure of a 3D volume. For decades, there is extensive research on the improvement of reconstruction quality and fidelity to deal with the many challenges imposed by experimental data collection, such as noise and missing wedge. In this work, we introduce a neural network based method to tackle the missing wedge problem. Distinguished from existing machine learning architecture, we propose a new two-step model implemented through generative adversarial networks (GAN) and autoencoder to inpaint the miss-wedge sinogram. The results have demonstrated the state-of-the-art performance. More importantly, the proposed architecture is robust to insufficient training data, which provides uniqueness in distilling and expanding the knowledge learned from limited training data to un-seen categories as semi-unsupervised learning. We will also discuss the difference between our method and others' work, especially in the sense of how we can consistently improve the model performance in practical scientific applications when ground truth is not available. The ability to reconstruct images in X-ray tomography with high accuracy and fidelity would gain us more reliable insights into objects' intrinsic structure and deepen the

understanding of specific scientific problems. This work is supported by the LDRD program at the FXI facility at NSLS-II, Brookhaven National Laboratory (BNL).

12:40 PM *CT03.06.04
Performance Evaluation of Crystallographic Analysis Methodologies in Diffractive Characterization of Nanocrystalline Powders Hande Öztürk[1] and I C. Noyan[2]; [1]Ozyegin University, Turkey; [2]Columbia University, United States

The potentials of facilitating nanocrystals in novel materials design and of enhancing existing materials in the form of advanced nanocomposites are attracting increasing attention to nanomaterials research. Due to the strong correlation between physical and chemical properties of nanocrystals and their sizes as well as atomic configurations, their production requires utmost control and precision. Hence developing accurate, reliable and robust characterization methods targeting nanocrystals is becoming an even more critical component of today's materials design and manufacturing activities. X-ray powder diffraction, being the gold standard of high-resolution materials characterization is the number one method employed in the analysis of nanocrystalline powders as well, although the fundamental principle behind the analysis of powder x-ray diffraction data is the assumption of infinitely-periodic stacking of atoms within individual grains, not strictly satisfied by nanocrystals due to their tiny sizes. That raises the question of whether we can use standard crystallographic analysis methods to solve for the average internal structure of nanocrystalline powders from their diffraction data.
In this talk I will address this question using computational modelling of powder diffraction from monodispersed nanocrystalline powders with grain sizes of 40 nm and below. To do that, I will first introduce our computational framework and present ideal diffraction data generated based on first-principle diffraction equations. This computed data will be treated as 'ideal experimental data' and then will be used to establish direct link between the diffracting nanocrystalline powder and its diffraction signature. Standard crystallographic analysis methodologies will be used to extract avarage structural characteristics of the nanocrystallne powder and they will be validated against the true structural parameters of the nanopowder by direct analysis of the atomic coordinates. Our conclusions are important in understanding the limits of applicability and validity of standard crystallographic analysis tools in x-ray diffraction data of nanocrystalline powders under ideal conditions, where the diffraction data is free from uncertainties and the diffracting sample is known down to the individual atomic positions. Moreover, our results will draw attention to the necessity of computational studies to investigate the diffraction phenomenon of x-rays from nanocrystalline powders and will motivate discussions on developing better data analysis algorithms compatible with the internal structure of nanocrystalline powders.

1:20 PM CT03.06.06
Morphology-Informed Correlation Across Multimodal Microscopy Data Rishi Kumar, Xueying L. Quinn and David Fenning; University of California, San Diego, United States

Synchrotron-based study of material behavior often involves the use of multiple modes of characterization, whether in a synchronous correlative microscopy approach or via sequential measurement. While synchronous multimodal characterization is a growing area, these studies most commonly consist of various measurements on different instruments at different times, each with their own quirks resulting from practical constraints like sample orientation and tool resolution. The difficulty in strictly correlating data generated across measurements can be quite high, especially so for samples with asymmetric and non-extended morphology such as individual micro- or nanoparticles and rough or porous films as can be found in solar cells and battery electrodes. To address this challenge, we present a morphology-informed ray-tracing approach to simulate probe-sample interactions in raster scanning instruments, allowing for proper spatial correlation of the data acquired across synchrotron-based and benchtop setups.

First, we generate a three-dimensional model of our sample from a map of local thickness. We then perform ray-tracing of the X-ray beam with our sample, accounting for the X-ray-sample interaction and the orientation of the beam, sample, and involved detectors. As a demonstrative example, we analyze sequential nanpoprobe X-ray diffraction and X-ray fluorescence maps of a state-of-the-art halide perovskite optoelectronic material. The ray-tracing yields a spatially-variant point-spread function weighting the contribution of all beam-intersected regions of the sample to the values recorded at the detectors at each point on the map, enabling deconvolution of the sample morphology from measured data and fair spatial correlation of data across measurements. Precise assessment of the sampled volume in correlative measurements will be increasingly necessary as experimental complexity increases at diffraction-limited storage rings.

1:35 PM CT03.06.07

Influence of Layer Charge on Hydration Properties of Synthetic Octahedrally Charged Na-Saturated Trioctahedral Smectites Doriana Vinci[1], Baptiste Dazas[2], Eric Ferrage[2], Martine Lanson[3], Valérie Magnin[3], Nathaniel Findling[3] and Bruno Lanson[3]; [1]Laboratoire PIMM, Arts et Métiers Institute of Technology, CNRS, France; [2]CNRS, IC2MP, Univ. Poitiers, France; [3]Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, IRD, IFSTTAR, ISTerre, France

Smectite hydration impacts dynamical properties of interlayer cations and thus the transfer and fate of H_2O, contaminants, and nutriments in surficial environments where these ubiquitous clay minerals are often one of the main mineral components. The influence of key crystal-chemical parameters on hydration, organization of interlayer species, and related properties has been described for tetrahedrally substituted trioctahedral smectites (saponites). Despite the ubiquitous character of octahedrally substituted smectites, that make most of the world bentonite deposits, the influence of charge location on smectite hydration properties has not largely investigated. In this work a set of octahedrally substituted trioctahedral smectites (hectorites) with a common structural formula $Na_xMg_{6-x}Li_xSi_{8.0}O_{20}(OH)_4$ and a layer charge (x) varying from 0.8 to 1.6 was synthesized hydrothermally from stoichiometric gels. The distribution of charge-compensating Na^+ cations and of associated H^2O molecules was determined experimentally from the modeling of X-ray diffraction data obtained along water vapor desorption isotherms. Distributions of charge-compensating cations and of associated H_2O molecules were also computed from GCMC simulations as a function of layer charge. Interlayer H_2O contents are similar in all Na-saturated smectite samples, independent of the location and amount of their layer charge. In contrast to synthetic saponite, for which stability of most hydrated layers was increased by in-creasing layer charge, the stability of synthetic hectorite hydrates is only slightly affected by layer charge. Consistently, the layer-to-layer distance of Na-saturated hectorite 2W (and 1W) layers is independent of layer charge. The contrasting hydration behavior of synthetic Na-saturated saponite and hectorite is likely due to different electrostatic attraction between the 2:1 layer and interlayer cation. Combined with previous results on saponites, the present data and sample set provides key constraints to assess the validity of force fields simulating clay-water interactions for an unmatched variety of smectite with contrasting locations and amounts of layer charge deficits.

Recent Innovations in Laboratory X-Ray Microscopes Wenbing Yun, Sylvia Lewis, David Vine, Benjamin Stripe, Sheraz Gul, Katie Matusik, Jeff Gelb, SH Lau and Janos Kirz; Sigray, Inc., United States

Innovations in laboratory x-ray source and x-ray imaging methodology are critical to realize intrinsic

advantages of x-ray microscopy for a wide range of applications. X-ray imaging using absorption, phase, and scattering/darkfield contrasts (tri-contrast) have been shown to provide unique and complementary structural information critical to many imaging applications, often missing in absorption contrast imaging alone. For example, scatter contrast has been shown to be superior to absorption contrast for imaging fine cracks. Phase contrast is far superior for imaging low Z (soft) materials than absorption contrast.

Significant improvement in tri-contrast x-ray imaging with laboratory x-ray sources is desirable, including options for operating over a wide energy range to image objects of various sizes and compositions, and to achieve high spatial resolution to visualize fine features.

Significant progress has been made in recent years in developing laboratory x-ray sources and methodologies to advance tri-contrast x-ray imaging. Sigray has developed a novel x-ray source using matrix array anode source technology (MAAST™) with an anode comprised of arrays of metal (e.g. Cu, W) microstructures as x-ray emitters embedded in a diamond substrate with excellent thermal conductivity. Under electron bombardment, the localized metal microstructures are effectively cooled due to the large thermal gradients relative to the diamond substrate.

The common approach to tri-contrast x-ray imaging involves the Talbot-Lau interferometer, which consists of three gratings. The first of these, the source grating, is used to provide the required coherence, but it has a number of drawbacks, including inefficient use of source x-rays as it absorbs more than 50%, narrow angular collimation with high aspect ratio grating structures for high energy x-rays and the consequent limit in imaging field of view. Additionally, for high energy x-rays, the fabrication of the source grating is extremely challenging. The MAAST x-ray source removes the need for the source grating entirely. It overcomes the drawbacks and offers many advantages.

Using these and other innovations, Sigray has developed x-ray microscopes with excellent capabilities. The design of the microscopes and their imaging performance will be reported and discussed.

2:40 PM CT03.07.02
Development of a New High-Energy X-Ray Diffraction NDT for High-Pressure Turbine Blades Alexiane Barbeau[1], Baptiste Joste[2] and Henry Proudhon[2]; [1]SAFRAN Tech, France; [2]Mines Paristech, PSL University, Centre des Matériaux, CNRS UMR 7633, France

In the aerospace industry, single crystal nickel-based high-pressure turbine blades are the most critical part of the engine. The thermo-mechanical resistance of the blade is mostly due to the monocrystalline arrangement to increase the creep strength and to the design of internal cooling circuits with complex geometry to reduce the blade temperature.
To ensure the single crystal arrangement is maintained throughout the part after the foundry process, a non-destructive test (NDT) has been developed. Indeed, the presence of another grain into the part can critically impede the performance of the blade, which may cause irreversible damage to the engine motor.

The proposed solution is to develop a new industrial NDT system using high energy Laue transmission diffraction, which represents a technological breakthrough in the current industrial environment. A compact laboratory high energy Laue diffraction system has been designed, which uses a high-energy X-ray source, a motorized support sample setup and a high efficiency X-ray detector. A compact X-ray slit system is used to control the footprint of the beam on the sample and the motorized stage is used to scan the sample in front of the beam. Typical high energy X-ray sources are powerful enough to go through several millimeters of nickel-based alloy allowing to scan entire parts sur as small turbine blades. Our experiments showed that to detect diffraction spots from the illuminated volume, the use of hybrid photon counting detector is desirable to increase the system performances (both faster data collection and detection of weak intensity reflection beams).

A forward simulation model of the Laue diffraction physics under the kinematic approximation has also been

developed and allows simulating any diffraction pattern according to the crystal structure. The forward model also takes into account the sample geometry, which can be as complex as a turbine blade with double walls and internal cavities. An in-house indexing algorithm based on the forward model, which takes into account the specificity of a laboratory system, allows to retrieve the crystal orientation from the experimental diffraction images and to detect new orientations in the pattern.

Experimental results show that Laue transmission diffraction method makes it possible to carry out an orientation mapping for an extended monocrystalline volume. Laue diffraction pattern analyses is able to reveal the potential presence of an undesirable grain in the volume.

Late News: Experimental Geometry Optimization of X-Ray Propagation-Based Phase Contrast Imaging
Hanna Dierks and Jesper Wallentin; Lunds universitet, Sweden

X-ray microscopy and tomography using propagation-based phase contrast (PB-PC) are powerful techniques to study low absorption samples on the micrometer scale. The main benefit of the technique is an increased contrast given by edge enhancement, that is, by near-field interference fringes around sharp edges. In setups with a divergent source, a trade-off between the distance dependent flux and the source coherence must be made. We present a systematical experimental and theoretical investigation of this trade-off, based on experiments with two different laboratory setups with high-resolution detectors: a custom-built system with a Cu microfocus source and a commercial system (Zeiss Xradia) with a W source.
The fringe contrast, contrast-to-noise ratio and fringe separation for a low-absorption test sample were measured for 130 different combinations of magnification and overall distances. We find that these figures-of-merit are sensitive to the magnification and that a theoretical optimum can be found that is independent of the overall source-detector distance. In general, we show that the theoretical models show excellent agreement with the measurements, if the X-ray source spectrum and the energy dependence of the detector sensitivity are considered. These results can be used when designing and optimizing the geometry of an imaging system, especially concerning the used magnification.

High-Resolution X-Ray Source with Advanced E-Beam Technology Emil Espes[1] and Anasuya Adibhatla[2]; [1]Excillum AB, Sweden; [2]Excillum Inc, United States

Driven by needs from scientific research, healthcare and industrial manufacturing, X-ray microscopy has been successfully transferred from synchrotrons to the laboratory and the spatial resolution has been pushed to sub-micrometer. One way to further improve the resolution is to use an X-ray source with a very small focal spot. At Excillum, based on advanced electron beam and target technologies, a state-of-art nanofocus x-ray tube has been developed which enables an isotropic, resolution of 150 nm line-spacing.

Typical nanofocus X-ray tubes are normally limited in X-ray flux, which leads to long acquisition times when performing nano-CT outside of the synchrotrons. The newly developed nanofocus X-ray tube at Excillum, NanoTube N2, has a greatly improved brightness compared to its predecessor, achieving a minimum of 3x higher power loading while still maintaining the same sharp focus. The high brightness of Nanotube N2 brings the possibility of reduced scan times, helping to mitigate any motion blur from samples or imaging system to further improve the spatial resolution.

The advanced electron optics of the nanofocus X-ray tube has internal calibration and validation of the electron focus size, translating to the X-ray spot size. This gives the user a confirmation in what the maximum achievable resolution is for each scan, as well as a continuous feedback on the performance of the tube.

Until now the NanoTube has been integrated into different Nano-CT systems for applications of materials science [1], biomedical [2] and has recently been integrated in to commercially available NanoCT-systems [3].

This presentation will cover the technology enabling the new tube, as well as a few user examples of how the high resolution, high power density tube has helped researchers discover previously unseen features in their samples.

3:25 PM CT03.07.05
Late News: A Compact Light Source Providing High-Flux, Quasi-Monochromatic, Tunable X-Rays in the Laboratory Benjamin Hornberger and Jack Kasahara; Lyncean Technologies, Inc., United States

There is a large performance gap between conventional, electron-impact X-ray sources and synchrotron radiation sources. An Inverse Compton Scattering (ICS) X-ray source [1,2] can bridge this gap by providing a narrow-band, high-flux and tunable X-ray source that fits into a laboratory at a cost of a few percent of a large synchrotron facility. It works by colliding a high-power laser beam with a relativistic electron beam, in which case the energy of the backscattered photons is in the X-ray regime. So far, the only ICS source in regular user operation is the Munich Compact Light Source (MuCLS) [3], a combination of Lyncean Technologies' commercially available Compact Light Source (CLS) [4] and a beamline with two endstations built by researchers at the Technical University of Munich [5]. The application focus of the MuCLS is biomedical imaging of centimeter-sized samples in the 15-35 keV energy range, well-matched to the beam properties of the Lyncean CLS with ~4 mrad divergence and spectral bandwidth of 3-5%.

Here we present a concept for an ICS X-ray source that is about two orders of magnitude brighter than the existing CLS design. Depending on configuration, it covers an X-ray energy range of about 30-90 keV, or 60-180 keV, well-suited to many applications in materials science. It will provide X-ray flux of up to 4 x 10^{12} photons/s within a beam divergence of 4 mrad and a bandwidth of around 10%. This is well-suited for high resolution, micro-CT imaging of millimeter-sized samples at micron resolution, with a flux density similar to some high-energy synchrotron beamlines. The beam properties of the new design are also compatible with focused beam applications such as high-energy diffraction, since using a lower divergence part of the beam with lower bandwidth allows the use of several types of X-ray optics commonly used at synchrotron beamlines.

In this presentation, we will discuss the novel concepts applied to the design of this X-ray source as well as the resulting beam properties. We will discuss several application examples in the areas of imaging and diffraction where this system can approach or meet the performance of synchrotron beamlines. This will allow transferring many research and industrial applications from the synchrotron, where capacity is limited, and enable longitudinal studies that aren't compatible with the synchrotron access model, to a local lab.

High Throughput Imaging Using Liquid MetalJet X-Ray Source Anasuya Adibhatla; Excillum Inc, United States

A conventional X-ray tube generates X-rays when highly energetic electrons are stopped in a solid metal anode. The fundamental limit for the X-ray power generated from a given spot size is when the electron beam power is so high that it locally melts the anode. The liquid-metal-jet anode (MetalJet) technology solves this thermal limit by replacing the traditional anode by a thin high-speed jet of liquid metal. Melting the anode is therefore no longer a problem as it is already molten, and significantly (about 10x) higher e-beam power densities can therefore by used making the MetalJet the brightest microfocus x-ray tube. The liquid-metal-jet technology results in stable and operational X-ray tubes running in over 100 labs around the world.

The applications include X-ray diffraction and scattering, several publications have also shown very impressive imaging results using liquid-metal-jet anode technology, especially in 2-D or 3-D phase-contrast imaging and X-ray microscopy. MetalJet sources also show their applicability in industrial imaging applications.

Phase-contrast imaging achieves a significant improvement on the contrast and resolution of soft-tissue with hard X-rays, however, the imaging quality, has been compromised by the low flux and brilliance using traditional microfocus tubes or adding optical elements. Therefore, the high brilliance liquid-metal-jet technology enables the development of laboratory-scale phase-contrast imaging systems. The high stability of the source meets the requirements of an ideal phase-contrast imaging technique. Several application examples will be given during the conference, illustrating the capability of MetalJet in commercial or in-house built X-ray microscopy system. The Kα line of gallium, the main component of the liquid alloy is above absorption edge of copper making MetalJet beneficial for imaging copper structures with high contrast.

Excillum has recently introduced next generation MetalJet E1 increasing the brightness further by powering a 30 µm spot with 700W. The resulting flux is 70 times more than a conventional sealed tube microfocus tube in the energy range of 24-29 keV and 10 times more in the full spectrum. The applications where E1 dominates the performance are phase contrast imaging, high-pressure single crystal diffraction, small angle x-ray scattering, high speed x-ray imaging to name a few. The dual port capability provides flexibility to users in setting up experiments.

8:00 AM CT03.04.05
Late News: *In Situ* Analysis of Microstructural Evolution of Metallic Alloys Under High Speed Rotational Shear Deformation by Synchrotron XRD Arun Devaraj[1], Tingkun Liu[1], Mathew Olszta[1], Changyong Park[2], Bharat Gwalani[1], Stanislav Sinogeikin[3], Suveen Mathaudhu[1] and Cynthia A. Powell[1]; [1]Pacific Northwest National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]DAC tools, United States

In order to develop shear-based solid phase processing methods, we aim to better understand the fundamental atomic scale mechanisms of mass and energy transfer in materials under shear deformation. To achieve this aim, we developed a first of its kind synchrotron-based in situ high-energy x-ray diffraction capability using a high-speed rotational diamond anvil cell (HSRDAC). HSRDAC provided time resolved synchrotron-based XRD results on lattice strain evolution and change in spatial variation of shear deformation induced alloying in Cu-Ni alloys. These in situ results were correlated with detailed microstructural characterization before and after shear deformation using transmission electron microscopy and atom probe tomography. This HSRDAC capability can provide new insights into the unique role of shear deformation in formation of metastable states, as well as in modifying the phase transformation pathways in a wide variety of alloy systems.

How the Polarization Quantum Can Cause Happiness or Distress at Perovskite Ferroelectric Surfaces, and Why It Matters for Energy Applications Nicola Spaldin; ETH Zurich, Switzerland

Using the example of multiferroic bismuth ferrite, we demonstrate how the interaction between the spontaneous ferroelectric polarization and the half-quantum-containing polarization lattice have a profound influence on the surface properties. With the help of density functional calculations, we identify energetically favorable happy (100) surface geometries, which are combinations of surface termination and polarization direction that lead to uncharged, stable surfaces. Switching the polarization causes these (100) surfaces considerable electrostatic distress, which must be compensated by the introduction of charged point defects or adsorbates such as water. We predict that the relative happiness or distress of the oppositely polarized surfaces should lead to an effective water splitting cycle on the bismuth ferrite (100) surface through polarization switching. We close by showing that there is an analogy between surface charge arising from ferroelectric polarization, and surface magnetization arising from magnetoelectric multipolization.

Point defects have played a major role in tuning the properties of materials over the last few decades. Controlling individual point defects in quantum heterostructures based on complex oxides presents new challenges, arising mostly from non-stoichiometry inherent to oxides. Here, we demonstrate the ability to tune point defects in $LaAlO_3/SrTiO_3$ (LAO/STO) oxide-based quantum heterostructures, using a newly-developed metal-organic pulsed laser deposition (MOPLD) growth technique with Ti flux provided by titanium tetraisopropoxide (TTIP). X-ray diffraction and Raman spectroscopy show that this approach opens a wide process window in which stoichiometry of STO can be controlled without structural changes. Depth-resolved cathodoluminescence spectroscopy reveals that STO films grown at higher TTIP flux have larger ratios of antisite Ti/Sr vacancies with lower concentration of oxygen vacancies. This leads to higher two-dimensional electron gas low-temperature mobilities at the LAO/STO interface and clear Shubnikov–de Haas oscillations. This result provides an essential part of the development of the next-generation complex oxide thin films and their heterostructures to investigate novel quantum phenomena.

8:50 AM BREAK

8:55 AM *CT04.01.03
Deciphering Electronic Correlations—An Atomic Perspective Yue Cao; Argonne National Laboratory, United States

Electronic correlation is arguably the most profound notion in condensed matter physics and often arises due to the strong interactions between the lattice and the electron charge, spin and orbital. Disentangling these degrees of freedom is thus critical to our understanding and manipulation of materials' properties but remains challenging due to the intricate interplay between these players. The difficulty fundamentally originates from the complicated energy landscape formed from often competing order parameters with almost degenerate energies. Here we demonstrate how a handful of experimental methods – electron diffraction, transport and X-ray pair distribution function – conspire to depict the role of atomic lattice vs. the electrons in the formation of electronic correlations.

In the Mott insulator Sr_2IrO_4 which structurally and electronically resembling the canonical high T_C superconductor cuprates, we recently observed a nematic order in the nonmagnetic normal state of the parent compound persisting below the Neel temperature and into the doped samples. The newly discovered nematic order has a correlation only a few nanometers and couples strongly to the lattice through the iridium 5d orbitals. We suspect the nematic order comes from competing ordering instabilities through the 'hidden' Fermi surface. Our observation challenges the accepted notions of nematicity in quantum materials and suggests that electronic nematicity can exist even in a correlated insulator and may cast new light on the understanding of non-conventional superconductivity.

9:20 AM CT04.01.04
Late News: Synthesis of Sr2IrxRu1-xO4 via High-Pressure Floating Zone Technique Zachary Porter and Stephen D. Wilson; University of California, Santa Barbara, United States

In the past decade, researchers have uncovered a rich electronic phase diagram between the Mott insulating antiferromagnet Sr_2IrO_4 and the superconductor Sr_2RuO_4. However, sample size has constrained available measurements, and sample quality may be obscuring emergent magnetic phases. Here we describe the synthesis of single crystalline $Sr_2Ir_xRu_{1-x}O_4$ ($0<x\leq0.6$) via a floating zone melting technique. We find that the use of a high pressure gas environment (~100 atm mixed O_2 and Ar) greatly decreases the evaporation of the IrO_2 reactant. The resultant gram-sized samples are more uniform in chemical composition and demonstrate unique

magnetotransport properties compared to previous work on flux-grown samples.

9:35 AM CT04.01.05
Late News: Post Electrocatalytic Cycling Examination of Defect Creation at Interfaces in LaFeO3-SrTiO3 Thin Films Bethany Matthews[1], Kayla Yano[1], Sandra Taylor[1], Michel Sassi[1], Rajendra Paudel[2], Andricus Burton[2], Byron Farnum[2], Ryan Comes[2] and Steven R. Spurgeon[1]; [1]Pacific Northwest National Laboratory, United States; [2]Auburn University, United States

Precise control of defects is paramount for control and manipulation of quantum phenomena. Defect formation at complex oxide interfaces can be caused by extreme environments. The inability to predict and control defect creation and evolution in environments, such as those encountered during catalytic cycling, predicates the ability to control and manipulate quantum properties and behavior and to access unique phenomena. To gain such control, it is important to understand the structural and chemical signatures associated with different defect types. LaFeO3 (LFO) is a novel perovskite system with strongly defect-regulated catalytic properties, which makes it a rich system to explore defect manipulation. This work focuses on characterizing cation and oxygen defect populations developed near interfaces in single-crystal LFO grown on (001)-oriented SrTiO3 substrates before and after electrocatalytic cycling. Scanning transmission electron microscopy (STEM) analyses are conducted using multiple modes of high-angle annular dark field, bright field, and annular bright field imaging to visualize the material microstructure. To complement imaging, local chemical and composition mapping is performed using electron energy loss spectroscopy (STEM-EELS). Our STEM-EELS measurements focus primarily on the O K edge, which is highly sensitive to local bonding and oxygen coordination environment. We discuss observed changes and their potential impact on the performance of this material.

9:50 AM CT04.01.06
Proximate Double Magnetic Transitions in $BeCr_2O_4$ Hector C. Mandujano[1], C. M. Naveen Kumar[2], Narayan Poudel[3], Krzysztof Gofryk[3], Thomas W. Heitmann[4] and Harikrishnan S. Nair[1]; [1]The University of Texas at El Paso, United States; [2]Technische Universität Wien, Austria; [3]Idaho National Laboratory, United States; [4]University of Missouri–Columbia, United States

The coexistence of two order parameters is a particular occurrence in bulk single-phase materials. Such materials possessing (anti)ferromagnetism, ferroelectricity, and ferroelasticity are known as multiferroics. $BeCr_2O_4$ belonging to *Pbnm* and *Pcmn* space group is one of the earliest reported multiferroic compounds. In this work, we revisit this mostly unexplored material with a focus on multiple magnetic transitions at low temperatures. In this compound, Cr (III) occupies octahedral 4*a* site and Be (II) occupies the tetrahedral 4*c* site. This adopts a close packing structure with a 90° and 138° Cr – O – Cr bonds allowing for interesting magnetic superexchange interactions. In the present work, $BeCr_2O_4$ powder has been prepared using solid-state reaction method and verified the phase purity and crystal structure using laboratory and synchrotron X-ray diffraction. The Rietveld refinement of the powder X-ray data was carried out using *Pbnm* orthorhombic space group yielding lattice parameters, a = 4.556 Å, b = 9.791 Å, c = 5.664 Å. The magnetic susceptibility as a function of temperature revealed two close-by anomalies at T_{N1} ~ 26.5 K and T_{N2} ~ 25.2 K, along with a third transition around 7.5 K, which are also observed in specific heat. Using the Curie-Weiss fit in the paramagnetic region, an effective magnetic moment is estimated to be 2.4 μ_B/Cr and the Curie-Weiss temperature is estimated to be -38 K indicating antiferromagnetic interactions. The reported antiferromagnetic structure is a noncollinear cycloidal spiral with a propagation vector along the *c*-axis with a large periodicity of 65 Å, and abnormally low Cr moment, 1.55 μ_B. We will present microscopic details of multiple magnetic orders which are previously unreported, using magnetometry, specific heat, synchrotron X-ray diffraction, and neutron diffraction data.

11:45 AM *CT04.02.01
Insights into the Collective Electronic Losses at Surfaces with Momentum Resolution Francois C. Bocquet; Forschungszentrum Jülich GmbH, Germany

Investigating the dispersion of phonons and collective charge modes with high surface sensitivity is best achieved with high-resolution electron energy loss spectroscopy (HREELS) [1]. However, a systematic dispersion measurement over the whole Brillouin zone can takes weeks with standard instruments, which measure the electron intensity sequentially, i.e., at one specific loss energy and one scattering angle at a time. Therefore, we have modified a high-resolution electron source to meet the requirements of commercial hemispherical electron analyzers with E(k) imaging capabilities [2]. This allows the parallel detection of electrons in a broad range of momenta without sample movement. In this contribution I will show application examples of this new development for phonon, plasmon and exciton dispersion on 2D materials, quantum materials and organic single crystals.

12:10 PM *CT04.02.02
New Capabilities of Inelastic Neutron Scattering for Studying Anharmonic Phonons Brent Fultz[1], Yang Shen[1] and Michael Manley[2]; [1]California Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States

The performance of the neutron source and instruments at the Spallation Neutron Source have now reached most of their full potential. The improvements in efficiency for inelastic neutron scattering are factors of hundreds beyond what was available a decade ago. With new experimental techniques, the momentum transfer $\boldsymbol{Q}$ can be aligned along all directions in a crystal, measuring energy spectra of phonons or magnons at all points in the Brillouin zone. Thermodynamic quantities that are sums over all phonons in a crystal can now be assessed phonon-by-phonon, and as functions of temperature.

Inelastic neutron scattering was used to measure all individual phonons in a single crystal of NaBr at temperatures of 10, 300 and 700 K. Even at 300 K the phonons, especially the optical phonons, showed large shifts in energy, with large broadenings from anharmonicity. Thermal expansion can be calculated by minimizing the free energy with respect to volume, V. In simple cases the free energy depends only on elastic energy and phonon entropy. Calculations were first performed with the quasiharmonic approximation (QHA), in which the phonon frequencies depend only on V, and on T only insofar as it alters V by thermal expansion. This QHA was an unqualified failure for predicting the temperature dependence of phonon energies, even 300 K. Ab initio computations of free energy that included anharmonicity from phonon-phonon interactions (and quasiharmonicity) successfully predicted both the temperature dependence of phonons and the large thermal expansion of NaBr. The anharmonicity was shown to arise the cubic anharmonicity of nearest-neighbor Na-Br bonds. Anharmonicity is not a small correction to the QHA predictions of thermal expansion and thermal phonon shifts, but dominates the behavior.

A quantum Langevin model, similar to models developed for optomechanics, was used to predict intermodulation phonon sidebands (IPS). Ab initio calculations of anharmonic phonons in rocksalt NaBr showed sideband features qualitatively as "many-body effects." Inelastic neutron scattering measurements on a

crystal of NaBr revealed diffuse intensity at high phonon energy from the upper sideband. Its partner, the lower sideband, proves to be an "intrinsic localized mode." The spectral weight in the IPS pair is broadened and redistributed by interaction with the thermal bath, treated in the Langevin model as random noise.

These new studies on NaBr were made possible by new experimental capabilities for inelastic neutron scattering. The study of thermal expansion required the temperature dependence of all phonons in the first Brillouin zone. The observation of IPS required low backgrounds and high intensities. Both these studies are now practical with inelastic neutron scattering.

12:35 PM *CT04.02.03
Real-Time Observation of Dynamic Modulations Over a Ferro-Rotational Charge Density Wave Liuyan Zhao; University of Michigan, United States

Dynamic control over phases of matter with electromagnetic (EM) radiation receives increasing popularity in recent years because of both its ultrafast time scale and its access to thermodynamically unapproachable phenomena. Till now, the realization of dynamic manipulation of unconventional orders, such as a high-rank multipolar order, awaits to be explored largely because the coupling between multipolar orders and EM fields is nonlinear and nontrivial. In this talk, using the commensurate charge density wave (CCDW) in 1*T*-TaS_2 as the archetype, we demonstrate the dynamic control over the ferro-rotational order, the antisymmetric components of the second-rank electric quadrupolar order. We first show the ferro-rotational nature of CCDW in 1*T*-TaS_2, broken mirrors but preserved inversion, by performing temperature-dependent rotation anisotropy-second harmonic generation (RA-SHG). We then present the dynamic modulation of this ferro-rotational CCDW order, using time-resolved-RA-SHG (tr-RA-SHG) that adopts the optical-pump, RA-SHG-probe scheme. We show that this ultrafast modulation manifests itself as the breathing and the rotation of RA-SHG patterns at three different frequencies in the neighborhood of the previously reported CCDW amplitude mode frequency, with the mode of the highest (lowest) frequency primarily in the breathing (rotation) channel and the middle one in both channels. We further reveal a sudden shift of these three frequencies and a dramatic increase in the breathing and rotation magnitudes across a critical pump fluence of ~ 0.5 mJ/cm^2, by performing fluence dependent tr-RA-SHG.

1:00 PM *CT04.02.04
Probing Transient Lattice Dynamics of Photo-Excited Quantum Materials with Mega-Electron-Volt Ultrafast Electron Diffraction Xiaozhe Shen, Duan Luo, Fuhao Ji, Alexander Reid, Stephen Weathersby, Jie Yang and Xijie Wang; SLAC National Accelerator Laboratory, United States

Quantum materials under excitation from ultrafast laser pulses have shown exotic properties, such as ultrafast topological phase transition [1] and formation of transient charge density wave [2]. A complete understanding of such dynamical phenomena requires multimodal characterization techniques to reveal the dynamics associated with spin, charge, orbital and lattice degrees of freedom under nonequilibrium states. Ultrafast electron diffraction (UED) is an emerging tool to respond to this requirement by its capability of resolving transient lattice dynamics. SLAC National Accelerator Laboratory has built a UED with mega-electron-volt (MeV) electron beams to push the instrumental resolution to atomic spatial and temporal scales [3,4]. In this talk, the instrumental performance of SLAC MeV UED as well as the configuration of the experimental platform will be briefly reviewed. Selected experimental results on topological materials, charge density wave materials as well as heterostructures from two-dimensional materials will be highlighted. Research and development efforts to further expand the capabilities of SLAC MeV UED will be discussed.

1:25 PM CT04.02.06

Surface Characterization of Self-Catalyzed MBE Grown Be-Doped GaAs Nanowires and Te-Doped GaAsSb Nanowires for Infrared Photodetector Application. Priyanka Ramaswamy[1], Rabin Pokharel[1], Mehul Parakh[1], Shisir Devakota[1], Fred Stevie[2], Jia Li[1] and Shanthi Iyer[1]; [1]North Carolina Agricultural and Technical University, United States; [2]North Carolina State University, United States

Over the last decade, III-V semiconductor nanowires (NWs) have significantly attracted researchers due to one-dimensional architecture, quantum confinement effects, and a higher tolerance for stress-strain mismatch that allow greater freedom in engineering combinations of material systems in a variety of NW architectures to meet the demands of next-generation optoelectronic devices. Dopant incorporation in a well-controlled manner is essential to produce abrupt interfaces, to engineer work functions, and to realize advanced devices in NW configuration successfully. Unfortunately, the knowledge obtained from the thin film studies on dopant incorporation and carrier concentration cannot be directly translated to NWs due to the dopant's influence on the growth kinetics and growth mechanisms. Hall effect, field-effect, and capacitance-voltage are the commonly used measurement techniques in thin films for the determination of carrier concentration that require highly sophisticated lithography steps. For the assessment of dopants in NWs, several characterization methods have evolved. However, the sample preparation of off-axis electron holography is complex and requires additional information about the NW and homogeneity. Secondary ion mass spectrometry and atom probe tomography require a standard of known dopant concentration and are destructive. Hence, conductive-atomic force microscopy (C-AFM), scanning Kelvin probe microscopy (SKPM), X-ray photoelectron spectroscopy (XPS), and ultraviolet photoelectron spectroscopy (UPS), provide a set of excellent characterization methods for doping assessment, as they do not involve any complex contact fabrications.

In this work, we evaluate the incorporation of Beryllium (Be) dopants in GaAs NWs and Tellurium (Te) dopants in GaAsSb NWs grown using self-catalyzed molecular beam epitaxy (MBE) with variation in Be cell temperatures (T_{Be}) from 750 ºC - 950 ºC and Te cell temperatures (T_{GaTe}) from 500 ºC - 570 ºC, respectively. The extensive research interest in GaAs and GaAsSb NWs stems from its narrow bandgap region covering the important optical telecommunication wavelengths of 1.3 µm and 1.55 µm.

The topographical and I-V measurements using C-AFM of the vertical single NW exhibited a significant enhancement in current with photoresponse of 4 nA and 5 nA at -1 V for GaAs doped with T_{Be} at 950 ºC and GaAsSb doped with T_{GaTe} at 550 ºC. A statistical increase in the carrier concentration of Be-doped GaAs at T_{Be} of 750 ºC, 850 ºC, and 950 ºC is found to be 9 x 10^{15} cm^{-3}, 7 x 10^{17} cm^{-3}, and 5 x 10^{18} cm^{-3}, respectively from COMSOL Multiphysics fitting. An estimated carrier concentration of 7.1 x 10^{17} cm^{-3}, 3.0 x 10^{19} cm^{-3}, and 3.0 x 10^{18} cm^{-3} are determined for the Te–doped GaAsSb NWs at T_{GaTe} of 500 ºC, 550 ºC, and 570 ºC, respectively. The elemental composition, work function, and carrier concentration of Be-doped GaAs and Te-doped GaAsSb NWs are further determined using XPS/UPS. With increasing T_{Be} for GaAs NWs, a shift in Fermi level (FL) towards the valence band provided evidence towards higher Be incorporation with T_{Be}-950 ºC having work function and carrier concentration of 5.6 eV and 6.0 x 10^{18} cm^{-3}. In Te–doped GaAsSb NWs, the FL is shifted towards the conduction band. The work function and the carrier concentration of Te – doped GaAsSb NWs at T_{GaTe} of 550 ºC are found to be 3.6 eV and 2.8 x 10^{19} cm^{-3}, respectively. The values of electron density from UPS concur very well with the values determined from C-AFM. The change in surface potential observed in doped NWs in SKPM also provided strong evidence of Be and Te incorporation. Hence, these surface analytical tools are found to be powerful characterization techniques for direct measurement of the dopant levels in NWs, which are critical for bandgap engineering design of optoelectronic devices.

Magnetic Topological Quantum Chemistry Bogdan A Bernevig; Princeton University, United States

Over the last 100 years, the group-theoretic characterization of crystalline solids has provided the foundational language for diverse problems in physics and chemistry. There exist two classes of crystalline solids: nonmagnetic crystals left invariant by space groups (SGs), and solids with commensurate magnetic order that respect the symmetries of magnetic space groups (MSGs). Whereas many of the properties of the SGs, such as their momentum-space corepresentations (coreps) and elementary band coreps (EBRs) were tabulated with relative ease, progress on deriving the analogous properties of the MSGs has largely stalled for the past 70 years due to the complicated symmetries of magnetic crystals. In this work, we complete the 100-year-old problem of crystalline group theory by deriving the small coreps, momentum stars, compatibility relations, and magnetic EBRs (MEBRs) of the single (spinless) and double (spinful) MSGs. We have implemented freely-accessible tools on the Bilbao Crystallographic Server for accessing the coreps of the MSGs, whose wide-ranging applications include neutron diffraction investigations of magnetic structure, the interplay of lattice regularization and (symmetry-enhanced) fermion doubling, and magnetic topological phases, such as axion insulators and spin liquids. Using the MEBRs, we extend the earlier theory of Topological Quantum Chemistry to the MSGs to form a complete, real-space theory of band topology in magnetic and nonmagnetic crystalline solids - Magnetic Topological Quantum Chemistry (MTQC). We then use this theory to perform a high through-put search of topological materials search, uncovering hundreds of topological magnetic materials.

Realizing Gapped Topological Surface States in Magnetic Topological Insulators $MnBi_{2-x}Sb_xTe_4$ An-Ping Li; Oak Ridge National Laboratory, United States

Gapped surface states are a prerequisite for realizing several desired topological states like the quantum anomalous Hall effect showing dissipationless chiral edge states, the topological axion states displaying quantized magnetoelectric effects, and Majorana fermions obeying non-Abelian statistics. Recent research interest has turned extensively toward $MnBi_2Te_4$, an intrinsic magnetic topological insulator, which is predicted to possess a large exchange gap in the surface states, potentially to exhibit exotic effects at room temperature. However, spectroscopic measurements with angle-resolved photoemission spectroscopy (ARPES) have shown contradictory results on the key feature needed for novel topological behavior: a magnetically induced gap between electronic energy bands. Some groups have observed the surface gap, while the others found no gap at Dirac point. The controversy can be ascribed to the large bulk carrier density of $MnBi_2Te_4$ coming from its highly electron-doped nature, whose fluctuation can significantly broaden the dispersion in ARPES data and overwhelm the fine structures around the Dirac point. It is thus imperative to engineer the materials to reduce the bulk carriers and to probe the surface electronic structures using local spectroscopy like scanning tunneling microscopy/spectroscopy (STM/STS).
Here we realize gapped surface states by tuning the bulk carrier density with Sb-substitution in $MnBi_{2-x}Sb_xTe_4$ (MBST) and characterizing the local band structure with quasiparticle interference (QPI) STM. Minimizing bulk carrier density results in the bulk-insulating MBST and allows us to access the surface states. A surface band gap of 50 meV has been revealed around the Dirac point inside the bulk band gap. *In situ* transport spectroscopy using our unique multiprobe STM has confirmed the surface nature of the carriers at the Fermi level through the exhibition of 100 % surface-dominant conductance. Moreover, the surface band gap is found

to be topologically protected and robust against magnetic field up to 9 T. Theoretical calculations based on density functional theory (DFT) have corroborated very well the experimental results, which reveal a topological axion insulator behavior of the MBST, consistent with recent observation of QAH effect.
This research was performed at the Center for Nanophase Materials Sciences which is a DOE Office of Science User Facility.

MnBi2Te4.nBi2Te3—The Ideal Marriage of Magnetism and Topology Ni Ni; University of California, Los Angeles, United States

Magnetic topological material provides a great platform for discovering new topological states, such as the axion insulators, the Chern insulators, and the 3D quantum anomalous Hall (QAH) insulators. Recently, MnBi2Te4 was discovered to be the first material realization of a van der Waals intrinsic antiferromagnetic topological insulator (TI) where the QAH effect was observed at a record high temperature in its two-dimensional limit. Since the interplay of the magnetism and band topology determines their topological natures, understanding and manipulating the magnetism inside magnetic TIs will be crucial. In this talk, I will present our discovery of two new magnetic topological materials MnBi2Te4.nBi2Te3 (n=1 and 3) which consist of alternating [MnBi2Te4] and n[Bi2Te3] layers [1, 2]. I will show that by reducing the interlayer magnetic coupling with the increasing number of spacer [Bi2Te3] layers, MnBi2Te4.nBi2Te3 can be tuned from Z2 antiferromagnetic TIs (n=0,1,2) to ferromagnetic axion insulators. Furthermore, I will show that a continuous fine control of the magnetism in MnBi4Te7 can be made by Sb doping where an AFM to FM switching emerges due to the formation of the Mn/Sb antisite disorders [3]. Our study provides a rare tunable material platform to investigate various emergent phenomena arising from the marriage of magnetism and band topology.

Late News: Comprehensive Database of Intrinsic Spin Hall Effect from High-Throughput Calculations Yan Sun[1], Yang Zhang[1], Qiunan Xu[1], Klaus Koepernik[2], Roman Rezaev[2], Oleg Janson[2], Jakub Zelezny[3], Tomas Jungwirth[3], Jeroen van den Brink[3] and Claudia Felser[1]; [1]Max Planck Institute for Chemical Physic, Germany; [2]Leibniz Institute for Solid State and Materials Research, Germany; [3]Institute of Physics, Czech Academy of Sciences, Czechia

The spin Hall effect (SHE) has its special position in the field of spintronics, which allows transforming a charge current into a spin current and vice versa without the use of magnetic materials or magnetic fields. To gain new insight into the physics of the SHE and to identify materials with a substantial spin Hall conductivity (SHC), with the developed automatic high-symmetric atomic Wannier function projection, we performed high precision, high-throughput ab initio electronic structure calculations of the intrinsic SHC for over 20,000 non-magnetic crystals. The calculations reveal a strong and unexpected relation of the magnitude of the SHC with the crystalline symmetry, which we show exists because large SHC is typically associated with mirror symmetry protected nodal lines in the band structure. From the newly developed database, we identify new promising materials. This includes materials with a SHC comparable or even larger than that the up to now record Pt as well as materials with different types of spin currents. Furthermore, we find that the existence and magnitude of unusual symmetry spin currents that do not have perpendicular directions of spin current flow, spin polarization, and the electrical field can be in many materials tuned by the orientation of the electrical field with respect to the crystal [1]. This could be helpful for designing new types of spin-orbitronics devices.

Late News: New Chemical Strategy to Design Magnetic Skyrmion Host Materials Ebube E. Oyeka[1], Michal J. Winiarski[2], Artur Blachowski[3], Keith M. Taddei[4], Allen Scheie[4] and Thao T. Tran[1]; [1]Clemson University, United States; [2]Gdansk University of Technology, ul., Poland; [3]Pedagogical University of Cracow, ul., Poland; [4]Oak Ridge National Laboratory, United States

Magnetic skyrmions, which are 3-dimensional topological excitations with a nano-sized particle character, have come to the forefront as potential applications in spintronic devices. These vortex-like spin nanostructures are stabilized by Dzyaloshinskii-Moriya asymmetric exchange interaction facilitated by strong spin-orbit coupling and broken inversion symmetry crystal lattice. However, designing new skyrmion-host materials presents a significant challenge. To address this, we propose a chemical strategy for inducing skyrmions in new classes of materials based on combinations of magnetic spin, asymmetric building units with stereo-active lone-pair electrons, and polar lattice symmetry. To demonstrate the viability of the proposed judicious design principles, we successfully synthesized $Fe(IO_3)_3$ with a non-centrosymmetric polar $P6_3$ space group, by using low-temperature reactions and characterized the crystal structure using powder synchrotron X-ray diffraction and single-crystal X-ray diffraction. The magnetic structure and magnetic spin evolution of this material were investigated by performing neutron diffraction, ^{57}Fe Mössbauer spectroscopy, magnetization, and heat capacity measurements. Density functional theory calculations were also performed to gain better insights into chemical bonding and exchange interaction of $Fe(IO_3)_3$. Our results demonstrate a connection between topological magnetism and stereo-active lone-pair electrons in compounds having extended polar lattice, expanding avenues to create new skyrmion materials. The results and knowledge gained from this study will be discussed.

Topological Semimetals with Unique Optical Properties Joel Moore[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

This talk starts by reviewing known examples of how topological materials generate new kinds of electrodynamic couplings and effects. We then turn to how topological Weyl and Dirac semimetals can show unique electromagnetic responses, moving from linear optics to nonlinear optics, and the search for specific materials realizing these possibilities. We develop theories for why nonlinear optics is very strong in some Weyl semimetals such as TaAs, and how in others with structural chirality, there is the possibility of a quantized chiral photocurrent. This nonlinear effect has a natural quantum e^3/h^2 and appears in chiral Weyl semimetals over a finite range of frequencies. We discuss interaction and disorder corrections to nonlinear responses in closing, along with a related correction to the anomalous Hall coefficient at finite wavevector.

5:40 PM *CT04.04.02
Tuning the Chern Number in Quantum Anomalous Hall Insulators Cui-Zu Chang; The Pennsylvania State University, United States

A quantum anomalous Hall (QAH) state is a two-dimensional topological insulating state that has a quantized Hall resistance of $h/(Ce^2)$ and vanishing longitudinal resistance under zero magnetic field (where h is the Planck constant, e is the elementary charge and the Chern number C is an integer). The QAH effect has been realized in magnetic topological insulators and magic-angle twisted bilayer graphene. However, the QAH effect at zero

magnetic field has so far been realized only for $C = 1$. In this talk, I will briefly talk about the route to the QAH effect in magnetically doped TI films/heterostructures. I will focus on our recent progress on the realization of the QAH effect with tunable Chern number (up to $C = 5$) in multilayer structures consisting of alternating magnetic and undoped topological insulator layers. Moreover, the Chern number of a given multilayer can be tuned by varying either the magnetic doping concentration in the magnetic topological insulator layers or the thickness of the interior magnetic topological insulator layer. In the last part of my talk, I will discuss the potential applications of the QAH insulators with tunable high Chern number and what we can do along this direction in the future.

Predicting Linear-, Nonlinear- and Hydrodynamic Phenomena in Quantum Materials Prineha Narang; Harvard University, United States

Discoveries in quantum materials, which are characterized by the strongly quantum-mechanical nature of electrons and atoms, have revealed exotic properties that arise from strong correlations. We anticipate that quantum materials to be discovered and developed in the next years will transform the areas of quantum information processing including communication, storage, computing. To realize this promise, first principles theoretical and computational frameworks for quantum materials are essential. In this context, I will present our recent work in *ab initio* approaches to the microscopic dynamics, decoherence and optically-excited collective phenomena in quantum matter at finite temperature to quantitatively link predictions with 3D atomic-scale imaging, quantum spectroscopy, and macroscopic behavior. Capturing these dynamics poses unique theoretical and computational challenges. The simultaneous contribution of processes that occur on many time and length-scales have remained elusive for state-of-the-art calculations and model Hamiltonian approaches alike, necessitating the development of new methods in computational physics. I will show our predictions of linear-, nonlinear-, and hydrodynamics in Weyl semimetals, accounting for microscopic electron-electron and electron-phonon scattering processes. I will discuss the anomalous landscape for electron hydrodynamics in systems beyond graphene, highlighting that previously-thought exotic fluid phenomena can exist in both two-dimensional and anisotropic three-dimensional materials with or without breaking time-reversal symmetry. Our work identifies phonon-mediated electron-electron interactions as critical in a microscopic understanding of hydrodynamics. Non-diffusive electron flow, and in particular electron hydrodynamics, has far-reaching implications in quantum materials science, as I will show in this talk. Finally, I will discuss our recent work in driving quantum materials out-of-equilibrium to control the coupled degrees-of-freedom, and present an outlook on similarly controlling newly-synthesized topological systems.

Correlation in 2D Materials—Magnetism, Proximity Effects and Reactivity Through the Lens of Quantum Monte Carlo Brenda Rubenstein, Daniel Staros, Gopal Iyer, Ravindra Nanguneri and Leonard Sprague; Brown University, United States

2D materials are an exciting new class of materials that hold great promise for a wide range of engineering applications because of their exceptional tunability. Indeed, these materials' band gaps, magnetic and topological properties, and conductivity can be dramatically altered just by stretching or stacking them. Despite their promise, however, our modern understanding of 2D materials is partially obscured by the fact that most have only been computationally modeled using Density Functional Theory (DFT), a theory that cannot readily describe electron correlation and is known to yield widely varying results for such central quantities as band gaps and molecular binding energies depending upon the exchange-correlation functional employed.

In this talk, I will describe my group's recent efforts to model an array of 2D materials using fully correlated quantum Monte Carlo (QMC) techniques and the unanticipated physics these efforts have revealed. First, I will discuss for which materials our simulations reveal the largest discrepancies between DFT and QMC. I will then illustrate the importance of using correlated methods in the modeling of proximity-induced magnetism and spin-orbit coupling in multilayer materials. Lastly, if time permits, I will detail how correlation influences carbon dioxide reduction on post-transition metal chalcogenides. Altogether, this work paints a more complete picture of the electronic structure and properties of this increasingly important class of materials.

8:15 PM CT04.05.01
Phase Selection of Nickel Sulfides via Precise Oxidation State Control in Molten Hydroxides—A High-Temperature Aqueous Analogue Xiuquan Zhou[1], David Mandia[1], Duck-Young Chung[1] and Mercouri G. Kanatzidis[1,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States

High-temperature solutions are promising for discovery of novel materials with interesting properties relevant to superconductivity, magnetism, energy conversion, etc. Despite highly effective for exploratory synthesis, they are much less predictable and offer little to no control of the oxidation state compared to aqueous solutions. Here, we demonstrate that molten hydroxides not only offers crystal growth but also exhibit similar acid-base chemistry like water. Although never before they have been used for the synthesis of a chalcogenide, we found it was surprisingly powerful. By precise oxidation state control in hydroxide mediums, not only we were able to grow single crystals of all known ternary K-Ni-S, we have successfully isolated several new phases. Among them, we have identified a new low-valence nickel-rich sulfide, KNi_4S_2 and discovered polytypism in the kinetically stablized $K_2Ni_3S_4$. By controlling the polytypism in $K_2Ni_3S_4$, we could obtain a dilute Kagome lattice, which could be a new spin liquid materials. In addition, using KNi_4S_2 as a template, we obtained a new layered binary Ni_2S by deintercalating K and a LiOH-intercalated Ni_2S by exchanging K with LiOH. This new Van der Waals building block of Ni_2S proves to be a new host layer for intercalation chemistry. The rich acid-base chemistry in molten hydroxides can lead to rational discovery of new materials.

This new compound KNi_4S_2 share great structural similarities to the tetragonal KNi_2S_2. However, unlike KNi_2S_2, it consists of doubly stacked Ni square sheets between two sulfur square sheets instead of edge-sharing NiS_4 tetrahedra. Thus, each Ni forms both Ni-S ionic bonding and Ni-Ni metallic bonding. In addition to its exotic crystal structure, this low-valence Ni compound also shares great similarities with nickelate superconductors. Recently, new excitement emerges following the report of superconductivity (T_c up to 15 K) in a heterostructure of NiO2 infinite-layer on pervoskite.[1] One of the most extraordinary features of this nickelate superconductor is its oxidation state, +1.0-1.2, which is nearly isoelectronic with the holedoped high-T_c cuprate superconductors.[2] However, unlike the parent phase of the curpate superconductors (antiferromagnetic), no long-range magnetic ordering has yet observed in the nickelate system. Thus, it is of great importance to elucidate the underlying magnetic ordering or lack thereof in the low-valence nickelate system. Here, our new $K_2Ni_3S_4$ compound not only shares similar Ni-square net with both the nickelate and Fe-based superconductors, but also offers a rare opportunity to study the long-range magnetic ordering in low-valence Ni compounds.

To fully understand their electronic properties, we carried out density functional theory (DFT) calculations. Very interestingly, after deintercalation the binary Ni_2S does not show a simple change in electron-filling. Instead, close to its Fermi level, an electron pocket and almost a hole pocket appear at the G and M points,

respectively, whereas there was only an electron pocket at the G point for the parent KNi_4S_2. This feature highly resemble the Fe-based superconductors especially the 122-type KFe_2Se_2 and the LiOH-intercalated FeSe. Although Ni_2S is not superconducting, but the magnetism is suppressed after the deintercalation. In addition, the Fermi surface nesting at the M point is not complete as there is no hole pocket for Ni_2S. However, if we can future oxidize Ni to between Ni +1-1.5, then a electron and hole pocket pair could be created and lead to superconductivity. This will link Fe-based superconductors to the new nickelate superconductors.

Uncovering the Mechanism of Single-Atom E-Beam Manipulation of Pnictogen Dopants in Silicon
Bethany M. Hudak[1,2], Alexander Markevich[3], Jiaming Song[4], Toma Susi[3] and Andrew Lupini[2]; [1]U.S. Naval Research Laboratory, United States; [2]Oak Ridge National Laboratory, United States; [3]University of Vienna, Austria; [4]Northwest University, China

Single-atom quantum devices, in which the spin state of an atom is used to encode a qubit, are promising architectures for quantum computers. In solid-state Si devices, this requires the precise positioning of subsurface qubit dopant atoms. The current state-of-the-art for single-atom positioning relies on scanning probe techniques such as atomic force microscopy (AFM) and scanning tunneling microscopy (STM). However, these techniques are limited to surfaces and often involve overgrowth layers to encapsulate the dopants, which could lead to the atoms diffusing from their intended positions. Recently, scanning transmission electron microscopy (STEM) has been demonstrated as a tool to directly position single atoms in graphene as well as in silicon by taking advantage of an Ångstrom-size probe that can be manually controlled. The ability to directly locate and position a single dopant atom in a 3D material opens up new avenues of device manufacturing, but the mechanism needs to be well-understood before the technique can be optimized and widely implemented. Here, we study the controlled positioning of subsurface pnictogen dopants in a thin silicon crystal. Using density functional theory molecular dynamics (DFT/MD) simulations, we uncover the atomistic mechanism through which the dopant atoms can be directed, unveiling a novel, damage-free atom exchange process. We study the Si group V dopants Bi, Sb, As, and P, revealing that the atom-exchange mechanism is limited to the large Bi and Sb dopants. New STEM experiments further demonstrate the ability to move the Sb dopants several lattice positions by dragging the electron probe across the sample, confirming that it is possible to manipulate Sb in the same manner that Bi could be directed.

Hydrogen Thermal Treatment Effects on Conductance Quantization in Pt/NiO/Pt Resistive Switching Cells
Yusuke Nishi; National Institute of Technology, Maizuru College, Japan

Resistive random access memory (ReRAM) is the emerging nonvolatile memories, which has a metal-oxide-metal structure. A resistive switching (RS) phenomenon offers useful applications for not only nonvolatile memories but machine learning for neural network. The RS phenomenon in a transition metal oxide-based ReRAM cell is usually explained as nonvolatile transitions in the cell resistance between high- and low-resistance states by formation and dissolution of localized conductive filaments in the oxide thin film, which is created by the first voltage application, called forming. I reported that conductance quantization in nickel-oxide (NiO)-based ReRAM cells sandwiched by platinum (Pt) electrodes was observed during forming [1,2]. When the scale of the weakest spot in the filament reaches an atomic size, conductance quantization can be expected to appear. Therefore, the RS cell includes a conductive filament with a quantum point contact (QPC) upon the voltage sweep [1]. However, variation of voltage to reach the quantized conductance was large, because the amount controllability of oxygen vacancies was possibly inadequate. In this study, I investigate hydrogen thermal treatment effects on how the amount or distribution of the oxygen vacancies are controlled.

A 60-nm-thick Pt bottom electrode was deposited by sputtering on a silicon-dioxide/p-silicon substrate. Next, a polycrystalline 80-nm-thick NiO with a columnar structure layer was deposited by radio-frequency reactive sputtering under oxygen gas flow rate precisely regulated. Pt top electrodes were subsequently deposited on the NiO layer. Several Pt/NiO/Pt ReRAM cells showed the first abrupt current jump by an initial voltage sweep to the cell, which made the cell conductance equivalent to the quantized conductance (=$2e^2/h$). Moreover, the continued voltage sweep brought about conductance quantization in the cells, indicating the formation of a conductive filament with a QPC. However, variation of the voltage to start the current jump was large and only several cells showed conductance quantization.

I attempted various thermal treatment of the RS cells in reduced or oxidized gas ambience. Thermal treatment above 300°C during more than 20 min resulted in poor RS endurance, indicating deterioration of ReRAM cells by a strong heat effect. Meanwhile, argon and oxygen thermal treatment below 200°C led to a subtle change of initial cell resistance (less than 5%) and few effects on the voltage variation and how many cells showed clear conductance quantization. Therefore, thermal treatment below 200°C was conducted in hydrogen gas, which possesses a high reducing reaction, to prevent the cells from heat deterioration effect.

Although hydrogen thermal treatment between 150°C and 200°C resulted in the delamination of Pt top electrodes during even less than 10 min, initial resistance of cells fabricated with a higher oxygen gas flow rate during NiO deposition decreased to moderate values and RS endurance in the treated cells was almost improved by the hydrogen treatment below 150°C. In high-angle annular dark field scanning transmission electron microscopy analyses of the NiO layers after the hydrogen thermal treatment, brightness of bright spots observed at grain-boundary triple-points in the NiO layers was similar with each other. Energy dispersive X-ray spectroscopy revealed that the average composition ratio of O to Ni along the thickness direction at triple-points was comparatively constant and smaller than the value within grains. These results indicate that conductive filaments with a QPC are formed along Ni- or oxygen-vacancy-rich grain-boundary triple-points, and that reducing reaction by hydrogen thermal treatment below 150°C leads to restriction of voltage variation and improvement of appearance probability of conductance quantization.

Stabilization of J-Aggregate Thin Films for Exciton-Polariton Microcavities Dane W. deQuilettes; Massachusetts Institute of Technology, United States

Exciton-polaritons are a hybrid state of light and matter and are a quantum playground for exploring Bose-Einstein condensation, superfluidity, quantum vortices, and quantum entanglement. Although room-temperature polariton condensation has now been observed in carbon nanotubes, organic molecules, and in lower dimensional metal halide perovskites, these coherent quantum states are difficult to control and study due to rapid photodegradation. Here, we show orders-of-magnitude improvements in the photostabilization of the lower polariton branch emission from J-aggregated cyanine dyes through use of amine-based light stabilizers and hygroscopic crystal matrices. These results will likely enable condensation in a wide range of materials where these quantum effects were previously inaccessible.

Materials Database Access—AFLOW.org and AFLUX Marco Esters; Duke University, United States

Computational materials databases play an important role in the design and synthesis of new compounds with desired physical properties. With more than three million entries, the AFLOW.org repository is the largest of its kind. This session will start with an introduction to AFLOW and its installation. It will conclude with a demonstration on how to use AFLUX, a search language developed for AFLOW, to query results from our database programatically. Python will be used to show how the data can be retrieved and returned in JSON format.

Structural Analysis and Generation of Materials—AFLOW-SYM, AFLOW Prototype Encyclopedia, and AFLOW-XtalFinder David Hicks; Duke University, United States

Classification of crystallographic structures is necessary for understanding and tuning the properties of materials. Coupling structural analysis tools with automatic methods for modeling compounds accelerates materials design. This part will introduce the symmetry and structure generation engines inside AFLOW. Participants will learn the AFLOW prototyping system, how to create structure files in various ab initio code formats, how to calculate the symmetries of a material, and how to compare structures. Python interfaces and web interfaces to these tools will be provided as well.

2:00 PM BREAK

3:00 PM *
Thermodynamics—AFLOW-CHULL and CCE Cormac Toher; Duke University, United States

One of the most important aspects of computational materials discovery is the prediction of synthesizability. The AFLOW Convex HULL (AFLOW-CHULL) application provides the tools to assess the stability and synthesizability of materials. Attendants will be taught how to use AFLOW-CHULL through both the command line and our web application. This part will also demonstrate how to correct the formation enthalpies of polar compounds (e.g. oxides), which are often inaccurate in standard density functional theory calculations, using the Coordination Corrected Enthalpies (CCE) method.

4:45 PM *
Disorder—AFLOW-POCC Corey Oses; Duke University, United States

Disordered materials such as high-entropy alloys have attracted considerable interest due to their enhanced physical properties such as high hardness. Modeling these materials, however, poses a considerable computational challenge. This section will cover AFLOW's Partial OCCupation (AFLOW-POCC) algorithm which has been successfully employed to predict six new high-entropy carbides. Participants will be introduced to the algorithm and learn how to use AFLOW to generate the structures to determine the properties of disordered materials.

Network Theory Meets Materials Science Christopher Wolverton; Northwestern University, United States

One of the holy grails of materials science, unlocking structure-property relationships, has largely been pursued via bottom-up investigations of how the arrangement of atoms and interatomic bonding in a material determine its macroscopic behavior. Here we consider a complementary approach, a top-down study of the organizational structure of networks of materials, based on the interaction between materials themselves. We demonstrate the utility of applying network theory to materials science in two applications: First, we unravel the complete "phase stability network of all inorganic materials" as a densely-connected complex network of 21,000 thermodynamically stable compounds (nodes) interlinked by 41 million tie-lines (edges) defining their two-phase equilibria, as computed by high-throughput density functional theory. Using the connectivity of nodes in this phase stability network, we derive a rational, data-driven metric for material reactivity, the "nobility index", and quantitatively identify the noblest materials in nature. Second, we apply network theory to the problem of synthesizability of inorganic materials, a grand challenge for accelerating their discovery using computations. We use machine-learning of our network to predict the likelihood that hypothetical, computer generated materials will be amenable to successful experimental synthesis. *** In collaboration with V. Hegde, M. Aykol, S. Kirklin, L. Hung, S. Suram, P. Herring, and J. Hummelshoj*

Late News: Optimizing Complex Geometries with Feed Forward Control and Machine Learning Clara Druzgalski, Gabe Guss, Ava Ashby, Simon Lapointe, Aiden Martin, Maria Strantza, Zachary Reese and Manyalibo J. Matthews; Lawrence Livermore National Laboratory, United States

Laser powder bed fusion (LPBF) enables the fabrication of complex metal parts for many industries. However, quality control of LPBF remains a challenge due to defects that negatively impact repeatability and reliability. Complex parts contain many features that are defect-prone such as overhangs, thin walls, and channels. Process parameters must be optimized to satisfy engineering requirements and reduce the likelihood of part failure. This work describes computational methods to identify defect-prone features and apply optimized parameters using feed forward control and machine learning models. This targeted approach adapts the laser parameters to improve dimensional accuracy and reduce porosity.

8:40 AM *CT05.01.03
Natural Language Processing for Materials Design—What Can We Extract From the Research Literature? Anubhav Jain; Lawrence Berkeley National Laboratory, United States

Traditionally, researchers have been able to leverage the tremendous wealth of information in the research literature only by reading and reviewing articles one at a time. This talk focuses on how advancements in natural language processing will make it possible to leverage the collective knowledge embedded in decades of previous research studies (often only represented in unstructured text documents) in novel ways. In this talk, I will provide a brief overview of natural language processing techniques and how they can be trained on the materials domain. Next, I will provide several examples of how such techniques are being leveraged to accelerate materials research. This includes the use of these algorithms to generate structured databases of materials properties (on which machine learning algorithms can be trained), to improve the ability to query and extract information from the body of research work, and even to make predictions of materials for functional applications. Finally, I will provide an outlook on the future of these techniques might be integrated into several different models of materials research and development.

9:05 AM CT05.01.04
Natural Language Processing for Insensitivity Classification of Energetic Materials Gaurav Kumar, Allen Garcia, Connor O'Ryan and Peter Chung; University of Maryland, United States

The vast and ever-increasing number of published text on energetic materials, written in natural language, opens doors for the application of Natural Language Processing (NLP) tools to extract information that can be used for characterization, design, and discovery of materials. In this work, we present how NLP can be used to extract information from open literature about energetics and their physical/chemical properties such as h_{50} impact sensitivity. We combine text from ~20000 journal articles and US patents to form our corpus. Two types of classifiers are developed (1) A binary classifier which categorizes the energetics into two groups i.e. sensitive or insensitive, and (2) A multinomial classifier which computes the likelihood of energetics‘ sensitivity as a function of distance within an embedding vector space to five common energetics whose insensitivities are well known. The binary classifier is evaluated by comparing the classifier result with a reference list of the energetics. The evaluation of the multinomial classifier is based on Kolmogorov-Smirnov test, Jensen-Shannon, Hellinger, and Wasserstein distances between statistical distributions developed from NLP and those generated using actual h_{50} data. The preliminary results indicate an accuracy of ~80% and an f-score of 0.86 for the binary classifier whereas the multinomial classifier consistently scores above a P-value of 0.90. This indicates that word embeddings can effectively capture the semantics of domain-specific language and that NLP, originally developed for natural language interpretation, can be extended to the study of materials, for instance, to

semantically learn how to characterize material properties and capture relationships between chemicals, their properties, and applications.

9:20 AM *CT05.01.05
Active Materials Exploration and Characterization with Bayesian Optimization Patrick Rinke; Aalto University, Finland

Data generation in materials science is often limited by the time it takes to perform experiments or simulations. To facilitate the exploration and characterization of complex materials, we have developed the Bayesian Optimization Structure Search (BOSS) code. BOSS is an active learning technique that strategically samples the parameter space of material-science tasks be it experimental or computational. BOSS proposes new data acquisition points for maximum knowledge gain, balancing exploitation with exploration. I will demonstrate BOSS' smart and efficient data strategy for two examples: 1) sustainable biomaterials and 2) hybrid organic-inorganic electronic materials. For 1), we extract lignin from wood samples with hydrothermal treatment. Lignin is further processed by chemical modification into sustainable composite materials (e.g. carbon fibers, thermoplastics and three-dimensional printed objects). Lignin extraction and processing is coupled to BOSS to visualize process-structure-property correlations and to efficiently optimize extraction and modification conditions. For 2), we couple BOSS to density-functional theory (DFT) calculations to study the adsorption of a camphor molecule on the Cu(111) surface. We identify 8 unique stable adsorbates. By matching the stable structures to atomic force microscopy (AFM) images, we conclude that the experiments feature 3 different structures of chemisorbed camphor molecules.

10:30 AM *CT05.02.01
Materials Informatics and Manufacturing Scalability and Sustainability Elsa Olivetti; Massachusetts Institute of Technology, United States

Data has become a fundamental ingredient for accelerating and optimizing materials design and synthesis. Advances in applying natural language processing (NLP) to material science text has greatly increased the size and acquisition speed of materials science data from the published literature. This presentation will describe work to extract information from peer reviewed academic literature across a range of materials with particular focus on developing strategies for manufacturing scalability and sustainability challenges. Examples will be drawn from use of alternative feedstocks in cement as well as solid state electrolyte development.

10:55 AM *CT05.02.02
Automated Multimodal Manufacturing Optimization Brian Giera, Adam Jaycox, Kyle DeVlugt, Joseph Nicolino, Brian Au and Sam Ludwig; Lawrence Livermore National Laboratory, United States

The characterization and fabrication of manufactured parts is often a serial process, where different post-processing steps and quality measurements are obtained in a non-co-located and nonautomated fashion. The traditional process for taking components from the design stage to a final, qualified component is an extremely personnel intensive series of steps that are typically treated as siloed activities. Thus, the development cycle (e.g. part specification, fabrication, and qualification) is subject to bottlenecks, making part repeatability difficult and costly to achieve, quantify, and optimize. This is true for established manufacturing processes and especially true for emerging advanced manufacturing technologies. To address this, we adopt an “object-

oriented" or modular methodology at all stages of manufacturing, fabrication, inspection, and so on. For instance, on such inspection modality is an automated metrology system that can perform a variety of inspection routines on arbitrary objects. Another module is a comprehensive NoSQL database that can log all data acquired at each step for every part fabricated by our system. We also create digital twins of each inspection and fabrication module that evolve over time as insights are extracted from the growing database. Although we exercise these capabilities using a suite of fused deposition model printers, the object-oriented approach is agnostic to any given manufacturing approach or inspection system. During this talk, we walk through key capabilities demonstrated with these modules and the implications towards automation of process design.

11:20 AM *CT05.02.03
Autonomous End-to-End Systems for Materials Discovery Muratahan Aykol and Joseph Montoya; Toyota Research Institute, United States

Autonomous research platforms driven by artificial intelligence have the potential to enable rapid identification of improved material components for technological devices, such as batteries or fuel cells, at significantly reduced research costs. In this talk, we will present our recent progress on the development of an end-to-end autonomous platform that helps materials scientists efficiently find or expand the space of optimal candidate materials with minimal intervention. This platform provides a software framework for (i) designing and testing of goal-oriented research agents that can flexibly combine machine learning with physical and chemical constructs as well as heuristics to guide the experiments, and (ii) seamless deployment of the designed agents in actual closed-loop experimental settings. In particular, we will present a recent implementation of this framework for on-demand, cost-effective discovery of stable inorganic materials by automated, intelligent control of crystal structure selection and density functional theory simulations. This platform is running uninterrupted on cloud computing resources, and have found thousands of previously unreported ground state or nearly stable inorganic compounds in binary and ternary metal oxide, sulfide, phosphide and metal-alloy chemistries, notably augmenting the layout of the phase diagrams in many of these systems.

11:45 AM CT05.02.04
Robotics-Enabled Exploration of Multicomponent Lead Halide Perovskites via Machine Learning Kate Higgins[1], Sai M. Valleti[2], Maxim Ziatdinov[3], Sergei Kalinin[2,3] and Mahshid Ahmadi[1]; [1]Joint Institute for Advanced Materials, United States; [2]University of Tennessee, United States; [3]Oak Ridge National Laboratory, United States

Metal halide perovskites (MHPs) have attracted considerable attention due to the combination of outstanding optoelectronic properties and low fabrication cost, making them uniquely attractive for various optoelectronic and sensing applications. Despite extensive effort, the synthesis of these materials preponderantly entails modifying a single compositional or synthesis variable and observing the structure and functionalities changes. Combined with lengthy processing and optimization times, this approach has largely been inefficient in its ability to explore vast design spaces. Here, we establish a workflow for the rapid synthesis and characterization of MHPs via combinatorial synthesis combined with rapid throughput photoluminescent measurements. We adopt an approach based on multivariate statistical analysis to gain insight into the variability of the photoluminescent properties across the compositional series. We map the compositional-dependent property (photoluminescence) and use the Gaussian Processing framework to determine associated uncertainties. From these uncertainties, we are then able to identify possible areas of interest and characterize them further. Overall, through the utilization of automated synthesis, we demonstrate how this workflow utilizes data-driven machine learning models for the accelerated discovery of large compositional spaces in MHPs with optimized properties for multifunctional optoelectronics.

SESSION CT05.03: Applications I
Session Chairs: Sanket Deshmukh and Steven Torrisi

1:00 PM *CT05.03.01
Machine Learning for the Modeling of Complex Energy Materials Nongnuch Artrith; Columbia University, United States

The properties of materials for energy applications, such as heterogeneous catalysts and battery materials, often depend on complicated chemical compositions and complex structural features including defects and disorder. This complexity makes the direct modeling with first principles methods challenging. Machine-learning (ML) potentials trained on first principles reference data enable linear-scaling atomistic simulations with an accuracy that is close to the reference method at a fraction of the computational cost. ML models can also be trained to predict the outcome of simulations (or experiments), bypassing explicit atomistic modeling altogether.

Here, I will give an overview of recent methodological advancements of ML potentials based on artificial neural networks (ANNs) [1-5] and applications of the method to challenging materials classes including metal and oxide nanoparticles and amorphous phases. Further, I will show an example of integrating large computational and small experimental data sets for the ML-guided discovery of catalyst materials [6].

1:25 PM CT05.03.02
Automated *In Silico* Screening of Nanoporous Materials for Enhanced CO_2 Capture Rodrigo F. Neumann[1], Fausto Martelli[1], Binquan Luan[1], Tonia Elengikal[1], Anshul Gupta[1], Guojing Cong[1], Mathias Steiner[1], Thomas Peters[2], Flor Siperstein[3] and Breanndan O Conchuir[1]; [1]IBM Research, Brazil; [2]University of Connecticut, United States; [3]University of Manchester, United Kingdom

One of the strategies for carbon capture and storage is to leverage the adsorption properties of nanoporous materials. The carbon emissions of point sources, such as power plants, can be significantly reduced by applying these materials to the post-combustion capture of flue gas. Zeolites [1], Metal-Organic Frameworks [2], Zeolitic Imidazolate Frameworks [3] and Porous Polymer Networks [4] are examples of promising nanoporous materials which can efficiently trap flue gas molecules in their pores with diameters of a few (tens of) Angstroms.

Carbon dioxide, as a small gas molecule with 3.3 Angstroms of kinetic diameter, represents roughly 10% of the composition of flue gas coming out of coal-fired power station exhausts. In order to be a good carbon capture material, the nanoporous structure must not only adsorb flue gas components but *preferentially* adsorb CO_2 as opposed to more abundant flue gas components, such as N_2. Therefore, both the absolute adsorbate loading and the relative CO_2/N_2 selectivity are important performance figures-of-merit to be considered.

Millions of possible crystalline nanoporous materials [5] have been identified for carbon capture, extending far beyond our capability to quantify *in silico* the adsorption performance of each individual nanoporous structure by brute force calculations. Experimentally fabricating and measuring the adsorption properties of each framework is also unrealistic, due to the time and cost constraints, leading to the requirement for a pre-screening step to improve the resource allocation. In this talk, we present our work on optimising the

classification mechanisms for characterizing nanoporous structures, enabling efficient high-throughput screening of materials for carbon capture.

Our automated material screening tool leverages cloud resources to spawn multiple computational experiments in parallel to rapidly explore the vast space of relevant nanoporous materials. A full computational experiment comprises, of not only the realisation of Grand Canonical Monte Carlo (GCMC) adsorption simulations, but also a full geometrical and topological characterisation of the material in terms of its crystalline structure as represented by a point cloud of atomic positions. These can be combined with machine learning to accelerate the estimation of adsorption properties based solely on the atomistic structure of materials.

1:40 PM CT05.03.03
Late News: Machine Learning with Persistent Homology and Chemical Word Embeddings Improves Predictive Accuracy and Interpretability in Metal-Organic Frameworks Aditi Krishnapriyan[1,2], Joseph Montoya[3], Maciej Haranczyk[4], Jens Hummelshoej[3] and Dmitriy Morozov[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Toyota Research Institute, United States; [4]IMDEA Materials Institute, Spain

Machine learning has emerged as a powerful approach in materials discovery. Its major challenge isselecting features that create interpretable representations of materials, useful across multiple predictiontasks. We introduce an end-to-end machine learning model that automatically generates descriptors that capture a complex representation of a material's structure and chemistry. This approach builds on computational topology techniques (namely, persistent homology) and word embeddings from natural language processing. It automatically encapsulates geometric and chemical information directly from the material system. We demonstrate our approach on multiple nanoporous metal–organic framework datasets by predicting methane and carbon dioxide adsorption across different conditions. Our results show considerable improvement in both accuracy and transferability across targets compared to modelsconstructed from the commonly–used, manually–curated features, consistently achieving an average 25–30% decrease in root-mean-squared-deviation and an average increase of 40–50% in R2 scores. A key advantage of our approach is interpretability: Our model identifies the pores that correlate best to adsorption at different pressures, which contributes to understanding atomic-level structure–property relationships for materials design.

1:55 PM *CT05.03.04
Defect Detection and Uncertainty Quantification in Property Prediction with Machine Learning Dane Morgan[1], Mingren Shen[1], Ryan Jacobs[1], Glenn Palmer[1] and Kevin Field[2]; [1]University of Wisconsin–Madison, United States; [2]University of Michigan–Ann Arbor, United States

In this talk I will discuss two areas of applications of machine learning to materials science and engineering.

First, I will share recent results on extracting defects automatically from electron microscopy images. Electron microscopy is widely used to explore defects in crystal structures, but human tracking of defects can be time-consuming, error prone, and unreliable, and is not scalable to large numbers of images or real-time analysis. In this work I discuss application of machine learning approaches to find the location and geometry of different defect clusters in irradiated steels. We show that performance comparable to human analysis can be achieved with relatively small training data sets. We explore multiple deep learning methods that provide various features, e.g., fast processing for video and pixel level categorization to simplify defect dimension determination.

Second, I will share some studies we have been doing to assess accuracy of materials property prediction from machine learning models. Machine learning provides a powerful tool to predict materials properties, but relatively little attention has been paid to the critical issue of assessing the domain of the machine learning model and the accuracy of the predictions within that domain. In this talk I explore the effectiveness of some model error estimation methods, including ensemble and Bayesian methods, and consider how these might be used to obtain accurate error estimates within with the domain of the model. We apply the results on a realistic problem of modeling dilute impurity diffusion coefficients in a host, demonstrating that the model can predict accurate values for new systems but that the domain and errors are essential to consider for effective use of the model.

2:20 PM CT05.03.05
Machine Learning the Quantum-Chemical Properties of Metal–Organic Frameworks for Accelerated Materials Discovery with a New Electronic Structure Database Andrew S. Rosen[1], Shaelyn M. Iyer[1], Debmalya Ray[2], Zhenpeng Yao[3], Alan Aspuru-Guzik[4,4], Laura Gagliardi[5,5], Justin M. Notestein[1] and Randall Snurr[1]; [1]Northwestern University, United States; [2]University of Minnesota Twin Cities, United States; [3]Harvard University, United States; [4]University of Toronto, Canada; [5]The University of Chicago, United States

Metal–organic frameworks (MOFs) are a widely investigated class of crystalline solids with tunable structures that make it possible to impart specific chemical functionality tailored for a given application. However, the enormous number of possible MOFs that can be synthesized makes it difficult to determine which materials would be the most promising candidates, especially for applications governed by electronic structure properties that are often computationally demanding to simulate and time-consuming to probe experimentally. Here, we have developed the first publicly available quantum-chemical database for MOFs (the "QMOF database"), which consists of properties derived from density functional theory (DFT) for over 14,000 experimentally synthesized MOFs. Throughout this study, we demonstrate how this new database can be used to identify MOFs with targeted electronic structure properties. As a proof-of-concept, we use the QMOF database to evaluate the performance of several machine learning models for the prediction of DFT-computed band gaps and find that crystal graph convolutional neural networks are capable of achieving superior predictive performance, making it possible to circumvent computationally expensive calculations. We also show how unsupervised learning methods can aid the discovery of otherwise subtle structure–property relationships using the computational findings in this work. We conclude by highlighting several MOFs with low band gaps, a challenging task given the electronically insulating nature of most MOF structures. The data and predictive models generated in this work, as well as the database of MOF structures, should be highly useful to other researchers interested in the predictive design and discovery of MOFs for the many applications dictated by quantum-chemical phenomena.

4:00 PM *CT05.04.01

Understanding and Visualizing Hyperspectral ToF-SIMS Data Sets Using Machine Learning Wil Gardner[1,2,3], David Winkler[2,4,5], Davide Ballabio[6], Benjamin Muir[3] and Paul Pigram[1]; [1]La Trobe University, Australia; [2]La Trobe Institute for Molecular Science, La Trobe University, Australia; [3]CSIRO Manufacturing, Australia; [4]Monash Institute of Pharmaceutical Sciences, Monash University, Australia; [5]School of Pharmacy, University of Nottingham, United Kingdom; [6]Milano Chemometrics and QSAR Research Group, Department of Earth and Environmental Sciences, University of Milano-Bicocca, Italy

The application of multivariate analysis to mass spectral data sets has been thoroughly investigated in recent decades. Contemporary studies, however, frequently involve large scale and complex data collections comprising libraries of spectra or hyperspectral mass spectrometry imaging (MSI) or depth profiling. The understanding and visualizing the complex relationships between peaks, pixels and voxels embodied in these data remains a major challenge. It is now recognized that most mass spectral data contain non-linear relationships, which has led to increased application of machine learning approaches to provide unique insights into the underlying surface chemistry.

We have exemplified the use of the self-organizing map (SOM), a type of artificial neural network, for analyzing time-of-flight secondary ion mass spectrometry (ToF-SIMS) data derived from spectral libraries, hyperspectral images and depth profiles. Recently, we developed a novel methodology, SOM-RPM, which incorporates the algorithm relational perspective mapping (RPM) to improve visualization of the SOM for 2D ToF-SIMS images. We have also used SOM-RPM to characterize and interpret 3D ToF-SIMS depth profile data, voxel-by-voxel. An organic Irganox™ multilayer standard sample was depth profiled using ToF-SIMS and SOM-RPM was used to create 3D similarity maps of the depth-profiled sample, in which the mass spectral similarity of individual voxels is modelled with color similarity. We used this similarity map to segment the data into spatial features, demonstrating that the unsupervised method meaningfully differentiated between Irganox-3114 and Irganox-1010 nanometer-thin multilayer films. The method also identified unique clusters at the surface associated with environmental exposure and sample degradation. Key fragment ions characteristic of each cluster were identified, tying clusters to their underlying chemistries. SOM-RPM has the demonstrable ability to reduce vast data sets to simple 3D visualizations that can be used for clustering data and visualizing the complex relationships within.

4:25 PM CT05.04.02

Charting the Low-Loss Region in Electron Energy Loss Spectroscopy with Machine Learning Laurien Roest[1], Sabrya E. van Heijst[1], Jaco ter Hoeve[2], Louis Maduro[1], Isabel Postmes[1,2], Juan Rojo[2] and Sonia Conesa-Boj[1]; [1]Kavli Institute of Nanoscience Delft, Netherlands; [2]VU Amsterdam & Nikhef, Netherlands

Electron energy-loss spectroscopy (EELS) within the transmission electron microscope (TEM) provides a wide range of valuable information on the structural, chemical, and electronic properties of nanoscale materials. A particularly important region of EEL spectra is the low-loss region, whose analysis makes possible charting the local electronic properties of nanomaterials from the characterisation of bulk and surface plasmons, excitons, and phonons to the determination of their bandgap and band structure. A major challenge for EELS data interpretation in this low-loss region is the presence of the zero-loss-peak (ZLP) associated to elastic scatterings. The presence of this ZLP often overwhelms the contribution from the inelastic scatterings between the TEM beam electrons with the sample such that relevant signals of low-loss phenomena risk becoming drowned in the ZLP tail. An accurate removal of the ZLP contribution is thus crucial in order to accurately map and identify key physical information from the low-loss region in EEL spectra. Several approaches to ZLP subtraction have been put forward in the literature. These methods are however affected by significant limitations: they based on specific, *ad-hoc* model assumptions about the ZLP, in particular concerning its parametric functional dependence on the electron energy loss ΔE, and they lack an estimate of the associated uncertainties.

Here we bypass these limitations by developing a model-independent strategy to realise a multidimensional determination of the ZLP with a faithful uncertainty estimate. Our approach is based on machine learning (ML)

techniques originally developed in high-energy physics to study the quark and gluon substructure of protons in particle collisions. It is based on the Monte Carlo replica method to construct a probability distribution in the space of experimental data and artificial neural networks as unbiased interpolators to parametrise the ZLP. The end result is a faithful sampling of the probilbility distribution in the ZLP space which can be used to subtract its contribution to EEL spectra while propagating the associated uncertainties. One can also extrapolate the predictions from this ZLP parametrisation to other TEM operating conditions beyond those included in the training dataset.

By means of this approach, we construct a ML model of ZLP spectra acquired in vacuum, which is able to accommodate an arbitrary number of input variables corresponding to different operation settings of the TEM. We demonstrate how this model successfully describes the input spectra and we assess its extrapolation capabilities for other microscope operation conditions. Further, we construct a one-dimensional model of the ZLP as a function of the energy loss ΔE from spectra acquired on two different specimens of tungsten disulfide (WS_2) nanoflowers characterised by a 2H/3R mixed polytypism. The resulting subtracted spectra are used to determine the value and nature of the WS_2 bandgap in these nanostructures as well as to map the properties of the associated exciton peaks appearing in the ultra-low loss region.

We also present results of further applications of our ML-subtracted EEL spectra to characterise the local electronic properties of TMD-based nanostructures. First, by means of the evaluation of the complex dielectric function via the Kramers-Kronig relations. Second, by implementing the automation of data analysis in spectral TEM images, where each pixel contains an individual EEL spectrum. By using ML regression and classification methods, one can identify relevant features of the spectra (peaks, edges, shoulders) with minimal human intervention and then determine how these features vary as we move along different regions of the nanostructure.

The framework presented in this work has been implemented and made available in an open source Python package, dubbed EELSfitter, and available from GitHub.

4:40 PM CT05.04.03
Discovery of Interpretable X-Ray Absorption Spectroscopy Signatures via Random Forest Machine Learning Models Steven B. Torrisi[1,2], Matthew Carbone[3], Brian Rohr[2], Joseph Montoya[2], Yang Ha[4], Junko Yano[4], Santosh Suram[2] and Linda Hung[2]; [1]Harvard University, United States; [2]Toyota Research Institute, United States; [3]Columbia University, United States; [4]Lawrence Berkeley National Laboratory, United States

X-ray absorption spectroscopy (XAS) produces a wealth of information about the local structure of materials, but interpretation of spectra often relies on easily accessible trends and prior assumptions about the structure. Recently, researchers have demonstrated that machine learning models can automate this process to predict the coordinating environments of absorbing atoms from their XAS spectra. However, machine learning models are often difficult to interpret, making it challenging to determine when they are valid and whether they are consistent with physical theories. In this work, we present three main advances to the data-driven analysis of XAS spectra: we demonstrate the efficacy of random forests in solving two new property determination tasks (predicting Bader charge and mean nearest neighbor distance), we address how choices in data representation affect model interpretability and accuracy, and we show that multiscale featurization can elucidate the regions and trends in spectra that encode various local properties. This multiscale featurization transforms the spectrum into a vector of polynomial-fit features, and is contrasted with the commonly-used “pointwise” featurization that directly uses the entire spectrum as input. We find that across thousands of transition metal oxide spectra, the relative importance of features describing the curvature of the spectrum can be localized to individual energy ranges, and we can separate the importance of constant, linear, quadratic, and cubic trends, as well as the white line energy. This work has the potential to assist rigorous theoretical interpretations, expedite experimental data collection, and automate analysis of XAS spectra, thus accelerating the discovery of new functional materials.

Late News: Machine Learning Force Fields for Understanding the Thermodynamics of Li-Ion Cathodes
Joshua Gabriel, Juan C. Garcia, Noah Paulson, John J. Low, Marius Stan and Hakim Iddir; Argonne National Laboratory, United States

Machine Learning Force Fields (MLFF) have emerged as a tool to accelerate the atomic scale modeling of materials while preserving accuracy of density functional theory calculations. A workflow for developing such an MLFF, which leverages state of the art deep learning high performance computing architectures available at the national laboratories, is presented and discussed. The MLFF is used to study the thermodynamics and structural changes of lithium nickel oxide (LNO) battery cathode material during room temperature operation. The results emphasize the complexity of phase stability in this system and demonstrate the predictive power of the MLFF method.

5:00 PM CT05.04.05
Improvement of Adhesion Between NiTi Alloy and Diamond-Like Carbon Film by Bayesian Optimization
Masafumi Toyonaga[1], Terumitsu Hasebe[1,2], Shunto Maegawa[2], Tomohiro Matsumoto[1,2], Atsushi Hotta[1] and Tetsuya Suzuki[1]; [1]Keio University, Japan; [2]Tokai University Hachioji Hospital, Japan

Surface coating is one of the most interesting methods for improving the mechanical, physical, chemical and biocompatible properties of materials and devices. Fluorine-incorporated diamond-like carbon (F-DLC) has received much attention as a coating material because of outstanding blood compatible properties which suppress fatal failure of the medical devices. However, it is well known that F-DLC thin films exhibit poor adhesion on metallic alloys and delamination or cracks are easy to occur after coating. In order to improve adhesion of F-DLC on metallic alloys, many scientific methods have been reported. Although some of these studies focused on introducing silicon-containing interlayers such as silicon-incorporated DLC (Si-DLC) between metallic alloys and F-DLC thin films to improve the adhesion properties, the film formation conditions of the interlayer that most improves the adhesion are not clear, and the method has not been established for optimizing the film formation conditions. Thus, we considered optimizing the structure of the interlayer using “Bayesian optimization”, which is known as one of machine learning. In this study, we optimize the structure of Si-DLC interlayer by Bayesian optimization to apply F-DLC to low blood compatible nickel-titaniumu (NiTi) alloy, which has been attracting attention as a material for medical devices due to superelasticity and shape memory.
The purpose of this study is evaluating the effectiveness of Bayesian optimization for determining optimal structures of interlayers between metallic substrates and F-DLC, and developing high blood compatible NiTi alloy by improving adhesion properties of F-DLC.
Si-DLC and F-DLC were prepared on NiTi substrates using radio frequency plasma enhanced chemical vapor deposition (RF-PECVD) equipment. The adhesion properties between NiTi substrates and DLC thin films were evaluated by the scratch test, and the structures of Si-DLC interlayer were updated successively by Bayesian optimization on the obtained data. Total of 30 Si-DLC interlayers were produced, and the highest adhesion could be improved to about 53 mN, while the lowest adhesion was about 22 mN. The one with the highest adhesion and the one with the lowest adhesion were deposited on the NiTi stents, and after performing the crimp test and the fatigue test, the surface was observed by Scanning Electron Microscope (SEM). As a result, no delamination was observed in the interlayer derived by Bayesian optimization, whereas delamination occurred in the sample in which structure was not optimized.
Therefore, this study shows that adhesion properties between metallic material and DLC thin film can be improved by Bayesian optimization. In addition, in the future, by applying machine learning in various researches in the field of materials, it is expected to develop materials with unprecedented excellent properties.

High-Throughput Electrochemical Screening of Deep Eutectic Solvent for Use in Redox Flow Batteries
Maria Politi and Jaime Rodriguez; University of Washington, United States

Deep eutectic solvents (DESs) are a class of materials with varied applications including catalysis and synthesis, extraction processes, drug solubilization and battery electrolytes. Their appeal stems from their broad electrochemical stability window, high electrical conductivity, low vapor-pressure, and low-flammability. These solvents present a depression in the melting point at specific molar ratios of organic components that can result in a liquid solution at moderate temperatures. A breadth of candidates with varying concentrations can be used to form DESs, leading to a vast design space. High throughput experiments and data-driven design strategies are key to accelerate the optimization of materials based on their physicochemical and electrochemical properties as well as engineering criteria (e.g. cost, safety, toxicity) for candidate DESs. The implementation of high-throughput tools allows for a rapid evaluation and screening based on metrics such as the melting point, potential stability window and ionic conductivity. Several high-throughput protocols have been designed for identifying the design space of molecules under investigation, their formulation and material characterization. Using data science principles, the molecules composing our basis set were identified using scoring based on metrics such as cost, melting point, toxicity and molecular weight. The formulation of deep eutectic solvents is automated through the use of a pipetting robot, combinatorial techniques and well-plates. Next, the melting point of the proposed mixtures is detected using an IR camera and hot-plate set-up. To screen for their electrochemical properties, 96-well plates with screen printed electrodes in combination with measurement techniques such as Cyclic Voltammetry (CV) and Electrochemical Impedance Spectroscopy (EIS) are implemented. Finally, to adapt high-throughput principles to the analysis of the data collection obtained through the aforementioned protocols, machine learning is leveraged for the data classification and data modeling. Furthermore, open-source Python-based packages have been developed and made available on GitHub. The combination of high-throughput experimentation and data analysis can greatly accelerate the design and screening candidate DES systems. This overall workflow could be easily adapted to other design spaces and applications.

Late News: A Materials-Informatics Based Study of Solid Electrolytes and Protective Coatings for Li Batteries
Shreyas Honrao[1,2], Xin Yang[3], Balachandran Radhakrishnan[1,3], Shigemasa Kuwata[3], Hideyuki Komatsu[4], Atsushi Ohma[4] and John Lawson[1]; [1]NASA Ames Research Center, United States; [2]KBRR Wyle, United States; [3]Nissan North America, United States; [4]Nissan Motor Company, Japan

All-solid-state batteries with Li metal anode can address the safety issues surrounding traditional Li-ion batteries as well as the demand for higher energy densities. However, the development of solid electrolytes and protective coatings simultaneously possessing high ionic conductivity and wide electrochemical stability has proven to be a challenge. Here, we present a data-driven approach to explore the Li compound space for promising solid electrolytes and coatings. This is accomplished through the generation of a large database of battery-related materials properties of Li compounds by computing Li+ migration barriers using bond-valence-based pair potentials, and stability windows using density functional theory energies. Using this database, we implement machine learning models that can accurately predict migration barriers and electrochemical stability windows for any new Li compound. Through feature engineering, we ensure that our models are both accurate and interpretable. We perform feature importance analysis on our models to highlight materials properties that can be tuned for future design of coatings/electrolytes. Our database and informatics approach provide a valuable tool for the rapid discovery of new solid-state battery chemistries.

Late News: Prediction of Bulk and Grain Boundary Ionic Conductivities for Solid-State Li-Ion Conductors by Machine Learning
Yen-Ju Wu[1], Takhiro Tanaka[1], Tomoyuki Komori[2], Mikiya Fujii[2], Hiroshi Mizuno[2], Satoshi Itoh[1], Tadanobu Takada[1], Erina Fujita[1] and Yibin Xu[1]; [1]National Institute for Materials Science, Japan; [2]Panasonic Corporation, Japan

A machine learning approach for identifying the important descriptors of the ionic conductivities of lithium solid electrolytes is proposed. This approach discriminates the factors of both bulk and grain boundary conductivities, which have been rarely reported. The effects of the interrelated structural, material, chemical and experimental properties on the bulk and grain boundary conductivities are investigated. The data are trained using the bulk and grain boundary conductivities of Li solid conductors at room temperature. Both the bulk conductivity and the grain boundary conductance of single grains were derived from 96 samples in three structural classes: perovskite, garnet, and NASICON. The important descriptors are elucidated by their feature importance and predictive performances, as determined by a nonlinear XGBoost algorithm: (i) the experimental descriptors of sintering conditions are significant for both bulk and grain boundary, (ii) the intrinsic bulk conductivity also changes with grain size, (iii) the local environment affects the grain boundary conductance that the lower coordinate number of Li shows higher grain boundary conductance. These findings can clarify ways of improving bulk conductivities and overcoming the limiting factors of grain boundary conductivities for solid-state Li-ion conductors.

End-to-End Differentiability and Tensor Processing Unit Computing to Accelerate Materials' Inverse Design Han Liu, Yuhan Liu and Mathieu Bauchy; University of California, Los Angeles, United States

Numerical simulations have revolutionized material design. However, although simulations excel at mapping an input material to its output property, their direct application to inverse design (i.e., mapping an input property to an optimal output material) has traditionally been limited by their high computing cost and lack of differentiability—so that simulations are often replaced by surrogate machine learning models in inverse design problems. Here, taking the example of the inverse design of a porous matrix featuring targeted sorption isotherm, we introduce a computational inverse design framework that addresses these challenges. We reformulate a lattice density functional theory of sorption in terms of a convolutional neural network with fixed hard-coded weights that leverages automated end-to-end differentiation. Thanks to its differentiability, the simulation is used to directly train a deep generative model, which outputs an optimal porous matrix based on an arbitrary input sorption isotherm curve. Importantly, this pipeline leverages for the first time the power of tensor processing units (TPU)—an emerging family of dedicated chips, which, although they are specialized in deep learning, are flexible enough for intensive scientific simulations. This approach holds promise to accelerate inverse materials design.

Graphical Model Parameters for Formation of 3D Nanomolecular Complexes Minjeong Cha[1,1], Emine S. Turali-Emre[1,1], Xiongye Xiao[2], Paul Bogdan[2] and Nicholas A. Kotov[1,1,1]; [1]University of Michigan, United States; [2]University of Southern California, United States

The design of new functional materials for drug or anti-viral medicines is essential in the biomaterials and pharmaceutical field. However, due to the lack of generalized descriptors for the pairwise interactions of nano molecules, the automatic design and prediction of nanomaterials' function in the biosystem remain one of the most challenging problems. Here, to understand the comprehensive parameters for the formation of nano-biomolecular complexes, the protein complex information is investigated. The abundant protein topology data

from nature allow us to access the key structural aspects for detecting the interaction levels of molecule pairs. The newly introduced features originated from the graph network model would provide a universal description of local properties of any nanostructures and also play crucial roles in predicting the interaction level in protein pairs, defined by the distances. The feature correlation dynamics based on the distance classes validate the significant contribution of graph network features in the interaction prediction algorithms. As the proof-of-concept applications of nanomolecular complexes' interacting sites prediction, the SARS-Cov-2 nucleocapsid protein dimer and experimentally proven protein and nanoparticle pairs are analyzed. The rapid and straightforward prediction of interaction sites in pairwise molecular complexes will enhance our understanding of multi-dimensional structural model parameters for the design rules.

7:25 PM CT05.05.04
Graph Theory for Design of Complex Biomimetic Nanostructures Nicholas A. Kotov; University of Michigan, United States

The main hurdle *on the pathway finding relationships between organization and properties of many biological materials is that the frameworks do not exhibit crystalline or any other long-range order that underpins many, if not all, structure-property correlations used for metals, ceramics, polymers, and other materials. Understanding of their organizational patterns and therefore, their mechanical, transport, electrical, and other properties will be essential for their engineering and requires a new approach to quantification of their structures.*
This talk will address this problem and pave the way to comprehensive and quantitative description of structural patterns observed in different biomaterials using the graph theory (GT) extensively used in sociology and informatics for evaluation of complex network architectures.
The nanostructures represented by self-assembled chiral nanoparticles [1], biomimetic composites [2], and protein complexes [3] will be represented using GT representations based on discretization of nanostructures into nodes being connected with a network of edges. The resulting graphs can be utilized for enumeration of hierarchical architecture materials, information content (complexity), and *structure-property correlations*. Predictions of properties based on GT representations and machine learning algorithms will be presented.

Symmetry Incorporated Graph Convolutional Neural Networks for Solid-State Materials Weiyi Gong[1], Hexin Bai[1], Peng Chu[1], Haibin Ling[2] and Qimin Yan[1]; [1]Temple University, United States; [2]Stony Brook University, The State University of New York, United States

Recently, graph convolutional neural network (GCN) has been applied in crystal structures with a crystal graph representation to achieve an accurate prediction of material properties. However, graph convolutions used in previous work are mostly performed in real space based on the geometric information of crystal structures. The lack of space group symmetry information in real and reciprocal space limits the prediction accuracy of electron structure related properties. In this talk, we will demonstrate the development of a graph convolutional neural network with global and local symmetries in both real and reciprocal spaces incorporated. The newly proposed

model gives accurate predictions, compared to the state-of-the-art atom-based graph neural network models, and inspiring physical insights in the correlation between orbital symmetries and electronic structure properties of solid-state crystalline systems.

Artificial Intelligence Towards Materials Maps Claudia Draxl[1,2] and Matthias Scheffler[2,1]; [1]Humboldt-Universität zu Berlin, Germany; [2]Fritz Haber Institute of the Max Planck Society, Germany

High-throughput studies provide much information but will never cover the vast chemical and structural space of materials. Thus, Artificial Intelligence (AI) must enhance our research of tomorrow – starting today. To predict novel candidate materials for a given application, possibly even in regions of the materials space that no-one would think of, our goal is to build a general "map of materials properties". A FAIR (findable and AI ready; a further-reaching interpretation of the original acronym) data infrastructure will be an important step for achieving this goal [1]. The NOMAD Laboratory [2] is a community effort and a living example for such infrastructure in computational materials science, comprising the NOMAD Repository (raw data) and its Archive (normalized, i.e. code-independent data), the NOMAD Encyclopedia, and the NOMAD Analytics Toolkit. A final breakthrough is, however, only possible if the combined insight from synthesis, experiment [3], theory, and simulations are brought together. I'll review where we are on this road that requires an immense but rewarding effort of the wide community.

The Search for New Materials Joe Pitfield and Steven P. Hepplestone; University of Exeter, United Kingdom

Atomic scale structure prediction is a significant area of focus, yielding results such as the Materials Project [3] and tools such as AIRSS [1] and CALPYSO [2]. However, such approaches are focused on the isolated bulk whereas grain boundaries, interfaces and other phenomena dominate device development. Here, we demonstrate using MgO and graphite, how interface physics can lead to unique material formation, contrasting how this differs from the bulk, and what the resultant new properties are.To do this, we have developed A-RAFFLE, our structure at interfaces prediction tool, built upon the ARTEMIS interface prediction software[4]. Here, we demonstrate the base capability of RAFFLE as a structure prediction tool, highlighting its strengths and limitations compared to other approaches, and then discuss how RAFFLE has been implemented to predict structures at the interface between different materials.

Automated Microstructural Feature Extraction for Accelerated Materials Discovery Baskar Ganapathysubramanian[1], Daniel Wheeler[2], Olga Wodo[3] and Jaroslaw Zola[3]; [1]Iowa State University of Science and Technology, United States; [2]National Institute of Standards and Technology, United States; [3]University at Buffalo, The State University of New York, United States

Data-driven based approaches facilitate a systematic way to develop mappings between microstructure and microstructure-sensitive properties. Incorporating data-driven approaches with physically meaningful descriptors enables the elucidation of the underlying physical mechanisms linking structure with property (explainable or interpretable AI). One critical aspect of such an approach is the ability to represent materials and their structure in machine-friendly formats. In this talk, we present our framework to compute a library of generic descriptors for micrographs. We combine two approaches: statistical descriptors (e.g., n-point correlations) with morphological and topological descriptors (e.g., graph-based descriptors). Using this integrated approach, we will benchmark a few problems in the arena of discovering and mining microstructure-property maps. We explain how this work lays the foundation for machine learning of microstructure-property relationships and enables information fusion between multiple scales.

MPDD: Material-Property-Descriptor Database Adam M. Krajewski, ShunLi Shang, Yi Wang and Zi-Kui Liu; The Pennsylvania State University, United States

Fundamentally, each ML study predicts some property and comprises three elements: a database, a descriptor, and an ML algorithm. These are combined in two steps. First, the data representation is calculated using the descriptor. Then the model is iteratively evaluated on this representation or adjusted to improve it. Both processes are nearly instantaneous compared to ab-initio based methods; however, with extensive databases or materials modeled with large super-cells (e.g., glasses), times can grow into days or years. We present a tool that can speed up total process orders of magnitude by removing the most time-intensive step, i.e., the descriptor calculation.

To accomplish that, we move from traditional sharing of only the material-properties data to sharing of the

descriptors-properties data corresponding to the material as well, employing a NoSQL MongoDB database. This change not only enables orders-of-magnitude faster and effortless machine learning of materials but also serves as a tool for an automated and robust embodiment of prior knowledge about them in a graph-like fashion. Furthermore, since the descriptors are often reused for related properties, our database provides a tremendous speed-up in the design space exploration.

Inverse Design of Self-Reporting Redox-Active Materials Using Quantum Chemistry Guided Active Learning Garvit Agarwal, Hieu A. Doan, Lily Robertson, Lu Zhang and Rajeev Surendran Assary; Argonne National Laboratory, United States

Redox flow batteries (RFBs) are a promising technology for stationary energy storage applications due to their flexible design, easy scalability and low cost. In RFBs, energy is carried in flowable redox-active materials (anolyte and catholyte redoxmers) which are stored externally and pumped to the cell during operation. Further improvement in energy density of RFBs requires design of redox-active materials with optimal properties i.e. wider redox potential window, higher solubility, and stability. Additionally, designing redoxmers with fluorescence enabled self-reporting functionality allows monitoring crossover of the redox-active material and state-of-health of the RFBs. Here we employ high-throughput density functional theory (DFT) calculations to generate database of reduction potentials, solvation free energies and absorption wavelengths of 1400 anolyte materials. Using simulated data, we develop accurate machine learning (ML) models to predict properties from simplified molecular input line-entry system (SMILES) representation of the molecular materials. The trained ML models are then used as surrogate models to drive the inverse material design loop using multi-objective Bayesian optimization to identify materials with optimum range of multiple properties. We demonstrate the improved efficiency of our active learning strategy as compared to the brute-force random search approach for discovering promising redox-active materials with desirable properties from a vast chemical search space of 2 million molecules.

10:45 AM CT05.07.02
Accelerated Prediction of Atomically Precise Cluster Structures Using On-the-Fly Active Learning Yunzhe Wang, Shanping Liu, Sam Norwood, Peter Lile and Tim Mueller; Johns Hopkins University, United States

The chemical and structural properties of nanoclusters are of great interest in numerous applications -- light emitting devices, catalysis, and biomedical imaging to name a few. A systematic study of structure-property relationship necessitates the knowledge of atomically precise structures of stable clusters over a variety of sizes. However, experimental characterization of the structures of these non-crystalline materials can be challenging. Computationally searching for stable structures is a feasible solution, but can be computationally expensive, as it is a global optimization problem. In this work, we present a procedure that can accelerate prediction of low-energy nanocluster structures by combining a genetic algorithm and an interatomic potential model actively learned on-the-fly. A pool-based genetic algorithm is implemented to efficiently sample the configuration space, and moment tensor potentials are used to rapidly relax and evaluate the energies of predicted clusters. The resulting procedure significantly accelerates the process of identifying low-energy cluster structures and is demonstrated on both bare and ligated clusters. The predicted lowest-energy nanoclusters are compared with the lowest energy structures reported in literature to validate this methodology. This workflow provides a feasible

way to systematically predict low-energy structures for nanoclusters at a large scale, which can greatly facilitate the discovery and design of novel nanomaterials for a wide range of applications.

11:00 AM CT05.07.03
Screening and Understanding Li Adsorption on Two-Dimensional Metallic Materials by Learning Physics Sheng Gong[1], Shuo Wang[2], Taishan Zhu[1] and Jeffrey C. Grossman[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Maryland, United States

Two-dimensional (2D) materials have been applied on addressing challenges in Li-ion batteries (LIBs). However, it is hard to screen Li interaction with 2D materials by conventional first-principle calculations or purely data-driven machine learning. In this work, in order to screen Li interaction with 2D metallic materials, we build a high-throughput screening scheme that incorporate the process of learning physics into the screening circle. First, we use density functional theory (DFT) and graph convolutional networks (GCN) to calculate the minimum Li adsorption energies on a small set of 2D metals, then we propose a three-step adsorption mechanism based on previous understandings of charge-transfer and ionization-coupling to explain the found linear relation between minimum Li adsorption energy and work function of 2D metals. We propose that, during adsorption, a Li atom first ionizes to be a Li^+ and an electron with the energy cost equal to the ionization potential of Li, then the electron transfers to the 2D metal and release the energy equal to the work function, and finally the Li^+ couples with the negatively charged 2D metal with the energy change of coupling energy. We use chemisorption theory to support the proposed charge transfer direction, and we apply the linear dependence on explaining previous observation of enhanced Li adsorption by doping and functionalization and infeasibility of second-layer Li adsorption. For coupling, we find that the previously proposed image-charge coupling provides reasonable trend but fails for 0-height adsorption, and we use random forest model to predict and understand the coupling process, and find that variances of elemental properties of component elements and packing density are the most correlated features related to coupling. Finally, we apply our models on discovering potential high-voltage materials and find that some fluorides and chromium oxides have minimum Li adsorption energies lower than -7eV, which breaks the record, and we show that our physics-driven models have strong ability of extrapolation and higher accuracy and transferability than purely data-driven models. We hope this work can not only deepen human understanding of Li binding nature and promote the application of 2D materials on Li-ion batteries, but also inspire researchers to use physics to simplify learning problems by decoupling the target property into simpler properties in high-throughput screening for problems that are hard for conventional DFT calculations and purely data-driven machine learning.

11:15 AM CT05.07.04
Multi-Fidelity Information Fusion DFT Study of Doped-Graphene Single Atom Catalysts Hud Wahab, Gaurav Raj, Patrick Johnson, Lars Kotthoff and Dilpuneet S. Aidhy; University of Wyoming, United States

Cost versus accuracy trade-offs are common in materials science and engineering, where a particular property of interest can be measured/computed at different levels of accuracy or fidelity. Intuitively, the higher the accuracy the most resource and time intensive, while the low-cost quicker alternatives tend to be noisy. In such situations, machine-learning-based multi-information source fusion (MISF) approaches can be employed to fuse information accessible from varying sources of fidelity and make predictions at higher levels of accuracy. In this study, we perform a comparative study on traditionally employed single-fidelity (SF) and MISF strategies, such as multi-fidelity co-kriging (CK), to compare their relative prediction accuracies and efficiencies for accelerated property predictions and high throughput chemical space explorations. We perform our analysis using DFT-computed Gibbs free energy data set of H adsorption for doped graphene for single atom catalyst applications. We discuss how Sure Independence Screening and Sparsifying Operator (SISSO) methods can be used to select relevant descriptors. Finally, we elucidate whether MISF based learning schemes outperform the traditional SF machine learning methods, and discuss if this can be generalized for cases involving large chemical space explorations.

Investigating the Shapes of Bottlebrush Polymers Using Machine Learning Sanket Deshmukh; Virginia Tech, United States

Bottlebrush polymers (BBPs) of thermosensitive polymers have potential applications in the field of biomedicine. They are a type of graft polymers in which thermosensitive polymer side-chains are grafted onto a polymer backbone. Above their lower critical solution temperature (LCST), the thermosensitive polymers can exhibit a coil-to-globule conformational transition. In this talk, we will discuss the effect of grafting density on the conformation of poly(N-isopropylacrylamide) (PNIPAM; LCST= ~305 K) side-chains in the BBPs with worm-like, cone-like, and cake-like shapes. We have performed coarse-grained (CG) molecular dynamics (MD) simulations of these BBPs at 290 K (below LCST) and 320 K (above LCST) in the presence of explicit CG water for 500 ns of these BBPs. The effect of temperature on the structure and shape of these BBPs were quantified by analyzing the simulation trajectories using convolutional neural network (CNN) based machine learning approach.

Searching Order within Disorder with AI-Automation Stefano Curtarolo; Duke University, United States

Critical understanding of large amount of data leads to new spectral descriptors for discovering entropic ceramics (e.g. metastability, synthesizability), their phase transitions (e.g. mixing, melting) and their remarkable properties (hardness, elasticity) [Nat. Rev. Mater. **5**, 295 (2020)]. Research sponsored by DOD.

1:50 PM CT05.08.03
A Phase Mapping Algorithm to Accelerate High Throughput Experiments Ming-Chiang Chang[1], Sebastian Ament[1], Maximillian Amsler[1,2], Duncan R. Sutherland[1], Carla P. Gomes[1], R. Bruce van Dover[1] and Michael O. Thompson[1]; [1]Cornell University, United States; [2]University of Bern, Switzerland

Developing high-throughput methods, leveraging both experimental automation and computer agent based autonomous exploration, is crucial to accelerate materials discovery. Advances continue to be necessary in advanced synthesis techniques and equally in improved materials characterization tools. In work with lateral gradient Laser Spike Annealing (lgLSA), we have demonstrated the power of spatially resolved spectroscopic and diffraction methods for rapidly assessing both composition and processing impacts on material properties. However, lgLSA dramatically increases the amount of such spectral data produced during experiments with even a single library, data which must be processed rapidly and efficiently to prevent bottle necks during the decision making in autonomous high-throughput workflows. X-ray diffraction (XRD) data is particularly difficult to manage because of the complicated behavior of spectra with changing composition, texture, and grain size distribution with processing conditions. Peak shifting, peak broadening, and modification of scattering intensities are but a few of the challenges to existing phase identification algorithms.
We introduce a general algorithm to efficiently identify constituent phases in XRD data from a library of ICSD patterns. This phase mapping algorithm was developed to be particularly appropriate for lgLSA (autonomous) explorations, exploiting the unique characteristics of the dense, temperature-dependent, diffraction data across a single laser scan experiment. While recent work has proposed deep-learning-based models for this problem, our algorithm is inspired by compressed sensing and is particularly inexpensive to run due to the physically-induced sparsity of the phases. Further, our algorithm incorporates peak-shifting due to alloying, something which even a recent deep-learning-based approach cannot handle. We demonstrate the capabilities of this algorithm using data from the Bi-Ti-O material system, resolving complex XRD patterns into constituents based on known

phases from crystal structure databases. The algorithm has proven to be robust for phase identification even in the presence of doping, alloying, strain, and atomic disorder. Results from a variety of other systems demonstrate the general applicability of the algorithm. Finally, the ability to rapidly identify constituent phases in spectral data is especially valuable in an active learning context, where the phase identification can feed into experimental design. We will discuss how the algorithm is incorporated in an autonomous materials discovery workflow using in-situ experimental decisions and efficient synchrotron-based analysis. The algorithm has potential to be incorporated into many different high-throughput workflows, and can be equally used to provide physical knowledge to train machine learning models for accelerated materials discovery.

2:05 PM CT05.08.04
High Dimensional Model Representation - Gaussian Process Regression—A Powerful Tool to Learn Multivariae Functions from Sparse Data Mohamed A. Boussaidi[1], Owen Ren[1,2], Dmitry Voytsekhovsky[2] and Sergei Manzhos[1]; [1]INRS, Canada; [2]Purefacts Inc, Canada

Machine learning approaches including neural networks (NN) and Gaussian process regression (GPR) are finding widepread use to recover functional dependencies from multidimensional data. As powerful as these approaches are, they may fail when data density is low, which is always the case in highly-dimensional cases. Some methods like GPR also cannot easily work with large datasets. Using modified high dimensional model representation (HDMR) to represent a multivariate function with machine-learned lower-dimensional terms allows recovering functions from very sparse data, down to ~2 data per dimension. Sub-dimensional component functions are easier to fit and to use. Specifically here we present a HDMR-GPR combination where the use of GPR to represent component functions allows nonparametric (unbiased) representation and the possibility to work only with functions of desired dimensionality, obviating the need to build an expansion over orders of coupling. All component functions are determined from a single set of samples. We test the method by fitting potential energy surfaces of polyatomic molecules as well as by computing vibrational spectra.

Comprehensive Comparison of Modern Sequential Design Approaches for Material Optimization—Application to Metal-Organic Frameworks Giovanni Trezza, Luca Bergamasco, Matteo Fasano and Eliodoro Chiavazzo; Politecnico di Torino, Italy

In a number of scientific contexts, the evaluation and optimization of an objective black-box function through the sequential performance of (physical and/or numerical) experiments can be prohibitively costly, especially when navigating in a high-dimensional domain. Modern sequential design algorithms based on machine learning are emerging as interesting options to address this issue, allowing to effectively explore particularly high-dimensional parameter spaces, with a minimal number of evaluations. In this framework, scientists can rationally choose the next experimental (or computational) setup to be analyzed while searching for the optimal candidate, without the need of relying on the luck of random guessing.
These general techniques find important applications in the broad area of material science (where the number of material descriptors or features can be impressively high), and hold promise to accelerate materials discovery and research. Here, we apply this approach to a database of 1000 Metal-Organic Frameworks (MOFs), which are innovative compounds employable in the energy field (e.g. thermal energy storage, carbon dioxide capture [1]). In particular, the aim is to find the best candidate in terms of a property of interest (e.g. water, carbon dioxide or other sorbate solubility) in the fewest number of trials navigating within a 58-dimensional feature space of properly selected material descriptors. In this work, we provide a comprehensive comparison of several state-of-the-art methodologies. This is accomplished both for the regression models over the initial set of 60 materials supposed to be known (random forest regression [2], Kriging [3], Gaussian process regression [4]) and for the strategies allowing to choose the next MOF to test (based on exploitation of high-performing candidates, exploration of poorly explored regions or entropic search [5]).
We observe that the convergence with these "smart" trajectories occurs before the average random guessing and, in many cases, in few dozens of evaluations. Differences among several strategies are shown and discussed.

Machine Learning Tools to Accelerate Scalable Perovskite PV Manufacturing Nicholas Rolston[1], Zhe Liu[2], Austin Flick[1], Thomas W. Colburn[1], Zekun Ren[2], Justin Chen[1], Tonio Buonassisi[2] and Reinhold Dauskardt[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States

One of the key requirements for commercializing perovskite PV is to develop a scalable fabrication process to produce high-efficiency PV devices. We have identified that process optimization is the most time-consuming step during the development of scalable deposition technology for perovskite devices. Because the process optimization involves a large number of process variables (*e.g.*, typically 10 – 20 variables or more), it is difficult for human intuition to solve efficiently, for example, with the trial-and-error approach or the conventional design of experiment method (*e.g.*, one variable at a time). The state of the art for applying machine learning tools in process optimization is still at a preliminary stage. In this work, we address the challenges of ML-assisted optimization of scalable perovskite PV processing by developing the interpretable framework of sequential learning and establishing an adaptable ML model using transfer learning. The open-air rapid spray plasma process (RSPP) for depositing and curing of perovskite films is a unique platform to test and deploy the proposed ML-guided framework because RSPP is able to conduct optimization experiments at high throughput with easy access to adjusting a wide range of process variables.

In this work, we develop a novel Bayesian-optimization-based model that utilizes the visual inspection of film quality as a probabilistic constraint and conducts a local optimization of the trusted regions after the global optimization. Using the developed model, we adopt the sequential learning framework (also known as active learning), which utilizes a small dataset to initiate an ML regression model and iteratively suggests and collects new data points to achieve the optimization task. Specially, six process conditions are identified as the key parameters to systematically optimize (namely, substrate temperature, process speed, spray flow rate, plasma height, plasma gas flow, and plasma duty cycle) in RSPP perovskite devices. With less than 200 experimental conditions (which is a tiny fraction of 40k experimental conditions in a grid search), we achieve: (i) faster process optimization and (ii) a better understanding of the heuristic relationship between PV performance and process variables using an interpretable and transferable machine learning framework. Finally, with the help of this ML framework, we are able to produce the highest perovskite PV efficiencies ever reported in ambient.

Towards Small-Data-Driven Materials Science Luca M. Ghiringhelli; Fritz Haber Institute of the Max Planck Society, Germany

The number of possible materials is practically infinite, while only few hundred thousands of (inorganic) materials are known to exist and for few of them even basic properties are systematically known. In order to speed up the identification and design of new and novel optimal materials for a desired property or process, strategies for quick and well-guided exploration of the materials space are highly needed. A desirable strategy would be to start from a large body of experimental or theoretical data, and by means of artificial-intelligence (AI) methods, to identify yet unseen patterns or structures in the data, and consequentially predictive (data-driven) models. This leads to the identification of maps (or charts) of materials where different regions correspond to materials with different properties. The main challenge on building such maps is to find the appropriate descriptive parameters (called descriptors) that define these regions of interest.
Here, I present novel methods for the AI-aided identification of descriptors and materials maps, based on symbolic regression, compressed sensing [1], and multi-task learning [2]. The mehods are tailored to yield predictive models (also) with "small-data", and are shown applied to important materials-science challenges such as the prediction of stability of perovskite materials, of novel topological insulators, and more.
I focus on the (verified) predictive power of the learned maps, which goes beyond the mere interpolation of more "traditional" AI approaches, and analyze current and future challenges.

Data-Driven Quantum Dot Synthesis Development in Flow Milad Abolhasani; North Carolina State University, United States

Inorganic lead halide perovskite (LHP) quantum dots (QDs) have recently emerged as a promising class of semiconducting materials for next-generation, solution-processed optoelectronic devices.[1] The unique properties of LHP QDs are mainly attributed to their high photoluminescence quantum yield (PLQY), high defect tolerance, facile bandgap tunability, and narrow emission linewidth.
Despite the substantial improvements in synthesis development of LHP QDs over the past five years, the conventional trial and error-based synthesis and formulation optimization methods have hindered their rapid adoption by energy technologies. Existing material development strategies very often fail to overcome the demands of colloidal QDs' vast synthesis and processing universe, resulting in time- and cost-intensive QD development efforts.
Recent advances in modular robotic material manufacturing and artificial intelligence (AI)-guided decision-making strategies, including deep neural networks (DNNs) and reinforcement learning (RL), provide an exciting opportunity to reshape the synthesis development and formulation discovery of precision-tailored QDs through the autonomous operation of a robotic QD synthesizer.[2]
In this work, we have developed the second generation of our *Artificial Chemist* technology;[3] a modular microfluidic platform [4] for data-driven, multi-step synthesis, optimization, and end-to-end manufacturing of colloidal LHP QDs. The AI-driven, multi-step chemical synthesis technique incorporates the modeling and uncertainty quantification of experimental responses and uses such models to strategically explore multivariate reaction space in a sequential, closed-loop, adaptive manner. This data-driven approach effectively couples the task of developing and training a surrogate model with the multi-objective optimization problem, which in practice results in accelerated chemical synthesis process development. The autonomous robotic QD synthesizer uses advanced DNNs and multi-stage decision-making policies trained on experimentally measured QD properties (generated *in house*) in tandem with state-of-the-art RL algorithms to strategically and intelligently explore QD design space, and thereby accelerate the synthesis optimization of LHP QDs for energy and chemical technologies. The reconfigurable Artificial Chemist technology utilizes a multimodal *in-situ* material diagnostic probe (absorption/photoluminescence (PL) spectroscopy) in conjunction with a real-time, ensemble DNN adaptive algorithm to enable simultaneous optimization of PLQY and size distribution of LHP QDs for

any desired emission color. The developed autonomous robotic experimentation technology with its modular flow reactors and QD processing modules can be readily adapted for data-driven development of other solution-processed nanomaterials.

Machine Learning Prediction of Creep Rupture Behavior for Metal Alloys Reihaneh Jamshidi; University of Hartford, United States

The design of alloys and composites with high creep resistance is of great interest, especially in high-temperature applications. Here we show that machine learning algorithms can predict creep behavior of steel alloys, more specifically creep-rupture lifetime and rupture stress, as a function of the alloy composition and processing methods. The machine learning approach was applied on a data set of 2000 alloys, and the predicted creep-rupture lifetime and rupture stress were in good agreement with most of the experimentally measured values. The results were mutually confirmed by two algorithms.

Development of an Artificial Intelligence (AI) Based Image Processing Tool to Detect Microstructural Variations in AM Ti-6Al-4V Rohan Casukhela[1], Sriram Vijayan[1], Meiyue Shao[1], Matthew Jacobsen[2] and Joerg R. Jinschek[1]; [1]The Ohio State University, United States; [2]Air Force Research Laboratory, United States

Recent research progress has already indicated the promising potential of metal additive manufacturing (AM), e.g. when producing Ti-6Al-4V (Ti64) parts for aerospace applications. The AM process is inherently non-equilibrium in nature, caused by rapid thermal cycling and consequent steep thermal gradients, producing parts with complex, anisotropic, and metastable microstructures [1]. As a result, there is a limited understanding of the physical metallurgy of AM, which restricts the qualification of AM parts for use in critical applications. Therefore, in order to rapidly qualify AM Ti64 parts with targeted properties, AM processes must be optimized based on a fundamental understanding of the *AM Ti64 processing – microstructure – property (PMP)* space. This gap in understanding can be reduced by developing statistical models assisting mapping the PMP space. These models must be sufficiently flexible to be applicable on a vast variety of datasets obtained from processing, characterization, and testing methods across multiple length scales. However, the low volume of microstructural data obtained from characterization techniques across multiple length scales is often identified as a significant barrier when developing statistical models with low uncertainty.

In the case of AM Ti64, scanning electron microscopy (SEM) based techniques provide valuable information about the variation in α/β microstructure throughout the AM build. High-contrast SEM images require long(er) dwell times, which limits the volume of images acquired in a reasonable amount of time [1]. Here, we also acquired large-area SEM images using low dwell times and utilized a deep-learning network to improve image quality by denoising these low-resolution images. The accuracy of the extracted microstructural data was compared with findings based on high-quality SEM images [1]. Artificial intelligence (AI)-based image processing tools that were used to extract microstructural information from these denoised images can serve as an input to the regression-based PMP model for AM Ti64. The uncertainty associated with model predictions will be presented. Finally, significance of the model will be discussed and alternative designs for subsequent experimental iterations to refine the model will be proposed.

4:50 PM *CT05.09.05
Coupling Machine Learning and Physics-Based Simulations to Accelerate Materials Design Bryce Meredig; Citrine Informatics, United States

Machine learning (ML) and physics-based simulations are highly complementary tools in computational materials design. ML models are flexible and computationally cheap, but they require sufficient training data and their accuracy suffers under extrapolation; physics-based simulations embed deep domain knowledge and often have broad applicability, but are computationally expensive. In this talk, we discuss using ML as a "glue" layer for multiscale simulations; automating physics-based simulations with the goal of enabling ML-driven sequential learning; and using uncertainty quantification in ML and simulations to improve both approaches to materials modeling.

5:15 PM CT05.09.06
Predicting Fracture Stress of Defective Graphene Samples Using Artificial Neural Networks Nuwan Dewapriya[1,2], Nimal Rajapakse[1,3], Priyan Dias[4] and Ronald Miller[2]; [1]Simon Fraser University, Canada; [2]Carleton University, Canada; [3]Sri Lanka Institute of Information Technology, Sri Lanka; [4]University of Moratuwa, Sri Lanka

The computational cost associated with atomistic modeling is often a bottleneck in the design and characterization of nanomaterials. For example, first-principles methods such as density functional theory can only be used to model a few hundred atoms at a time due to the extremely high computational cost associated with them, and therefore such methods cannot be used to study atomistic processes such as crack propagation. On the other hand, computationally efficient continuum mechanical approaches (e.g., finite element method) are not directly applicable to the nanomechanical problems because such methods do not generally consider surface energy effects and the discrete nature of atomic structures, which are quite significant when the characteristic dimension of a system is a few nanometers. Molecular dynamics (MD) simulations strike a balance between the computational cost and accuracy for nanomaterial modeling. Alternatively, machine learning techniques (e.g., neural networks) provide an opportunity to extract underlying features of data obtained from MD simulations while offering novel insights into the mechanics of nanoscale structures.

In this work, we employed both shallow and deep neural networks to predict the fracture stress of graphene samples containing various numbers and distributions of vacancy defects. Data required to model the neural networks was obtained from MD simulations. First, we developed shallow neural networks to predict the fracture stress of defective graphene samples at various temperatures and vacancy concentrations. Sensitivity analysis was performed to explore the features learned by the neural networks, and their behavior under extrapolation was also investigated. Subsequently, we developed deep convolutional neural networks to predict the fracture stress of graphene samples containing random distributions of vacancy defects. Results reveal that the neural networks have a strong ability to predict the fracture stress of defective graphene under various processing conditions. This work demonstrates some opportunities and challenges in modeling of neural networks using data obtained from MD simulations to solve complex nanomechanical problems.

Explaining Neural Network Predictions of Material Strength Terrell N. Mundhenk[1], Ian A. Palmer[2], Brian Gallagher[1], Barry Chen[1], Gerald Friedland[3] and Yong Han[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Massachusetts Institute of Technology, United States; [3]University of California, Berkeley, United States

We recently developed a deep learning method that can determine the critical peak stress of a material by looking at scanning electron microscope (SEM) images of the material's crystals. However, it has been somewhat unclear what kind of image features the network is keying off of when it makes its prediction. It is common in computer vision to employ an explainable AI saliency map to tell one what parts of an image are important to the network's decision. One can usually deduce the important features by looking at these salient locations. However, SEM images of crystals are more abstract to the human observer than natural image photographs. As a result, it is not easy to tell what features are important at the locations which are most salient. To solve this, we developed a method that helps us map features from important locations in SEM images to non-abstract textures. We do this as follows. We obtain the most salient locations from the network trained on SEM images using a method called FastCAM. We selected it because it has been empirically shown to produce saliency maps that correspond well to what is actually important in the image. We also run texture images from the Describable Texture Dataset (DTD) through the SEM image trained neural network. For both SEM and DTD images, we extract a feature vector from the most salient location in the activation tensors. This gives us a feature vector which has better definition than if we averaged across layers, which is the most common method. We then find the nearest neighbors between SEM feature vectors and DTD feature vectors. This tells us which textures are most like the salient locations in our SEM images. By correlating over the full set of SEM and DTD feature vectors we then have clear texture trends we can relate to critical peak stress. For instance, a low peak stress correlates strongly with textures described as stratified, braided or bumpy. High peak stress correlates with textures such as flecked, dotted or grid like. We had prior hypothesized that flecked and dotted like textures were associated with a higher peak stress. However, the other textures revealed yet unknown processes that might affect material strength. We will discuss the pro's and con's of using DTD to describe the textures of materials as it relates to critical peak stress. For instance, some textures in the set should probably be split into subcategories and in general can be ambiguous.

Using Deep Learning to Find High Performance Phase-Change Switchable Metasurface Reflectors
Jonathan Thompson[1,2] and Matthew Mills[2]; [1]Azimuth Corporation, United States; [2]Air Force Research Laboratory, United States

Metasurfaces of 1D gratings and 2D pillars arrays of the phase-change material $Ge_2Sb_2Te_5$ (GST) are investigated as an active switchable reflector. The large index contrast between the amorphous and crystalline phase-states, in conjunction with the highly tunable metasurface geometry, allows us to selectively engineer an agile device that shows both high reflectance and transmittance for 2 μm wavelengths when switched between states. While the many degrees of freedom metasurfaces introduce are beneficial for spectral tuning, the large parameters spaces are also problematic insofar they are often impossible to exhaustively search when using traditional simulation methods like rigorous coupled wave analysis (RCWA). Nevertheless, we are able to completely search these large parameter spaces with millions of designs by employing artificial neural networks that have been trained using only a fraction of the total number of possible designs. These spectra predicting networks (SPN) achieve an accuracy of 98% and a simulation speed up of 10^5x compared to the RCWA simulations that they were trained on. The exhaustive search using SPNs allows us to find optimal designs, where we discover several GST metasurface designs with ~95% reflectance and ~80% transmittance between phase-states.

8:25 PM CT05.10.03
Late News: Automatic Characterization of Single-Walled Carbon Nanotube Film Morphologies Using Computer Vision Phillip Williams, Nicole Rice and Benoit Lessard; University of Ottawa, Canada

When establishing the relationships between processing conditions, film morphologies and performance of Single-Walled Carbon Nanotube (SWNT) based devices, the device characteristics are easily measured and quantified, and the processing conditions are known and tightly controlled. On the other hand, the film morphology is often known either at a qualitative level, or through manual analysis which is both slow and error prone, as well as an inefficient use of a researcher's time. This gap presents a significant challenge to the construction of next-generation devices, since the current approaches focus on establishing processing condition to device performance relationships without being able to control for the actual morphologies of the SWNT devices which incidentally can vary significantly even at fixed processing conditions.
The use of Artificial Intelligence (AI) and Computer Vision (CV) can augment the current approaches used for analyzing devices by providing detailed metrics on the film morphologies using a software only approach, meaning that fast, accurate and reproducible analysis can be done at much larger scales and levels of detail than previously feasible.. The analysis pipeline uses Atomic Force Microscopy (AFM) height data to calculate metrics that are currently collected manually – such as linear density – as well as providing entirely new information not available from any machine or manual technique, such as the positions, orientations, and lengths of each individual carbon nanotube in a device.
There are two main steps to the data analysis procedure. First, a file containing the height of the film at various positions is ingested and segmented into a bitmap which represents the presence or absence of a nanotube at a given position in the film. The second step is application of various algorithms to the segmentation bitmap to extract relevant metrics. The segmentation processes consists of several steps which are designed to identify if a given point in a film belongs to a nanotube or not. This is accomplished by using adaptive thresholding techniques such as Otsu's method or Yen thresholding, as well as more traditional techniques such as edge detection, image filters and data preprocessing. The final output of this segmentation process is a matrix of true and false values, indicating if a given pixel belongs to a nanotube (true) or if belongs to the substrate that the nanotube was deposited on (false). Once the segmentation is complete, two solvers are applied to the data. The first is an algorithm that iterates through each row and column of the segmentation bitmap and detects how many nanotubes intersect with that row or column. This allows us to compute the linear density of the film at every point in the device, providing an obvious advantage over the current practice of graduate students hand-counting the intersections at a few positions in the AFM image. The other solver is a Genetic Algorithm (GA) based solver which attempts to find a set of nanotube parameters – orientations, positions and sizes – which would produce the same film morphology observed. Once the parameters of each individual nanotube is extracted, secondary processing can extract metrics such as the distribution of sizes and orientations of the nanotubes, to give a clear set of quantifiable observations describing the film morphology. Using our analysis methodology, we can automate characterization traditionally done manually, as well as produce entirely novel insights into the film morphology of SWNT devices in a matter of minutes or hours without the need for specialized equipment or multi-million dollar hardware.

Image Deconvolution and Resolution Enhancement in Scanning Probe Microscopy Using Deep Learning Lalith Krishna Samanth Bonagiri, Harry Feldman and Yingjie Zhang; University of Illinois at Urbana-Champaign, United States

Machine learning has been proved to substantially improve the existing imaging and characterization techniques in the field of material science. Currently, researchers in this area are using deep learning for classification and segmentation of the images/data for pattern recognition and thus enabling the automation of imaging techniques, particularly scanning probe microscopy (SPM). However, none of these well-developed deep learning techniques focussed on removing the tip convolution effect in SPM which would truly help in enhancing the spatial resolution of the resulting images. Tip convolution in SPM is a well-known phenomenon. To model this process mathematically, set theory and mathematical morphological operators such as dilation

and erosion have been used previously by many researchers. However, it is quite cumbersome to select the size of the structuring element and the morphological operation to obtain the tip shape and an accurate ground truth image. Apart from that, there are no existing learning-based algorithms, which are primarily required because the tip evolves with time and so does the artifact. Here in, we report a deep learning framework to remove the tip effect through a feature pyramid based neural network. We use nanoparticles of various shapes as model systems to perform AFM experiments and deconvolute tip-shape effects and are able to successfully reconstruct the actual nanoparticle shape using the neural network. This work can be generalized to all scanning probe microscopy techniques and can enable image deconvolution in real-time during experimental measurements.

Rapid and Flexible Classification of Scanning Transmission Electron Microscopy Data Using Few Shot Learning Sarah M. Akers, Elizabeth J. Kautz, Bethany Matthews, Le Wang, Yingge Du and Steven R. Spurgeon; Pacific Northwest National Laboratory, United States

Control of property-defining materials defects for quantum computing and energy storage depends on the ability to precisely probe structure and chemistry at the highest spatial and temporal resolutions. Modern scanning transmission electron microscopy (STEM) is well-suited to this task, having yielded rich insights into defect populations in many systems. However, the dilute nature and complexity of materials defects, coupled with their varied representations in STEM data, makes reliable, accurate, high-throughput statistical defect analysis a significant challenge. Possible analysis approaches include low-level pixel processing, or even the application of machine learning methods for classification and image segmentation. However, the latter requires large sets of labeled training data that are difficult to obtain for many practical materials science studies. Here, we describe the use of an emerging few shot learning capability for rapid and flexible STEM data classification. This approach requires minimal information at the start of the analysis and uses a generally pre-trained encoder network to make inferences on experimental data. Our results show drastic improvements in data annotation costs, reproducibility, and scalability in comparison to neural network training from scratch. We demonstrate how few shot techniques can quickly extract feature maps and global statistics from a variety of STEM data, enabling a new quantitative understanding of defect populations.

9:25 PM CT05.10.06
Machine Learning to Reveal Nanoparticle Dynamics from Liquid-Phase TEM Videos Lehan Yao, Zihao Ou, Binbin Luo, Cong Xu and Qian Chen; University of Illinois at Urbana-Champaign, United States

Transmission electron microscopy (TEM) has been applied to nanomaterials characterization for decades, and with the recent development of liquid-phase TEM, the nanoscale dynamics including nanoparticle diffusion and superlattice crystallization can also be revealed. However, the quantitative parameter extraction directly from image/video data is still prone to challenges such as high noise and inhomogeneous background. Conventional manual measurement produces better accuracy but suffers from extremely low efficiency, while computer algorithm-assisted segmentation is fast but is tricky in terms of parameterization. Here, we integrate the computer-based fast analysis together with the smart vision of human beings by applying machine learning algorithms. The talk will be focused on automated image analysis of conventional TEM and nanoscale dynamics study from liquid-phase TEM, both enabled by machine learning. In our customized workflow, we develop methods to simulate TEM images, serving as the training dataset for the U-Net neural network. We then apply the trained neural network to liquid-phase TEM videos of different colloidal nanoparticle systems, revealing a diversity of properties including their diffusion and interaction, reaction kinetics, and assembly dynamics. We expect our framework to push the potency of TEM to its full quantitative level in a high-throughput and statistically significant fashion.

9:30 PM CT05.10.07
Deep Learning for Super-Resolved Atomistic Predictions from Atom Probe Tomography Aditi Sonal, Jith

Sarker, Baishakhi Mazumder and Kristofer Reyes; University at Buffalo, The State University of New York, United States

Atomistically resolved techniques such as Atom Probe Tomography (APT) and Molecular Dynamics simulations provide rich, complex and high-dimensional data. Often, however, such information is coarse-grained for ease of human-based analysis. Such coarse-graining results in loss of information present in the raw data. In this talk, we propose an alternative methodology using deep residual convolutional neural networks. We show how using such models, we can identify spatially-local, atomistically-resolved characterization of material structure. As an example, we apply the technique to identifying crystal phase in $Al_xGa_{1-x}O_3$ material characterized by APT. We demonstrate a procedure for obtaining super-resolved identification of crystal structure to attenuate classification results in the face of noisy and incomplete data typical of APT. We also demonstrate how the use of synthetic atomistic simulations of crystal structure can assist in this atomistically-resolved structural characterization task, allowing the use of such DL-based techniques in situations where the presence of specific structures is ambiguous.

Late News: Advances in Image Driven Machine Learning for Microstructure Recognition and Characterization Arun Baskaran[1], Elizabeth J. Kautz[2], Wufei Ma[1], Aritra Chowdhury[3], Bulent Yener[1] and Daniel Lewis[1]; [1]Rensselaer Polytechnic Institute, United States; [2]Pacific Northwest National Laboratory, United States; [3]GE Global Research, United States

Machine learning (ML) or artificial intelligence (AI)-enabled materials design and discovery has recently emerged as a new paradigm in material science. An important sub-field within this broad area is image-driven machine learning(IDML), which has supplemented material characterization techniques beyond what was possible with conventional stereography and image analysis methods. Microstructure characterization is important for material design as it enables the development of processing-structure-property relationships that are critical to several research areas such as alloy design, assessment of corrosion resistance, failure analysis, etc. In this presentation, the state of the art of IDML for materials characterization is discussed using a set of functional modules, defined such that each module performs a specific role in the IDML workflow. Such an overview permits answering granular questions about the field such as the impact of IDML at different spatial length scales, the diversity of machine learning models adopted in the field, etc. One of the emerging techniques to have been adopted in the field is generative models for constructing synthetic and novel microstructures, and towards data augmentation. The results from applying a progressive growing generative adversarial network (pg-GAN) to generate a dataset of synthetic microstructures of a binary U-Mo alloy is detailed. The quality of the synthetic microstructures is evaluated by comparing these images and the real images in Fourier space, and investigating the presence of correlated background noise. Finally, the work in progress in using a transfer learning strategy on GANs to generate microstructures is reported, and the effect of this strategy on the microstructure quality, convergence time, and the size of the training dataset is discussed.

10:00 PM CT05.10.09
Leveraging Uncertainty from Deep Learning for Trustworthy Materials Discovery Workflows Jize Zhang, Bhavya Kailkhura and Yong Han; Lawrence Livermore National Laboratory, United States

We are witnessing a significantly growth of works that integrate deep learning to material application workflows. In such context, the uncertainty (or confidence) associated with the prediction from deep neural net would be of utmost importance, because it can be further leveraged to aid decision makings in cost-effective material discovery and synthesis process. Here, we investigate into answering several common challenging questions material scientists might encounter in such material application workflows, by leveraging the deep neural network's predictive uncertainty information. We first show that the uncertainty information enables the user to determine the necessary amount of training data for the deep neural net to achieve the desired accuracy level. Next, we present a framework that guides the deep learning model to avoid making predictions on confusing samples based on the uncertainty information. Finally, we show that the uncertainty is also helpful in

detecting out-of-distribution data. Specifically, we find out that an uncertainty-based out-of-distribution (OOD) detection scheme is already accurate to identify a wide range of real-world shifts in data, e.g., changes in the image acquisition conditions or changes in the synthesis conditions. We demonstrate the effectiveness of the proposed approach on a real-world example, where we classify molecular crystals produced under various synthesis/processing conditions from their microstructure information (scanning electron microscope images) using deep neural networks.

Machine Learning Aided Discovery of Patterns in Crystal Chemistry Krishna Rajan; University at Buffalo, The State University of New York, United States

In this presentation we provide an overview of how we can transform the "genomics" paradigm in materials discovery to a "connectomics" approach to materials design. We provide examples of our new approach of mapping diverse information and discovering connections between structure and functionality in materials chemistry, by harnessing machine learning methods that utilize both the statistical and topological aspects of data. This can help to aid targeted materials discovery based on discovering the best pathways for future discoveries. We show how this "connectomics" approach can uncover hidden patterns associated with structure-property relationships in complex crystal chemistries.

8:25 AM CT05.11.02
Discovering Relationships Between OSDAs and Zeolites Through Data Mining and Generative Neural Networks Zachary Jensen[1], Soonhyoung Kwon[2], Daniel Schwable-Koda[1], Rafael Gomez-Bombarelli[1], Yuriy Roman-Leshkov[2], Manuel Moliner[3] and Elsa Olivetti[1]; [1]Massachusetts Institute of Technology, United States; [2]Masdar Institute of Science and Technology, United States; [3]Universitat Politècnica de València, Spain

Zeolites are crystalline, microporous materials extensively used in various industrial applications including catalysis, water decontamination, and NO_x abatement. Many of these zeolites are synthesized using an organic structure directing agent to guide towards that specific zeolite structure. Several strategies exist for finding suitable OSDAs for different zeolites including domain-specific heuristics, molecular dynamics simulations, and transition state mimicking. However, predicting new OSDAs for both existing and novel zeolite structures remains inexact and very challenging. To advance the goal of understanding interactions between OSDAs and zeolites, we take a data-driven approach that has been largely missing from the current state of research. We use natural language processing and text mining techniques to extract an exhaustive data set of known pairs of OSDAs and zeolites from the scientific literature. Next, we mine this data to elaborate on trends between the three-dimensional structure of the OSDA and the zeolite. Specifically, we examine several small-cage zeolites such as CHA, LTA, and AEI which exhibit strong correlations with OSDAs and have significant industrial applications. Finally, we develop a generative neural network trained on the literature data to suggest OSDA molecules for specific zeolites. We then use this model to examine several interesting zeolite systems including CHA and SFW to suggest potential replacement OSDAs.

8:40 AM CT05.11.03
Graph-Based Deep Learning for Designing Stable Interfaces for Solid-State Batteries Shubham Pandey[1], Vladan Stevanovic[1,2], Peter C. St. John[2] and Prashun Gorai[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

Solid-electrolytes (SEs) offer numerous advantages over their liquid-state counterparts in solid-state batteries including, increased safety, wider operating temperatures, and higher energy densities. However, commonly used SEs and electrodes are thermodynamically unstable at the solid-solid interfaces. Decomposition phases forming at the interfaces may be ionically resistive or electronically conducting, which is undesired for battery design. There is a pressing need to search for new SEs and cathodes that will form stable metal anode-electrolyte and electrolyte-cathode interfaces. Thermodynamic stability of solid interfaces can be assessed through a convex hull construction based on the formation enthalpies of competing phases, which can be calculated from DFT total energies. To allow fast prediction of stability, in this work, we built crystal graph convolutional neural networks (CGCNNs) as a surrogate for predicting DFT total energies. Current implementations of CGCNN models for predicting total energy/formation enthalpy of inorganic materials are inaccurate for high-energy hypothetical structures. A model that is accurate for total energy predictions of not only ground-state (GS) but also high-energy hypothetical structures is desired when considering new materials for designing stable solid interfaces. To this end, we trained CGCNN models on DFT total energies from NREL Materials Database that contains GS or near-GS structures and a unique dataset containing ~10,000 hypothetical structures, including high-energy structures. The trained models achieve mean absolute errors of ~40 meV/atom for both GS and high-energy structures. These models will enable materials discovery efforts for designing stable interfaces in solid-state batteries as well as for other functional applications.

8:55 AM CT05.11.04
Machine Learning Stability Rules for Complex Ionic Compounds and Its Application in the Discovery of New NASICON Materials Bin Ouyang[1], Jingyang Wang[1], Tanjin He[1], Christopher J. Bartel[1], Haoyan Huo[1], Yan Wang[2], Valentina Lacivita[2], Haegyeom Kim[3] and Gerbrand Ceder[3]; [1]University of California, Berkeley, United States; [2]Samsung Research America, United States; [3]Lawrence Berkeley National Laboratory, United States

Nowadays, various tools are readily available to perform high-throughput computational discovery of new materials. The next grand challenge is to bridge the gap between computational prediction and experimental accessibility. To fulfill this goal, elemental compatibility is the first thing to be understood. In the field of ionic solids established stability rules such as the Goldschmidt tolerance factor and the Pauling's rules work reasonably well in ionic solids that have relatively simple compositions and bond topologies, such as perovskites. However, when it comes to complex ionic compounds, the combinatorial space becomes very large and a handy stability model is mostly absent. To establish stability rules for complex ionic solids with the aid of machine learning tools, we take the NASICON type materials as a prototype system. The complexity of NASICONs is a challenge for ML as these compounds have four types of cation sites and are able to have both cation and polyanion mixing. In this work, we developed and applied a suite of high-throughput computation, physical interpretation, and machine learning tools to reveal the stability rules of NASICONs across all compositional and elemental space. We have decoupled the stability origin of NASICON materials into bond compatibility and site miscibility as well as present a two-dimensional "tolerance factor" that can be used to estimate the synthetic accessibility of NASICON materials with only basic elemental information. With the established stability principle, we have successfully synthesized more than ten new NASICONs in unexplored chemical spaces. We hope our work can provide insights in bridging the state-of-the-art machine-learning techniques and data-mining tools to accelerate the discovery of complex ionic compounds.

9:10 AM *CT05.11.05
Combining Machine Learning and Multiscale Modeling for Accelerated Battery Manufacturing Optimization Alejandro A. Franco[1,2,3]; [1]Université de Picardie Jules Verne, France; [2]Réseau du Stockage Electrochimique de l'Energie (RS2E), France; [3]Institut Universitaire de France, France

Lithium ion batteries (LIBs) are playing a crucial role in the ongoing energy transition, in particular through the renewed emergence of electric vehicles. However, the increasing climate change requires us to develop innovative approaches to accelerate the optimization of LIBs. In this lecture i will present an innovative hybrid

computational approach, combining machine learning (ML) and multi-scale modeling (MSM), allowing to predict the impact of manufacturing parameters on lithium ion battery (LIB) electrode properties. Manufacturing parameters include electrode slurry composition and solid to liquid ratio, coating speed, slurry drying temperature, calendering pressure, temperature and rolls speed. Resulting electrode properties include mesostructure information (spatial organization of active and inactive material particles, particles percolation, tortuosity factors, porosity, etc.) and electrochemical performance indicators (overpotentials and specific capacities upon galvanostatic discharge and charge). The ML techniques are used for predictive classification and regression, based on in house experimental databases, and for the acceleration of the parameterization of the physical-based models within the MSM workflow. The overall approach is developed in the context of the ARTISTIC project [1] and allows performing both direct and inverse design of the optimal manufacturing conditions maximizing given electrode descriptors such as energy and power density. Concrete demonstration examples will be provided on the basis of LIB electrodes made of graphite and Nickel-Manganese-Cobalt active materials, illustrating the strong capabilities of the approach to accelerate the optimization of LIB manufacturing processes.

Calibration of Thermal Spray Microstructure Simulations to Experimental Data Using Bayesian Optimization David Montes de Oca Zapiain, Theron M. Rodgers, Dan S. Bolintineanu, Carianne Martinez, Aaron Olson and Nathan W. Moore; Sandia National Laboratories, United States

Thermal spray deposition is able to generate thick coatings of metals, ceramics and composites materials. This process is inherently stochastic and thus yields coatings that exhibit hierarchically complex internal structures that affect the overall properties of the coating. While, rules-based simulations are able to model the coating process; their accuracy and efficacy are governed by the set of pre-defined rules which are calibrated to specific material and processing conditions to accurately model particle spreading upon deposition. Nevertheless, not all parameters are able to be calibrated to experimental results. We present a protocol that automatically and efficiently determines the parameters that yield the synthetic microstructure with the closest statistics to the experimentally observed coating. This protocol starts by robustly quantifying the microstructure using 2-point

statistics and then representing the statistical quantification in a low-dimensional space using Principal Component Analysis. Subsequently, our protocol leverages a combination of Gaussian Processes Regression and Bayesian Optimization to determine the parameters that yield the minimum distance between synthetic microstructure and the experimental coating in this low-dimensional space in an accurate and computationally-efficient manner.

Machine-Learning the Structural Stability of Intermetallic Phases with Domain Knowledge of the Interatomic Bond Thomas Hammerschmidt; Ruhr University Bochum, Germany

The performance of machine-learning depends critically on the quality of the descriptors. In the case of learning atomic-scale properties, like formation energies obtained from density-functional theory (DFT) calculations, the descriptors are typically based on measures of the atomistic geometry and the distribution of chemical elements. Here, we construct descriptors that additionally include domain knowledge of the interatomic bond from a hierarchy of coarse-grained electronic-structure methods. In particular, we use tight-binding (TB) and analytic bond-order potentials (BOPs) that are derived from a second-order expansion of DFT. We demonstrate that a recursive solution of the TB problem and the closely related moments of the electronic density-of-states at the BOP level establish a smooth relation between the local atomic environment and the formation energy. This first level of domain knowledge of the interatomic bond shows high predictive power in machine-learning applications already with simple, qualitative TB/BOP models. We demonstrate this for the prediction of the formation energy and the band gaps of transparent conductors. As second level of domain knowledge we include the bond chemistry in terms of bond-specific TB Hamiltonians that are obtained from downfolding the DFT eigenspectrum of molecular dimers. As third level of domain knowledge we include the role of the valence electrons by determining approximate non-selfconsistent bond energies with BOP using bond-specific TB Hamiltonians. We demonstrate the application of these descriptors of the second and third level to the prediction of the formation energy of intermetallic phases and discuss their high relative importance as compared to other descriptors.

12:10 PM CT05.12.02
Late News: Machine Learning Potentials for Copper Alloys Angel Diaz Carral[1], Xiang Xu[2], Azade Yazdan Yar[1], Siegfried Schmauder[2] and Maria Fyta[1]; [1]Institute for Computational Physics, University of Stuttgart, Germany; [2]Institut für Materialprüfung, Werkstoffkunde und Festigkeitslehre (IMWF), Germany

Copper based alloys, due to their high electrical conductivity and high strength, are of great importance for electric and electronic applications such as connectors or lead frames. We investigate Cu-Ni-Si-Cr alloys with a different type and concentration of impurities through computational means. Our simulations provide us with structural data and energetics, which are further training Machine Learning (ML) algorithms to build ML

potentials. These will in turn be used in larger scale simulations to design alloys with desired properties. We first provide a methodological approach based on the comparison of different ML descriptors in order to better understand and model the Cu alloys. We discuss the impact of this approach in providing a framework for an optimum design of multicomponent materials, such as alloys.

12:25 PM CT05.12.03
Late News: Investigating Representations of Local Atomic Environments with Topology Optimization
Arindam Debnath and Wesley Reinhart; The Pennsylvania State University, United States

Advances in machine learning (ML) continue to accelerate materials discovery, but key challenges remain in knowledge representation for local atomic environments. State-of-the-art predictive performance can be obtained with many different types of features ranging from hand-crafted and human-interpretable features in the case of models like decision trees to learned features only meaningful to a computer in the case of approaches based on deep neural networks. Hand-crafted features informed by fundamental physics and human intuition often require less training to achieve robust performance, while purely learned features may provide less bias and greater predictive power since the model is free to identify the most salient descriptions of the data. In fact, many models fall in between these two extremes; a prevalent example are the rotation-invariant features which have been utilized to learn force fields for use in classical Molecular Dynamics (MD) simulations from ab initio calculations. While model development for these applications typically focuses on predictive performance, we are interested in the information that can be gleaned from the low-dimensional latent spaces which are learned as a by-product of these ML workflows.

We have recently developed a new representation of local atomic environments which is highly effective when combined with unsupervised manifold learning to embed the local environments of particles observed in classical MD simulations into a low-dimensional latent space. Our unsupervised scheme provides comparable performance to recent supervised methods while requiring only a fraction of the training data. However, this comes at a cost – our representation cannot be directly inverted to sample real-space structures from the latent space. Here we introduce a topology optimization scheme to generate ensembles of local atomic environments from the low-dimensional latent space. Representative samples of our rotation- and permutation-invariant features are drawn from the latent space in regions of interest such as metastable transition states. Then backpropagation is applied to optimize the real-space positions of atoms in the local environment to match the target features. This is similar in spirit to reverse Monte Carlo, except faster convergence can be achieved using gradient descent.

While less efficient for the inverse problem than deterministic, deep-neural-network-based approaches, our sampling scheme incidentally allows us to study the efficacy of different representations of local atomic environment. We investigate different choices of rotation- and permutation-invariant features by attempting to invert the environments observed in colloidal crystallization, ice nucleation, and binary mesophases back to real-space configurations. The results provide valuable information regarding advantages and limitations for different types of features, which should help select better features for predictive models in the future.

12:40 PM CT05.12.04
Late News: Machine Learning Prediction of the Hubbard U for Materials Containing Transition Metals
Casey N. Brock, Anand Chandrasekaran, Yuling An, Shaun Kwak and Mathew Halls; Schrödinger, Inc., United States

Standard approximations to the exchange-correlation functional for density functional theory (DFT) calculations tend to over-delocalize d and f electrons, causing critical systematic errors in predictions of material properties. A standard approach to correcting these errors is applying a Hubbard potential via an additional parameter, U. Often, the value of U is chosen empirically to reproduce measured values of the band gap or other properties. Alternatively, the Hubbard U value can be calculated explicitly using linear response or perturbation theory approaches, but these calculations are tedious and computationally expensive. In this work,

we outline a machine learning (ML) framework for predicting Hubbard U values for inorganic solids containing a single transition metal element. For this purpose, we generate a training set of over 200 periodic structures and the corresponding U values for the constituent transition metal sites based on density functional perturbation theory calculations. We then utilize descriptors for inorganic periodic systems to build ML models to predict Hubbard U values for novel structures outside the training set. The most important set of descriptors for predicting the Hubbard U potential for the examined materials systems are highlighted, with an analysis of outstanding trends and variations of its value across the d-block elements. Finally, we investigate the sensitivity of critical materials properties such as the formation energy and band-gap, to variations in the Hubbard U correction.

12:55 PM CT05.12.05
Automated Training of Many-Body Machine Learned Force Fields Jonathan Vandermause and Boris Kozinsky; Harvard University, United States

Machine learned (ML) force fields have emerged as a powerful tool for performing large-scale molecular dynamics simulations at near-DFT accuracy, but training many-body force fields that are interpretable, efficient, and uncertainty-aware remains an important open challenge. In this talk, we present Bayesian force fields that unite three popular frameworks—the Atomic Cluster Expansion (ACE), Gaussian Approximation Potentials (GAP), and Spectral Neighbor Analysis Potentials (SNAP)—opening the door to scalable, uncertainty-aware molecular dynamics simulations of complex materials. We first show how a multi-species generalization of the N-body ACE descriptor can be used to define a tunable many-body kernel similar to the Smooth Overlap of Atomic Positions kernel used in GAP models. We use this kernel to construct sparse Gaussian process (GP) force fields, and show that uncertainties derived from the predictive posterior distribution of the GP correlate with true model error on independent test sets.

The reliability of these uncertainties is the key feature of our approach that enables FLARE—Fast Learning of Atomistic Rare Events—an adaptive method for training force fields on the fly during molecular dynamics. This automated learning procedure takes an arbitrary structure as input and begins with a call to DFT, which is used to train an initial GP model on the forces acting on an arbitrarily chosen subset of atoms in the structure. The GP then proposes an MD step by predicting the forces on all atoms, at which point a decision is made about whether to accept the predictions of the GP or to perform a DFT calculation. The decision is based on the epistemic uncertainty of each GP force component prediction, which estimates the error of the prediction due to dissimilarity between the atom's environment and the local environments stored in the training set of the GP. In particular, if any uncertainty exceeds a chosen multiple of the current noise uncertainty of the model, a call to DFT is made and the training set is augmented with the forces acting on the highest uncertainty local environments, the precise number of which can be tuned to increase training efficiency. All hyperparameters are optimized whenever a local environment and its force components are added to the training set, allowing the error threshold to adapt to novel environments encountered during the simulation. We show that the final trained GP can be mapped onto an equivalent and much faster linear model resembling SNAP and qSNAP models, which we implement in the molecular dynamics program LAMMPS to scale our ML-driven simulations to tens of thousands of atoms over nanosecond timescales.

Our automated procedure for training fast Bayesian force fields allows a wide range of material compositions to be explored in a closed-loop fashion with minimal human supervision. As a demonstration, we apply our method to the shape memory alloy nitinol, and show that we accurately capture the martensite/austenite phase transition that occurs in this material at ambient pressure. We discuss how model uncertainties can be used to systematically expand the training set, enabling exploration of the effects of dopants, defects, and nonequiatomic compositions on the martensitic transition temperature.

Heterogeneous Sensing and Scientific Machine Learning for Quality Assurance in Laser Powder Bed Fusion Aniruddha Gaikwad[1], Brian Giera[2], Gabe Guss[2], Jean-Baptiste Forien[2], Manyalibo Matthews[2] and Prahalada Rao[1]; [1]University of Nebraska–Lincoln, United States; [2]Lawrence Livermore National Laboratory, United States

Laser Powder Bed Fusion (LPBF) is the predominant metal Additive Manufacturing (AM) technique that benefits from a significant body of academic study and industrial investment. Despite LPBF's widespread use, there still exists a need for process monitoring to ensure reliable part production and reduce post-build quality assessments. Towards this end, we develop and evaluate machine learning-based predictive models using height map derived quality metrics for single tracks and the accompanying pyrometer and high-speed video camera data collected under a wide range of laser power and laser velocity settings. We extract physically intuitive low-level features representative of the meltpool dynamics from these sensing modalities and explore how these vary with the linear energy density. We find our Sequential Decision Analysis Neural Network (SeDANN) model – a scientific machine learning model that incorporates physical process insights – outperforms other purely data-driven black-box models in both accuracy and speed. The general approach to data curation and adaptable nature of SeDANN's scientifically informed architecture should benefit LPBF systems with an evolving suite of sensing modalities and post-build quality measurements.

2:40 PM CT05.13.02
High-Throughput Correlative Microscopy and Spectroscopy for Nano-Laser Development Ruqaiya Al-Abri, Hoyeon Choi and Patrick Parkinson; The University of Manchester, United Kingdom

Single-element monolithic lasers which can be heteroepitaxially grown or heterogeneously integrated onto a silicon platform have been long sought for photonic integrated circuitry, and as nanoscale light sources for research.
A promising solution for integrated coherent light is using semiconductor nanowires produced with III-V[1] or other emerging materials[2]. These structures allow easy hetero-integration onto silicon[3], and they act as both waveguide and gain material, however to date, silicon-integrated, room-temperature and continuous lasing has proven elusive. One key reason for this has been the challenge of repeatable characterisation – a small variation in the geometry or material properties (such as doping) of each nanowire can have an amplified effect on lasing due to the inherent non-linearity of this process, masking systematic properties of this system. In other words, ensemble measurements are meaningless, while single nanowire measurements are insufficient in the presence of heterogeneity.
High-throughput imaging and spectroscopy can be used to provide geometrical, material and functional measurements of large numbers of single nanowire lasers. By studying 100 to 100,000 nanowire lasers from each growth, we correlate performance metrics such as threshold or lasing wavelength with controllable characteristics such as wire length, diameter, doping or transfer process. Using this methodology we have demonstrated material optimization for high quantum efficiency via doping[4], cavity analysis using time-resolved interferometry[5,6], and statistical improvements in fabrication[7] processes. Each study has enabled record low optically pumped thresholds for III-V nanolasers towards room-temperature continuous lasing, and by integrating pick-and-place techniques[8], we have demonstrated a combined high-throughput analysis and fabrication platform.
Our methodology – big-data for nano-optoelectronics – makes use of a high-speed data acquisition platform to generate large amounts of single-element data. We correlate electron microscopy, optical microscopy, spectroscopy and functional measurements on each wire through a self-registration process[9] and stream this data

to a commodity database. This data can be analysed through a MATLAB or Python package, maximising the potential for data reuse. We demonstrate this approach for two applications: optimization of single perovskite nanowire laser, and for an intra-material study of end-facet reflectivity. This methodology is widely transferable to other material systems where single-element correlative study is essential to separate underlying physical processes from high levels of inter-object heterogeneity.

2:55 PM CT05.13.03
Implementation of Benchtop NMR as an Online, High-Throughput Sensor in Automated Synthesis Systems Anh Le-McClain; Magritek Inc., United States

The recent development of the high-performance benchtop Nuclear Magnetic Resonance (NMR) spectrometers equipped with high-resolution permanent magnets and flow cells enables a new way to do on-line/in-line monitoring of chemical reactions. Monitoring reactions with NMR provides not only the structural information about different chemical species generated during chemical reactions, but also their quantitative measurements (without the need of a calibration curve) to obtain the reaction's kinetics. Benchtop NMR with reaction monitoring capability can be conveniently incorporated as an online, high-throughput sensor in automated synthesis systems working with artificial intelligence (AI). This presentation will highlight the implementation of benchtop NMR in monitoring chemical reactions, as well as serving as a sensor for an organic synthesis robot using a convolutional neural network.

3:10 PM CT05.13.04
High-Throughput and Data-Driven Strategies for the Design of Deep Eutectic Solvent Electrolytes Jaime Rodriguez, Maria Politi and Lilo D. Pozzo; University of Washington, United States

Within the framework of green chemistry, Deep Eutectic Solvents (DES) have been identified as promising candidates for use in many applications, including battery electrolytes. DES are characterized by two or three materials that associate with each other through hydrogen bond interactions, resulting in a eutectic mixture whose freezing point is below that of the individual materials. This design space is overwhelmingly large and poses a challenge for screening a vast and diverse set of materials. Here we present a strategic approach consisting of high throughput experimentation (HTE) coupled with data science driven analysis to identify exceptional DES candidates based on key physiochemical and electrochemical properties. Much of our HTE adopts methods that are already used frequently in the biotech and pharmaceutical industries, most notably performing parallel syntheses and analyses in 96-well-plate formats. DES samples are first synthesized using an open-sourced automated liquid handling robot. DES melting points are then determined by monitoring the melting process with an infrared camera and identifying the temperature at which the thermal conductivity of the samples changes abruptly. The solubility of battery redox-species is determined via UV-VIS well-spectrophotometers. Finally, the electrochemical stability window and cycling properties of DES electrolytes are measured in high-throughput by using screen-printed electrodes on 96-well plates adapted for use with a standard potentiostat. The ability to rapidly and efficiently collect data also creates a need for the development and use of automated processes for data analysis, which have been developed in an open-sourced format by our group. This approach to HTE also allows for the incorporation of data science techniques, such as feature extraction and machine learning, that further aid in probing a design space that is ultimately too large for

experimental methods alone.

3:25 PM CT05.13.05
Machine Learning Modeling of Photodiode Signal for Selection of Laser Parameters in Laser Powder Bed Fusion Additive Manufacturing Simon Lapointe, Clara Druzgalski, Gabe Guss and Manyalibo Matthews; Lawrence Livermore National Laboratory, United States

Parts produced through metal additive manufacturing suffer from irregular quality, often exhibiting dimensional inaccuracies and defects such as cracks, pores, underfill, spatter, and balling. The development of approaches to control and optimize the additive manufacturing process are essential to improve part quality. Process parameters such as the laser power, velocity, beam size, and scan path should be optimized throughout the manufacturing process. However, incorporating the combined effects of material, geometry, and complex underlying physics into the optimization strategy can be particularly challenging. In this work, a data-driven approach for the selection of laser process parameters is proposed. Stainless steel parts of different shapes and sizes are printed with varying laser power and velocity strategies while collecting photodiode signal data. Using machine learning, a forward model is built to predict the track-wise photodiode signal along the scan path using laser parameters and geometry features as inputs. This model helps understand and quantify how the photodiode signal is influenced by the laser process parameters (laser power and velocity) and the part geometry (dimensions, overhangs, corners, etc.). Additionally, an inverse model is built to predict the laser parameters corresponding to a given track-wise photodiode signal and geometry features. The inverse model allows the selection of laser parameters to maintain a desired photodiode signal. The performance of the inverse model is assessed by deploying it on a test part which geometry differs from the parts used for training.

Late News: High-Throughput Reaction Screening for Accelerated Materials Research Thomas Mustard; Schrodinger, United States

All specialty chemicals and advanced materials are produced from lower value feedstock or precursors by specialized chemical reactions. Empirical reaction tuning is a laborious and expensive process. In contrast, reliable and efficient first-principles workflows can be employed in a high-throughput fashion to survey chemical design space and inform experimental development. Systematic evaluation of steric and electronic contributions provides an unprecedented fundamental understanding of factors controlling a target reaction. With these structure-property relationships, one can re-design a reaction or catalyst to achieve desired activity. Paired with automated high throughput screening the rate of discovery and understanding is accelerated.
- Reaction/Catalysts activity and selectivity predictions from simulations
- High-Throughput automated methods for in silico reaction screening
- Examples in areas of hydroformylation, epoxy-amine thermosets

Unique Challenges on NNP Development and Ways to Overcome Them Wonseok Jeong, Sungwoo Kang, Changho Hong, Jeong Min Choi and Seungwu Han; Seoul National University, Korea (the Republic of)

Recently, machine-learning (ML) approaches to developing interatomic potentials are attracting considerable attention because it is poised to overcome the major shortcoming inherent to the classical potential and density functional theory (DFT), i.e., difficulty in potential development and huge computational cost, respectively. In particular, the high-dimensional neural network potential (NNP) suggested by Behler and Parrinello is attracting wide interests with applications demonstrated over various materials. However, as ML potentials have a fundamental difference from traditional physics-based force fields, they have unique challenges to overcome for reliable accuracy. In this presentation, we share some of the challenges and our experiences in overcoming them with detailed examples.
First, we discuss the challenge of modeling defective systems. We found that to model defective systems with high accuracy, the sampling bias must be treated with care. Next, we show that when modeling dynamic systems with a large number of chemical reactions, the uncertainty estimation in atomic-resolution is necessary. The efficient uncertainty estimation in atomic-resolution can be obtained through a replica NNP ensemble. Furthermore, we will show that NNPs can be used as highly accurate surrogate models in exploring large space of crystal structures. This enables finding the stable crystal structure for complicated multicomponent systems. Finally, we discuss some of the future challenges in NNP development, and possible solutions to the challenges.

Late News: Analysis on the Strengthening Mechanism of Aluminum Alloys with Bayesian Learning for Neural Networks Shimpei Takemoto[1], Kenji Nagata[2], Takeshi Kaneshita[1], Yoshishige Okuno[1], Junya Inoue[3] and Manabu Enoki[3]; [1]Showa Denko K.K., Japan; [2]National Institute for Materials Science, Japan; [3]The University of Tokyo, Japan

We discuss the strengthening mechanism of 2000 series aluminum alloy using neural networks. To understand the process-structure-property relationship in aluminum alloys, we have constructed a linear neural network with a single hidden layer whose input, hidden, and output layer nodes correspond to process parameters, structure features, and mechanical properties, respectively. We have applied the replica-exchange Monte Carlo method, an extended Markov chain Monte Carlo (MCMC) method, for the Bayesian inference of the optimal neural network architecture. When predicting ultimate tensile strength and tensile yield strength simultaneously, the Bayesian inference suggests that the neural network with two hidden layer nodes is optimal. This approach enables us to identify dominant combinations of additive elements and heat treatments for strengthening aluminum alloys. We have also conducted thermodynamic calculations of the equilibrium phase fraction using the Thermo-Calc software for each of the hidden layer nodes to discuss the strengthening mechanism of aluminum alloys.

Accurate Band-Gap Database for Semiconducting Inorganic Materials—Implementation of Hybrid Functional Sangtae Kim[1], Miso Lee[1], Changho Hong[1], Youngchae Yoon[1], Hyungmin An[1], Dongheon Lee[1], Wonseok Jeong[1], Dongsun Yoo[1], Youngho Kang[2], Yong Youn[1] and Seungwu Han[1]; [1]Seoul National University, Korea (the Republic of); [2]Incheon National University, Korea (the Republic of)

Among the various physical properties of materials, one of the fundamental characteristics of materials is band gap (E_g). The E_g of material provides a detailed description of the material's optoelectronic, optical, thermoelectric, and electronic properties, and is a good indicator in distinguishing materials (conductors, semiconductors, and insulators). In particular, semiconductors are used in various fields because of the unique characteristics of materials. For instance, in photovoltaic devices, materials with a direct E_g of ~1.3 eV, corresponding to the Shockley-Queisser limit, are favored as photo-absorbers that maximize the solar-cell efficiency. In power electronics, semiconductors with $E_g \geq 3$ eV are employed to sustain high electric fields. Currently, there are several inorganic material databases providing band gaps based on the Generalized Gradient Approximation (GGA) functional, including Materials Project, the Automatic Flow of Materials Discovery Library (AFLOWLIB), the Open Quantum Materials Database (OQMD), and the Joint Automated Repository for Various Integrated Simulations (JARVIS) (the JARVIS provides E_g based on meta-GGA, which significantly improves the accuracy). In spite of the importance of the band gap, however, calculated band gaps

are underestimated due to the limitation of the conventional density functional theory (DFT) scheme. As a related issue, many small-gap semiconductors such as Ge, InAs, PdO, Zn_3As_2, and Ag_2O, are misclassified as metals, which can affect selection of narrow-gap semiconductors in IR sensors, for instance. (In JARVIS, some of these errors are resolved by meta-GGA). In addition, the material containing un-filled d-bands shows an incorrect band gap because magnetics involved in spin configuration affect band splitting. For instance, the antiferromagnetic NiO has an experimental E_g of 4.3 eV, but the computational E_g ranges over 2.2-2.6 eV in the ferromagnetic ordering and GGA functional while the correct antiferromagnetic ordering produces 4.5 eV within the hybrid functional.
In this study, we construct an accurate bandgap database using Automated *Ab initio* Modeling of Materials Property Package (AMP^2), which is a fully automated package for DFT calculations. The AMP^2 has an exclusive algorithm to correct the band gap more accurately: Density of state (DOS) Indicator and 'One-shot' hybrid calculation. In order to consider the magnetic properties of spin ordering, the Ising model was also introduced to improve the accuracy of the E_g. The Ising model simply describes the magnetic exchange energy from the spin pair and exchange parameters. We newly devised a method to calculate the exchange parameter through the fitting method and optimize that. The database consists of 10,481 materials that encompass most inorganic solids with E_g ranging between 0 and 5 eV. To verify our database, we compared it with the experimental band gap dataset and magnetic structure database (MAGNDATA). Through 116 benchmark materials for band gap, the root-mean-square error (RMSE) with respect to experimental data is 0.36 eV, significantly smaller than 0.75-1.05 eV in the existing databases. The resulting data are available online at SNUMAT.

Developing Machine-Learning Potentials from Disordered Structures for Crystal Structure Prediction
Changho Hong[1], Jeong Min Choi[1], Wonseok Jeong[1], Sungwoo Kang[1], Suyeon Ju[1], Kyeongpung Lee[1], Jisu Jung[1], Yong Youn[2] and Seungwu Han[1]; [1]Seoul National University, Korea (the Republic of); [2]National Institute for Materials Science, Japan

Crystal structure prediction (CSP) is a problem of finding a structure with global-minimum free energy. It can be broken down into two problems: a searching algorithm in configuration space of structures and a method of evaluating free energy. Various heuristic algorithms such as genetic algorithms have been developed for efficient search. First-principles calculation based on density functional theory (DFT) has been chosen as its non-empirical nature allows accurate evaluation of energies. The DFT-based CSP has been successful in identifying inorganic crystals under extreme conditions and organic crystals. One interesting field to apply CSP is structure prediction of ternary or higher (simply multinary hereafter) inorganic crystals at ambient conditions. CSP can accelerate the low throughput of experimental synthesis. Considering major technological breakthroughs in display and battery industries have been achieved from new materials such as $InGaZnO_4$ and $Li_{10}GeP_2S_{12}$, more rapid discovery of novel materials is very important. However, multinary materials have a momentous increase of atomic arrangements where permutation of different species becomes an important factor. This demands much more efficient methods of evaluating free energy than DFT. Recently, machine-learning potentials such as neural network potential (NNP) draw much attention for its accuracy of DFT and yet much faster speed. But absence of information on structures imposes a big hurdle to constructing training sets. To deal with this impediment, we propose a way to build NNP as a robust surrogate model of DFT for predicting the most stable structure of multinary compounds at ambient conditions. The central approach is to train an MLP over disordered structures such as liquid and amorphous phases. The molecular dynamics (MD) simulation of liquid phase can start from a random distribution and reach equilibrium quickly at high temperature. Then, the liquid phase is quenched to an amorphous phase. This makes it possible to forge training sets without any knowledge of unknown crystals except for the chemical composition. The short-range order in disordered phases resemble that of crystalline phases and local fluctuations during MD can also sample diverse local environments. To demonstrate accuracy of NNP, we compare NNP and DFT energies for Ba_2AgSi_3, Mg_2SiO_4, $LiAlCl_4$, and $InTe_2O_5F$ over experimental phases as well as low-energy crystal structures that are generated theoretically. For every material, we find strong correlations between DFT and NNP energies, ensuring that the NNPs can identify the most stable structures and properly rank low-energy crystalline

structures. We also find that the evolutionary search combined with NNPs can evaluate low-energy metastable phases more efficiently than one with DFT. With this proposed way to training reliable machine-learning potentials for the crystal structure prediction, this research offers efficient method to search uncharted multinary phases.

Efficient Sampling for Training Set of Machine Learning Potentials Using Metadynamics Dongsun Yoo, Jisu Jung, Wonseok Jeong and Seungwu Han; Seoul National University, Korea (the Republic of)

Machine learning potentials (MLPs) are attracting enormous interests as a promising computational tool, which provides the accuracy of quantum mechanical calculations with the speed of classical interatomic potential. MLPs have extended their application to the complex system, including phase-change materials, nanoclusters, and catalysts. We have to make the training set cover diverse configurations, which can appear during the simulation, to get reliable simulation because MLPs can guarantee certainty only within the training set. The training set is made from a specific target static structure or DFT-based molecular dynamics (MD) simulations typically. However, such a manual sampling requires expertise in the target system and iterative trial-and-error data augmentation with enormous computation time.
Therefore, we suggest a metadynamics that uses the local environment of an atom, which is the input vector of MLPs, as collective variables. These collective variables keep the system from revisiting the symmetrically identical structure. We can sample a wide range of configurations autonomously where just high-temperature MD cannot visit. We demonstrate the metadynamics with a Pt surface with hydrogen, followed by an application on the GeTe system.

Koopmans Spectral Functionals: Charged Excitations from Functional Theories Nicola Marzari; École Polytechnique Fédérale de Lausanne, Switzerland

I will discuss the theory and practice of Koopmans spectral functionals, aiming to reproduce total energies and spectra of molecules and materials with functional formulations. A comparison many-body perturbation theory is provided for ionization potentials and electron affinities of molecules and band structures of solids, showing an agrement with experiments comparable to the current state-of-the-art, and at a fraction of the computational costs. I will illustrate also the implementation in open-source periodic-boundary condition codes. Work done in collaboration with Nicola Colonna, Riccardo de Gennario, Edward Linscott, Linh Nguyen, and Andrea Ferretti.

8:24 AM *CT06.01.02
The Connector Theory Approach—Principles and Development of Functionals Ayoub Aouina[1], Marco Vanzini[2], Matteo Gatti[3,1] and Lucia Reining[3,1]; [1]Institut Polytechnique de Paris, France; [2]EPFL, Switzerland; [3]CNRS, France

One important approach for the description of quantum many-body systems is to design functionals: observables or effective potentials are expressed in terms of relatively simple quantities, such as the density or a one-body Green's function, instead of calculating expectation values with many-body wavefunctions. However, although efficient approximations for such functionals exist for some important observables, such as the total energy, they still lack precision for many applications, and other observables cannot be accessed in a satisfactory way. For example, Density Functional Theory (DFT) and Time-Dependent (TD) DFT still face major difficulties to describe strongly correlated systems, or excitonic effects in optical spectra. For other observables, even less is known about how to build good density functionals.
One way of designing approximations is to use results of model systems. In this talk we will show how model results can be used in an in principle exact way, called "Connector Theory", in order to describe observables and systems of interest. Within this approach, a quantity of interest is calculated for a model system as function of a parameter once and forever, and the results are stored. Under certain conditions, the result for an appropriate choice of parameter can then be used to replace a value of interest in a given real system. This choice of parameter is called "connector".
We will discuss the principles and general properties of such an approach. Of course, in practice, the connector has to be approximated. We will show that formulating the problem in this way is a convenient starting point for approximations, and a strategy to build systematic approximations will be presented. Some discussion and results can be found in [1,2].

High-Throughput Computation of Raman- and Second Harmonics Optical Spectra for Automated Characterization of 2D Materials Kristian S. Thygesen; Technical University of Denmark, Denmark

Raman spectroscopy is frequently used to identify composition, structure and layer thickness of 2D materials. Here, we describe an efficient first-principles workflow for calculating resonant first-order Raman spectra of solids within third-order perturbation theory employing a localized atomic orbital basis set. The method is used to obtain the Raman spectra of around 1000 different monolayers selected from the Computational 2D Materials Database (C2DB)[1]. On basis of this database, we propose an automatic procedure for identifying a material based on an input experimental Raman spectrum and demonstrate it for the cases of MoS_2 (H-phase) and WTe_2 (T″-phase)[2]. Employing a similar computational methodology, we calculated nonlinear optical (NLO) spectra of about 400 non-centrosymmetric semiconducting monolayers. NLO phenomena such as harmonic generation, Kerr, and Pockels effects are of great technological importance for lasers, frequency converters, modulators, switches, etc. Recently, 2D materials have drawn significant attention due to their strong and unique NLO

properties. Sorting the non-resonant nonlinearities of the monolayers with respect to bandgap E_gap reveals an upper limit proportional to E_gap^-4, which is neatly explained by a generic two-band model. We identify multiple promising candidates with giant nonlinearities and band gaps ranging from 0.4 to 5 eV, some of which approach the theoretical upper limit and greatly outperform known materials[3].
The comprehensive libraries of ab initio Raman and NLO spectra are freely available via the C2DB website(https://cmrdb.fysik.dtu.dk/c2db/).

Partial Order-Disorder Transition in Thermoelectric Clathrates Revealed by a Novel Approach for Temperature-Dependent Properties of Alloys
Claudia Draxl[1], Maria Troppenz[1], Santiago Rigamonti[1] and Jorge O. Sofo[2]; [1]Humboldt-Universität zu Berlin, Germany; [2]The Pennsylvania State University, United States

Intermetallic clathrate compounds have a huge compositional and configurational space that allows for tailoring their properties towards a high thermoelectric efficiency. Semiconducting behavior is often difficult to achieve due to the intricate interplay between electronic structure, temperature, and disorder. For instance, in the complex clathrate compound $Ba_8Al_xSi_{46-x}$, the configuration of the Al atoms in the crystal framework drastically affects the electronic behavior [1]. This is most strikingly the case at the technologically relevant composition × = 16, whose ordered ground state is semiconducting, while disordered structures at higher energies are metallic. We have developed a multi-scale approach, based on statistical thermodynamics combined with the cluster-expansion method [2] and *ab initio* calculations which allows us to calculate the temperature-dependent effective band structure of alloys without relying on effective medium approximations [3]. With its help, we discover a semiconductor-to-metal transition that is accompanied by an order-disorder phase transition at 582 K.

Quantum Simulations of Heterogeneous Materials on Classical and Near-Term Quantum Computers
Giulia Galli; The University of Chicago, United States

In this talk I will present strategies to predict and design materials for next generation technologies by combining theories based on quantum mechanics, and algorithms and codes running on high performance classical computers, and, in some cases, on near-term quantum computers. I will specifically focus on predicting and designing materials to build radically novel sensors and computers, so as to move in earnest into the quantum information age.

10:30 AM *CT06.02.01
Electronic and Optical Excitations from Screened Range-Separated Hybrid Density Functional Theory
Leeor Kronik; Weizmann Institute of Science, Israel

The concept of optimal tuning (OT) of range-separated hybrid (RSH) functionals has become an important tool for overcoming the fundamental gap problem and the charge transfer excitation problem in molecular systems. Here, this concept is extended to the solid state by introducing dielectric screening and orbital localization into the functional form. This approach, couched rigorously within the generalized Kohn-Sham formalism of density functional theory, can produce quantitatively the same one and two quasi-particle excitation picture given by many-body perturbation theory (MBPT), without any empiricism. Specifically, for covalent/ionic semiconductors and insulators, accurate band structures and optical absorption spectra, which agree well with those obtained from MBPT, are obtained. For molecular solids, the approach predicts the correct gap renormalization - even from single molecule calculations if a polarizable continuum model is used in an electrostatically consistent manner – and also predicts absorption spectra well.

Room Temperature Superfluorescence from a Single Nanocuboid John P. Philbin[1], Joseph Kelly[2], Lintao Peng[3], Igor Coropceanu[4], Dmitri V. Talapin[4,3], Eran Rabani[5,6,7], Xuedan Ma[3] and Prineha Narang[1]; [1]Harvard University, United States; [2]Stanford University, United States; [3]Argonne National Laboratory, United States; [4]The University of Chicago, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]Tel Aviv University, Israel; [7]University of California, Berkeley, United States

Single-photon superradiance arises when a collection of identical emitters are spatially separated by distances much less than the wavelength of the light they emit and results in the formation of a superradiant state that spontaneously emits light with a rate that scales linearly with the number of emitters. This collective phenomena has only been demonstrated in a few nanomaterial systems, none of which have used quasi-2D nanoplatelets as the emitter. In this work, we rationally design a single colloidal nanomaterial that hosts multiple (nearly) identical emitters. Specifically, by combining molecular dynamics, atomistic electronic structure calculations, and model Hamiltonians methods, we show that quasi-2D nanoplatelets oriented along each face of a “nanocuboid” can serve as the (nearly) identical emitters required to observe both superradiant and subradiant phenomena. Utilizing layer by layer growth techniques to synthesize a nanocuboid, we demonstrate single-photon superfluorescence via single-particle time-resolved photoluminescence measurements at room temperature. The realization of superradiant and subradiant states in these single nanocuboids opens the door to ultrafast single-photon emitters and may provide an avenue to entangled multi-photon states via superradiant cascades.

This work is partially supported by the Army Research Office MURI (Ab-Initio Solid-State Quantum Materials) under Grant No. W911NF-18-1-0431. JP is a Ziff Fellow at the Harvard University Center for the Environment.

11:10 AM CT06.02.03
Symmetry Adapted Real Space Density Functional Theory for Helical Nanostructures—Application to Torsional Deformations in Group-IV Nanotubes Hsuan M. Yu and Amartya S. Banerjee; University of California, Los Angeles, United States

The mathematical framework for classifying nanostructures shows that a vast class of such materials can be described as being *helical*, i.e., their spatial atomic arrangement possesses helical symmetries. Helical nanostructures include important technological materials such as nanotubes, nanowires, nanoribbons and nanosprings; miscellaneous chiral structures encountered in chemistry; and examples from biology, including tail sheaths of viruses and many common proteins. Helical nanostructures have received much attention recently due to their unusual and interesting material properties, including e.g., their strong association with

ferromagnetism, ferroelectricity and superconductivity, unique transport characteristics, and the existence of strong coupling between their mechanical and optical/transport properties.

Given the relative abundance of helical nanostructures and their scientific and technological importance, there is a pressing need to have reliable and efficient computational tools for studying such structures. In this work, we will describe the formulation and implementation of a first principles simulation tool for helical nanostructures based on a symmetry adapted real space formulation of Kohn-Sham Density Functional Theory. Specifically, the computational method employs a finite difference discretization of the governing equations in so called *helical coordinates*, and handles symmetries arising from common helical groups by using an appropriate version of the Bloch theorem for such systems. This combination of features of the method allows one to simulate for example, the behavior of nanotubes of arbitrary chirality *ab initio*.

We utilize the newly developed computational tool to carry out a first principles study of various nanotubes. In particular, we will describe the behavior of group IV nanotubes under twisting deformations as revealed by our simulations. We will describe interpretation of some of the mechanical properties of these tubes, computed *ab initio*, from the perspective of elasticity theory. We will also highlight the interplay between mechanical strains and electronic states in these materials and comment on the effects of structural relaxation.

11:25 AM *CT06.02.04
Stochastic Many-Body Methods for Quasiparticle Excitations in Nanoscale Systems Vojtech Vlcek; University of California, Santa Barbara, United States

I will present recent developments in predicting electronic excitations using the combination of stochastic computational techniques and many-body theory. The methodology relies on operators' decomposition via random vectors and recasting expectation values as statistical estimators. In practice, the implementation of diagrammatic methods employs real-time and real-space sampling.[1] This formalism leads to substantial computational savings and reduced scaling with the number of electrons; it enables first-principles predictions of quasiparticle energies in systems with thousands of atoms. In detail, I will describe our recent work on simulating nanoscale condensed systems within the linear scaling stochastic GW approximation.[2,3,4] Further, I will show that statistical sampling of interactions is an efficient route to go beyond GW: I will detail our work on the stochastic GWΓ approach, which combines non-local vertex corrections in the screened Coulomb interaction and self-energy.[5] I will demonstrate that the vertex corrections affect unoccupied states, improve the quasiparticle energies, and capture multi-quasiparticle excitations otherwise missing in GW.[5,6] Despite the increased complexity of the self-energy, the stochastic GWΓ scales linearly with the system size.

Improving Stochastic Green's Function Methods for Localized States in Low-Dimensional Heterostructures Mariya Romanova and Vojtech Vlcek; University of California, Santa Barbara, United States

First, we will present a new embedding approach [1] in the stochastic GW technique [2-4] that enables efficient treatment of the impurity states with high accuracy and minimal effort. The method is based on a partitioning of the Green's function and screened Coulomb potential into the deterministic subspace (usually containing localized states) and the stochastic subspace (the rest of the Hilbert space). The enhanced stochastic-deterministic sampling minimizes statistical errors in energies of localized quasiparticles.
Further, we will present a new technique for the stochastic decomposition of the many-body interactions into

additive subspace contributions. We partition the Hilbert space and compute the polarization self-energy via sampling selected charge density fluctuations in real space and time. The decomposition accounts for quasiparticle scattering by correlations from a particular subspace. We identify couplings among different areas (spatial or energetic), e.g., screening contributions in quantum interfaces.
We exemplify our approaches on N-vacancy defects in pristine monolayer and an hBN - graphene bilayer (> 2,000 electrons). We demonstrate the new hybrid stochastic-deterministic approach reduces statistical errors and leads to more than an order of magnitude savings in computational time. The computed subspace self-energy unveils how interfacial couplings affect electronic correlations and identifies contributions to excited-state lifetimes. While the embedding is necessary for the proper treatment of impurity states, the decomposition yields new physical insight into quantum phenomena in heterogeneous
systems.

Late News: Electronic Structure of Mixed-Dimensional Metallophthalocyanine-MoS2 Heterojunctions from Screened Range-Separated Hybrid Functionals Qunfei Zhou[1,2], Zhenfei Liu[3], Tobin Marks[1] and Pierre Darancet[2]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States; [3]Wayne State University, United States

Mixed-dimensional heterojunctions (MDHJ) comprised of 0D molecules deposited on 2D materials are actively being explored for opto-electronic applications. As a result of the extreme heterogeneity in the density of states and dielectric screening of these systems, properties of MDHJs are impacted by numerous distinct and competing energy scales, including local and non-local electronic correlations, interfacial dipole and orbital hybridization, which complicates theoretical description of MDHJs accurately. Here we analyze the electronic structure of 0D-2D (metallophthalocyanines-MoS_2) heterojunctions using multi-objective optimization of range-separated hybrid functionals that incorporates screened exact exchange for asymptotically-correct Coulomb potential. We obtain electronic structures consistent with experimental photoemission results in both energy level alignment and electronic band gaps, representing a significant advance compare to standard DFT methods. We elucidate MoS_2 valence resonance with the transition-metal phthalocyanine non-frontier 3*d* orbitals and how they contribute to emergent interfacial properties. This resonance is also highly dependent on the transition metal identity, enabling controlled tunability of the 0D/2D MDHJs. Based on our calculations, we derive parameter-free, model self-energy corrections to semi-local density functional theory for mixed-dimensional heterojunctions at different dielectric environment in an efficient way. In a broader context, these results illustrate how theory can impact the design and realization of precisely tailored mixed dimensional heterojunctions for specific opto-electronic functions.

1:00 PM *CT06.03.01
Subspace Embedding and Downfolding Techniques for the Bethe Salpeter Equation Diana Qiu; Yale University, United States

Ab initio many-body perturbation theory methods, like GW and GW plus Bethe Salpeter Equation (GW-BSE), are well-established and highly-accurate techniques for calculating the quasiparticle and optical properties of moderate-sized systems. There remain, however, a number of challenges when it comes to scaling up these techniques to address systems with a large number of heterogeneous atoms, various forms of aperiodicity, and large energy scales well-outside the optical regime. In this talk, I will discuss our newly developed subspace embedding and downfolding techniques for GW-BSE calculations on low-dimensional and amorphous systems that exemplify these challenges. In particular, we apply GW-BSE to study optical properties of heterostructures of quasi two dimensional (quasi-2D) materials, as well as the effect of electron-hole interactions on core-level spectra of quasi-2D materials and amorphous water, including dynamic effects due to scattering to the electron-hole continuum. The calculations are made possible through a combination of physically motivated approximations and algorithms, including non-uniform spatial sampling, low-rank approximations, and subspace embedding and matrix downfolding techniques. We find that electron-hole interactions play an essential role in the scattering of core-level excitations with excitations from the valence band.

1:25 PM CT06.03.02
Enabling Linear Scaling Exact Exchange for Heterogeneous Systems Hsin-Yu Ko[1], Zachary M. Sparrow[1], Marcos F. Calegari Andrade[2], Owen L. Crane[1], Brian G. Ernst[1], Peace Kotamnives[1], Yan Yang[1], Yang Yang[1], Eric G. Fuemmeler[1] and Robert DiStasio[1]; [1]Cornell University, United States; [2]Princeton University, United States

Hybrid functionals reduce the self-interaction error in semi-local density functional theory (DFT) and provide a semi-quantitative description of the electronic structure in systems throughout chemistry, physics, and materials science. However, the high computational cost associated with evaluating the exact exchange (EXX) interaction limits hybrid DFT from treating large-scale condensed-phase systems. To address this challenge, we have developed a linear-scaling real-space approach that exploits the sparsity in the EXX interaction using local orbitals (MLWFs). The resulting massively parallel algorithm (*exx*) provides an accurate evaluation of all EXX quantities and enables hybrid DFT based *ab initio* molecular dynamics (AIMD) of large-scale finite-gap systems with a wall time cost comparable to semi-local DFT [1]. Since *exx* was optimized to treat *homogeneous* systems, its performance degrades when treating highly anisotropic *heterogeneous* systems with multiple phases and/or components. In this work, we discuss three major theoretical and algorithmic advances that enable efficient and accurate hybrid DFT based AIMD of large-scale heterogeneous systems, and showcase the extended *exx* module when treating a complex solid-liquid interface.

1:40 PM CT06.03.03
Molecular to Mesoscopic Design of Novel Plasmonic Materials—Combining First-Principles Approach with Electromagnetic Modelling Alireza Shabani[1], Mehdi Khazaei Nezhad[2], Neda Rahmani[1], Yogendra K. Mishra[1], Biplab Sanyal[3] and Jost Adam[1]; [1]University of Southern Denmark, Denmark; [2]Ferdowsi University of Mashhad, Iran (the Islamic Republic of); [3]Uppsala University, Sweden

To date, due to the rapid progress in science and technology, the efforts for reaching new plasmonic materials are extensively growing. Although the most often used noble metals, such as Au and Ag, demonstrate a strong optical response in plasmonics and metamaterials, some of their inherent features make them less suitable for real-world applications. In this work, we aim to seek new alternative plasmonic materials by proposing a novel and reliable method via manipulating the characteristic response of candidate compounds such as Al/Ga doped Zinc Oxide (A/GZO), ZrN, TiN and Silicon allotropes. This method merges two powerful computational

approaches, namely, density functional theory (DFT) and electromagnetic (EM) simulations by the finite-element method (FEM) and more rigorous methods (e.g. TMM, RCWA). We first perform a series of DFT calculations, including the structural relaxation of plasmonic material candidates, to find the crystal structure with minimum energy, for different exchange-correlation functionals such as GGA, LDA. In a second step, we analyse the simulated material's electronic and optical properties to illustrate potential metallic behaviour, from the viewpoint of material science, via electronic density of states (DOS), band structure and optical dispersion functions (real and imaginary parts). To evaluate the found material's performance in a semi-real plasmonic system, we subsequently extract the optical dispersion parameters, such as refractive index data as well as Drude-Lorentz parameters of complex dielectric permittivity from our calculated DFT. We finally feed the generated optical dispersion data into an EM-solver for optical simulations of any desired optical system and investigate its efficiency for suitability in plasmonic applications. Our method comprises the possibility for verification with experimental data on each level. From there on, we can optimize digitally the molecular structure, paving the way to predict the proposed compounds' plasmonic functionality, overcoming the persistent hurdles introduced by pure experimental works.

Embedded Cluster Density Approximation for Performing High-Level Density Functional Theory Calculations in Large Systems Chen Huang; Florida State University, United States

We have developed the embedded cluster density approximation (ECDA) for scaling up high-level Kohn-Sham density functional theory (KS-DFT) calculations in large systems. ECDA is a local correlation method formulated in the framework of KS-DFT. In ECDA, a cluster is defined for each atom based on the density embedding theory. The cluster's exchange-correlation (XC) energy density is then calculated using advanced, orbital-based XC functionals. The system's XC energy is obtained by patching clusters' XC energy densities in an atom-by-atom manner. We have derived an efficient way to calculate the system's XC potential, making ECDA fully self-consistent and suitable for studying charge reorganization in heterogeneous materials. ECDA is a variational method, and analytical forces have also been derived. Numerical examples show that ECDA can be applied to various systems that have different bond types, which makes ECDA a nearly black-box method.

Uncovering Electron Scattering in Goniopolar Materials from First Principles Yaxian Wang and Prineha Narang; Harvard University, United States

Electron scattering on a non-trivial Fermi surface topology plays an important role in electron transport, thus giving rise to exotic phenomena such as violation of Wiedemann Franz law, hydrodynamic electron flow, unusual phonon decay etc. Recent experimental discoveries in axis-dependent conduction polarity, or goniopolarity, have observed that the charge carriers can conduct like either electrons or holes depending on the crystallographic direction they travel along in layered compounds such as NaSn2As2 and PdCoO2, the latter of which also features hydrodynamic electron flow. In this talk, we present an ab initio study of electron scattering in such systems. Taking NaSn2As2 as an example, we study different microscopic scattering mechanisms from ab initio and present the electron-phonon scattering time distribution on its Fermi surface in momentum space, the anisotropy of which is proposed to be the origin of the axis-dependent conduction polarity. Further, we obtain the overall anisotropic lifetime tensors in real space at different electron chemical potentials and temperatures and discuss how they contribute to the macroscopic thermopower. While we find that the contribution of the in-plane and cross plane lifetimes exhibits a similar trend, the concave portion of the Fermi surface alters the electron motion significantly in the presence of a magnetic field, thus flipping the conduction polarity as measured via the Hall effect. Our calculations and analysis of NaSn2As2 also suggests the strong possibility of hydrodynamic electron flow in the system. These results together have implications for electron lifetimes in a broad class of new quantum materials and provide key, general insights into electron scattering on open Fermi surfaces.

Electron Hydrodynamics—Microscopic Origins and Effects of Macroscale Geometries George Varnavides[1], Adam S. Jermyn[2], Yaxian Wang[3], Uri Vool[3], Assaf Hamo[3], Amir Yacoby[3], Polina Anikeeva[1] and Prineha Narang[3]; [1]Massachusetts Institute of Technology, United States; [2]Flatiron Institute, United States; [3]Harvard University, United States

Electrons in condensed matter can flow collectively when their momentum is on-average conserved during microscopic scattering processes. This 'hydrodynamic' regime has been observed in graphene,[1-2] and more recently in bulk materials such as WTe2 at moderately low temperatures and micrometer lengthscales.[3-4] This enables direct observation of strong electron interactions otherwise challenging to measure. Competition between the ballistic, at low temperatures and nanometer lengthscales, and diffusive regimes, at high temperatures and millimeter lengthscales, suggests this phenomenon can only be observed in a narrow temperature/lengthscale window.

In this work, we compute temperature-resolved microscopic scattering rates for a broad range of materials, from first principles. We then utilize these, together with crystal symmetry constraints, to compute an effective viscosity tensor - which we use as a diagnostic tool for hydrodynamic material candidates.

Despite momentum conservation inside the material, electron scattering at the boundary lead to the unique spatial signatures, such as Poiseuille flow, observed in experiments.[1-4] We investigate the effect of nanoscale geometries on these viscous electron fluids by using two independent methods: i) Macroscopic solution of the electronic Navier Stokes equation using the ab-initio viscosity tensors computed above,[5] ii) Microscopic solution of the spatially-resolved Boltzmann transport equation using the ab-initio scattering matrix.[6]

This works paves the path in experimentally-observable signatures of hydrodynamic electron flow based on first principles diagnostics.

Late News: Modeling Polaron Hopping in Ternary Spinel Oxides Maytal Caspary Toroker; Technion-Israel Institute of Technology, Israel

The small-polaron hopping model has been used for several decades for modeling electronic charge transport in oxides. Despite its significance, the model was developed for binary oxides, and its accuracy has not been rigorously tested for higher-order oxides. To investigate this issue, we chose the $Mn_xFe_{3-x}O_4$ spinel system, which has exciting electrochemical and catalytic properties, and mixed cation oxidation states that enable us to examine the mechanisms of small-polaron transport. Using a combination of experimental results and DFT+*U* calculations, we find that the charge transport occurs only between like-cations (Fe/Fe or Mn/Mn). And due to asymmetric hopping barriers and formation energies, we find that the polaron is energetically preferred to the

polaron, resulting in an asymmetric contribution of the Mn/Mn pathways.

Late News: Role of Surface Ligands and Disorder on Bandgap Tunability in Silicon Nanoparticles
Katerina Dohnalova Newell[1], Prokop Hapala[2] and Corentin Morice[1]; [1]University of Amsterdam, Netherlands; [2]Institute of Physics, Czechia

Silicon nanoparticles (Si-NPs) represent one of many types of nanomaterials, were the origin of emission is difficult to assess due to a complex interplay between the core and surface chemistry, especially due to silicon's strictly covalent chemistry. Band-gap tunability in ideal fully crystalline hydrogen capped Si-NPs is predicted to span from infrared to ultraviolet spectral range, but this is rarely observed in practice.

In this work, we simulate "fuzzy band structure", radiative rates and HOMO-LUMO energy (band-gap size) tunability of ~2nm Si-NPs. In particular we asses the role of surface, such as (i) covalently bonded atoms/molecules, (ii) strain and (iii) disorder. Simulations are done on the density functional theory level and compared with experimental results by a state-of-the-art single-dot correlative microscopy tool. By this method, the size of the individual NPs is measured by an atomic force microscopy (AFM) and the optical band-gap is evaluated from a single-dot photoluminescence measured on the very same NPs. We propose that (a) covalently bonded species alter the overal energy levels and transition rates, (b) strain reduces the radiative rates and (c) disorder reduces the bandgap tunability range. Our observations might explain the often obsered puzzlingly fast radiative rates in organically capped Si-NPs and weak size tunability in most epxerimentally realized Si-NP systems.

8:30 AM CT06.04.03
Late News: Synthesis and Characterization of Up-Converting Gd2O3:Er3+,Yb3+, Mg2+ Nanoparticles
Aleksandra Wosztyl[1,1], Krzysztof Fronc[2], Bozena Sikora[2], Tomasz Wojciechowski[2], Roman Minikayev[2], Wojciech Paszkowicz[2], Kamil Sobczak[1], Przemyslaw Kowalik[2], Katarzyna Lysiak[1], Danek Elbaum[2], Jacek Szczytko[1] and Izabela Kaminska[2]; [1]University of Warsaw, Poland; [2]Institute of Physics, Polish Academy of Sciences, Poland

Nowadays there are many attempts in the world of science to harness quantum mechanics. One of the widely explore fields with the potential of practical usage is the anti-Stokes emission phenomena. Obtained during the research gadolinium oxide nanoparticles doped with selected metals were used to investigate energy transfer between erbium (Er^{3+}) and ytterbium (Yb^{3+}) ions and enhance of the efficiency of anti-Stokes emission by doping structures with magnesium ions (Mg^{2+}).

The examined materials were synthesized by a homogeneous precipitation method for 2 hours at a temperature of 85°C. The crystal structure arrangement was obtained by calcining at a temperature of 990°C for 3 hours. The nanoparticles were characterized with several methods. Size and form were analyzed by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The crystal structure was determined by X-ray diffraction (XRD). The atomic composition of the nanoparticles was characterized by energy-dispersive X-ray spectroscopy (EDS). Optical properties were analyzed by using photoluminescence measurements. Finally, nanoparticles were incubated with mouse mammary carcinoma (4T1) cells for 24h to examine their suitability for use in biology as luminescent markers.

As result, nanoparticles show luminescence in the visible region - emission maxima occur at a wavelength of 565 nm ($^4S_{3/2} \rightarrow {}^4I_{15/2}$, $^2H_{11/2} \rightarrow {}^4I_{15/2}$) and 663 nm ($^4F_{9/2} \rightarrow {}^4I_{15/2}$) during excitation with a semiconductor laser

with a wavelength of 980 nm (continuous wave). An increase in the effectiveness of the anti-Stokes emission process was observed - an 8-fold increase in red luminescence efficiency was obtained for nanoparticles doped with 2.5% Mg^{2+} compared with non-doped nanoparticles (Gd_2O_3: 1% Er^{3+},18% Yb^{3+}). The measurements were carried out at a laser power density of 12 $W \times cm^{-2}$. The nanoparticles were dissolved in a dimethyl sulfoxide solution. The nanoparticles' diameter was 380 nm, 282 nm, and 260 nm (before calcining). The diameters of the obtained nanoparticles - are 302 ± 37 nm and 278 ± 36 nm (after a calcining) respectively.

8:45 AM CT06.04.04
Late News: Mechanistic Insights into the Reactivity of the Pd Catalyst for Hydrodechlorination of Trichloroethylene Chaitra Shenoy[1], Shelaka Gupta[2], Kirti Verma[1], Tuhin S. Khan[3] and M. A. Haider[1]; [1]Indian Institute of Technology Delhi, India; [2]Indian Institute of Technology Hyderabad, India; [3]CSIR - Indian Institute of Petroleum, India

Periodic, density functional theory calculations were employed to understand the hydrodechlorination of trichloroethylene (TCE) over different facets of a palladium catalyst. In order to accomplish this, the Pd surface was modelled as terrace sites (Pd(111)) and undercoordinated sites (Pd (211), Pd (100) and Pd (110)). The most stable binding configuration of TCE on the Pd surface was found to be through the di-σ mode of binding, wherein each carbon atom of the TCE molecule sits on top of the Pd atom. Comparing TCE adsorption over Pd facets, TCE shows the highest binding energy of -178 kJ/mol over Pd (110). TCE, upon adsorption on Pd, immediately undergoes dechlorination followed by subsequent hydrogenation of the hydrocarbon intermediates as the activation energies for C-Cl bond dissociation steps were quite low in comparison to the hydrogenation steps. As a result, the catalyst tends to undergo poisoning due to the chlorine atoms accumulated on the surface. Chlorine binds to the Pd facets as follows: Pd (110) > Pd (211) > Pd (100) > Pd (111), indicating rapid poisoning of the undercoordinated sites in comparison to the terrace site. This also suggests deactivation of smaller sized Pd nanoparticles. The strongly adsorbed Cl atoms react with hydrogen to form HCl.

9:00 AM CT06.04.05
Late News: Chemically Graded Metal/Ceramic Interface—A High Throughput DFT Study Prince Gollapalli and Satyesh K. Yadav; Indian Institute of Technology Madras, India

Interface between metal and ceramic is assumed to be atomically sharp as mixing of anions or cations (that is part of metal and ceramic) is not expected to be thermodynamically favorable. Contrary to this belief, we establish that in Ti/TiN system, it is thermodynamically favorable for N in TiN to cross over by forming N vacancy, to Ti forming interstitial solid solution. First-principles calculated value of N vacancy formation energy in TiN is 2.17 eV and N interstitial formation in Ti is –3.84 eV. Sum of the two values, which we call as driving force indicate that mixing of anions across the Ti/TiN interface is favorable.

To explore other combinations of metal/ceramic systems that could plausibly result in chemically graded interface by mixing of anions across the interface, we calculate C, N and O vacancy formation energy in range of carbides, nitrides and oxides respectively and interstitial formation energy in metals like, Ti, Zr, Hf, V, Nb, Ta, Al, Mg, Cr, and Fe. This covers range of technologically important metal/ceramic interfaces. We find that transition metals group elements, IV B and V B are more likely to form a chemically graded interface with nitrides and carbides. However, Al_2O_3 and MgO, show a large positive vacancy formation energy, are likely to form sharp interface with any metal, which explains the reason for using them as substrates for film growth. Formation of chemically graded interface results in gradual variation of structural parameter (like lattice parameter) and properties (elastic constants) across the interface. Such chemically graded interface could lead to better properties of the heterostructure involving metal/ceramic interfaces.

9:15 AM CT06.04.06
Late News: DFT Simulations to Understand Electrocatalytic Properties of Double Perovskite NdBa1-xSrxCo2O5+d (x=0, 0.25, 0.50) Jyotsana Kala, Uzma Anjum, Brajesh K. Mani and M. A. Haider; Indian Institute of Technology Delhi, India

$LnBaCo_2O_{5+d}$ type of layered double perovskite materials have received much attention as solid oxide fuel cell cathode materials owing to their high oxygen ion concentration, high electronic conductivity and catalytic activity towards oxygen reduction. In the present work, Nd-based double perovskites $NdBa_{1-x}Sr_xCo_2O_{5+d}$ (NBSCO, x= 0, 0.25 and 0.50) have been studied computationally.
Plane wave Density functional Theory based calculations using VASP were performed in order to examine the electrocatalytic properties of $NdBa_{1-x}Sr_xCo_2O_{5+d}$ double perovskite material. In view of the application of NBSCO material for SOFC cathodes, the bulk oxygen vacancy formation energies (E_{ov}) have been calculated computationally for oxygen vacancies created in all possible planes (BaSr/O, Nd/O and Co/O) and surface energies (γ) of the structure with different surface terminations (BaSr/Co, Nd/Co, Co/BaSr and Co/Nd) along (001) direction. Nd/O plane observed to have lowest oxygen vacancy formation energy among all the three possible planes in (001) direction of bulk NBSCO. This shows Nd/O plane to have high oxygen vacancy concentration. For x=0, 0.25 and 0.50, BaSr/O plane have highest oxygen vacancy formation energy showing a difficulty in oxygen vacancy creation in BaSr/O plane as compared to other planes. This suggested less oxygen anion diffusivity in BaSr/O plane. However, on doping one fourth and half of the Ba with Sr resulted in an improved bulk oxygen vacancy characteristic of BaSr/O plane. Different energetics of different terminal surfaces shows importance of surface terminations. The results of first principles calculations for surface energies were analyzed and compared for different terminal surfaces. For NBCO material, low surface energies have been observed for Ba/Co termination. Due to lower surface energies, Ba ions have tendencies to segregate towards surface. This is in accordance with the DFT simulations and molecular dynamics simulations of other Ba containing $LnBaCo_2O_{5+d}$ layered perovskites [1-5]. Doping the material with Sr have also shown similar trend in surface energies of BaSr/Co terminal surface.

9:30 AM CT06.04.07

Late News: Construction of an EAM Type Interatomic Potential Model Describable of Metallic Polytype Energetics Shinya Ogane[1], Riku Sato[1], Taku Miyakawa[2], Yuta Tanaka[2], Kazumasa Tsutsui[2] and Koji Moriguchi[1,2]; [1]Tohoku University, Japan; [2]Nippon Steel Corporation, Japan

Many crystalline compounds are composed of one or more structural units. When these units can be “stacked” in different ways to form stable or metastable phases, the resulting phases are known as polytypes. Among these polytypes, the crystalline systems composed of close-packed (CP) layers have especially attracted attention on their fundamental and technological properties. While these polytypes are often experimentally observed in

wide-bandgap semiconductors, SiC systems are particularly known to show several hundred polytypes [1]. The long period stacking ordered (LPSO) Mg alloys with light weight, high specific strength, and high heat resistance are also recently drawing attention as a metallic system with similar polytypism to that in SiC [2, 3]. For both systems, the physical mechanism behind polytype selection is not yet fully understood.
Predicting polytype phase stability for a material has still been a long-standing issue in condensed matter physics and/or materials science. This stems from the fact that the atomistic interactions on polytype energetics might be surprisingly quite complex and delicate despite the simplicity of their geometrical structure. In this situation, some theoretical studies have recently been reported. Polytypism for the finite range Lennard-Jonesium based on the classical atomistic simulations has shown that its ground state structures can include not only fcc (3C) and hcp (2H) but a wide range of more complex stacking sequences depending on the interatomic interaction distance [4]. In addition, the enthalpy of any CP structure for a given element is recently found to be characterized as a linear expansion like a convergent series which describe the stacking configuration [5]. In the previous work, we have also presented a consideration of total energetics for the CP polytypes based on the geometrical analysis for the correlation between interlayer interactions and interatomic ones in CP polytypes [6]. These theoretical results suggest that short-range interactions are not enough to describe the CP polytype energetics and provide significant insights for creating interatomic models successfully showing the polytypes other than 3C and 2H structures as a ground state, those have never yet been implemented as far as the authors know.
Since the ground state for pure lanthanum (La) is the CP stacking structure with four layers along the c-axis in the unit cell, i.e. the double hexagonal CP structure (DHCP), the pure La can be an important reference system for studying the polytype formation. It is, therefore, possible to investigate the essential factors determining the polytype selection rule through the dynamical analyses for La. In the present work, we report on the process of constructing an interatomic potential with good descriptiveness on the La polytype energetics, that can be used for molecular dynamics (MD) simulations.
The Embedded Atom Method (EAM) type functions reported by Mishin et al. [7] are adopted for constructing the potential model in this study. Since our previous theoretical studies have shown that the long-range nature of interatomic interactions is an important factor in determining the ground state of polytype energetics [3, 6], the cutoff radius has been carefully selected considering the computational speed in MD simulations. Other basic properties and transferability of the EAM type potential constructed will be discussed in the presentation.

9:35 AM CT06.04.08
Late News: A Comparative Study on Convergent Series Lattice Models for Close-Packed Polytype Energetics Riku Sato[1], Shinya Ogane[1], Taku Miyakawa[2], Kazumasa Tsutsui[2], Yuta Tanaka[2] and Koji Moriguchi[1,2]; [1]Tohoku University, Japan; [2]Nippon Steel Corporation, Japan

Polytypism is a special case of polymorphism when the two polymorphs differ only in the stacking of identical two-dimensional sheets or layers. The polytypes are characterized by a stacking sequence with a given repeat unit along the hexagonal c-axis direction and are theoretically possible to have endless permutations of the sequences. Among these polytypes, the crystalline systems composed of close-packed (CP) layers have especially attracted attention on their fundamental and technological properties for many years.
Predicting polytype phase stability for a material has still been a long-standing issue in condensed matter physics and/or materials science. This situation stems from the fact that the atomistic interactions on CP

polytype energetics might be surprisingly quite complex and delicate despite the simplicity of their geometrical structure. We have proposed a computational method coupled with three theoretical tools (PGA: polytype generation algorithm; FPC-DFT: first-principles calculations based on the density functional theory; and ANNNI: axial next-nearest-neighbor Ising model), which can make us possible to efficiently investigate the structural energetics for diverse nonequivalent polytypes [1]. The equilibrium theories based on the ANNNI model that is well known in the field of statistical mechanics have played an efficient role in the study of the origins of polytypism [2, 3].
We have constructed an ANNNI model including interactions up to the third-nearest neighbor layer with four-spin term to investigate the static energetics of a wide variety of CP polytypes for 17 kinds of metallic elements in our recent work [4]. Using this ANNNI model, we can discuss phase stability of polytypes based on inter-layer interactions for the metallic systems [4]. We have also presented a theoretical consideration of total energetics for the close-packed (CP) polytypes based on the interlayer partial energy model where the total energy constructed from the two-body interatomic interactions is projected onto the interlayer interactions in CP polytype structures [5]. Our theoretical study suggests that the descriptiveness on polytype energetics changes according to the atomic interaction distance and the effective interatomic distance that controls the ground state for the polytype energetics can be inferred from the distribution of polytype structural energetics [5].
Loach and Ackland have recently proposed another convergent series lattice model on the polytype energetics where the stacking order description is different from that in the ANNNI model [6]. They emphasize that the model proposed is more useful than the classical ANNNI model since it converges more rapidly. While these theoretical results suggest that the convergent series lattice model such as the ANNNI and/or Loach's model is a powerful tool to describe the polytype energetics, the accuracy, the convergency and the physical meaning for each model have not been completely clarified and not been mutually compared with each other.
In the present work, a comparative study on convergent series lattice models for close-packed polytype energetics are carried out using both ANNNI and Loach's models. Using these models extracted from the first-principles calculations within the generalized gradient approximation (GGA), we will discuss the inter-layer interactions, the polytype phase diagrams, and the physical relation between the ANNNI and Loach's models.

Late News: Evolution of Catalytic Active Sites in Methane Dehydroaromatization Reaction. Iqra Ahangar, Sonit Balyan, M. A. Haider and Kamal K. Pant; Indian Institute of Technology Delhi, India

With the discovery of new sources of natural gas, hydrocarbon products obtained from natural gas are providing a greater avenue to reduce dependence on coal and petroleum-based products. In this regard, direct conversion of methane to aromatics in non-oxidative environment is explored as an energy efficient route, as it eliminates the production of syngas and also eradicates the separation of COx from the product. For methane dehydroaromatization (MDA) reaction, Mo/HZSM-5 is widely used as the catalyst, yielding high selectivity for aromatics. Though, the catalyst is rapidly deactivated by coke formation in the form of polyaromatics hydrocarbon. And this remains an issue to be resolved. One thought to improve catalyst stability is arising from a detailed understanding of the catalytically active site which is dictating the protocols of catalyst synthesis, choice of the metal precursor, carburizing environment. Here in this work, utilizing density functional theory (DFT) calculations, we are discussing the implication of the oxycarbide species of molybdenum versus the carbide species in activating methane and formation of ethylene/acetylene intermediates. Overall, the results are highlighting the fundamental mechanistic insights on the active sight, which may provide a clue for rational

catalyst design.

Large-Scale Real-Space Electronic Structure Calculations Sambit Das[1], Bikash Kanungo[1], Phani Motamarri[2] and Vikram Gavini[1]; [1]University of Michigan–Ann Arbor, United States; [2]Indian Institute of Science, India

Electronic structure calculations, especially those using density functional theory (DFT), have been very useful in understanding and predicting a wide range of materials properties. Despite the success of DFT, and the tremendous progress in theory and numerical methods over the decades, the following challenges remain. Firstly, the state-of-the-art implementations of DFT suffer from cell-size and geometry limitations, with the widely used codes in solid state physics being limited to periodic geometries and typical simulation domains containing a few thousand electrons. This limits the complexity of materials systems that are accessible to DFT calculations. Secondly, most electronic structure calculations rely on the pseudopotential approximation, treating only the valence electrons. Recent studies have elucidated many scenarios where the pseudopotential approximation and the widely used pseudopotentials are unsatisfactory. Lastly, there are many materials systems (such as strongly-correlated systems) where the widely used model exchange-correlation functionals are inaccurate. Addressing these challenges will enable large-scale all-electron quantum-accuracy DFT calculations, and can significantly advance our predictive modeling capabilities of complex materials systems.

This talk will discuss our recent advances towards addressing the aforementioned challenges. In particular, the development of computational methods and numerical algorithms for large-scale real-space DFT calculations using adaptive finite-element discretization will be presented, which form the basis for the recently released DFT-FE open-source code. The computational efficiency, scalability and capability of DFT-FE will be presented, and contrasted with other widely used codes. In an effort to overcome the limitation of the pseudopotential approximation, recent progress in developing accurate, efficient, and scalable all-electron DFT calculations will be presented. Further, ongoing efforts, and related thoughts, on developing a framework for a data-driven approach to improve the exchange-correlation description in DFT will be discussed.

Quantum for Quantum—*Ab initio* Calculations in Chemical and Materials Sciences Using Near-Term Quantum Computation Stefan A. Bringuier and Pejman Jouzdani; General Atomics, United States

The use of *Ab initio* methods to address problems in chemical and material sciences (CMS) which are solved using classical computation is a mature and robust field. With the nascent field of quantum computing (QC) anticipated to grow and make advancements in the upcoming decades, now is a suitable time to investigate quantum algorithms and methodologies that positively augment or advance *Ab initio* calculations. We present a brief overview of leading quantum algorithms for noisy intermediate-scale quantum devices that target CMS problems, which include the successful variational quantum eigensolver (VQE). We discuss our two recent QC approaches for calculation of both ground and excited states. The first of these methods utilizes a subspace projection of a problem Hamiltonian in conjunction with the VQE algorithm to obtain the excited states accurately. The second method utilizes a quantum device to prepare and measure an effective Hamiltonian in

the computational basis of a qubit register. In this capacity, the quantum device acts as a coprocessor that can efficiently prepare the Hamiltonian for post-processing on a classical computer. The methods discussed are numerically demonstrated for small molecular systems (e.g., H_2, LiH), but in general, are suitable for larger chemical or material systems with appropriate quantum hardware resources. While mainstream QC may still be far away, we are at an opportunistic intersection for the materials community to think about how to address CMS problems using computing devices governed by quantum theory.

Quantum Algorithms for Predicting Strongly Correlated Matter Kade Head-Marsden and Prineha Narang; Harvard University, United States

Computationally tractable treatment of correlated quantum matter is a challenging problem relevant to chemistry, physics, and material science. It has been predicted that quantum computers have the potential to reduce the computational scaling from exponential to polynomial, however, environmental noise experienced by these devices has stymied the practical realization of this speed-up. With recent progress in quantum hardware, quantum devices are closer than ever to being capable of computationally investigating static and dynamic properties of strongly correlated systems. Here, I will discuss recently developed quantum algorithms to consider strongly correlated quantum systems. In particular I will focus on the dynamics of fermionic open quantum systems and static properties of condensed matter systems.

Towards an Accurate and Efficient Order-*N* Framework for Real-Space Condensed-Phase Hybrid Density Functional Theory Robert DiStasio; Cornell University, United States

By including a fraction of exact exchange (EXX), hybrid functionals reduce the self-interaction error in semi-local density functional theory (DFT), and thereby furnish a more accurate and reliable description of the electronic structure in systems throughout chemistry, physics, and materials science. However, the high computational cost associated with hybrid DFT limits its applicability when treating large-scale and complex condensed-phase systems. To overcome this limitation, we have devised a highly accurate and linear-scaling (order-*N*) approach based on a local (MLWF) representation of the occupied space that exploits sparsity when evaluating the EXX interaction in real space [1]. In this work, we present a detailed description of the theoretical and algorithmic advances that are needed to perform hybrid DFT based *ab initio* molecular dynamics (AIMD) simulations of large-scale finite-gap condensed-phase systems using this approach. This is followed by a critical assessment of the accuracy and parallel performance of the *exx* algorithm when performing AIMD simulations of liquid water and several ice phases in the canonical (*NVT*) and isobaric-isothermal (*NpT*) ensembles. With access to high-performance computing (HPC) resources, we demonstrate that *exx* enables hybrid DFT based AIMD simulations of systems containing 500-1000 atoms with a wall time cost comparable to semi-local DFT. In the strong-scaling limit, this cost is split evenly between computation, communication, and processor idling; as such, we also discuss a three-pronged strategy that directly attacks each of these contributions and reduces the overall wall time cost by approximately an order of magnitude for large-scale heterogeneous systems. With these developments, this work takes us one step closer to routinely performing AIMD simulations of large-scale condensed-phase systems for sufficiently long timescales at the hybrid DFT level.

Modeling Metal-Insulator Transition of VO_2 with GGA with Small Hubbard Parameters Daniel Koch, Kumar Prabhakaran, Mohamed Chaker and Sergei Manzhos; INRS, Canada

Studying the metal-insulator transition (MIT) of VO_2 from first-principles generally requires the use of computationally expensive hybrid density functionals, while the less resource-intense functionals of the generalized gradient approximation (GGA) -type commonly fail to correctly describe the relative thermodynamic stabilities, crystal-, or electronic structures of the semiconducting and metallic monoclinic and rutile phases of VO_2. Unfortunately, investigating e.g. the effect of low-concentration doping on the VO_2 transition temperature requires simulation cell dimensions for which hybrid density functionals quickly become unfeasible. We present an overview of the underlying difficulties connected to the use of GGA functionals on the VO_2 MIT in commonly employed quantum chemistry codes and demonstrate that a computational setup using localized basis functions, pseudopotentials and a GGA functional with a small Hubbard correction helps achieving simultaneous description of qualitative band structure features, crystal geometries, and the MIT temperature of VO_2 correctly.

Towards First-Principles Quantum Monte Carlo for Quantum Materials Paul Kent; Oak Ridge National Laboratory, United States

We review recent advances towards first-principles quantum monte carlo (QMC) on general materials, including those where spin-orbital phenomena, strong electron correlation, and van der Waals interactions are significant. QMC methods provide very high accuracy and are in principle generally applicable. However fundamental improvements are required to study quantum materials as well as general materials incorporating elements from across the periodic table. Additionally, QMC methods generally make use of trial wavefunctions from other approximate theories to control the Fermion sign problem, introducing a systematic bias to the calcualtions. For simple bulk materials these trial wavefunctions can now be converged and the systematic error reduced[1,2]. This can accelerate methodological improvements by enabling cross validation and studies of the efficiencies of different QMC methods such as real space diffusion QMC and auxiliary field QMC. In terms of applications, these advances open the possibility to determining the total uncertainty in predicted properties of both quantum and general materials.

The methods described have been implemented in the open source QMCPACK code[3,4], https://qmcpack.org .

Late News: Towards a Topological Quantum Chemistry Description of Correlated Systems—The Case of the Hubbard Diamond Chain Mikel Iraola[1,2], Niclas Heinsdorf[3], Apoorv Tiwari[4,5], Dominik Lessnich[3], Thomas Mertz[3], Francesco Ferrari[3], Mark Fischer[4], Stephen Winter[3,6], Titus Neupert[4], Frank Pollmann[7], Roser Valentí[3] and Maia García Vergniory[2,8]; [1]University of the Basque Country, Spain; [2]Donostia International Physics Center, Spain; [3]Goethe University, Germany; [4]University of Zurich, Switzerland; [5]Paul Scherrer Institute, Switzerland; [6]Wake Forest University, United States; [7]Technical University of Munich, Germany; [8]IKERBASQUE, Spain

The recently introduced topological quantum chemistry (TQC) framework has provided a description of universal topological properties of all possible band insulators in all space groups based on crystalline unitary symmetries and time reversal. While this formalism filled the gap between the mathematical classification and the practical diagnosis of topological materials, an obvious limitation is that it only applies to weakly interacting systems-which can be described within band theory. It is an open question to which extent this formalism can be generalized to correlated systems that can exhibit symmetry protected topological phases which are not adiabatically connected to any band insulator. In this work we address the many facettes of this question by considering the specific example of a Hubbard diamond chain. This model features a Mott insulator, a trivial insulating phase and an obstructed atomic limit phase. Here we discuss the nature of the Mott insulator and determine the phase diagram and topology of the interacting model with infinite density matrix renormalization group calculations, variational Monte Carlo simulations and with many-body topological invariants. We then proceed by considering a generalization of the TQC formalism to Green's functions combined with the concept of topological Hamiltonian to identify the topological nature of the phases, using cluster perturbation theory to calculate the Green's functions. The results are benchmarked with the above determined phase diagram and we discuss the applicability and limitations of the approach and its possible extensions.

WITHDRAWN-NO REG (CT06.06.03) Identifying Design Principles for Solid State QM/MM Embedded Cluster Modelling Harry Jenkins and Andrew Logsdail; Cardiff University, United Kingdom

The current most popular computational method in modelling surface reactions is periodic planewave density functional theory (DFT)[1]. Periodic DFT is both expansive in its functionality, and easy to use. However, there are still some major limitations. For instance, the preferred basis representation of planewaves is inefficient for high-level hybrid-DFT approaches; large models are needed for isolated catalytic chemistry, with many tens or hundreds of atoms included but redundant in calculations, as all atoms need to be treated quantum mechanically, even if they are far from the “active site”. In addition, periodic surface models cannot be used to model charged defects due to technical incompatibilities when trying to include any compensating background charge.

As an alternative, hybrid quantum- and molecular-mechanical (QM/MM) modelling can be coupled with an embedded cluster approach, which combines the high accuracy of QM modelling, with the high efficiency of MM modelling (MM), all in an aperiodic model that reproduces the bulk environment[2]. However, the uptake of QM/MM in the solid-state community is limited by the bespoke nature of the model configuration, which typically requires empirical tuning to achieve accuracy comparable to the periodic DFT approaches.

In this work, we present our progress in outlining systematic design principles for QM/MM models, based initially on work using MgO. This has been pursued using the ChemShell[3] software package, with FHI-aims[4] used to perform DFT calculations, using both popular GGA approaches, compared to periodic DFT, and high-level exchange-correlation functionals (PBE0).

The focus of the work is understanding how cluster design principles, such as partitioning of the QM-region, determining coordinates of the unrelaxed cluster, and fixing different regions of the cluster during relaxation, affect the accuracy of measurable results. Our overall aim is to deliver an automated approach to cluster construction, with objective justification for each step involved.

Self-Interaction Corrected Functional Calculaions as Alterantive to Semi-Empirical DFT+U and Hybrid Functional Calculations Hannes Jonsson; University of Iceland, Iceland

While Kohn-Sham density functional theory (DFT) using GGA, meta-GGA functional approximations has been remarkably successful in a variety of applications, there are several important cases where it fails. Increasingly, this is being remedied by semi-empirical DFT+U or hybrid functional calculations where parameters are adjusted in one way or another to obtain acceptable results. A variational and self-consistent implementation of the Perdew-Zunger self-interaction correction (PZ-SIC) using complex optimal orbitals has instead been developed and applied to several such systems and found to give good results. Calculations of electronic holes in oxide crystals, transition metal clusters, Rydberg excited states and localized charge state that are absent in GGA and meta-GGA level calculations will be presented. The computational effort of the PZ-SIC calculations scales with system size in the same way as DFT/GGA calculations but the prefactor is large since an effective potential needs to be evaluated for each orbital (calculations that could, however, be carried out in parallel) and optimal orbitals need to be found in terms of the Kohn-Sham orbitals at each iteration. PZ-SIC is an example of an extended functional form where the energy depends explicitly on the orbital densities, not just the total electron density and thereby goes beyond Kohn-Sham DFT. While significant improvements are obtained with PZ-SIC, the orbital density dependent functional form could be exploited more generally to develop a self-interaction free functional rather than as a correction to Kohn-Sham functionals, thereby providing an optimal mean field theory for materials calculations.

Understanding phase stability and diffusion kinetics in structurally unstable but dynamically stabilized phases from first principles Sara Kadkhodaei; University of Illinois at Chicago, United States

The phase diagram of numerous materials of technological importance features high-symmetry high temperature phases that exhibit phonon instabilities. Leading examples include shape-memory alloys, as well as ferroelectric, refractory, and structural materials. In this talk I will introduce a new thermodynamic model for free energy calculation in these phases from first principles [1]. This model efficiently explores the system's ab-initio energy surface by partitioning it into piecewise polynomials around local minima, which is combined with a continuous yet constrained sampling in the vicinity of these local minima. I present the application of this model to the bcc phase of titanium as well as the austenite and martensite phases in NiTi and PtTi shape memory alloys, in which we illustrate that constant anharmonicity-driven hopping between local low-symmetry distortions stabilizes the system to maintain a high-symmetry time-averaged structure [2]. In addition, I will try to shed light on diffusion kinetics in dynamically stabilized phases based on a first-principles approach within the transition state theory [4]. Finally, I introduce the implementation of the model as an open-access and fully automated software toolkit called the Piecewise Polynomial Potential Partitioning (P4), which can be integrated into the Alloy Theoretic Automated Toolkit (ATAT)[3].

Spin Dynamics and Exciton Recombination in Quantum Materials from First-Principles Yuan Ping; University of California, Santa Cruz, United States

Designing new quantum materials with long-lived electron spin states is in urgent need of a general theoretical formalism and computational technique to reliably predict spin lifetimes. We present a new, universal first-principles methodology based on density matrix (DM) dynamics for open quantum systems to calculate the spin-phonon relaxation time of solids with arbitrary spin mixing and crystal symmetry. In particular, this method describes contributions of the Elliott-Yafet (EY) and D'yakonov-Perel' (DP) mechanisms to spin relaxation, corresponding to systems with and without inversion symmetry, on an equal footing[1]. Our ab initio predictions are in excellent agreement with experimental spin lifetime for a broad range of materials, such as Si, Fe, MoS_2, graphene and its interfaces as well as GaAs.

We then implemented real-time DM dynamics for ultrafast Kerr rotation and studied spin dynamics under external electric and magnetic field. Through the complete theoretical descriptions of pump, probe and scattering processes including electron-phonon, electron-impurity and electron-electron scattering, our method can directly simulate the nonequilibrium ultrafast pump-probe measurements for coupled spin and electron dynamics and is applicable to any temperatures and doping levels. We use this method to simulate spin dynamics of GaAs and obtain excellent agreement with experiments. It is found that the relative contributions of different scattering mechanisms and phonon modes vary considerably between spin and carrier relaxation processes. Importantly, we point out that at low temperatures the electron-electron scattering becomes very important and causes the strong reduction of spin relaxation time under in-plane magnetic fields.

In addition, we will also introduce our recent work on radiative and nonradiative exciton recombination in two-

dimensional systems from many-body perturbation theory and its applications on designing point defects as single photon emitter and spin qubits in hexagonal BN[2-6]. Our work underscores the predictive power of first-principles techniques for key physical properties to quantum information science.

Late News: Calculation of the Magnetostatic Dipole-Dipole Correction to Periodic Spin-Density Functional Theory Using an Auxiliary Magnetic Charge Density Lorien A. MacEnulty[1,2] and David D. O'Regan[1]; [1]Trinity College Dublin, Ireland; [2]Drake University, United States

The dipole-dipole contribution to the total energy and potential due to unpaired electron spin is the magnetostatic analogue to the Hartree electrostatic term. It contributes at order $1/c^2$ in the Breit-Pauli Hamiltonian and is therefore neglected in both non-relativistic spin-density functional theory (DFT) and non-collinear DFT calculations including spin-orbit. The term is technologically important, however, since it induces the shape anisotropy effect critical in the design of nanoscale magnetic devices; in and of itself, the term perhaps warrants investigation as an intriguing physical phenomenon.

In this work, we develop a practical algorithm for non-self-consistent but non-perturbative calculations of the spin dipole-dipole correction to the total energy in periodic and molecular systems [1]. To this end, we make use of an auxiliary—and, ultimately, physically fictitious—magnetic charge density, determined via the magnetization intrinsic to the collinear (or non-collinear) spin-density associated with ground-state systems with vanishing free current density. The affiliated magnetic scalar potential is defined by means of a magnetic Poisson equation, and from this the magnetic field is calculated. Immersing the magnetization back into this magnetic field generates the non-self-consistent energy correction.

We developed a versatile module, compatible with the capacities of Mathematica, for calculating this energy for spin-densities in generalized periodic unit cells, to be used as a post-processing tool with any standard DFT code. Using this, we compared the strength of the magnetostatic energy to the electrostatic energy for a number of test systems, finding a ratio consistently on the order of the square of the fine structure constant, as is coherent with the term's position in the relativistic expansion. Our approach may highlight the magnetic charge density's aptitude both as an auxiliary for computing the properties of magnetic quantum systems and, more generally, for inclusion in the development of exchange-correlation functionals in relativistic DFT.

6:25 PM CT06.07.05
Investigation of the Octahedral Center site Effect in the Antiperovskite Mn_3NiN Evelyn J. Triana and Andres C. Garcia Castro; Universidad Industrial de Santander, Colombia

The antiperovskite family Mn_3AN (A = Zn, Cu, Ni, ..) exhibits negative thermal expansion, piezomagnetism, and non-collinear antiferromagnetism (AFM) due to the presence of magnetic frustration on the magnetic structure of the manganese atoms in the (111) planes [1]. Previous research on this material has been mostly focused on experimental findings, and it has dedicated primarily on understanding the magneto-structural properties of these antiperovskites. Interestingly, we found few theoretical studies devoted to elucidate the influence of the central anionic site in the Mn_3NiN antiperovskite. Therefore, our study focuses on theoretically investigating, through first-principles density functional theory (DFT) calculations, the effect of the nitrogen's site on the structural and electronic properties of the antiperovskites Mn_3NiN. Therefore, our main analysis consists of observing changes in the electronic structure by analyzing the band structure, density of states, and the oxidation state of the atoms in the presence and absence of nitrogen considering the allowed four noncollinear antiferromagnetic orderings. Our results show a tangible modification of the electronic structure close to the Fermi energy as well as structural changes, associated to the lattice parameter, due to the incorporation of nitrogen.

6:30 PM CT06.07.06
Theoretical Investigation of the Spin-Phonon Coupling in the Antiperovskite Mn_3NiN Leonardo Florez Gomez and Andres C. Garcia Castro; Universidad Industrial de Santander, Colombia

The manganese-based antiperovskite nitrides family is formed by magnetic materials that exhibit non-collinear antiferromagnetism in the presence of magnetic frustration. Different reports have confirmed the existence of a strong coupling between the magnetic structure and the crystalline structure in the in members of this family, for example in Mn_3NiN. As such, this coupling has been confirmed by piezomagnetism [1], magnetovolume effects [2], and negative thermal expansion [3] studies.

So far, theoretical studies focused on clarifying this coupling and phenomenon in antiperovskites are rare in the literature. This possibly because phonon calculations, including non-collinear magnetism formalism are a challenging task in these type systems. In this research, we theoretically studied the spin-phonon coupling in Mn_3NiN through first-principle DFT calculations. We aimed to understand the relation between the behavior of the phonons and the magnetic orderings of the material, taking into consideration correlation effects. To achieve this, we computed and analyzed the phonon frequencies, eigenvectors, and phonon dispersion curves for each of the two magnetic orderings that have been experimentally confirmed in the material [4]. From these results the phonon modes involved in the coupling were determined. Our results theoretically demonstrate the dependence of phonons on magnetic ordering and correlation effects in Mn_3NiN. With this study, we expect to contribute to future research in the field of antiperovskites that display a coupling between structure and magnetism.

Opto-Mechanics Driven Fast Martensitic Transition in Two-Dimensional Materials Ju Li; Massachusetts Institute of Technology, United States

Inspired by optical tweezers, we show that laser pulse with selected frequency can drive an ultrafast diffusionless martensitic phase transition of two-dimensional ferroelastic materials such as SnO and SnSe monolayers, where the unit-cell strain is tweezed as a generalized coordinate that affects the anisotropic dielectric function and electromagnetic energy density. At laser power of 10^10 W/cm2, the transition potential energy barrier vanishes between two 90°-orientation variants of ferroelastic SnO and SnSe monolayer, respectively, so displacive domain switching can occur within picoseconds. The estimated adiabatic thermal limit of energy input in such optomechanical martensitic transition (OMT) is at least 2 orders of magnitude lower than that in Ge-Sb-Te alloy. [Nano Lett. (2018) 7794]

***Ab Initio* Signatures of Phonon-Mediated Hydrodynamic Transport in Semimetals** Yaxian Wang[1], George Varnavides[1,2] and Prineha Narang[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States

Hydrodynamic electron flow in condensed matters has been one of the most active research areas recently. While progress from both theory and experimental techniques are made, open questions regarding the underlying mechanisms still remain. We utilize *ab initio* techniques to treat the electron scattering events explicitly, and show in combination with Boltzmann transport equation a more applicable metric of hydrodynamic transport taking into account temperature, channel width, and impurity length, which can be directly verified by various experimental techniques. By investigating different electron scattering mean free

paths in PdCoO2, ZrSiS, and TaAs2, we show that that phonon mediated electron-electron interaction could lead to much shorter momentum conserving mean free path (*lmc*) than momentum relaxing *lmr*, facilitating hydrodynamic behavior in systems where the direct Coulomb interaction is largely screened.
We further discuss the momentum relaxing lifetimes on their Fermi surfaces, and show that at low temperatures, hole pockets feature much longer lifetimes than electron pockets, providing a window for momentum conserving scattering events to dominate. Importantly, our findings on TaAs2 suggest that linear Dirac-Weyl bands as well as the bands that contribute to phonon-mediated diagrams are critical in search of promising candidates for hydrodynamic flow. Other key ingredients include high mobility carriers, low density of states compensated systems, and large electron-phonon matrix elements. The plethora of low symmetry crystals whose Fermi surfaces are composed of *d* orbitals from the transition metal and *p* orbitals from the metalloids provides a much larger pool for further study. This work provides *ab initio* signatures of material-specifics to explore hydrodynamic electron flow in a much larger family of condensed matter systems, and thus offers insights into study of electron interactions through transport phenomena.

8:40 AM *CT07.01.03
Excitons and Quantum Light-Matter Interactions in Layered van der Waals Structures Kristian S. Thygesen; Technical University of Denmark, Denmark

Two-dimensional (2D) materials like the transition metal dichalcogenides (TMDs) and their van der Waals bonded layered structures present interesting opportunities for studying and controlling light-matter interactions and for developing e.g. room temperature excitonic devices. Engineering of the dielectric environment represents a powerful strategy to control the excited states in 2D materials without compromising their structural integrity. We show that the quasiparticle band gap of a 2D semiconductor can be tuned by hundreds of meV by varying the concentration of free carriers in a nearby graphene sheet via electrostatic doping[1]. The recent development of high-κ 2D materials present new opportunities for dielectric engineering. We demonstrate that the exciton Rydberg series of a supported TMD monolayer changes qualitatively when the dielectric screening within the 2D semiconductor becomes dominated by the substrate. In this regime, the distance dependence of the screening is reversed and the effective screening increases with exciton radius, which is opposite to the conventional 2D screening regime. Consequently, higher excitonic states become underbound rather than overbound as compared to the Hydrogenic Rydberg series[2].
Bilayer TMDs present further opportunities for creating novel excitonic states and manipulating their properties. Indeed, interlayer excitons with electrons and holes located in different layers can be realized in structures with Type-II band alignment. I will present a joint theory-experiment collaboration demonstrating electrical control of interlayer excitons in bilayer MoS2 up to room temperature. The large out-of-plane dipole of the interlayer excitons makes then highly sensitive to the perpendicular electric field and leads to giant Stark shifts of up to 60 meV. The work verifies an earlier theoretical prediction about the mixed intra-interlayer nature of the excitons in TMD homobilayers [3].
Finally, I will present some recent results on ab-initio calculations of spontaneous emission rates in van der Waals heterostructures. Specifically, it is shown that highly confined graphene plasmons can lead to extremely high Purcell factors for intersubband transitions in few-layer TMDs sandwiched between graphene and a perfect metal. Among other things, we demonstrate the importance of using ab-initio electronic wave functions (as compared to simpler model wave functions) for obtaining realistic rates.

Frist-Principles Theory of Nonlinear Responses in Two-Dimensional Materials and Topological Materials
Xiaofeng Qian; Texas A&M University, United States

Materials with strong nonlinear responses play important roles in advanced optoelectronics and photonics. Large nonlinear responses such as second harmonic generation recently observed in 2D and topological materials spurred tremendous interest, offering great opportunities for developing ultrathin nonlinear optical devices free of phase-matching bottleneck. Here, we report our recent effort on first-principles theory and simulation of nonlinear responses in low-dimensional materials. First, we will present our study of second harmonic generation, shift photocurrent, and circular photocurrent in semiconducting 2D materials and reveal their microscopic origins in terms of interband and intraband contributions. We show that it is possible to realize ferroicity-driven nonlinear photocurrent switching by taking advantage of the inherent coupling between nonlinear susceptibility and underlying symmetry, ferroic order, and light polarization. Second, we will present on theoretical prediction and experimental demonstration of ferroelectric nonlinear anomalous Hall effect in time-reversal invariant few-layer WTe_2 and show that Berry curvature dipole and shift dipole can serve as new order parameters for noncentrosymmetric systems, paving the theoretical foundation for nonlinear quantum electronics such as Berry curvature memory. Finally, we will introduce our recent work on nonlinear photocurrent in PT-symmetry magnetic topological quantum materials. We predict that magnetic shift photocurrent can be magnetically switched between two antiferromagnetic states with time-reversed spin orderings in bilayer antiferromagnetic MnBi2Te4. External electric field can break PT-symmetry and enable normal shift photocurrent that are electrically switchable and tunable down to a few THz regime, suggesting bilayer antiferromagnetic MnBi2Te4 as a tunable platform with rich THz and magneto-optoelectronic applications. Nonlinear optical and photocurrent responses thus provide a powerful alternative for deciphering electronic structures and interactions, particularly fruitful for probing and understanding 2D materials, topological materials, and other quantum materials.

Crystal Phases of Charged Interlayer Excitons in van der Waals Heterostructures Igor Bondarev[1], Oleg Berman[2], Roman Kezerashvili[2] and Yurii Lozovik[3]; [1]North Carolina Central University, United States; [2]New York City College of Technology, United States; [3]Institute of Spectroscopy, RAS, Russian Federation

We study the properties of charged interlayer excitons (CIE) in highly excited vdW heterostructures [1] — a compound fermion system with the permanent dipole moment that was observed recently in Transition-Metal-Dichalcogenide bilayers [2]. We predict the existence of new strongly correlated collective CIE states, the long-range ordered phases of the excited bilayer heterostructure — the crystal phase and the Wigner crystal phase. We evaluate the critical temperatures and density for the formation of such many-particle cooperative compound fermion states. We demonstrate that they can be selectively realized with bilayers of properly chosen electron-hole effective mass ratio by just varying their interlayer separation distance. Compound fermion systems featuring permanent electric dipole moments are of both fundamental and practical importance due to their inherently unique many-body correlation effects between electric-dipole and spin degrees of freedom. The spin in such systems could potentially be used for quantum information processing and its correlation with the dipole moment provides an opportunity for spin manipulation through optical means. Fundamental cooperative crystallization phenomena we predict will greatly increase the potential capabilities of such systems to open up new avenues for experimental exploration and novel device technologies with van der Waals heterostructures.

11:45 AM *CT07.02.01
Computational Spectroscopy from First Principles Giulia Galli; University of Chicago, United States

We discuss first principles, computational methods and strategies to predict light-activated processes in materials for sustainability (e.g. to understand and design photo-electrochemical cells) and for quantum information science (e.g. color centers in semiconductors). In particular we present methods to study materials at finite temperature, by coupling first principles molecular dynamics and many body perturbation theory.

Interpretations of Ground-State Symmetry Breaking and Strong Correlation in Time-Dependent Density Functional Theory John P. Perdew[1], Adrienn Ruzsinszky[1], Jianwei Sun[2], Niraj Nepal[1] and Aaron Kaplan[1]; [1]Temple University, United States; [2]Tulane University, United States

Strong correlations within a symmetry-unbroken ground-state wavefunction can show up in approximate density functional theory as symmetry-broken spin-densities or total densities. They can arise from soft modes of fluctuations (sometimes collective excitations) such as spin-density or charge density waves at non-zero wavevector. Familiar examples are the unobservable but revealing symmetry breaking in stretched H_2 and the observable symmetry breaking in antiferromagnetic solids. The example discussed here is the static charge-density wave/Wigner crystal phase of a low density (69) jellium. Time-dependent density functional theory is used to show quantitatively that the static charge density wave is a soft plasmon. More precisely, the frequency of a related density fluctuation drops to zero, as found from the frequency moments of the spectral function. Our calculation is based on a recent constraint-based wavevector- and frequency-dependent jellium exchange-correlation kernel.[1] (Work supported by NSF DMR and DOE BES.)

Electronic Excitations—Describing Couplings in Space and Time Lucia Reining[1,2]; [1]Centre National de la Recherche Scientifique, France; [2]Institut Polytechnique de Paris, France

Green's functions are efficient tools to study many-body systems. Because the one-body Green's function is non-local in space and time, it gives more direct access to phenomena which reflect coupling of different

regions of space and to memory effects in time, than approaches based on density functionals. Examples for such couplings are the occurrence of single and multiple plasmons, excitons, or satellite structure in excitation spectra. Still, existing approximations in the framework of many-body perturbation theory are often not sufficient to capture all these phenomena.

In this talk we will discuss extensions of Green's functions approaches beyond the previous state-of-the-art. This will include the description of coherent inelastic x-ray scattering [1], coupling of electron-hole excitations [2], and the description of charge dynamics. We will conclude by discussing promising routes for the future.

Transport in Gapped Bilayer Graphene Nanostructures Angelika Knothe and Vladimir Falko; National Graphene Institute, The University of Manchester, United Kingdom

Quantum nanostructures, e.g., quantum wires and quantum dots, are needed for applications in quantum information processing devices, such as transistors or qubits. In gapped bilayer graphene (BLG), one can confine charge carriers purely electrostatically, inducing smooth confinement potentials and thereby limiting edge-induced perturbances, while allowing gate-defined control of the confined structure. I will report on a series of works on electrostatically confined nanostructure in gapped BLG. We demonstrated, e.g., how some of BLG's unusual properties, i.e., its states' Berry curvature-induced orbital magnetic moment and the mini valleys and band inversions of its non-parabolic low-energy dispersion, translate into a BLG quantum wire's transport properties and a quantum dot's single- and two-electron states. We investigated both theoretically, and in collaboration with experiments, how to tune these features of BLG nanostructures externally to make them useful in future quantum technology applications.

Ionic Gate Spectroscopy of 2D Semiconductors Alberto Morpurgo; University of Geneva, Switzerland

Owing to their very large geometrical capacitance, ionic liquid gated devices allow unique experiments to be performed. Possibly the best known example is the possibility to induce superconductivity at the surface of different insulators. Ionic liquid gated devices, however, have more to offer. In this talk I will show how ionic liquid gated transistors based on many different 2D semiconductors and van der Waals interfaces can be used to perform precise, quantitative spectroscopic measurements of the energy of band edges. These measurements allow the straightforward determination of the size of the band gap of many semiconducting 2D materials in mono, bi and multilayer form. Thy also allow the determination of the band alignment of two different materials used to form a van der Waals interface, a quantity that is normally difficult to measure reliably by means of other techniques. If times allows, I may also present very recent development on double gated devices, i.e. in devices in which a 2D semiconductor is coupled to two independent ionic gates on opposites sides.

***Ab Initio* Many-Electron Green's Function Approach to Excited States in Materials—Correlated**

Multiparticle Excitations and Time-Dependent Phenomena Steven G. Louie[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Many fascinating phenomena in nature owe their emergence from the interactions of large number of particles. In this talk, I will discuss some recent progress in understanding and computing excited-state phenomena in materials, especially those that are relevant to energy conversion, transport and storage. Many-electron interactions are dominant in many of these phenomena/properties. Several illustrative examples will be presented, including: strongly bounded correlated multiparticle excitations, such as trions and biexcitons, in quasi 1D and 2D semiconductors; universal slow yet tunable plasmons as well as giant excitonic enhancement of shift currents in 2D materials; and remarkable many-electron features in optical-field-driven, time- and angle-resolved photoemission spectroscopy (ARPES). *Ab initio* studies of these novel phenomena are made possible because of newly developed first-principles methods based on an interacting many-particle Green's function approach.

This work was supported by the U. S. Department of Energy and the National Science Foundation. I would like to acknowledge collaborations with members of the Louie group.

2:40 PM CT07.03.02
Exciton Dynamics in Pentacene Crystal from GW-BSE Galit Cohen[1], Dana Novichkova[1], Diana Qiu[2] and Sivan Refaely-Abramson[1]; [1]Weizmann Institute of Science, Israel; [2]Yale University, United States

Exciton dynamics underlie materials optoelectronic functionality, and it is of great interest to understand how material structure and composition influences the involved transport properties. In this work we study the connection between exciton dispersion and dynamics from a new approach, based on many-body perturbation theory within the GW-BSE approximation. By accounting for the exciton bandstructure, we relate its time-evolution and radiative recombination processes to the underlying material structure. We demonstrate this approach on the pentacene molecular crystal, a well-studied system with nontrivial excitonic processes and unique structural features. We explore exciton dispersion and relate it to the directionality of the light polarization due to crystal packing and to anisotropy in the exciton propagation. We further discuss band to band transitions that dominate the radiative lifetime and thermalization effects. Our results provide an insight into exciton transport properties as they are affected by the structural features of the pentacene crystal.

Theoretical Spectroscopy from the UV to the Hard X-Ray Region—Example of Ga_2O_3 Claudia Draxl[1], Christian Vorwerk[1], Dmitri Nabok[1] and Francesco Sottile[2]; [1]Humboldt-Universität zu Berlin, Germany; [2]LSI, Ecole Polytechnique, CNRS, CEA, Institut Polytechnique de Paris, France

Many-body perturbation theory (MBPT) is the state of-the-art approach to determine neutral excitations in solids and has been applied with considerable success to determine optical, UV, and x-ray absorption spectra. However, theoretical studies so far have focused on a specific energy region, studying either core or valence excitations. In this talk, we present an all-electron MBPT approach that overcomes these limitations [1]. We show how it can be used to calculate absorption and inelastic scattering spectra, from the optical to the x-ray region. While these spectroscopic techniques probe either the valence or core excitations, the interplay of the two can be revealed by resonant inelastic x-ray scattering (RIXS). We present a novel many-body approach to determine RIXS spectra in solids [2], which makes use of the valence and core excitations determined within our all-electron approach. We demonstrate with the example of the wide-gap oxide Ga_2O_3 [3] how the excitation pathways determine the spectral shape of the emission, and demonstrate the nontrivial role of electron-hole correlation in the RIXS spectra. We also discuss how RIXS can be employed to determine the nature of bound valence excitons in this material.

Late News: Quasiparticle Excitations and Band Structures in Organized Donor-Acceptor Copolymers
Guorong Weng and Vojtech Vlcek; University of California, Santa Barbara, United States

I will present our recent study of the quasiparticle excitations and band structures in organized donor-acceptor copolymers. We employ many-body perturbation theory, which accounts for the polarization effects among polymers, to calculate the quasiparticle energies in bulk polymers. Our computed results are in excellent agreements with the photoemission spectra data. We discover two types of states supporting band transport in bulk copolymers: the conjugated bands and impurity states. The non-local exchange interactions are found to enhance the band transport of hole along the polymer axis, but hinder the transport across the chain. The polarization interactions are found to stabilize charge carriers and hinder band transport. Further, we discover that depending on the molecular arrangement, bulk copolymers sustain electron and hole transport in two orthogonal directions; the holes are most efficiently transported along the polymer and the pi-pi stacking directions, while the electrons are transport along the edge-to-edge stacking direction.

Progress in First-Principles Calculations of Electron-Phonon Couplings Feliciano Giustino; The University of Texas at Austin, United States

First-principles calculations of electron-phonon interactions are becoming an increasingly popular tool for the study of functional materials at finite temperature. As a result, several new techniques have been developed during the past decade to address a broad array of properties and phenomena, ranging from superconductivity to light-matter interactions [1]. Within this context, I will describe some recent developments in calculations of phonon-limited carrier transport and polaron physics. I will outline the Boltzmann transport formalism [2] and its application to the calculation of transport coefficients, and I will illustrate this technique by discussing carrier mobilities in wide-gap semiconductors [3], hybrid organic-inorganic halide perovskites [4] and two-dimensional materials [5]. Then I will describe our work phonon-mediated electron localization, and the formation of polarons in bulk and low-dimensional materials [6,7].

CT07

5:15 PM *CT07.04.01
Understanding the Nature and Fate of Excitons in Complex Light-Absorbing Materials from First Principles Jeffrey B. Neaton[1,2,3]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute, United States

The ability to synthesize and probe new classes of light-absorbing with tunable structure and composition – such as 2d transition-metal dichalcogenides, organic semiconductors, and halide perovskites – has driven the need for new intuition linking atomic- and molecular-scale morphology to their photophysics, and in particular the nature and fate of excitons. Here, I will discuss the use of ab initio density functional theory and many-body perturbation theory for computing photoactive excited states in complex light-absorbing materials including electron-phonon and exciton-phonon interactions. For transition metal dichalcogenides, we explore how exciton-phonon interactions renormalize defect levels and lead to decoherence channels for excitations associated with deep in-gap states; for organic acene crystals, we develop and use an approach to compute hopping diffusion rates for self-trapped excitons; and, finally, for halide perovskites, we discuss generalization of the BSE framework to include phonon screening via introduction of an exciton-phonon kernel, and demonstrate a significant renormalization of exciton binding energies. We also develop a general Wannier-Mott model for excitons including phonon screening, clarifying its importance in polar semiconductors. In each of the three examples presented, I will emphasize implications for experiments and new principles for the design of these systems materials. This work supported by the Department of Energy and the Department of Defense; computational resources provided by NERSC.

5:40 PM CT07.04.02
Tunable Edge States of Nanoribbons by Density Functional Theory and GW Approximations Adrienn Ruzsinszky, Hong Tang, Bimal Neupane and Niraj K. Nepal; Temple University, United States

Two dimensional materials (2D) are of interest due to their remarkable physical and chemical properties. Bending is the computationally efficient route to tune fundamental/optical gaps for device functionality [1]. Under mechanical bending, some transition metal dichalcogenide (TMD) monolayer nanoribbons undergo highly nonuniform local strain within the curved layers, much larger than uniaxial strain, making band edge states more tunable in these 2D materials. This helps to remove the strong Fermi-level pinning in the flat states, making the materials usable in contact-engineering. Many-body GW approximations can provide accurate band structures for solid materials. We use GW calculations along with recent meta-GGA density functionals to check the tunability of the band edges of MoS2 nanoribbon with various widths. We are particularly focusing on non-empirical meta-GGAs developed for band-gap prediction [2], as computationally cheaper alternatives to hybrid functionals and GW approximations.
Work is supported by DOE-BES DE-SC0021263.

5:55 PM *CT07.04.03
Moiré Twistronics in Transition-Metal Dichalcogenide Heterostructures David A. Ruiz-Tijerina; Universidad Nacional Autónoma de México, Mexico

Heterostructures formed by vertically stacked layers of transition-metal dichalcogenides (TMDs) exhibit a long-range atomic registry modulation known as a moiré pattern, caused by the slight incommensurability and/or twist angle between the layers. Carriers and excitons in the heterostructure perceive the moiré pattern as a superlattice potential capable of fundamentally altering their energy and optical spectra through miniband formation [1] and localization by confinement [2].

In this talk I shall discuss such effects, paying especial attention to heterobilayers formed by TMDs whose electron or hole band edges are nearly degenerate. This condition promotes resonant interlayer hybridization of both carriers and excitons, leading to the formation of hybridized exciton (hX) states, i.e., coherent superpositions of intra- and interlayer excitons that simultaneously possess a large oscillator strength and electric dipole moment [3]. At small twist angles, umklapp scattering by the moiré superlattice results in hX minibands, recently observed in $MoSe_2/WS_2$ structures [4]. The optical response of these moiré hX minibads is thus highly tunable by electrical means and twist angle control, providing an engineering pathway for the material's optoelectronic response. Finally, I will argue that hybridized excitons are ubiquitous in

heterostructures of TMDs and their alloys, and discuss their importance for new twistronic materials for optoelectronics.

Determining the Linear Optical Properties of Transition Metal Doped Zinc Selenide from a First-Principles Approach Nicholas Pike[1,2] and Ruth Pachter[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Wide bandgap group II-VI chalcogenides have been used in multiple optical applications. For example, doping ZnSe by first-row transition metal atoms leads to localized states within the bandgap and thus changes to the structural, electronic, and optical properties of the ZnSe host. Here we explore the properties of ZnSe for a series of transition metal dopants using first-principle calculations. We discuss the level of theory applied for calculation of the electronic structures, using a metaGGA exchange-correlation functional with a Hubbard U correction. Our calculated absorption spectra in the infrared and visible spectral ranges demonstrate agreement with experimental measurements. The electronic structures correctly predict the spectroscopic fingerprints, and using Tanabo-Sugano diagrams, the crystal field energy in these materials.

6:35 PM CT07.04.05
Computational Analysis of Critical Points in Temperature Dependent and Time Resolved Ellipsometry Spectra of Ge Using Digital Filtering Carola Emminger[1], Stefan Zollner[1], Nuwanjula S. Samarasingha[1], Farzin Abadizaman[1], Jose Menendez[2], Shirly Espinoza[3], Steffen Richter[4], Mateusz Rebarz[3], Oliver Herrfurth[5], Martin Zahradnik[3], Rudiger Schmidt-Grund[6] and Jakob Andreasson[3]; [1]New Mexico State University, United States; [2]Arizona State University, United States; [3]ELI Beamlines, Czechia; [4]Linköping University, Sweden; [5]Universität Leipzig, Germany; [6]TU Ilmenau, Germany

Critical points (CPs) are structures in the dielectric function (DF) which are related to interband transitions and depend on temperature and doping. We analyze CPs in the DF of bulk Ge measured with static and time-resolved spectroscopic ellipsometry using a linear filter technique based on Gaussian kernels recently introduced by Le, Kim, Kim, and Aspnes [1], which combines interpolation, noise reduction, scale change, and differentiation.
Utilizing this linear filter method, we calculate the second derivatives of the complex DF with respect to energy of experimental data taken in the spectral range of the direct band gap E_0 at various temperatures from 10 K to 718 K. The choice of the filter width is crucial to eliminate noise while preserving information at the same time and is defined according to the onset of white noise in the Fourier coefficients determined from a discrete Fourier transform of the data [1].
Applying a Levenberg-Marquardt algorithm, the second derivatives are fitted simultaneously with the imaginary part of the DF to a lineshape based on the Elliott-Tanguy theory [2] considering excitonic effects present at the direct band gap. The Elliott-Tanguy lineshape depends on the excitonic binding energy, the effective masses of the valence and conduction bands, the dipole matrix element, the threshold energy, and a broadening parameter. Effective masses of the conduction band and the heavy (hh) and light hole (lh) valence bands at cryogenic temperatures, as well as the matrix element are taken from literature. For the data set at 10 K, fitting only the band gap energy and the broadening parameters of the hh- and lh-bands provides reasonable fitting results for both the imaginary part and the second derivatives of the DF. For data above 10 K, the temperature dependence of the effective masses and the matrix element are considered. A red shift of the direct

band gap energy with increasing temperature is found as well as an increase in broadening which can be fitted using a Bose-Einstein statistical factor taking into account electron-phonon interactions.
The same analysis method is applied to the E_1 and $E_1+\Delta_1$ CPs of Ge dependent on photo-excited charge carrier density and temperature obtained from femtosecond pump-probe ellipsometry measurements [3]. Using a two-dimensional CP lineshape, the amplitude, excitonic phase angle, threshold energy, and broadening parameters are determined as functions of delay time. We find a distinctive change of the various parameters and a relaxation which starts at about 4 ps after the pump pulse. The decrease of the E_1 and $E_1+\Delta_1$ energies suggests a laser heating of about 20 K to 40 K, respectively. In the analysis of these data, we are especially interested in changes to the E_1 and $E_1+\Delta_1$ band gaps due to many-body effects (such as band gap renormalization and band filling), broadenings (due to screening of the electron-phonon interactions), spin-orbit coupling strengths, and excitonic phase angles as a function of the delay time between the pump and probe pulses.

6:50 PM CT07.04.06
Tight-Binding DFT Investigation of Structural, Vibrational and Transport Properties of Graphene-Single-Walled Carbon Nanotube Hybrid Junctions Juhi Srivastava and Anshu Gaur; Indian Institute of Technology Kanpur, India

Single-walled carbon nanotubes (SWNT) and single-layer graphene (SLG) both are allotropes of sp^2 hybridized carbon with unusual and unique properties owing to their 1D and 2D nature, respectively. In recent years, there has been a push to use hybrids of carbon nanotube and graphene for various applications which take benefit of their unique properties while overcoming the limitations of individual components. A constitutive understanding of the interactions between SWNT and SLG will allow modification and tailoring of the properties of hybrid nanostructures as desired for various applications. This work focuses on the computational study of various interactions between SWNT and SLG in their hybrid nanostructures. In some of the recent experimental works, charge transfer between the constituents (SWNT and SLG), owing to their small work-function difference, is considered to be responsible for changes in their electronic and vibrational properties in the hybrid system. However, other forms of interaction between atoms of SWNT and SLG, such as van der Waal's (vdW) forces which may lead to localized structural deformations, may also have pronounced effect on measured properties. The interactions between carbon atoms of SWNT and SLG at close proximity may also result in electronic structure of the system that is unique to the hybrid nanostructure and different from either component (SWNT and SLG). These changes affect the overall performance of the devices based on SWNT-SLG hybrids with respect to the pristine constituents. We present the effect of various factors arising due to the interactions between atoms of SWNT and SLG, i.e. the van der Waal's (vdW) forces, structural deformation and the charge transfer, on the structural, vibrational, electronic, and transport properties of hybrid nanostructures, investigated computationally within the framework of tight-binding density functional theory (TB-DFT). These factors are already known to affect the vibrational properties on SWNT and SLG individually and are also seen to affect the Raman active phonon frequencies of SWNT and SLG within the hybrid system. In this work, we have explored the role of individual factors and interplay between them to estimate their relative contribution to the total changes observed in phonon frequencies in the hybrid systems. From our calculations, it is apparent that the structural deformations and the vdW forces acting on the atoms are the main factors to affect the vibrational properties of components within the hybrid, with structural deformation being the leading factor. We also observe that the charge transfer between SWNT and SLG is not enough at the equilibrium separation of ~3 Å to cause any significant changes in the Raman active phonon mode frequencies. With decreasing separation between SWNT and SLG, the charge transfer increases, however, the resulting vdW forces increase much more rapidly and hence would remain the prime factor to cause changes in vibrational properties. These interactions also affect the electronic structure and electronic transport (calculated within the non-equilibrium Green function (NEGF) formalism) in the hybrid nanostructures. The electronic structure of

hybrid nanostructures with various separations between SWNT and SLG and its effect on overall transport behavior is investigated to gain better understanding. We believe that our study would be helpful in comprehending experimentally observed behavior in hybrid nanostructures and may lead to the design of new hybrid systems with desirable properties.

Exploiting Quantum Plasmonics for Enhanced Functionalities of Low-Dimensional Heterostructures
Zhenyu Zhang; University of Science and Technology of China, China

In systems of reduced dimensionality containing metals as constituent building blocks, the pertinent conduction electrons are quantum mechanically confined, and their collective excited states of motion are termed plasmons. Recent research has witnessed intensive efforts on exploiting the rich quantum nature of plasmonic excitations in a wide variety of processes, including photon entanglement, solar energy harvesting, electron dephasing, and catalysis, to name just a few. In this talk, we will briefly review situations where the quantum nature of plasmons is bound to play a vital role. Then we will use a few recent representative systems to demonstrate how quantum plasmonics can be exploited to enhance the performance of low-dimensional heterostructures for optimal functionalities. Our first example is the enhanced energy transfer between plasmons and excitons in the strongly coupled regime known as the plexcitons. Here, we reveal the various spectroscopic signatures of the coupling strength and its tunability in systems of molecular species adsorbed on noble metal nanoparticles. The next example is the demonstration and understanding of drastically enhanced phase coherence of the electron transport in graphene proximity coupled with a plasmonic system. Pushing further on the scope, we show in the third example how plasmons can join force with phonons in enhancing the superconducting transition temperatures of interfacial superconductors and beyond.

Landau Levels and Energy Level Alignment for 2D Valleytronics and Spintronics Su Ying Quek; National University of Singapore, Singapore

Two-dimensional materials are promising candidates for next generation quantum devices. Rational bottom-up design of these functional materials rests on the ability to predict from first principles physical properties that are fundamental to the proposed functionalities. In this talk, we first present a first principles approach to predicting the Landau levels in monolayer H-phase transition metal dichalcogenides, which are 2D valleytronic materials. We obtain Landau levels that are symmetric in the K and K' valleys, shifted by a valley Zeeman term.[1] By using Hamiltonians with increasing levels of sophistication, we evaluate the effects of many-body interactions on the single-band orbital magnetic moments at the valleys. The resulting Landau levels are valley- and spin-polarized, and are in good agreement with recent experiments.[2] We next address the problem of energy level alignment in mixed-dimensional heterostructures, using state-of-the-art approaches to many-body perturbation theory in the GW approximation. Our GW approach (XAF-GW) [3] can be applied to large interface systems in the presence of non-covalent interfacial hybridization. We show that cobalt phthalocyanine (CoPc) molecules assembled on a 2D vanadium diselenide substrate are promising candidates for spintronics and quantum information applications. The spin on CoPc is not quenched, and spin-dependent tunneling barriers exist due to many-body interactions in the interface-hybridized states.[4] These same many-body interactions result in a shoulder in the unoccupied spectra which is also observed in experiment.

Substrate Screening Effect on Quasiparticle Energies and Optical Properties of Two-Dimensional Interfaces with Lattice Mismatch Chunhao Guo[1], Junqing Xu[1], Dario Rocca[2] and Yuan Ping[1]; [1]University of California, Santa Cruz, United States; [2]University of Lorraine, France

Two-dimensional (2D) materials and their interfaces have recently emerged as promising platforms for exotic physical phenomena and outstanding applications. Previous methods of including substrate screening for quasiparticle energies can be only applicable to interfaces of two systems' lattice constants with certain integer proportion, which often requires a few percentage of strain. To solve this problem, we developed an efficient and accurate reciprocal-space interpolation technique for dielectric matrices that made quasiparticle energy calculations possible for arbitrarily mismatched interfaces free of strain [1]. We applied this method to obtain quasiparticle corrections at GW approximation for arbitrary mismatched 2D interfaces, by interfacing hexagonal boron nitride (hBN) with SnS2 and phosphorene at their natural lattice constants.
We then employed this method to study the effect of substrates on optical properties of 2D materials, by solving the Bethe-Salpeter equation. We obtained a perfect agreement with experimental non-rigid 1s and 2s excitonic shifts with increasing layer thickness of WS2, where the 1s peak is nearly unchanged with the number of layers, in a sharp contrast to 2s excitonic peak. Similarly, the 1s peak position of hBN was less sensitive than 2s excitonic peak when varying its substrate materials. We explained this observation in terms of the scaling relation of 1s and 2s exciton binding energy with a 2D hydrogen Wannier exciton model, and the linear scaling between exciton binding energy and quasiparticle band gap due to the environmental screening. At the end, we predicted a longer radiative lifetime of hBN with substrate screening than the one of free-standing hBN. [1] C. Guo et al, arXiv:2007.07982

Intersystem Crossing and Exciton-Defect Coupling of Spin Defects in Hexagonal Boron Nitride Tyler J. Smart[1,2], Kejun Li[1], Junqing Xu[1] and Yuan Ping[1]; [1]University of California, Santa Cruz, United States; [2]Lawrence Livermore National Laboratory, United States

Despite the recognition of two-dimensional (2D) systems as emerging and scalable hostmaterials of single photon emitters or spin qubits, uncontrolled and undetermined chemical nature of thesequantum defects has been a roadblock to further development. Leveraging the design of extrinsic defects cancircumvent these persistent issues and provide an ultimate solution. Here we established a completetheoretical framework to accurately and systematically design new quantum defects in wide-bandgap 2Dsystems. In particular, many-body interactions such as defect-exciton couplings are vital for describing excitedstate properties of defects in ultrathin 2D systems. Meanwhile, nonradiative processes such as phonon-assisted decay and intersystem crossing rates require careful evaluation, which compete together withradiative processes. From a thorough screening of defects based on first-principles calculations, we identifiedthe Ti-vacancy complex as a promising defect in hexagonal boron nitride for spin qubits, with a triplet groundstate, large zero-field splitting, and a prominent intersystem crossing rate highly desirable for spin-stateinitialization and qubit operation.

Single Crystal Growth and Transport Properties Studies of Non-Symmorphic Material $CuBi_2O_4$ Tekiyah Robinson, Kory Wells, Jonathan Valenzuela, Doyle Temple, Leroy Salary and Sunil Karna; Norfolk State University, United States

Topological materials having 8-fold electronic degeneracy protection by nonsymmorphic symmetries of a crystal exhibit double Dirac fermions which have been predicted in $CuBi_2O_4$. Here, we have grown $CuBi_2O_4$ single crystal using floating zone crystal growth technique. Polycrystalline X-ray diffraction shows that $CuBi_2O_4$ crystallizes in the space group *P*4/*ncc* which consists of planar $[CuO_4]^{6-}$ units with Bi^{3+} ions occupying the spaces between units. The magnetization and specific heat indicate a transition to the antiferromagnetic order at TN = 43 K, in agreement with earlier literature reports. In this poster, the detailed magnetoresistance measurements in different crystal orientations will be also presented.

The Electronic States of MoS_2-ITO—Experiment and Theory Manuel A. Ramos[1], Oscar Alberto López Galán[1], John Nogan[2], Torben Boll[3,4] and Martin Heilmaier[3]; [1]Universidad Autónoma de Ciudad Juárez, Mexico; [2]Sandia National Laboratories, United States; [3]Karlsruhe Institute of Technology–Institute for Applied Materials, Germany; [4]Karlsruhe Institute of Technology, Germany

The electronic states for indium-tin-oxide/molybdenum disulfide ($In_2Sn_2O_7/MoS_2$) crystal interface have been calculated by meaning of density functional theory using CASTEP code with ultrasoft pseudopotentials and revised Perdew-Burke-Ernzerhof (RPBE) functional in General Gradient Approximation (GGA). All molecular models were built using experimental information from atom probe tomography measurements on ITO-MoS_2 thin films as previously reported [1,2]. The experimental APT data indicates no segregation between species; however, some oxygen- molybdenum chemical bonding was detected corresponding to vertical <101>-direction growth of 2H-MoS_2 crystallites onto ITO during RF-sputtering deposits. The density of states indicate a semi-metallic character which are in agreement with Ohmic behavior of resistivity values of ρ ~24-27 (Ω/m) as measured by four-point probe in ITO/MoS_2 thin film samples, as well bending of electronic semiconducting bands of MoS_2 when its on conctact with ITO.

Diffusion and Chemical Stress—Induced Stress Effects in Ion Exchanged Inorganic Silicate Glass
Guglielmo Macrelli; Isoclima SpA, Italy

Diffusion of atoms, ions and molecules in solid materials may result in local mechanical stress. A review is presented of literature studies in semiconductors materials, high temperature oxidation and electrochemical charging and discharging of electrodes in lithium ion batteries. The main focus is inorganic silicate glasses submitted to alkali ion-exchange below glass transition temperature. Interdiffusion driven ion-exchange in glass results in stress effects that are used in technological applications for glass articles strengthening. These processes are extensively and widely used in screen covers for consumer electronics and structural windows for architectural and transportation applications. Optical effects are also discussed as a consequence of ion interdiffusion and its relationship with residual stress. Underpinning physics of ion exchange in glass is reviewed in respect to both stress build-up and relaxation considering, that ion exchange is a irreversible mass transfer process performed on a non-equilibrium state of matter which spontaneusly relaxes towards a metastable supercooled liquid state.

Chemo-Mechanically Coupled Feedback Interactions and the Challenges to Building Robust Predictive Models Nithya Subramanian[1], Chiara Bisagni[1] and Laura Nielsen Lammers[2,3]; [1]Delft University of Technology, Netherlands; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States

Novel materials enable solutions to the global challenges that we face today pertaining to energy and the environment. The realization of materials technology that allows for reliable lightweight structures, improved energy storage, improved efficiency of waste/nutrient recovery, etc. critically hinges on our understanding of strongly coupled material behavior under a wide range of conditions. Some natural as well as engineered material systems exhibit an interplay between their chemistry and mechanical response as the microstructures of these materials dynamically evolve as a response to their chemical composition/reaction kinetics. In some cases, even when our understanding of said coupled behavior is advanced, there are limitations to how we can account for them in computational models owing to a need for multiscale transfer of information. Building predictive mechanics models that can accurately capture the origins of material behavior by explicitly incorporating the chemical structure of constituents and reaction kinetics can be computationally prohibitive. This brings up the need for effective upscaling strategies in multiscale, multiphysical models that can preserve traceability across scales.
Here, we explore strategies for upscaling the mechanochemistry captured through all-atom classical and reactive molecular dynamics simulations in a few example materials such as polymer adhesives, engineered nanocomposites, and clay-rich porous media that are used in aerospace, electrochemical, and geological applications.

The polymer curing reaction in a multicomponent aerospace-grade epoxy is modelled based on a cut-off distance-based approach that determines bond formation. The resulting degree of conversion of the polymer and its glass transition temperature are confirmed with experimental data. We also studied the chemical and physical interactions in nanocomposites where carbonaceous nanoparticles are dispersed in a thermoset polymer. The interfacial adhesion (arising from chemical functionalization and non-bonded forces) between the nanoparticles and surrounding polymer is also quantified as a function of the degree of conversion of the polymer and the chemical composition (% wt. of nanoparticle in the nanocomposite). From a large combination of these simulations, we determined the effect of the nanostructure and chemistry of the polymers and nanocomposites on their elastic properties, crack initiation from bond breakage and chain sliding, traction-separation behavior at crack openings and fracture toughness. In the case of clay minerals whose chemical-mechanical coupling has tremendous implications for their role as geological barriers for the subsurface disposal of nuclear waste, we modelled the water and ion diffusion, clay swelling states and ion exchange selectivities for a range of pore fluid chemical compositions and concentrations. The swelling pressure, and therefore, the stress states of clay tactoids (containing multiple layers of clay minerals) was determined as a function of the local chemical composition.
In all the above-mentioned studies, the molecular models provide valuable insight into the dependence of stress states and interfacial load transfer on the chemical composition and the energetics of reactions. We then use a stochastic representative volume element (RVE) approach to march up the length scale while accounting for uncertainties characterized at the molecular scale. With the stochastic RVEs, we can predict the 'bulk' stress response and associated damage propagation under a given loading condition. The choice of parameters (and their probability distributions to make a stochastic prediction) to be included in the RVE model depends on the material system and its related performance parameter of interest. For example, in clay minerals, our interest is to predict the swelling and collapse of mineral layers (the swelling pressure & stress state) as a function of water activity and ambient conditions whereas the interest in polymer adhesives is to predict crack nucleation and propagation. Holistic computational models that can provide top-down/bottom-up traceability of chemical-mechanical coupling can be a valuable tool in our arsenal to advance and accelerate the design and certification of these material systems in critical applications.

8:40 AM *CT08.01.03
On the Role of Stress in Microstructure Evolution During Thermo-Chemical Surface Engineering Marcel A. Somers and Thomas L. Christiansen; Technical University of Denmark, Denmark

Thermochemical surface engineering of metals is characterized by a deliberate and targeted modification of the (sub)surface region of metals, with the aim to improve materials performance with respect to fatigue, wear, corrosion and combinations thereof. Generally, thermochemical surface engineering is understood in terms of thermodynamics and diffusion kinetics to describe the evolution of the microstructure under the influence of the chemical modification at elevated temperature. Associated with the change in composition in the surface-adjacent region strains and stresses are introduced. These strains/stresses affect the thermodynamics and the kinetics of the ingress of chemical species and, consequently, the microstructural evolution. This contribution illustrates several of the effects of composition-induced stresses/strains during thermochemical surface engineering with interstitials in metals through examples from activities in the authors' research group. The presentation includes experimental as well as modelling aspects. The following examples are covered.
1. The dissolution of N and/or C into stainless steels and high entropy alloys (HEAs) at temperatures below 725 K for N and below 825 K for C is associated with the development of a supersaturated solid solution of interstitials in the fcc phase. This supersaturation is "kinetically stabilized" by sluggish decomposition, because of slow diffusion of substitutionally dissolved components. The lattice expansion caused by dissolution of N or C is accommodated elastically for low interstitial contents, leading to strengthening. As solid solution strengthening scales with the cube root of composition squared and biaxial compressive stresses caused by lattice expansion scale linearly with composition, plastic accommodation will occur above a threshold composition. Also, with an increase in N content long range ordering (LRO) of N atoms is encountered. The combination of elasto-plastic accommodation of lattice expansion and LRO leads to anisotropic growth of the developing case.

2. Hcp titanium can dissolve high contents of oxygen and is applied for surface hardening of Ti and its alloys. The thermo-chemical treatment of Ti in CO above the hcp-bcc transition temperature leads in principle to the uptake of both O and C. Since C has a very low solubility as compared to O, hence, primarily O is dissolved, thereby stabilizing a case of hcp-Ti atop bcc-Ti. The conversion of bcc to hcp is associated with the introduction of tensile stresses in the hcp case, leading to crack development in the hard and brittle part of the case close to the surface. Upon cracking, CO ingress leads to the development of a mixed interstitial compound Ti(C,O) along the crack surface, thereby converting this part into an extremely wear resistant Ti-surface, with a hardness of up to 3,000 HV.
3. Oxidizing of ZrCuAl-based bulk metallic glass (BMG) below the glass transition temperature is a potential thermo-chemical surface engineering treatment of BMGs. Within the BMG an internal oxidation zone (IOZ), consisting of nano-crystalline ZrO2, develops. The volume expansion caused by zirconia formation leads to compressive residual stresses in the IOZ. The theoretical stresses are 30 times higher than the experimentally determined stress levels, indicating that stress relaxation has occurred. This is accomplished by shear band formation in the BMG adjacent to the IOZ, which later affects the ZrO2 development of the advancing oxidation front. In addition, the compressive stresses induce outward diffusion of “noble” elements, as for example Ag (if present) and Cu. Surprisingly, segregation of these noble elements at free surfaces, as the outer surface, but also crack surfaces, leads to crystalline metallic regions, which can be considered as self-healing in the case of crack formation. Depending on the oxygen partial pressure, Cu can oxidize upon arrival at the surface.

Magnetic Force Microscopy Based Investigation of Molecule Impact on Magnetic Tunnel Junction Based Molecular Devices Pawan Tyagi; University of the District of Columbia, United States

This paper discussed the experimental magnetic force microscopy (MFM) studies on MTJMSDs. We showed that molecules are much more than simple spin channels between two magnetic electrodes. MFM produced vivid evidence showing that a paramagnetic molecule covalently bonded to the two ferromagnetic electrodes catalyzed a large-scale ordering on ferromagnetic electrodes and impacted several hundred-micron areas near molecular junctions. Transport studies showed that paramagnetic molecule induced long-range impact on ferromagnetic electrodes resulted in several orders of current suppression at room temperature. Future studies with various forms of magnetic tunnel junctions and molecules are in order. The present work provides the details about the efficacy of cost-effective, and mass producible liftoff based molecular device fabrication.

Novel Insights into Corrosion Processes by Advanced X-Ray Methods Christiane Stephan-Scherb[1,2]; [1]Federal Institute for Materials Research and Testing, Germany; [2]Freie Universität Berlin, Germany

A variety of materials of technological interest change their properties through contact with reactive media. Solid-gas reactions lead to a variety of reaction products on the surfaces and internal interfaces. The observation of nucleation and growth processes in the environment where they occur (in situ) from a chemical-structural perspective is especially challenging for aggressive atmospheres. The talk presents innovative approaches to study corrosion mechanisms using advanced X-ray methods. Using energy dispersive X-ray diffraction and X-ray absorption spectroscopy in different tailor made environmental reaction chambers, valuable insights into high temperature oxidation and sulfidation processes were gained. Fe-based alloys were exposed to hot and

reactive atmospheres containing gases like SO_2, H_2O and O_2 at 650°C. During the gas exposure the tailor made reaction chambers were connected to a high energy diffraction end station at the synchrotron. The crystallization and growth of oxide and sulfide reaction products at the alloy surfaces were monitored by collecting full diffraction pattern every minute. Careful examination of shape and intensity of phase-specific reflections enabled to a detailed view on growth kinetics. These studies showed, oxides are the first phases occurring immediately after experimental start. As soon as reactive gas media enter the chamber, the conditions change and different reaction products, such as sulfides start to grow. A comparison of different gas environments applied, illustrated the differences in the type of reaction products. The in situ observation of high temperature material degradation by corrosion made it possible to study the contribution of phases, which are not stable at room temperature. For instance, wuestite ($Fe_{1-x}O$), was frequently observed at high temperatures in humid gases on Fe with 2 wt.% and 9 wt.% chromium, but not at room temperature. The strength of the occurrence of this phase additionally explains why, despite a higher Cr content, ferritic alloys with 9 wt.% Cr in a challenging atmosphere prevent the intrinsic formation of protective layers. The in situ observations were supplemented by careful considerations of thermodynamic boundary conditions and detailed post characterization by classical metallographic analysis. Additionally, the structure and chemistry of the dominant oxide layers were evaluated using X-ray absorption near edge structure spectroscopy. The talk will give an overview about chances and challenges for studying high temperature corrosion phenomena by advanced X-ray methods.

12:10 PM CT08.02.02
Modeling of Mass Transfer and Alpha Case Formation in Investment Casting of Titanium Alloys Sharon Uwanyuze, Stefan Schaffoener, Sanjubala Sahoo and Pamir Alpay; University of Connecticut, United States

Titanium alloys have excellent corrosion resistance, high-temperature strength, low density, and biocompatibility. Therefore, they are increasingly used for aerospace, chemical, and biomedical applications. Moreover, investment casting is a well-established process for manufacturing near-net-shape intricate parts for such applications. However, mass transfer arising from metal-mold reactions is still a major problem that drastically impairs the surface and properties of the castings. This work investigates the interfacial reactions and mass transfer problems that lead to alpha case formation. Improvements based on modeling and experimental validation are discussed, highlighting ceramic oxide refractories namely—zirconia, yttria, calcia, alumina, and novel perovskites particularly calcium zirconate and barium zirconate. It was found that while mold material selection is vital, alloy composition should also be carefully considered in mitigating metal-mold reactions and mass transfer.

12:25 PM *CT08.02.03
Degradation of Zirconium Alloys in Nuclear Reactors Studied by Atom Probe Tomography Mattias Thuvander, Johan Eriksson and Hans-Olof Andrén; Chalmers University of Technology, Sweden

The uranium dioxide nuclear fuel of light water reactors is contained in 4 m long tubes with a diameter of about 10 mm and a wall thickness of about 0.7 mm, called cladding tubes. The cladding tubes are made of zirconium alloys, the main reason being the very low cross section of Zr for thermal neutrons. The cladding tubes are subjected to several degradation mechanisms, including water-side corrosion, hydrogen pick-up and irradiation damage, affecting the mechanical integrity, which restricts the usage of the fuel. There are several different Zr alloys that are used for cladding tubes. We have studied Zircaloy-2, which is commonly used in boiling water reactors. It has a composition of Zr-1.5%Sn-0.15%Fe-0.1%Cr-0.05%Ni, and it is known that Fe, Cr and Ni play important roles for the performance of the alloy. These elements have a low solubility and precipitates of $Zr_2(Fe,Ni)$ and $Zr(Fe,Cr)_2$ form. In order to study both the corrosion behavior and the neutron damage, atom probe tomography (APT) is a very useful technique, combining a sub-nm resolution in 3D with a high elemental sensitivity. By analyzing the oxide and the metal/oxide interface of samples corroded in autoclave it was shown that Fe and Ni were segregated at grain boundaries in the metal and that these segregations were inherited by the inwards growing oxide. Modeling provided support for that Fe present at oxide grain boundaries should reduce hydrogen pick-up, whereas the opposite should be true for Ni. We have also analyzed Zircaloy-2 after

in-reactor exposure, for three and nine years, respectively. The neutron irradiation leads to a gradual dissolution of the precipitates as well as formation of dislocation loops. It was found that the dissolved Fe, Cr and Ni segregates to the loops. This is very interesting, although it is not clear how this segregation affects the growth and stability of the loops, or the corrosion and hydrogen pick-up behavior.

12:50 PM CT08.02.04
Influence of Pack Cementation Time and Annealing on Microstructure of Cu Nanofoams Processed by Dealloying Hung T. Pham[1], Péter Jenei[1], Csilla Kádár[1,2,3], GiGap Han[4], Heeman Choe[4] and Jeno Gubicza[1]; [1]Eötvös Loránd University, Hungary; [2]Budapest University of Technology and Economics, Hungary; [3]MTA–BME Lendület Composite Metal Foams Research Group, Hungary; [4]Kookmin University, Korea (the Republic of)

Cu nanofoams processed by dealloying were studied as a promising applicant for anode material in lithium-ion batteries. Pack cementation were applied to produce the precursor materials for different times (3, 6, 12 and 15 h). The microstructure of the specimens was studied after the dealloying process. Samples produced with 6 h pack cementation time were also annealed to investigate the influence of heat treatment on the microstructure of Cu nanofoams. The foam structure was examined by scanning electron microscopy (SEM). The phase composition of the materials was determined using X-ray diffraction (XRD). Furthermore, X-ray line profile analysis (XLPA) was utilized for quantitative characterization of the diffraction domain size, the dislocation density and the twin fault probability.

Characterization of Early Stages of Radiation Damage in Metals and Alloys with Positron Annihilation Spectroscopy Filip Tuomisto; University of Helsinki, Finland

The early stages of radiation damage in metals and alloys are governed by phenomena on the atomic scale. The most elementary are the creation of individual vacancies and interstials (Frenkel pairs) and their motion that leads to either their annihilation or evolution towards larger defect clusters. The detailed mechanisms of the evolution of the radiation damage strongly depend on the defect-matrix-solute-impurity interactions. Experimental identification of the radiation-induced defects and the characterization of their properties is crucial for developing a detailed understanding and physics-based predictive models for radiation damage. Positron annihilation spectroscopy is a set of methods selectively sensitive to vacancy-type (open volume) defects [1]. It can be used to identify the sizes of the defects from mono-vacancies to clusters of tens of missing atoms, with concentration sensitivity in the range 10 ppb - 100 ppm. The chemical identity of the atoms immediately surrounding the vacancy-type defects can also be identified to a certain extent. Experiments can be performed with near-surface depth resolution up to a few microns, as well as in the bulk of the material, in a temperature range 10 - 1000 K, allowing for various in situ irradiation experiments.
I will review some of the recent positron annihilation experiments dealing with early-stage radiation damage in tungsten and high-entropy alloys (HEAs). The results obtained in tungsten include the direct determination of mono-vacancy and interstitial migration barriers [2] that employ irradiation experiments at cryogenic temperatures for freezing in the radiation-induced defects, and hydrogen-vacancy-cluster interactions at elevated temperatures [3]. In HEAs, the experiments reveal atomic-scale segregation already at the early stages (below 1dpa) of radiation damage [4] and non-trivial effects of C interstitials in the HEA matrix on hydrogen irradiation induced damage [5]. Finally, I will discuss preliminary results obtained in C and N interstitial

containing HEAs that show intriguing mono-vacancy migration barrier behavior most likely related to the unusual effects of these interstitials on the distribution of local lattice distortions.

2:40 PM *CT08.03.02
In Situ TEM Observation of Mechanochemical Coupling Induced Materials Degradation Chongmin Wang and Daniel Schreiber; Pacific Northwest National Laboratory, United States

Active functioning of materials will often trigger, or be accompanied by, one or more deleterious processes, such as oxidation, corrosion, fatigue, and thermal or mechanical effect, which in turn will couple with the active process to collectively affect the materials behavior and functionality. In a typical example, electrochemically driven functioning of a rechargeable battery inevitably induces thermal and mechanical effects that couple with the electrochemical process and collectively govern the performance of the battery. A direct visualization of such a coupling effect appears to be a fundamental challenge. In this presentation, we will discuss the utility of in-situ TEM to directly probe the mechanochemical coupling effect, intending to unravel mechanical effect on ionic transport, oxidation induce stress generation, mechanical effect on lithium dendrite growth, and electrochemical induced crystal deformation. We demonstrate that the intricate coupling of electrochemical, thermal, and mechanical effects will surpass the superposition of individual effects.

3:05 PM CT08.03.03
Late News: Electrolyte Conditions in Li-Ion Batteries in Presence of a Thermal Gradient Joaquin Guillamon[1], Corey Love[2], Rachel Carter[2], Xue Yang[1] and Amit Verma[1]; [1]Texas A&M University - Kingsville, United States; [2]U.S. Naval Research Laboratory, United States

Safety is an important concern in Li-ion battery operation and storage. As both energy stored per unit volume and higher current densities have increased in these batteries, energy dissipation in the form of heat has become one of the main issues for proper battery operation. As temperature increases, secondary chemical reactions may be initiated. These reactions release more heat and undesired products, triggering an auto-catalytic feedback process to occur, which is commonly classified into thermal-runaway mechanisms. This can potentially lead to a complete degradation of the battery, and possible explosion or combustion of the battery components.
Several researchers have worked on developing models to predict thermal behavior under conditions with potential thermal runaway outcomes on Li-ion batteries. The first studies proposed a model that emulates the solid electrolyte interface (SEI) decomposition and regeneration reactions on a standard 18650 cylindrical cell. Later works extended these models and included the reactions of cathode decomposition and electrolyte decomposition with potential combustion. Although macroscopic level energy balance helps to predict potential thermal behavior in a battery of multiple layers, the study of all the different transport mechanisms that happen inside a single layer battery is essential for a better understanding of the process taking place when temperature begins to rise. With the aim of improving heat dissipation inside a battery, the electrolyte is a key component to consider as it can potentially handle heat flux easier through convention within the solution.
This work investigates spatially dependent electrolyte conditions in the presence of a thermal gradient to produce an electrolyte-centric thermal runaway model. Non-current conditions are considered for this specific case study, emulating oven-test experiments, or storage conditions. The objective of the study is to model transport mechanisms that can potentially lead to thermal degradation of the battery. Li-ions, momentum, and thermal flux are the main components of the analysis. Numerical simulation techniques are used for this purpose. Findings show that non-uniform temperature distribution triggers free convection mechanisms within the electrolyte solution. According to our results, electrolyte stratification should be appreciated at the microscopic level. A thorough comprehension of the transport processes taking place inside the battery should

contribute to mitigate damage induced due to thermal abuse conditions.

3:20 PM CT08.03.04
Late News: Coupled Effects of Stress and Hydrogen on Stress Corrosion Cracking of Fe-Based Alloys
Arun Devaraj, Sten Lambeets, Mathew Olszta, Tingkun Liu, Joshua Silverstein and Daniel Perea; Pacific Northwest National Laboratory, United States

When Fe alloys are subjected simultaneously to an applied tensile stress and a corrosive, high-temperature aqueous medium, interplay of hydrogen and oxygen interactions with the alloy microstructure are thought to lead to intergranular stress corrosion cracking (SCC). Using transmission electron microscopy and in situ atom probe tomography we develop atomic scale understanding of this mechanochemical coupling during SCC of model Fe-18Cr-10Ni alloy. Specifically, the structure and composition of oxide layers and elemental partitioning as well as hydrogen segregation at the oxide-metal interface was revealed as a function of prior deformation. These new insights are expected to provide the scientific basis for tailoring the microstructure of metallic alloys used in nuclear and automotive applications to control the impact of coupled extreme environments of corrosion, stress, and temperature.

Fundamental Insight into Crack Retardation Behavior Through Advanced Characterization Elaine West; Naval Nuclear Laboratory, United States

Stress corrosion and corrosion fatigue cracking of structural materials used in the commercial nuclear power industry must be well understood to ensure the integrity of the reactor plant. While the cracking behaviors are generally recognized to show an Arrhenius temperature dependence, depature from this behavior has been observed at high temperatures. Mechanistic understanding of this behavior would support the development of improved predictive models for crack growth. Advanced characterization of crack tips and corrosion films have provided important insights into these behaviors. Chemical and mechanical signatures of crack retardation behavior will be discussed in the context of potential retardation mechanisms.

***Ab Initio* Study of Mechanochemical Coupling at Materials Interfaces** Zhuohan Li and Izabela Szlufarska; University of Wisconsin–Madison, United States

Mechanical forces and chemical reactions at materials interfaces are often coupled to each other. This coupling is relevant to fields such as rock friction, micro/nano devices, wafer bonding. In particular, in sliding contacts, compressive and shear stress can activate interfacial chemical bonding reactions, resulting in higher friction and adhesion, higher wear rate, and higher tribofilm and tribo-polymerization production rate. The mechanochemical coupling has been generally described by phenomenological theories, including the Eyring model. In these theories, the activation energy for a chemical reaction is increased or decreased by the mechanical work done on the system , where is the stress acting on the system, and is the activation volume. The physical meaning of activation volume has been under debate for decades, but the magnitude of the activation volume is often considered to be comparable to the dimension of the local deformation of chemical bonds participating in the reaction. However, recent experimental results showed that the range of activation volumes can be quite large even for the same material system. For example, for tribochemical wear of silicon

tips, where the wear is due to the chemical bond formation and breaking at the interface, the range of activation volumes can be as large as ~6.7-115 $Å^3$. With such a large range, the physical picture of the activation volume corresponding approximately to the dimension of the local volume involved directly in stretching or compressing of the chemical bonds might be oversimplified.
In order to understand the physico-chemical coupling at interfaces, we performed *ab initio* calculations of stress-induced reactions silica/silica interfaces. Our results show that the mechanochemical response arises not only from the interface region, where the chemical reaction occurs, but there is also a significant (and in some cases dominant) contribution from the deformation of the bulk solid. The relative contributions from each region depend on the stiffness of these regions, and the softer region dominates the response to the mechanical work done on the system. We also demonstrate that the contribution from the bulk region can be large even for stiff materials. This is because the near surface-region of the solid can be significantly softer than the bulk solid. The larger stresses experienced by the near-surface regions of two materials in contact can also lead to a larger mechanochemical response from the near-surface region. Our study provides new insights into the physical origins of the mechanochemical coupling at interfaces and the meaning of the activation volume.

Late News: Interplay Between Defect Transport and Cation Spin Frustration in Corundum-Structured Oxides Amitava Banerjee, Aaron A. Kohnert, Edward E. Holby and Blas Uberuaga; Los Alamos National Laboratory, United States

Despite the fundamental importance of mass transport, there is still a lack of knowledge regarding the mechanisms in many materials. In particular, how the magnetic spin structure interacts with migrating defects is unclear. Here, using density functional theory to examine cation interstitial transport in corundum-structure oxides, Al_2O_3, Cr_2O_3, and Fe_2O_3. These oxides have their own technological importance in various applications, such as diagnostic windows in nuclear energy systems, protective surface coatings, catalyst supports, magnetic storage, etc. In this study, we reveal an interplay between the migration of the interstitial and the magnetic structure of the oxide. The magnetic spin configuration impacts the migration energy of the migrating defect but, critically, the defect modifies the spin configuration. Thus, the two aspects change in concert to modify one other. This has profound implications for mass transport in magnetic materials.

Investigations on the Corrosion Resistance Enhancement of Electroless Ni-P Coating by Incorporating Corrosion Inhibitor-Loaded Nanocapsules Jiankuan Li, Chong Sun and Jingli Luo; University of Alberta, Canada

The ever-increasing energy demand has driven the search for new oil and gas resources in harsh environments. However, corrosion problems of carbon steels in oil and gas production under harsh operational conditions and during the product transportation considerably impede the productivity and cause safety concerns. Majority of these corrosion problems are related to CO_2 corrosion. In the journey of seeking solutions, a high-phosphorus electroless Ni-P coating has gained growing attentions as an advantageous candidate to carbon steels due to its good balance between the outstanding anti-corrosion performance and reasonable cost.
When Ni and P atoms are co-deposited under the catalytic effect of adsorbed hydrogen atoms in the coating deposition process, H_2 gas bubbles are easily produced and left in the coating to form “micropores” that favor the penetration of aggressive medium and lead to coating degradation. To effectively mitigate electrolyte penetration and coating degradation, we designed a smart Ni-P coating incorporated with nanocapsules that enable the release of the pH-responsive corrosion inhibitor when corrosive medium reaches the micropores.
In this work, the microstructure and chemical compositions of as-fabricated Ni-P coating and nanocapsule-incorporated Ni-P coating were analyzed by SEM, EDS, XPS and AFM, and the corrosion behaviors of the two coatings in the CO_2-saturated NaCl solution were then evaluated by potentiodynamic polarization measurements and EIS. The results show that BTA-loaded nanocapsules are successfully incorporated into Ni-P coating without altering the microstructure and deposition rate, and the presence of nanocapsules significantly reduces the coating porosity by filling in the micropores. As a result, the corrosion resistance of the smart

coating notably increases due to the release of BTA originated from the local acidification of the micropores, as compared to the as-deposited coating. A good anti-corrosion stability is further confirmed by few noticeable corrosion pits and no evidence of lateral coating disbondment at the coating/substrate interface after immersion tests. This study offers new insights into developing smart electroless Ni-P coatings by incorporating nanoscale functionalized additives.

Special Water as New Constitution for Soft Materials Zhenhui Qi and Mehmood Elahi; Northwestern Polytechnical University, China

The inspiration derives from the concept of structural water in nature that water molecules are bound inside hydrophobic pockets and help to stabilize protein structures. However, water has rarely been found a similar role in material science. By using this water-activated glue, the resulting supramolecular polymeric materials exhibits strong adhesion to surfaces, and can be reused many times without losing its performance. Considering the unique feature of water, this discovery triggered the transition of negative role of water, and we started the water-centered the soft material design.

8:40 PM CT08.05.02
Modifying Surface Free Energy via Water Adsorption for Nano-Bonding^{TM} Piezo-Electrics $LiTaO_3$ and $LiNbO_3$ with Si and SiO_2 at Room Temperature Mohammed Sahal, Abbie Ellison, Shefali Prakash, Srivatsan Swaminathan, Riley Rane, Brian Baker, Lauren Puglisi, Robert Culbertson and Nicole Herbots; Arizona State University, United States

The formation of hetero-structures between, either piezo-electric $LiTaO_3$ or $LiNbO_3$ with Si-based materials exhibits three major issues: the mismatch of crystal structure, of their lattice constants and of their coefficient of thermal expansion (CTE). In particular, the thermal expansion of $LiTaO_3$ or $LiNbO_3$ crystals is much larger. It differs from Si and SiO_2 by an order of magnitude.

The present work uses Nano-Bonding^{TM} [1] to directly bond $LiTaO_3$ and $LiNbO_3$ to Si and SiO_2. This is done via Surface Energy Engineering (SEE). In synergy, SEE modifies the surface hydro-affinity and the surface energy to far-from-equilibrium states. These are more likely to react in air at room temperature. H_2O vapor is used to catalyze bonding of $LiTaO_3$ and $LiNbO_3$ to Si and SiO_2.

Hydro-affinity and surface energies are mapped across 4-6” wafers via Three Liquid Contact Angle Analysis (3LCAA). Mapping is done in air in a Class 100 Laminar Flood hood. Hydro-affinity is mapped via the water contact angle. Surface Energy is computed using van Oss-Chaudury-Good theory [2], via the mapping of contact angles of two polar liquids (water and glycerin), and non-polar α-bromo-naphthalene. The measured surface energies are found to be close for the (110) orientation for both $LiTaO_3$ and $LiNbO_3$. They are 41 ± 2 mJ/m^2 for $LiTaO_3$ and 39 ± 2.5 mJ/m^2 for $LiNbO_3$ respectively.

The $\triangle G_{Piezo\text{-}Si\text{-}H2O}$ of interaction computed from measured surface energies by applying van Oss- Chaudhury-Good theory [2] for *‘as received’* $LiTaO_3$, with ‘*after SEE’* Si and SiO_2 were -0.1 mJ/m^2 and -16.8 mJ/m^2 and for *‘as received’* $LiNbO_3$, with ‘*after SEE’* Si and SiO_2 were -13.4 mJ/m^2 and -28 mJ/m^2.

Thus $\triangle G_{Piezo\text{-}Si\text{-}H2O}$ values are < 0, to bond *'as received'* hydrophobic $LiTaO_3$ and $LiNbO_3$ with *'after SEE'* hydrophilic Si and SiO_2 in the presence of atmospheric moisture. Experimentally, SEE based on these computations is found to be successful in activating Nano-Bonding™ (at room temperature in 25 % HR) of $LiTaO_3$ to Si, and $LiNbO_3$ to SiO_2.

8:55 PM CT08.05.03
Computational Insights into Dopant Enhanced Li Vacancy Distribution and Energetic Changes in Ga Doped LLZO Changlong Li[1], Lindsay Roy[2], Nancy Birkner[1], Kyle Brinkman[1] and Lindsay Shuller-Nickles[1]; [1]Clemson University, United States; [2]Savannah River National Laboratory, United States

Ga-doped $Li_7La_3Zr_2O_{12}$ (LLZO) has been experimentally fabricated with high lithium ionic conductivity and is a promising candidate for the electrolyte in all-solid-state Li-ion batteries. However, the thermodynamic properties of Ga-doped LLZO remain underreported. In this study, Coulomb energy analysis for large disordered crystal with supercell program and density functional theory (DFT) calculations provide insights into the compositional and structural stability of $Li_{56-3x}Ga_xLa_3Zr_2O_{12}$, where x = 0, 1, 2, 4, 6, 8. The lattice parameters decrease with increased Ga concentration because of the smaller ionic radii of the dopant and the formation of Li vacancies. Relationships between local coordination environment of Ga dopants and Li vacancies were considered, leading to an understanding of the configurational preferences in Ga-doped LLZO and the potential for correlated configurational dependencies of Li mobility. The enthalpy of formation as calculated based on the binary oxide reactants, for Ga-doped LLZO increases from -1540.72 kJ/mol for undoped tetragonal $Li_{56}La_{24}Zr_{16}O_{96}$ to -1411.70 kJ/mol for $Li_{32}Ga_8La_{24}Zr_{16}O_{96}$. The trend in enthalpy of formation with respect to the Ga concentration is in agreement with recently reported experimental calorimetry measurements, which are reported for the nominal formula unit $Li_{7-3x}Ga_xLa_3Zr_2O_{12}$ (where x = 0, 0.25, 0.5, 0.75, and 1). Detailed energetic analysis associated with a stepwise increase in [Ga] were performed to understand the changes in thermodynamic stability with increased Ga content. The relation between Li-ion conductivity and the stability of the Ga-doped LLZO emphasizes that a balance must be achieved between the increase in Ga concentration, which drives the formation of Li vacancies necessary for Li migration.

Modeling of Microstructure Evolution of Metallic Materials Under the Influence of Diffusion, Chemical Reaction, Passivation, Sensitization, Electrical and Mechanical Loading San-Qiang Shi; The Hong Kong Polytechnic University, China

A computational framework based on multi-phase-field method was developed to study the complex microstructure evolution of metallic materials under the influence of chemical reaction, bulk and surface diffusion, surface passivation, sensitization, applied electrical and/or mechanical loading in aqueous or gas environment. The proposed framework makes use of the Allen-Cahn equation for phase variables, Cahn-Hilliard equation for conserved variables, Nernst-Planck equation and Poisson's equation for electrochemical condition, together with mechanical equilibrium equations. When chemical reactions were involved, the reaction rate was expressed as a function of the chemical (or electrochemical) potentials of reactants and products based on a detailed balance of reactions. The framework was applied to study pitting corrosion of steels with or without the formation of insoluble corrosion products, stress corrosion cracking, corrosion of metal matrix composite under mechanical loading, high temperature metal oxide formation under the influence of high PB ratio, intergranular corrosion of sensitized aluminum alloys, nano-porous structure evolution during chemical dealloying of binary alloys. The characteristics of the model predictions agree well qualitatively, in many cases also quantitatively, with the experimental observations. This work was supported by grants from the

Research Grants Council of Hong Kong (PolyU 152140/14E and PolyU 152174/17E).

9:50 PM CT08.05.06
Late News: Theoretical and Experimental Evaluation of Elastic Moduli of Fluoroethylene Carbonate and Vinylene Carbonate Polymers in Solid Electrolyte Interface of Silicon Anode Yuki Kamikawa[1], Koji Amezawa[1] and Kenjiro Terada[2]; [1]Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Japan; [2]International Research Institute of Disaster Science, Tohoku University, Japan

Precisely evaluating the mechanical properties of polymeric components in a solid–electrolyte interphase (SEI) is crucial for ensuring its mechanical stability on silicon anodes, which significantly expand during lithiation. However, the complex inorganic/organic nanocomposite structure of SEIs hinders the ability to directly measure the elastic moduli of its constituent polymer components. To address this issue, in our prior DFT study, we proposed a theoretical methodology to determine these elastic moduli. First-principles calculations were performed to evaluate the energy barrier for a 1,2-radical shift in different carbons in the corresponding polymers. Using the identified crosslinking sites, the elastic moduli of the crosslinked fluoroethylene carbonate (FEC) and vinylene carbonate (VC) polymers were evaluated, which could not be directly measured on the formed SEI. Our calculations provided evidence of the elastic behavior of polymeric species in the SEI formed by the electrochemical reduction of FEC and VC on the surfaces of silicon anodes. Moreover, these findings suggested a new avenue for attaining mechanically stable SEIs on silicon anodes through the chemo-mechanical design of an inorganic/organic nanocomposite structure based on those mechanical properties. Then, cyclic nanoindentation tests and numerical methods were used to quantify the elasto- and viscoelasticity of SEIs as well as the effects of the stress field in the silicon anode material below the SEI, thus enabling the precise evaluation of the elastic modulus of the SEI. Instrumented nanoindentation was used to quantitatively measure the indentation force response on the heterogeneous surface of composite electrodes. The measured results showed that the mechanical properties of the SEI as determined by the Hertz model resulted in a significantly overestimated elastic modulus. The stress field in underlying Si significantly affected the results, especially for a thinner SEI thickness, and could cause the false appearance of a mechanically bilayered structure of the SEI with a hard, inorganic inner layer and a soft, outer polymeric layer. The elastic modulus of the SEI formed in the FEC electrolyte agreed with first-principles results and supported the recent solid-state NMR results demonstrating the existence of polymeric species in the interfacial region of the FEC-SEI and the silicon anode. In addition, the results corroborated recent transmission electron microscopy–electron energy loss spectroscopy and density functional theory results revealing that the FEC-SEI exhibits a nano-composite structure with inorganic particles distributed in crosslinked poly(FEC).

Screening Corrosion-Resistant Binary Magnesium Alloys Through High-Throughput Computations Yaowei Wang, Tian Xie and Hong Zhu; Shanghai Jiao Tong University, China

Magnesium (Mg) alloys have shown great potential as both structural and biomedical materials due to their high strength-to-weight ratio and good biocompatibility. However, poor corrosion resistance limits their further application, while alloying is believed to be one of the most effective strategies to develop corrosion-resistant Mg alloys. Traditional new magnesium alloy development is mainly based on the experiments, which is time-consuming and low-efficient. Recently, high-throughput computational method has become a useful tool to screen promising materials for various applications. In this work, we first collected 27919 (including repeated) Mg intermetallics structures from online databases, from which 332 stable candidates were selected. Then, the equilibrium potential based on Nernst equation were calculated and 50 Mg intermetallics with smallest equilibrium potential difference from that of Mg matrix and hence the lowest thermodynamic driving force of galvanic corrosion were reserved. Additionally, the adsorption energy of hydrogen adatom on the intermetallic surfaces were obtained for the further prediction of exchange current density based on the volcano curve. From the idea of small cathodic exchange current density and thermodynamic driving force of galvanic corrosion, several intermetallics were selected to be the promising phases for corrosion-resistant binary alloys. Our work not only predicts some new corrosion-resistant strengthening phases, but also provides a high-throughput

screening strategy for corrosion-resistant alloy design, which can also be extended to screen ternary intermetallics or other alloy systems.

10:20 PM CT08.05.08
Phase-Field Modelling of Chemo-Mechanical Coupling in High Temperature Oxidation and Aqueous Corrosion of Metals Chen Lin[1] and Haihui Ruan[2]; [1]Sun Yat-sen University, China; [2]The Hong Kong Polytechnic University, Hong Kong

In this talk, a phase-field model (PFM) is introduced to study high temperature oxidation and aqueous corrosion of metals in a mechanico-chemical coupled field. The reaction rate is expressed as a function of the electrochemical potentials of reactants and products and conforms to the generalized Butler-Volmer relationship. The Gibbs free energy is expressed as a sum of chemical potential, interfacial energy, electrostatic potential energy, and mechanical strain energy of the system. And the variation of phase order parameter is governed by the Allen-Cahn type equation, which is derived from the equivalence of reaction rate and phase transformation rate. This governing equation captures the influences of reaction kinetics, elemental concentration, electric potential, and mechanical deformation. Coupled with the generalized Nernst-Planck equation, the Poisson equation, and the mechanical equilibrium equation, the complete set of phase-field equations are implemented. The proposed PFM is applied to study the corrosion mechanisms for the two typical scenarios: (i) the oxide scale roughening induced by high-temperature oxidation, and (ii) the localized corrosion in the wet environment. The numerical results of the first case unravel the roughening mechanism of oxide scale in an inward growth process, which is consistent with experimental results. In addition, it is shown that the initial metal surface morphology also significantly influences the resulted scale roughness, which renders a way to mitigate roughening-induced stress concentration and cracking in some applications. For localized corrosion, we study a complex corrosion process that involves mechano-electrochemical coupling, anodic dissolution, insoluble depositions (IDs) formation, and resulted Galvanic-pitting corrosion. Based on a quantitative investigation into the effects of Cl^- concentration, pH value, mechanical loading, and electric field, we reveal the autocatalytic process of pitting assisted by increasingly aggressive chemical environment and concentrated stress and study how the external electric field can arrest assisted corrosion and prolong service lifetime.

Completing the Picture of Oxidation on Copper Yun-Jae Lee[1], Ly T. Trinh[2], Taehun Lee[1,3], Krisztián Palotás[4], Seyoung Jung[5], Jungdae Kim[2] and Aloysius Soon[1]; [1]Yonsei University, Korea (the Republic of); [2]University of Ulsan, Korea (the Republic of); [3]Princeton University, United States; [4]Institute for Solid State Physics and Optics, Hungary; [5]Pusan National University, Korea (the Republic of)

The oxidation of copper surfaces has been studied extensively in literature — from simple oxygen chemisorption structures to the formation of complex surface oxides and thin oxide films. Having an accurate atomistic model for this metal/oxide interface plays a pivotal role in determining interfacial processes in many copper-based technologies, ranging from electronic circuitry wirings to chemical catalysis in carbon dioxide reduction. The "29" and "44" complex surface oxides represent two of the most classical embryonic oxides on Cu(111). Although many attempts have been made to offer a detailed atomistic model of these surface oxides, their atomic structures remain elusive and ambiguous. In this work, we address this open question via state-of-the-art *ab initio* scanning tunneling microscopy (STM) and spectroscopy (STS) simulations that go beyond the simplistic Tersoff-Hamann's approach where the (functionalized) metal tips are explicitly included, and are corroborated by precise single crystal growth methods (with ultra-low surface roughness) and high-resolution STM/STS experiments. In particular, we reexamine the "29" structure and elucidate a complete atomistic model for the larger "44" surface oxide, thus completing the picture of early oxidation on copper.

Late News: Organic Photovoltaic Cell—A Promising Indoor Light Harvester for Self-Sustainable Electronics Harrison Ka Hin Lee[1], Zhe Li[1], Jiaying Wu[2], Jeremy H. Barbe[1], Sagar Jain[1], Sebastian Wood[3], Emily Speller[1], Fernando Castro[3], James Durrant[2,1] and Wing Chung Tsoi[1]; [1]Swansea University, United Kingdom; [2]Imperial College London, United Kingdom; [3]National Physical Laboratory, United Kingdom

Organic photovoltaic devices have attracted significant interest for outdoor energy harvesting, as they have unusual properties including easy tunability of optical and electrical properties, and can be fabricated by low-cost, mass production methods. However, the potential for organic photovoltaic devices for indoor application (i.e. harvesting indoor light for self-sustainable electronics, e.g. power sensors) is much less explored. While there were a few initial studies on this topic, the power conversion efficiency of organic photovoltaic devices under indoor lighting (fluorescence lamp or white LEDs) is still low at that time. In 2016, our team revised the potential of organic photovoltaic devices for indoor applications by using the more state-of-the-art materials (at that time), which demonstrated good efficiency under indoor lighting. By exploring the design rules for indoor light harvesting, in 2018, we demonstrated a record high power conversion efficiency at that time (28% under 1000 lux fluorescent lamp: significantly better than silicon). These two crucial findings have then been leading to very active and significant amount of research on organic photovoltaic devices for indoor applications in the research community. In this talk, I will present the findings (and the design rules), and we believe that organic photovoltaic devices for indoor applications have much more promising potential to be commercialized (compared to outdoor applications), and can have significant impact on powering the "Internet of Things" for smart home, office, supermarket, buildings, etc.

8:15 AM EL01.01.02
Late News: Charge Separation in Blends of New C60 Fullerenes Derivatives and P3HT—In Search of Acceptors for Efficient Organic Photovoltaics Maciej Krajewski, Piotr Piotrowski, Wojciech Mech, Krzysztof P. Korona, Jacek Wojtkiewicz, Marek Pilch, Andrzej Kaim, Aneta Drabinska and Maria Kaminska; University of Warsaw, Poland

Organic solar cells (OSCs) have attracted a lot of attention in the last decade. The main advantage of OSCs is low-cost fabrication process and greater versatility than inorganic cells due to their flexibility and lightweight. The active layer of OSC comprises a blend of donor and acceptor material. The most frequently used donors are conductive polymers, such as P3HT and PTB7. The most widely used acceptor is C60 fullerene derivative:

phenyl-C61-butyric acid methyl ester, PC61BM.
To operate properly, the OSC structure must allow for the separation of photogenerated hole-electron pairs. The final efficiency (PCE) is strongly correlated with the effectivity of the charge separation process[1] occurring in the active layer, so the understanding of the charge transfer mechanism is necessary for further development of the OSCs. The main aim of this research was to determine the structural characteristics of fullerene derivatives important for improving the performance of OSCs.
In our study four newly synthesized fullerene C60 derivatives with different aromatic substituents and their blends with P3HT were selected to study the charge transport processes in the active layer. Two of them were functionalized with either one or two tiophene residues. Likewise the two others were functionalized with either one or two pyrene residues. To study these processes, light-induced Electron Spin Resonance (LESR) along with photoluminescence (PL) and time-resolved photoluminescence (TRPL) techniques were applied.
During illumination PC61BM:P3HT blend exhibits exceptionally intense charge separation that is evident in the LESR spectrum as prominent two lines[2]. The intensities of these two lines provide information on the number of photoexcited and separated electrons and holes in the steady-state, which is one of the decisive factors influencing later the PCE of solar cells. The LESR signal of the all studied materials also showed two characteristic lines indicating charge transfer within the blend. Interestingly, blends with the molecules having only one aromatic substituent showed much stronger LESR signal, making them more predestinated for photovoltaic applications. Molecules with two aromatic substituents showed much more modest signal.
PL and TRPL techniques were applied to trace the photo-carriers behavior inside the active layer. Radiative recombination and charge separation are two competing processes that lead to light emission and photocurrent generation, respectively. The observation of PL decay provides information on charge separation effectivity. Studies showed that the most effective PL decay is observed in blends of P3HT and fullerene derivatives with one aromatic substituent. On the other hand, blends of symmetric fullerene derivatives with P3HT did not exhibit significant PL attenuation. Therefore, it can be concluded that the separation of electrons and holes is ineffective in them.
The final step was to fabricate OSCs with an active layer made of blends of these new fullerene derivatives with P3HT, and their characterization. The results obtained with LESR and PL/TRPL techniques showed very high consistency with *J-V* characteristics of OSCs. Best performing were the cells with fullerene derivatives, for which blends with P3HT exhibited two prominent LESR lines and fast PL decay. However, even the best PCE values obtained for cells with new fullerene derivatives were lower than PC61BM:P3HT reference cell (0.17% vs. 2.23%). This may be caused by lower solubility of these new materials and less optimized fabrication process. Still, the correlation of carrier separation efficiency, observed in the LESR and PL/TRPL measurements, with the PCE obtained from *J-V* characteristics of the respective OSCs was clearly visible.
Acknowledgments: Research was co-founded by project TECHMATSTRATEG1/347431/14/NCBR/2018 (NCBiR).

In bulk heterojunction (BHJ) solar cells, the heterojunction interface between electron donor and acceptor drives the exciton-to-charge conversion, yet it also adds to energy and carrier losses. In principle, in low-bandgap non-fullerene acceptor (NFA) BHJs both electron affinity (EA) and ionization energy (IE) offsets should equally control the internal quantum efficiency (IQE). Allegedly, exciton-to-charge conversion is

efficient even for close-to-zero offsets. Here, we rebut both notions and demonstrate that counterintuitively, the charge transfer from the exciton rather than the further charge separation is the limiting step controlled by the IE offset and secondly, that sizeable IE offsets are required to reach high exciton-to charge conversion efficiency. We find that efficient Förster Resonant Energy Transfer to the low bandgap acceptor precedes the charge transfer, which thus always occurs via hole transfer from the acceptor, hence the unimportance of the EA offset. We discuss the reasons for the threshold IE offset in terms of interface energetics and find that two physical parameters are sufficient to describe the evolution of the IQE with IE offset on a very large range of material systems. Our model also explain other experimental observations such as barrierless charge separation and the difficulty of observing CT states emission and absorption in NFA based systems.

Intrinsic efficiency limits in low-bandgap non-fullerene acceptor organic solar cells. *Nat. Mater.* (2020). https://doi.org/10.1038/s41563-020-00835-x

8:45 AM EL01.01.04

Diluted Organic Semiconductor-Insulator Ternary Photovoltaics Chuanfei Wang[1], Xianjie Liu[1], Yiqun Xiao[2], Jonas Bergqvist[3], Xinhui Lu[2], Feng Gao[3] and Mats Fahlman[1]; [1]Linköping University, Sweden; [2]The Chinese University of Hong Kong, China; [3]IFM, Linköping University, Sweden

The diluted organic semiconductor-insulator binary blend strategy recently has been used both in organic field electric transistors (OFETs) and polymer light emitting diodes (PLEDs) to improve (opt)electronic performance, processability, mechanical and environmental stability. The advantages shown in diluted OFETs and PLEDs potentially could be exploited in organic photovoltaics (OPVs) and thus the application of the diluted strategy in OPVs deserves attention. However, OPVs using the diluted semiconductor strategy have not yet been reported, possibly because introducing high concentration insulators (≥10%) as filler in the bulk heterojunction binary donor-acceptor blend offers additional challenges as compared to the OFET and PLED applications. For example, exciton dissociation occurring at the bulk donor/acceptor interfaces will be suppressed if thick insulator regions form inside the donor/acceptor junctions. Similarly, transport and collection of free charge carriers following exciton dissociation can be hindered by either encapsulation of a donor/acceptor domain inside an insulator shell, or by insulator material segregation to either or both electrodes forming dense interface layers. Either inefficient exciton dissociation into free charges or decreased charge transport and collection is sufficient to significantly degrade the photovoltaic properties and thus prevent application of the diluted semiconductor strategy.
Here we successfully prepared solution-processed diluted OPVs by blending the state-of-the-art donor and acceptor polymers with commonly used insulators (Sol. RRL 2020, 4, 2000261). We show that “ideal” donor/acceptor bulk interfaces and interpenetrating donor/acceptor penetrating network can be maintained in the resulting ternary blends, yielding improved OPV performance such as: an order of magnitude improved hole mobility, reduced radiative and nonradiative recombination, as well as enhanced environmental and thermal stability. In addition, when the diluted organic solar cells are upscaled in area, the cell performance is 5 times less reduced compared to the pristine undiluted organic solar cells – a crucial advantage for commercial application. Finally, thicker ternary blend films can be deposited yielding the same degree of semi-transparency in the optical spectrum as the binary donor-acceptor blends, vastly improving printability of semi-transparent OPVs. Our findings imply that interpenetrating donor-acceptor network can be maintained in diluted ternary blend and the diluted strategy can be used to construct improved ternary devices involving internal penetrating donor-acceptor heterojunctions such as OPVs and organic photo detectors.

9:00 AM EL01.01.06

Counterintuitive Efficiency Trends in Dilute-Donor TAPC:C_{60} Organic Solar Cell Blends Explained by Probing Ultrafast Charge Dynamics. Gareth J. Moore[1], Martina Causa’[1], Josue Martinez Hardigree[2], Safakath Karuthedath[3], Ivan Ramirez[2], Anna Jungbluth[2], Frédéric Laquai[3], Moritz Riede[2] and Natalie Banerji[1]; [1]University of Bern, Switzerland; [2]University of Oxford, United Kingdom; [3]King Abdullah University of Science and Technology, Saudi Arabia

Understanding the interplay between film morphology, photophysics, and its relation to device performance in bulk heterojunction organic photovoltaics remains challenging. Using the well-defined morphology of vapor-deposited TAPC:C_{60} blends, from the surprisingly more efficient dilute-donor (5% TAPC) to the less efficient intermixed systems (50% TAPC), we see the morphological effects on charge generation and recombination on an ultra-fast time scale. With the use of ultrafast transient spectroscopy we are able to follow each step of the charge generation process and give an explanation for the counterintuitive efficiency trends in these organic solar cells.

First, we show that both Frenkel and Charge Transfer excitons generate photocurrent over the entire fullerene absorption range, giving advantage to the dilute-donor blend with more C_{60}.
Second, we show a novel technique for selectively monitoring interfacial and bulk C_{60} clusters via their electro-absorption, demonstrating an energetic gradient that assists free charge generation.
Third, we identify a fast (<1 ns) recombination channel, where free electrons recombine with trapped holes on isolated TAPC molecules which should harm the performance of dilute solar cells. We, however, give evidence that this recombination is mitigated when electrons are rapidly extracted in efficient devices, reminding us that more than just the active layer needs to be considered when designing efficient organic solar cells. [1]

9:15 AM EL01.01.07
Improved Mechanical Properties of Polar Polythiophene Through Copolymerization or Blending with Urethanes Sepideh Zokaei[1], Renee Kroon[1], Mariavittoria Craighero[1], Johannes Gladisch[2], Claudia Cea[3], Bryan Paulsen[4], Lucas M. Kneissl[1], Wonil Sohn[4], Dion Khodagholy[3], Anna I. Hofmann[1], Anja Lund[1], Gustav Persson[1], Arne Stamm[5], Per-Olof Syrén[5], Eva M. Olsson[1], Jonathan Rivnay[4], Eleni Stavrinidou[2] and Christian Muller[1]; [1]Chalmers University of Technology, Sweden; [2]Linköping University, Sweden; [3]Columbia University, United States; [4]Northwestern University, United States; [5]KTH Royal Institute of Technology, Sweden

Polar polythiophenes with oligoethylene glycol side chains are an emerging class of materials that attract considerable attention for energy harvesting and storage as well as bioelectronics. The polar side chains enhance the compatibility with molecular dopants and improve the electrical conductivity and thermal stability of the doped material. However, polar polythiophenes are exceedingly soft at room temperature due to a sub-zero glass transition temperature. To enhance the versatility of these polymers, strategies are needed that permit to modulate their mechanical stiffness. In this contribution, we report our efforts to copolymerize a polar polythiophene with urethane blocks. Further, we describe wet spinning of its blend with polyurethane into fibers. The resulting materials feature elasticity and stretchability, yet higher stiffness. In addition, the copolymer and blend continue to display a high degree of electrochemical activity and electrical conductivity when chemically doped.

9:18 AM EL01.01.08
Smart Properties of PEDOT:PSS Carsten Dingler, Matthias Wieland, Henry Müller and Sabine Ludwigs; Institute of Polymer Chemistry, Germany

Polymer electronics has developed into an independent field of research as conducting polymers combine high, metal-like conductivity with the generally desired properties of commodity polymers. The additional responsiveness of conjugated polymers to various stimuli such as heat, electric voltage, or humidity has now also promoted efforts to fabricate sensors and actuators for wearable devices and electronic skin (e-skin). In this work, functional properties and the stimuli-responsiveness of smart materials such as particularly poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) were studied. PEDOT:PSS has become one of the most promising candidate for applications in polymer electronics for, e.g., its remarkably high conductivity, the exceptional stability in air, and green processability from a dispersion in water.[1] In addition, the electronic

conductivity of PEDOT combined with the polyelectrolytic PSS provide this polymer blend with a multi-responsivity.
The redox activity of PEDOT, for example, imparts electrochromism to PEDOT:PSS. This implies that the color can be switched through an electrochemical trigger,[2] which is commonly used in electrochromic window or display applications. PEDOT:PSS exhibits not only a dark blue but also an almost colorless, transparent state when applied as a thin film. In one approach of this work, this could be exploited to make responsive photonic fibers.[3] The hygroscopic nature of PSS also provides PEDOT:PSS with a dependence of various properties on the relative humidity (r.H.). This implies, for example, that electronic and ionic conductivity could be tuned and strongly depended on the water uptake of the films.[4] Furthermore, swelling with water by absorbing humidity from the environment was used to fabricate humidity-triggered bilayer actuators.[5] It could be demonstrated that for the tailor-made design of such actuators precise knowledge of the mechanical properties of the components as well as the corresponding dependence on r.H. is of utmost importance.[5]

The Effect of the Dielectric Environment on Electron Transfer Reactions at the Interfaces of Molecular Sensitized Semiconductors in Electrolytes Davide Moia[1,2], Masato Abe[1], Pawel Wagner[3], Nagatoshi Koumura[4], Jenny Nelson[2], Piers Barnes[2] and Shogo Mori[1]; [1]Shinshu University, Japan; [2]Imperial College London, United Kingdom; [3]University of Wollongong, Australia; [4]Interdisciplinary Research Center for Catalytic Chemistry, National Institute of Advanced Industrial Science and Technology, Japan

Electron transfer reactions at the interfaces of molecular sensitized semiconductors in electrolytes represent the basic steps in the working mechanism of several electrochemical and photo electrochemical systems for energy conversion and storage. For example, in dye sensitized solar cells, the design of interfaces that favor the desirable flow of photo-generated electronic charges towards the device contacts and that limit the rate of undesirable processes associated to energy loss is key to optimize device performance. [1] The identification of effective device design rules requires knowledge on the main factors influencing the kinetics of electron transfer. One such factor is the dielectric environment where charge transfer reactions occur. Electron transfer theories predict pronounced dependence of the rates of charge transfer between free molecules in solution on the polarity of the environment, where more polar solvents are expected to result in lower transfer rates. An appropriate description of this relation for electron transfer reactions involving molecules sensitizing semiconductors in electrolytes must account for the restricted geometry of these systems and is currently missing.

In this contribution, we present rates of electron transfer reactions involving photo-oxidized thiophene–carbazole-based molecules on oxide semiconductors in inert or redox-active electrolytes measured using transient absorption spectroscopy. [2] We explore the extent to which the dielectric properties of the surrounding medium can explain the rates of three different charge transfer processes occurring in these systems. We consider the hole hopping between molecules anchored to the semiconducting oxide surface, [3] the electron transfer from the oxide to the photo-oxidized molecule (electron-hole recombination) and the hole

transfer from the sensitizing molecules and a redox couple dissolved in the electrolyte solution (regeneration). Strikingly, we observe no clear correlation between the activation energy of hole hopping between molecules on oxide surfaces or the recombination rate between photogenerated electrons in the oxide and holes on the adsorbed molecules and the dielectric properties of the surrounding solvent. On the other hand, we show that fast electron transfer from cobalt complexes to photo-oxidized molecules is observed when using solvents with low polarity. Further to these findings, we show that the activation energy of hole hopping tends to increase with time following initial photogeneration of the holes, which emphasizes the role of energetic disorder in the molecular monolayer on charge transport. Moreover, we show that the recombination rate in different solvents scales with the hole hopping rate, consistent with our previous study. [4] Based on our findings, we highlight the importance of electronic coupling between the redox-active components and their solvation, besides the reorganization energy and the driving force, in the determination of electron transfer rates at molecular sensitized interfaces in electrolytes. Our study points to new strategies that allow to control electron transfer rates at interfaces of organic and hybrid photoelectrochemical systems and optoelectronic devices.

Late News: Re-Assessment of Published Figures of Merit for Transparent Conducting Electrodes Aman Anand, Md Moidul Islam, Rico Meitzner, Ulrich S. Schubert and Harald Hoppe; Friedrich Schiller University Jena, Germany

Transparent conducting electrodes (TCEs) are one of the essential components of solar cells and other optoelectronic devices such as touch screens, electrochromic windows, flat panel displays, etc. Proper selection of specific TCEs is important to achieve efficient optoelectronic devices. A figure of merit (FOM) is an often-used quantity to rate the performance of TCEs. In this work, we have re-assessed the existing figures of merit and compare them with a new proposal from our side by applying them to specific material systems. It is demonstrated that the newly proposed FOM provides decisive information for the application specific development of material systems employed for TCEs.

9:27 AM EL01.01.11
The Role of ITIC and Its Derivatives on the Operational Stability of Organic Solar Cells Sri Harish Kumar Paleti[1], Sandra Hultmark[2], Leif Ericsson[3], Ellen Moons[3], Christian Muller[2] and Derya Baran[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Chalmers University of Technology, Sweden; [3]Karlstadt University, Sweden

Despite advances in the power-conversion efficiencies of NFA-based organic solar cells, limited operational lifetime presents a stumbling block for their commercialization. Operational lifetime is assessed by the endurance of organic solar cell performance under constant thermal and light stress. Here, we study the operational stability of the organic solar cells based on the ITIC and its derivatives. We show that a fine-grained ternary blend including ITIC-4F and ITIC-4Cl mixture enhances the thermal stability. The halogenated ITIC derivatives readily co-crystallize and forms a fine-grained ternary blend with nanometer-sized domains. This results in a stable performance at 130 ºC for at least 205 hours. We further show that the long-range order of the NFA crystals can only partly enhance the photo-stability of the organic solar cells. And, structural stability of the non-fullerene acceptor is also necessary to improve the photo-stability of the organic solar cells. These observations are confirmed using Nuclear Magnetic Resonance spectroscopy, High Resolution- Mass Spectroscopy, AFM-IR, and GIWAXS. Our results indicate that the ternary approach enables the use of high-temperature processing protocols and emphasizes the need for a more informed structural design of NFAs and unveils routes to minimize impurities, during synthesis, which affect the photostability of the NFA and thereby solar cells.

9:30 AM EL01.01.12

Influence of Side Chains on the N-Type Organic Electrochemical Transistor Performance David Ohayon[1], Achilleas Savva[1], Weiyuan Du[1], Bryan D. Paulsen[2], Jonathan Rivnay[2], Iain McCulloch[1] and Sahika Inal[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Northwestern University, United States

Organic bioelectronics has experienced tremendous growth over the past two decades thanks to the expansion of the library of organic electronic materials available. Electron conducting (n-type) polymers are particularly suitable to translate biological events that involve the generation of electrons. However, n-type polymers that are stable when addressed electrically in aqueous media are relatively scarce, and the performance of existing ones lags behind their hole conducting (p-type) counterparts. Here, we report a new family of donor-acceptor type polymers based on naphthalene-1,4,5,8-tetracarboxylic-diimide-bithiophene (NDI-T2) backbone where the NDI unit always bears an ethylene glycol (EG) side chain. We study how small variations in the side chains tethered to the acceptor as well as the donor unit affect the performance of the polymer films in the state-of-the-art bioelectronic device, the organic electrochemical transistor (OECT). First, we show that substitution of the T2 core with an electron withdrawing group (i.e., methoxy) or an EG side chain leads to ambipolar charge transport properties and causes significant changes in film microstructure revealed by ex situ X-ray scattering studies, which overall impairs the n-type OECT performance. We thus find that the best n-type OECT performer is the polymer that has no substitution on the T2 unit. Next, we evaluate the distance of the oxygen from the NDI unit as a design parameter by varying the length of the carbon spacer placed between the EG unit and the backbone. We find that the distance of the EG from the backbone affects the film order and crystallinity, and thus, the electron mobility. As such, we develop the best performing NDI-T2 based n-type OECT material to dates. Our work provides new guidelines for the side chain architecture of n-type polymers for OECTs and insight on the structure-performance relationships for mixed ionic-electronic conductors, crucial for devices where the film operates at the aqueous electrolyte interface.

Late News: Optoelectronics of Disordered Solid-State Morphologies—Advances in Atomic-Scale Simulations Towards Design of High-Performance OLEDs Hadi Abroshan, Paul Winget, Casey N. Brock, Shaun Kwak and Mathew Halls; Schrödinger, Inc., United States

Organic-light emitting diodes (OLEDs) are becoming increasingly complex, consisting of multiple components with hybrid architectures. Hence, there is a growing demand for a computational approach to accurately describe sub-nanoscale phenomena, while being robust and scalable to unveil the origin of emergent layer and device-scale properties. To date, the majority of computational OLED designs rely on estimating materials properties in the gas phase. However, OLED materials are applied as thin solid films where intermolecular interactions have a significant impact on overall device performance. In this work, we present a multi-tiered computational workflow to efficiently study the optoelectronic properties of OLED materials in realistic disordered thin films. A range of robust and validated methods are combined to reveal impacts of the amorphous solid-state morphologies on the static and dynamic optoelectronic properties. The hierarchical approach of this work provides a thorough mechanistic understanding of materials performance for systematic design and development of future smart OLEDs as well as emerging electronic devices.

Causal Structure-Property Relationships in Organic Photovoltaics by Integrating Resonant X-Rays and Device Dynamics Brian A. Collins; Washington State University, United States

With efficiencies >20% on the horizon, non-toxic and massively scalable organic solar cells are approaching economic viability. In order for the technology to approach limiting performance, it is necessary to establish a more definitive and detailed model on how molecular ordering drives device dyanmics. Although many structure-property correlations can be found in the literature, it is critical to establish causal relationships to move the field forward. I will describe our advanced nanostructure characterization simultaneous to comprehensive device dyanmics that are directly connected to performance. This allows us to analyze correlated trends in structure and dyanmics to determine cause and effect more definitively. Our novel combination of synchrotron X-ray techniques allows us to derive a complete set of morphological parameters that includes details of donor-acceptor interfaces. We also have developed a photophysical measurement strategy using time-delayed collection field to quantify each fundamental stage in the charge generation process. By probing morphology on the devices themselves, our studies reveal unprecedented clarity on the effect of molecular mixing, crystallinity, and device interfaces on charge generation and extraction at operating conditions. The outcome is an increasingly resolved model of ideal device morphology. Such a model will enable new device processing strategies and help advise molecular design in pursuit of performance limits and commercialization of this exciting technology.

10:55 AM EL01.02.02
Late News: Development of Polymers for Scalable Organic Photovoltaics Alyssa Chinen-Mendez, Hualong Pan and Reed Eisenhart; Phillips 66, United States

ShieldPower^{TM} polymers were developed at Phillips 66 for use in the photoactive layer of scalable organic photovoltaics. This talk will highlight their development from lab to pilot scale evaluation, focusing on the key parameters that enable ShieldPower^{TM} polymers to reach high power conversion efficiencies using scalable coating techniques. The polymers combine high conductivity, as determined by time-resolved microwave conductivity experiments, and good solubility to enable photoactive layers with films >200 nm in thickness to be coated from non-halogenated solvents via slot-die coating in ambient air in a pilot fabrication line resulting modules that reach 5.3% power conversion efficiency. Further tuning the polymers' absorption properties and structures allows for blends with a stable non-fullerene electron acceptor to achieve power conversion efficiencies that remain constant over 250+ hours of illumination.

11:10 AM EL01.02.03
Late News: Understanding the Role of the Solubility of Axially Substituted SiPcs on Their Performance as Ternary Additives in Organic Photovoltaics Mário C. Vebber, Jaclyn Brusso and Benoit Lessard; University of Ottawa, Canada

Organic photovoltaics (OPVs) had their performance greatly improved in the past decade, thanks to careful molecular design and process optimization, even approaching the efficiency of single-junction inorganic devices. However, such state-of-the-art OPVs rely heavily on complex polymers and compounds, whose synthesis is not scalable and unlikely to make it to market. Thus, the enhancement of low-cost OPV active layers, such as P3HT:$PC_{61}BM$, is a relevant and often overlooked topic OPV research. A common way to improve P3HT:$PC_{61}BM$ blends is to increase its relatively narrow light absorption range by adding a ternary additive that is sensitive to complementary wavelengths. Silicon phthalocyanines (SiPc) have been shown to be efficient ternary additives due to their strong light absorptivity, high electron mobility, chemical versatility and scalability of manufacture. The addition of a small amount of soluble, axially substituted SiPc (OR-SiPc) have been reported to increase the current of P3HT:$PC_{61}BM$ devices by 25% and the overall efficiency by as much as 50%. One of the main challenges faced when engineering new or improving existent active layers is the lack of

robust design rules and property-performance relationships, leaving researchers and engineers to rely on time-consuming try-and-error approaches. In this context, we have synthesized 8 different OR-SiPc and evaluated how their properties impact their efficiency as additives in OPVs. The novel OR-SiPcs were synthesized by reacting different alkyl chlorosilanes of different lengths with Cl-SiPc. Characterization of the compounds has shown that all 8 OR-SiPcs possess similar surface energies and virtually identical optical and electronic properties, such as band gap (Ebg), ionization energy (IE), and energy levels. Alternatively, due to the different alkyl chain lengths in the axial positions, their solubility can change greatly. We were able to demonstrate that when OR-SiPc is added to P3HT:$PC_{61}BM$, device efficiency follows a nearly parabolic trend with respect to the additive solubility. The best performance was achieved by the additive whose solubility value was the closest to that of the donor polymer, P3HT. Based on these results and previously reported properties of the system, we have surmised that matching the solubility of the OR-SiPc and P3HT is beneficial because it favours the migration of the additive to the donor:acceptor interface, where its efficiency is maximized. OR-SiPc with solubilities below 20 mg ml^{-1}, for instance, tended to precipitate out of solution and form a separate crystalline phase, rather than migrating to the interface, making it less efficient at mediating the charge transfer between P3HT and $PC_{61}BM$. More research is needed to verify if a similar effect is observed in different systems and additives, nonetheless, this is an important step towards more robust design-rules for OPVs.

11:25 AM EL01.02.04

Color-Neutral, Semitransparent Organic Photovoltaics for Power Window Applications Yongxi Li[1], Hafiz K. Sheriff[2], Xia Guo[3], Zhengxing Peng[4], Harald Ade[4], Maojie Zhang[3] and Stephen Forrest[1]; [1]University of Michigan, United States; [2]University of Michigan–Ann Arbor, United States; [3]Soochow University, China; [4]North Carolina State University, United States

Semitransparent organic photovoltaic cells (ST-OPVs*)* are emerging as a solution for solar energy harvesting on building facades, rooftops and windows. However, the trade-off between power conversion efficiency (*PCE*) and the average photopic transmission (*APT*) in color-neutral devices limits their utility as attractive, power-generating windows. We demonstrate a semi-transparent OPV that achieves a high power conversion efficiency of 10.8% and visible transparency of ~50% using a simple non-fullerene acceptor (NFA) with strong near-infrared (NIR) absorption and simplified synthetic step. Contrary to expectations, stronger NIR absorption and closer molecular packing are obtained by employing an additive in these partially, instead of fully fused rigid NFAs. By combining NIR-absorbing material sets with an optical outcoupling structure that reduces trapping of visible radiation within the cell, that increases the NIR reflectivity, we overcome the trade-offs between efficiency, transparency, and device appearance. These results significantly surpass other semi-transparent solar cell technologies based on organic and other thin film materials systems, showing a promising future for ST-OPVs as power generating windows and other solar energy harvesting applications[1].

[1] Yongxi Li, Xia Guo, Zhengxing Peng, Boning Qu, Hongping Yan, Harade Ade, Maojie Zhang* and Stephen R. Forrest*; Color-Neutral, Semitransparent Organic Photovoltaics. ***PNAS***, 2020, 117, 21147-21154.

11:40 AM EL01.02.05

Late News: Linking Solution Phthalocyanine-Cannabinoid Interactions to Analyte Induced Changes for Organic Thin-Film Transistor Sensing Zachary Comeau, Benoit Lessard and Adam Shuhendler; University of Ottawa, Canada

Phthalocyanine (Pc) based organic thin-film transistors (OTFTs) have been demonstrated as a powerful platform for rapid low-cost sensors of atmospheric parameters, volatile gasses, and small organic molecules including cannabinoids. However, traditional characterization and testing of new materials or analytes requires highly specialized equipment and expertise. Alternatively, solution-based screening can limit manufacturing burden, allowing for a broad range of assays, and is employed here with the goal of expediting sensor development. Spectroelectrochemistry is used to probe molecular interactions between cannabinoids (Δ^9-tetrahydrocannabinol (THC) or cannabidiol (CBD)) with and without a cannabinoid sensitive chromophore (Fast Blue BB) against a variety of phthalocyanines (Pcs). Spectroelectrochemical changes to the Q-band region

of the Pc spectra in the presence of analytes can be related to modified ratios of Pc-Pc orientations in solution. 2D-NMR is used to further elucidate unique Pc-Pc and Pc-analyte interactions, providing additional insight on atomic level interactions. Through altered Pc-Pc orientations, analytes can induce physical alterations to Pc thin-film morphology and structure, consequently, modifying electrical performance beyond charge trapping effects. Additionally, the effects of Pc peripheral and axial substitutions on analyte interactions and their relationship with film structure and performance is examined. Substitutions allow for an additional level of Pc tunability and are demonstrated to specifically further enhance OTFT sensing responses by up to 96%. Thus, with spectroelectrochemical solution-based screening, a range of potential materials for OTFT small organic molecules sensing applications can be rapidly assayed and OTFT responses can be predicted.

12:10 PM EL01.02.07
Time-Resolved Optical Spectroscopy of Organic Mixed Conductors Priscila Cavassin, Olivier Bardagot, Julien Réhault and Natalie Banerji; University of Bern, Switzerland

Polymers that exhibit both electronic and ionic conductivity have garnered attention for their numerous applications in bioelectronics, neuromorphic systems and batteries. [1] In the field of bioelectronics, the organic electrochemical transistor (OECT) takes advantage of this property to interface with biological systems and convert ionic and electronic signals. [2] Despite recent advances in its fabrication and materials choice, there is a lack of understanding on central roles that are important for the optimal operation of the OECT, like the ionic transport and the morphological impact in its performance. [1] To this end, we have characterised the electrochemical doping and dedoping of poly(3-hexylthiophene) (P3HT) thin films using in-situ time-resolved Vis-NIR spectroscopy. We are able to follow the evolution of the doping with great time resolution, and by decomposing the spectra we can identify the different species involved in the process. Furthermore, we developed a kinetic model to describe the interconversion between the species. Additionally, by changing the degree of crystallinity of the P3HT films, we are able to identify can morphology affect ionic transport in the film.

12:13 PM EL01.02.08
Charge Transport on the Picosecond Time Scale in Non-Fullerene Acceptors Kaila M. Yallum and Natalie Banerji; Universität Bern, Switzerland

As the field of Organic Photovoltaics (OPVs) evolves, the need for fundamental understanding of the utilized materials grows along with it. Historically, OPVs feature fullerene-based electron acceptors, yielding efficiencies around 10-12%. Recently, efficiencies of over 17% have been achieved thanks to the use of non-fullerene accpeptors (NFAs).

In order for the overall performance of OPVs to show such improvement, the processes involved in photocurrent generation must be optimized as well. Charge transport is one of the critical processes that requires further investigation in these systems. While single-carrier devices are commonly used in order to deduce the mobility of charge carriers in the steady state, Electromodulated Differential Absorption (EDA) spectroscopy is the principal technique employeed in this project. This powerful technique can be used to qualify charge mobility on the picosecond time scale following photo-excitation, by recording the changes in electroabsorption (EA) over time with 100 femtosecond resolution. Carrying out these measurements in differing electric fields, drift and diffusion mechanisms of charge transport can be distinguished.

The highest performing OPVs of recent years, those achieving 17% photoconversion efficiencies, have featured

BTP-4F as the acceptor material. For this reason, the ITIC and BTP NFA families have been chosen for this project in order to qualify how charge transport changes with different molecular packing and core structures. In addition to investigating the sterics of these systems, the electronics will also be investigated by using a series of substitutions of the IC end group featured in both NFA families. Because the focus of this project is on the NFA domains of the OPV devices, the samples used for this project were neat NFA devices.

When studying these two NFA families under EDA conditions, it becomes quite clear that charge transport is largely influenced by the cores of these molecules. Further investigation is underway to understand how the morphology of the NFA regions will affect charge transport.

12:16 PM EL01.02.09

Late News: Molecular Design Optimization of Fused Electron-Deficient Semiconducting Polymers for N-Type Organic Thermoelectrics and Electrochemical Transistors Maryam Alsufyani[1], Rawad K. Hallani[2], Xingxing Chen[2], Suhao Wang[3], Marc-Antoine Stoeckel[3], Reem Rashid[4], Xudong Ji[4], Kai Xu[3], Bryan Paulsen[4], Helen Bristow[1], Hu Chen[2], Mingfei Xiao[5], Henning Sirringhaus[5], Jonathan Rivnay[4], Simone Fabiano[3] and Iain McCulloch[1,2]; [1]University of Oxford, United Kingdom; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]Linköping University, Sweden; [4]Northwestern University, United States; [5]University of Cambridge, United Kingdom

N-type semiconducting polymers have been recently utilized in thermoelectric devices, however they have typically exhibited low electrical conductivities, in contrast to p-type semiconductors. This is due in particular to the n-type semiconductor's low doping efficiency, and poor charge carrier mobility. Strategies to enhance the thermoelectric performance of n-type materials include optimizing the electron affinity (EA) with respect to the dopant to improve the doping process, increasing the charge carrier mobility through enhanced molecular packing and introducing polar side chains to improve the miscibility with dopant. Here, we report the design, synthesis and characterization of three fused electron-deficient copolymers P1-P3, incorporating electron withdrawing lactone unit along the backbone. The polymers were synthesized using metal-free aldol condensation conditions to explore the effect of acene size and side chains, on the electrical conductivity. Acene size optimization of P1 and P2 has been investigated, their performance provided a great insight into designing P3, which incorporated polar side chains. The polymers have exhibited the largest electron affinity of -4.68 eV and when n-doped with N-DMBI, electrical conductivities of up to 1 S cm^{-1}, Seebeck coefficients of -220 mVK^{-1} and maximum Power factors of 5 mWm^{-1} K^{-2} were observed. Moreover, the polar nature of P3 has intrigued us to explore its performance in aqueous electrolytes of Organic electrochemical transistors (OECTs). OECT results indicated high transconductance of 0.35 S cm^{-1} and [μC*] of 0.92 F cm^{-1} V^{-1} s^{-1} , exceeding the state of the art materials. These results suggest a promising high-performance building block for both n-type organic thermoelectrics and OECTs, and also highlight that high electrical conductivities can be realized in conjugated polymers with careful molecular engineering.

Late News: Correlating Morphology with Mechanical Properties in High-Efficiency Ternary Organic Solar Cells Zhongxiang Peng[1], Yanhou Geng[1,2] and Long Ye[1,3]; [1]Tianjin University, China; [2]International Campus of Tianjin University, China; [3]North Carolina State University, United States

Organic photovoltaics (OPVs) based on nonfullerene small molecule acceptors have been the subject of renewable energy research in the past five years. Ternary photovoltaic blends comprising a polymer donor, a nonfullerene small molecule acceptor, and a fullerene acceptor have proved to be most efficient active layers for OPV devices. However, the morphological parameters and their relations with mechanical properties and photovoltaic performance of this type of highly efficient polymer:nonfullerene:fullerene OPVs are still unknown to date.
To address this question, we characterized the thin-film microstructure and mechanical behavior of the best-performing ternary OPV active layer (PM6:N3:$PC_{71}BM$). Specifically, we alter the relative weight ratio of acceptors and systematically examined the composition dependence of photovoltaic performance, surface/bulk morphology, and mechanical parameters of the ternary blend films. It is shown that the addition of 20 wt% $PC_{71}BM$ to the acceptor component results in the highest power conversion efficiency (PCE) and crack-onset strain (COS) (Figure 1a). Most notably, we discover that it is possible to predict the elastic modulus of the ternary blend films by an extended Halpin-Tsai model (Figure 1b). This work provides simple guidelines for predicting the mechanical properties of many electronic devices based on ternary blends.

Late News: Thermodynamic Properties and Molecular Stacking Explain Performance of Four P3HT:Nonfullerene Organic Solar Cells Mengyuan Gao[1], Yanhou Geng[1,2] and Long Ye[1,3]; [1]Tianjin University, China; [2]International Campus of Tianjin University, China; [3]Department of Physics, Organic and Carbon Electronics Laboratories (ORaCEL), United States

The film morphology of polymer solar cells (PSCs) plays a significant role in the photovoltaic process that cannot be ignored, which associates with light-harvesting, exciton dissociation, and charge transport. In addition, the morphological stability of the PSCs is largely dependent on the amorphous-amorphous molecular interactions of the components, which can be described by the Flory-Huggins interaction parameter χ_{aa}. However, in the semi-crystalline blend systems, more complex thermodynamic interactions as reflected by crystal-amorphous interaction parameter (χ_{ca}), amorphous-crystal interaction parameter (χ_{ac}), and crystal-crystal interaction parameter (χ_{cc}), which are complementary to χ_{aa}. Here, we apply the Thermodynamic self-consistency theory coupled with Flory-Huggins theory to determine the various interaction parameters and establish the relationships between interaction parameter, morphology, and device performance of binary P3HT:nonfullerene blends, based on four nonfullerene small molecule acceptors (ITIC, Y6, O-IDTBR, ZY-4Cl). Moreover, the parameters related to molecular stacking are probed by grazing incidence X-ray diffraction and correlated partially with device performance. Chiefly, this study highlights the importance of both thermodynamic properties and molecular stacking to provide guidance for understanding morphology and device performance.

Endothermic Charge Separation in Efficient Non-Fullerene Organic Solar Cells Philip Chow; The

University of Hong Kong, Hong Kong

Organic solar cells based on non-fullerene acceptors can show high charge generation yields despite near-zero donor-acceptor energy offsets to drive charge separation and overcome the mutual Coulomb attraction between electron and hole, but the underlying mechanism remains unclear. In this talk I will present experimental results showing that free charges in these systems are generated by thermally activated dissociation of interfacial charge-transfer states. This process occurs over hundreds of picoseconds at room temperature, three orders of magnitude slower than comparable fullerene-based systems. Upon free electron-hole encounters at later times, both charge-transfer states and local emissive excitons are regenerated, thus setting up an equilibrium between local excitons, charge-transfer states and free charges. Our results suggest that the formation of long-lived and disorder-free charge-transfer states in these systems enables them to operate closely to quasi-thermodynamic conditions with no requirement for energy offsets to drive interfacial charge separation and achieve suppressed non-radiative recombination.

Quantitative Evaluation of Thermoelectric Characteristics of Small-Molecule Organic Semiconductors Based on Electronic Structure Calculations Masahiro Ohno, Koji Shimizu and Satoshi Watanabe; The University of Tokyo, Japan

Organic thermoelectric materials have attracted much attention as promising candidates for low-cost, near-room-temperature and flexible power generators which are desirable power supplies for flexible electronics. However, molecular design strategies to realize efficient thermoelectric conversion are not well established because little is known regarding microscopic origin of their thermopower. Many of recent studies employ conventional polymer semiconductors such as poly(3,4-ethylenedioxythiophene) (PEDOT) and poly(3-hexylthiophene-2,5-diyl) (P3HT) and focus on optimizing doping conditions and/or developing novel nanostructures. Aiming to break this situation, we propose a calculation method for quantitative evaluation of thermoelectric properties of organic semiconductors (OSCs) which facilitates preliminary screening of candidate materials and the exploration of novel organic thermoelectrics. We focus on small-molecule semiconductors in this study since their highly crystalline nature is advantageous for efficient thermoelectric conversion[1].
One of the present author (Ohno) and his collaborators have shown that the Seebeck coefficient (which is the most important indicator of the conversion efficiency and is defined as induced thermoelectric voltage per unit temperature difference) of crystalline OSCs can be calculated from the effective density of states (DOS) measured experimentally using the Mott formula[1]. Then the crucial point of our calculation method is the evaluation of the effective DOS of bulk small-molecule OSCs with taking account of the thermally induced structural fluctuation (which is non-negligible even at room temperature) originating from the fact that small-molecule OSCs usually form molecular solids bound by weak van der Waals force. To take account of this fluctuation, we propose to conduct classical molecular dynamics (MD) simulations followed by electronic structure calculation based on density functional theory (DFT).
To demonstrate the validity of the proposed method, we calculated the effective DOS and Seebeck coefficients of pentacene and rubrene whose thermoelectric properties are experimentally tested enough. In our MD simulations, we adopted the general AMBER force field, which describes intra- and inter-molecular interactions including van der Waals force and has been confirmed to be applicable to bulk OSC crystals. MD calculations were performed to simulate equilibrium states at the pressure of 1 atm at 300K, and 100 crystal structures were sampled every 5 ps (5000 steps) from the trajectories. For each sampled structure, DFT calculations were conducted using projector augmented wave method and Perdew-Wang 1991 (PW91) functional.
Although each of the DOS had sharp peaks owing to disorder-induced carrier localization, the effective DOS of bulk crystal were well approximated as an average of adequate number of DOS. Its exponentially decaying shape near the band edge was in good agreement with experimental results. The value of Seebeck coefficients estimated from the decay rates of the effective DOS were 0.26 mV/K for pentacene and 0.17 mV/K for rubrene. These values agree quantitatively with experimental results[2], so we expect that the proposed method is applicable to materials exploration. In the presentation, relationships between structures and thermoelectric

properties will also be discussed in depth.

Late News: Synthesis and Characterisation of Phosphonated PEDOT for Energy-Efficient, Bioelectronic Devices Jonathan A. Hopkins[1], Kristina Fidanovski[1], Lorenzo Travaglini[1], Pawel Wagner[2], Klaudia K. Wagner[2], Antonio Lauto[3], David L. Officer[2] and Damia Mawad[1]; [1]UNSW Sydney, Australia; [2]University of Wollongong, Australia; [3]Western Sydney University, Australia

Organic electrochemical transistors (OECTs) developed for integration in bioelectronic devices utilise a conjugated polymer (CP) as the active material in the channel. The utility of OECTs has been demonstrated in various bioapplications including monitoring and stimulating biological cells.[1,2] In these applications, we want OECTs to be energy-efficient, requiring low threshold voltages to activate, and operating in accumulation mode such that they only use energy when switched "on". Unfortunately, many existing CPs for aqueous OECTs lead to depletion mode operation, which requires a constant potential to keep the device "off" and so is more energy intensive. These materials also require crosslinking or post-treatment to prevent their dissolution in water,[3] and their biocompatibility with certain cell lines may be limited by their high acidity.[4]

To overcome these limitations, we have synthesised a new CP, poly(ethylenedioxythiophene) bearing isopropyl-protected phosphonate groups (PEDOT-Phos), and performed its characterisation to elucidate its structure-property relationships. PEDOT-Phos is solution-processible from organic solvents, producing films which are readily proton doped with non-oxidising acids and undergo reversible electrochemistry in aqueous electrolytes. PEDOT-Phos can also be used in energy-efficient, aqueous OECTs with accumulation mode operation and low threshold voltages. These devices have the added advantages of high volumetric capacitances, good transconductances, and no requirement for additives or post-treatments. With these encouraging properties, PEDOT-Phos has great potential for emerging bioelectronic devices which combine good performance with improved energy efficiency.

9:00 PM EL01.05.01

Late News: Resonant Tender X-Ray Diffraction for Disclosing the Molecular Packing of Paracrystalline Conjugated Polymer Films Chris McNeill[1], Guillaume Freychet[2], Eliot Gann[3], Lars Thomsen[4] and Xuechen Jiao[1]; [1]Monash University, Australia; [2]Brookhaven National Laboratory, United States; [3]National Institute of Standards and Technology, United States; [4]ANSTO, Australia

The performance of optoelectronic devices based on conjugated polymers is critically dependent upon molecular packing; however, the paracrystalline nature of these materials limits the amount of information that can be extracted from conventional X-ray diffraction. Resonant diffraction (also known as anomalous diffraction) occurs when the X-ray energy used coincides with an X-ray absorption edge in one of the constituent elements in the sample. The rapid changes in diffraction intensity that occur as the X-ray energy is varied across an absorption edge provide additional information that is lost in a conventional nonresonant experiment. Taking advantage of the fact that many conjugated polymers contain sulfur as heteroatoms, this work reveals pronounced resonant diffraction effects at the sulfur K-edge with a particular focus on the well-studied electron transporting polymer poly([*N*,*N*′-bis(2-octyldodecyl)-naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyl]-*alt*-5,5′-(2,2′-bithiophene)), P(NDI2OD-T2). The observed behavior is found to be consistent with the theory of resonant diffraction, and by simulating the energy-dependent peak intensity based on proposed crystal structures for P(NDI2OD-T2), we find that resonant diffraction can discriminate between different crystalline packing structures. The utilization of resonant diffraction opens up a new way to unlock important microstructural information about conjugated polymers for which only a handful of diffraction peaks are typically available.

Thickness-Driven Polymorphism of Dinaphthothienothiophene (DNTT) Revealed by High-Resolution X-Ray Diffraction Nobutaka Shioya, Takafumi Shimoaka and Takeshi Hasegawa; Kyoto University, Japan

Among many promising organic semiconducting materials, dinaphthothienothiophene (DNTT) shows outstanding device performances in terms of charge transport and air stability, which exceeds those of the conventional prototypical material of pentacene. Although many reports demonstrate the excellent device performances of DNTT, a comprehensive understanding of thin film growth is lacking. In fact, the thin-film structure has long been believed to be identical to the single-crystal structure. In other words, polymorphs of DNTT have never been observed so far.
In the present study, the thickness-dependent structural evolution is revealed by means of high-resolution X-ray diffraction. This technique apparently reveals the existence of the “thin-film” phase [1], which has long been missed by the conventional analytical limit. This is also supported by infrared spectroscopy. The present study strongly suggests that a thickness-dependent structural change is a common phenomenon for rod-like organic molecules including DNTT. This study is believed to provide an in-depth understanding of thin film growth of common organic semiconductors.

Late News: Collective Effects on Molecular Orientation in Growth of Organic Thin Films Sae Nagai, Yuta Inaba, Toshio Nishi, Hajime Kobayashi and Shigetaka Tomiya; Sony Corporation, Japan

Control of the molecular orientation in organic semiconductor (OSC) films is essential to improve the performance of organic electronic devices. However, specific parameters for controlling molecular orientation have not yet been fully understood. In this study, we focus on the impact of growth temperature on molecular orientation in OSC films. We used pentacene on SiO_2 as a model system and applied p-polarized multiple-angle incidence resolution spectrometry (pMAIRS) for investigating the variation of molecular orientation. The molecular orientation of films varied with growth temperature from lying (molecules orient parallel to the

substrate) to standing (molecules orient perpendicular to the substrate) orientation. This change suggests that the formation of a standing orientation is thermally activated compared with the lying state. The nucleation of standing-oriented islands occurs by molecular self-assembly at sufficiently high temperatures. Conversely, molecules deposit in a lying state at low temperatures owing to hinderance of the kinetic barrier to reorientation from lying to standing states. We defined a collective orientation barrier (COB) as an energy barrier for the reorientation processes throughout the growth. We estimated the COB from an Arrhenius plot of the probability to form a standing orientation, derived from the dichroic ratio measured by pMAIRS. We found that the COB in the growth of pentacene on the SiO_2 system was approximately 0.02 eV. The COB is a key parameter for determining the molecular orientation and can be utilized for the control of molecular orientation of OSC films to improve the performance of organic electronic devices.

How to Control the Thermoelectric Properties of Organometallic Coordination Polymers? Bob C. Schroeder; University College London, United Kingdom

Developing highly conducting and air-stable n-type semiconductors have proven to be extremely challenging, despite intensive research efforts and a need for better-performing materials. Not only would highly conducting interlayers facilitate charge extraction, respectively injection, when used in organic solar cells or light-emitting diodes, but also accelerate the development of emerging plastic electronic technologies like organic thermoelectrics. Thermoelectric generators convert heat into usable electricity, due to the Seebeck effect. Constructing an efficient thermoelectric generator based on organic semiconductors, however, has proven difficult, primarily due to a significant shortage of suitable materials. While organic p-type semiconductors are abundant and relatively easy to dope, there is a shortage of suitable n-type materials and appropriate dopants. One approach that has proven popular in recent years is extrinsic doping of conjugated polymers. By mixing molecular dopants into a polymer matrix, it is possible to enhance the overall conductivity of the semiconductor to a certain degree, before morphological instabilities take over and cause microscopic phase separation of the dopant and polymer matrix, significantly limiting the doping efficiency.

In this paper, we will present a new approach to intrinsic organic conductors, namely organometallic coordination polymers. We will discuss how the choice of ligand and coordinating metal cation affect the electrical properties of the material and demonstrate how both the ligand and metal cation can be exploited to control the electrical characteristics. We will discuss how material purification affects the overall performance and elucidate the charge transport mechanism in this material class. Contrary to extrinsically doped semiconducting polymers, the organometallic coordination polymers exhibit excellent ambient and morphological stability and could pave the way to a new class of robust organic conductors for plastic electronic applications.

University, Belgium

The ‘phonon-glass electron-crystal’ concept has triggered most of the progress that has been achieved in inorganic thermoelectrics in the past two decades. Organic thermoelectric materials, unlike their inorganic counterparts, exhibit molecular diversity, flexible mechanical properties and easy fabrication, and are mostly ‘phonon glasses’. However, the thermoelectric performances of these organic materials are largely limited by low molecular order and they are therefore far from being ‘electron crystals’.
Here, we report a molecularly n-doped fullerene derivative with meticulous design of the side chain that approaches an organic ‘PGEC’ thermoelectric material [1]. This thermoelectric material exhibits an excellent electrical conductivity of >10 S/cm and an ultralow thermal conductivity of <0.1 W/mK, leading to the best figure of merit $ZT = 0.34$ (at 120 °C) among all reported single-host n-type organic thermoelectric materials. The key factor to achieving the record performance is to use ‘arm-shaped’ double-triethylene-glycol-type side chains, which not only offer excellent doping efficiency (~60%) but also induce a disorder-to-order transition upon thermal annealing. This study illustrates the vast potential of organic semiconductors as thermoelectric materials.

8:40 AM EL01.06.03
Late News: Design Considerations for Conformable Hybrid X-Ray Detectors—Influence of Organic Semiconductor Molecular Weight Maheshani Prabodhi Alwis Nanayakkara[1], Mateus Masteghin[1], Laura Basirico[2], Ilaria Fratelli[2], Andrea Ciavatti[2], Beatrice Fraboni[2], Imalka Jayawardena[1] and S. Ravi P. Silva[1]; [1]University of Surrey, United Kingdom; [2]Università di Bologna, Italy

The use of X-ray radiation detectors has gradually increased over the past couple of decades in a wide variety of applications ranging from medical diagnostics, industrial inspection, scientific research, to cultural heritage preservation. However, the object of investigation in most situations is of complex shape and geometry, while the detectors available to study them are rigid and flat. Such incompatibility between the object and detector results in numerous issues including vignetting and distortion of images. As a result, there is a growing requirement for conformable or curved detectors. Organic-inorganic hybrid (OIH) semiconductors are one of the most rapidly advancing class of novel materials for X-ray detection, that can be effortlessly printed on flexible substrates by using low-temperature wet deposition techniques. Furthermore, the use of OIH semiconductors as a soft matrix is expected to enable the fabrication of conformable detectors. Among them, the OIH detector concept that involves X-ray stopping bismuth oxide (Bi_2O_3) nanoparticles (NPs) incorporated into an organic bulk heterojunction (BHJ) consisting of p-type polymer Poly(3-hexylthiophene-2,5-diyl) (P3HT) and the n-type [6,6]-Phenyl C71 butyric acid methyl ester ($PC_{70}BM$) is highly versatile due to its exceptional characteristics such as high broadband sensitivity, ultra-low dark currents, and fast response times[1,2]. However, P3HT is generally regarded as a polymer that can crystallise depending on its molecular weight, and thereby influence the mechanical characteristics of the detector such as bendability, which is vital for conformable detectors. However, there has been very little work reported so far in this regard, especially for thick devices typically required for X-ray detection. In this study, we emphasize the importance of tuning the molecular weight of the P3HT polymer on achieving a perfect balance between the detector performance and bendability characteristics. Through fabricating conformable hybrid detectors with P3HT molecular weights in the range of 25-60 kDa, we demonstrate that there is a strong correlation between the detector performance, bendability characteristics, and crystallinity of the film. In particular, we observe the suitability of higher P3HT molecular weights for achieving detectors with a higher level of mechanical flexibility under repeated bending cycles. These observations are explained based on the internal microstructure of these films which results in higher mechanical cohesion within the film. This study highlights the importance of understanding and optimizing fundamental material properties towards designing highly conformable detectors, a fact that has not been reported in depth so far.

Diverse Anharmonic Structural Dynamics in Organic Semiconductors—Beyond the Quasi-Harmonic Approximation Maor Asher[1], Remi Jouclas[2], Nitzan Kahn[1], Guillaume Schweicher[2], Roman Korobko[1], Yves H. Geerts[2] and Omer Yaffe[1]; [1]Weizmann Institute of Science, Israel; [2]Université libre de Bruxelles, Belgium

The low-frequency lattice dynamics of small-molecule organic semiconductors have a significant impact on their transport properties. Many current studies do not take into account the possible strong anharmonic behavior of the lattice dynamics in these materials. In my presentation, I will show that similar molecules can have significantly different degrees and expressions of anharmonic lattice dynamics. I will do that by presenting the lattice dynamics of BTBT, ditBu-BTBT, diC8-BTBT, diPh-BTBT, and DNTT single crystals measured by polarization-orientation (PO) Raman combined with temperature-dependent Raman in the low-frequency range. I will show an expression of strongly anharmonic lattice dynamics in BTBT indicated by the change of the PO Raman dependence of the lattice vibrations as the temperature is increased. This anharmonic expression is almost completely suppressed in the other crystals. I will also show other expressions of anharmonicity in the form of an order-to-disorder phase transition in ditBu-BTBT and a polymorphic phase transition in diC8-BTBT. I will discuss the physical origin of these anharmonic expressions, addressing their large-amplitude motion and their anharmonic potential energy surface. I will argue that these expressions of anharmonicity are not captured within the quasi-harmonic framework. I will also talk about the effect of these anharmonic expressions on the nonlocal electron-phonon interactions, and their decoupled nature.

9:10 AM EL01.06.05
Predictive Modelling of Structure Formation in Semiconductor Films Produced by Meniscus-Guided Coating Jasper Michels[1], Ke Zhang[1], Philipp Wucher[2], Pierre Beaujuge[2], Wojciech Pisula[1] and Tomasz Marszalek[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]King Abdullah University of Science and Technology, Saudi Arabia

Meniscus-guided coating methods, such as zone casting, dip coating and solution shearing, are scalable laboratory models for large-area solution coating of functional materials for thin-film electronics. Unfortunately, the general lack of understanding of how the coating parameters affect the dry-film morphology upholds trial-and-error experimentation and delays lab-to-fab translation. In this contribution we present a modelling study focusing on the prediction of dry-film morphologies produced by meniscus-guided coating of a crystallizing small molecular solute. Our model reveals how the interplay between coating velocity and evaporation rate determines the crystalline domain size, shape anisotropy and regularity. If coating is fast, evaporation drives the system quickly past supersaturation, giving isotropic domain structures. If coating is slow, depletion due to crystallization stretches domains in the coating direction. The predicted morphologies have been experimentally confirmed by zone-casting experiments of the organic semiconductor 4-tolyl-bithiophenyl-diketopyrrolopyrrole. Although here we considered a molecular solute, our model can be applied broadly to polymers and organic–inorganic hybrids such as perovskites.

9:25 AM *EL01.06.06
Controlled Crystallization and Electrochemical Doping Strategies of Films Based on the Two Work-Horses P3HT & P(NDI2OD-T2) Sabine Ludwigs; University of Stuttgart, Germany

Both, poly(3-hexylthiophene) (P3HT) and poly{[N,N'-bis(2-octyldodecyl)-1,4,5,8-naphthalenediimide-2,6-diyl]-alt-5,5'-(2,2'-bithiophene) (P(NDI2OD-T2)), can be regarded as the work-horses of the organic

electronics community.
Based on our earlier crystallization studies on P3HT[1] my talk will give an overview about our recent findings on structure-function relationships of (P(NDI2OD-T2)[2]. The involvement of liquid-crystalline phases, in particular nematic-like preordering in highly concentrated solutions is demonstrated. Solvent vapor annealing is shown to lead to large area alignment in spherulite-like superstructures with semi-crystalline structures. Particularly nice is the applicability of blade-coating to achieve highly anisotropic fiber-containing films where both the bulk and the surface morphology can be determined.[3] These findings show completely different growth behavior than previously developed for P3HT.[1]
Using such well-defined morphologies we can access detailed structural insights into chemical and electrochemical doping mechanisms.[4,5] An alternative way of inducing charge carriers in the bulk polymer film is *ex-situ* electrochemical doping.[6] Here the charge carriers are generated inside a three-electrode setup in electrolyte by applying a static electrochemical doping potential. Our experiments show that the generated charged species are stable in the solid state enabling 4-line probe conductivity and absorption measurements. An advantage of our electrochemical doping technique is the ability to fine-tune the charge carrier density inside the polymer film and hence control the resulting conductivity. Conductivities as high as 220 S/cm over large electrochemical potential windows can be reached for P3HT films. Maximum conductivities in P(NDI2OD-T2) films are limited to 10^{-3} to 10^{-2} S/cm which is ascribed to a mixed valence conductivity mechanism in such conjugated redox polymer films.[4]

Pushing the Limits of Electron Microscopy of Conjugated Polymers Enrique D. Gomez; The Pennsylvania State University, United States

Imaging of polymers by transmission electron microscopy (TEM) or scanning transmission electron microscopy (STEM) remains a challenge due to the low contrast between domains and sensitivity to the electron beam. Recent advances in instrumentation for electron microscopy have aimed to push the resolution limit, leading to remarkable instruments capable of imaging at 0.5 Å. But, when imaging soft materials, the resolution is often limited by the amount of dose the material can handle rather than the instrumental resolution. Despite the strong constraints placed by radiation sensitivity, recent developments in electron microscopes have the potential to advance polymer electron microscopy. For example, we have used monochromatated sources for spectroscopy and imaging based on differences in the valence electronic structure of conjugated polymers, electron tomography to map nanoscale inhomogeneity in polymer density, and direct electron detectors to minimize the required dose for imaging and thereby image lattice planes in crystalline polymers. Key to these efforts is

characterization of the mechanism for radiation damage in the TEM, which suggests new strategies to minimize damage, and thereby push the resolution limit down to 3.6 Å (for example, for PffBT4T-20D). Altogether, the field of polymer electron microscopy is poised to make significant advances in the near future.

10:55 AM EL01.07.02
Late News: Computation of Meisenheimer Complexes Formed to Act as Dopants for Semiconducting Polymers Leading to High Power Factors for N-Type All-Organic Thermoelectrics Connor Ganley, Jinfeng Han, Tushita Mukhopadhyaya, Howard E. Katz and Paulette Clancy; Johns Hopkins University, United States

Organic semiconducting materials have already been commercialized for applications such as organic light-emitting diodes (OLEDs), organic field effect transistors (OFETs), and photovoltaic devices. Recent work in the Howard Katz group at Johns Hopkins University has produced two novel organic doped *n*-type polymer semiconducting thermoelectric materials, PNDIC1TVT and PBDOPVTT, with σ values of 0.2 S cm-1 and 0.75 S cm-1, respectively, and power factors (PF) of 67 μW m-1 K-2 and 58.1 μW m-1 K-2, respectively. A doped form of PNDIC1TVT appears to have the highest power factor value yet reported for a solution-processed conjugated organic-doped *n*- type polymer thermoelectric material. However, the molecular origin of this enhancement is uncertain, motivating a computational investigation of this system.
We used density functional theory to probe the nature, structure, and properties of an adduct forming between fluoride anion, an established but electrochemically unlikely n-dopant, and a model electron-accepting naphthalenetetracarboxylic diimide (NTCDI) subunit as a representative n-type conjugated polymer segment, to investigate the hypothesis that an adduct may act as an intermediate in the fluoride doping mechanism of the semiconducting polymer. Our contribution uses the ORCA code with Ahlrichs' def2-TZVP basis set with a B97-D3 functional, based on our previous investigations and recommendations by Grimme (*Phys. Chem. Chem. Phys.*, 2011). We confirmed adduct formation between the two species and identified three positionally unique sites at which a fluoride dopant was capable of *datively* bonding to the NTCDI, most strongly and somewhat surprisingly at the carbonyl carbons. Subsequent simulations explored the impact of positive counterions, cesium and tetramethylammonium. Our results confirmed the lack of experimental observations of cesium-containing adducts, which we predict would not form from a binding energy standpoint. We also found that the adducts had an ionization potential that was nearly 1 eV *less* than the dopants themselves, indicating a greater likelihood that the adduct was the source of doping rather than the pure fluoride salts. These results suggest that a fluoride ion-based Meisenheimer adduct could be a particularly effective fluoride intermediate to act as a dopant for *n*-type polymers and might be used for high-performance *n*-type organic thermoelectrics. We also conducted an analogous study on adduct structures using electron-donating thiophene oligomer segments and scandium triflate and tris(pentafluorophenyl)borane Lewis acids, which could also serve as p-dopants. Our results showed that the doped adduct electron affinities were at most 0.5 eV more negative than the pure Lewis acids, meaning that considering dielectric and entropic effects, they could serve as polymer p-dopants. This study strongly supports the hypothesis that adduct formation is a plausible mechanism for conjugated polymer doping by dopants that do not appear to have sufficient electrochemical driving force on their own, and suggests that adduct dopants could also contribute to useful density of states profiles for polymer thermoelectrics.

Late News: Reversible Charging of Redox-Active Conjugated Polymers Beyond the Polaronic State in Aqueous Electrolytes Alexander Giovannitti[1], Anna Szumska[2], Iuliana Petruta Maria[2] and Jenny Nelson[2]; [1]Stanford University, United States; [2]Imperial College London, United Kingdom

Conjugated polymers are an interesting class of materials for electrochemical devices since their electrochemical properties can be tuned by chemical design strategies to enable redox activity in various electrolytes. For example, redox activity in aqueous electrolytes can be achieved by attaching polar side chains to the polymer backbone, which enables ionic transport and allows volumetric charging of polymer electrodes.[1] While this approach has been beneficial for achieving low apparent redox potentials in aqueous solution, little is known about the relationship between water uptake during the electrochemical charging

process of conjugated polymers and their redox-potentials and stabilities, particularly for electron-transporting conjugated polymers. We find that excessive water uptake during the electrochemical charging of polymer electrodes is harming the reversibility of electrochemical processes and results in mechanical instabilities of the polymer electrodes, requiring control of the swelling through side-chain engineering. We show that small changes of the side chain composition can significantly increase the redox-stability of the materials in aqueous electrolytes, improving the capacity of the polymer by more than one order of magnitude. We further study the charging process by employing density functional theory calculations to explain shifts of the electrochemical redox-potentials of water-swollen polymer films. Our results show that water uptake is beneficial for achieving low redox-potentials. Additionally, we investigate the affinity of the charged polymer to undergo unwanted side reactions with the electrolyte and find a high retention of the charged, reduced, conjugated polymers in pH neutral aqueous electrolytes, but only in the absence of molecular oxygen. Our work shows the importance of chemical design strategies for achieving high redox-stabilities for conjugated polymers in aqueous electrolytes.

Late News: Quantifying Charge Carrier Localization in Chemically Doped Semiconducting Polymers
Riley C. Hanus, Shawn Gregory, Samuel Graham and Shannon Yee; Georgia Institute of Technology, United States

The use of semiconducting polymers continues to grow despite the lack of a robust theory for how chemical doping, polaron formation, and spatial inhomogeneity localize charge carriers in these materials. Charge transport in semiconducting polymers ranges from localized (hopping-like) to delocalized (metal-like), and no quantitative model exists to fully capture this spectrum of transport behavior and its dependency on charge carrier density. In this study, we develop and validate a charge transport model that quantifies charge carrier localization and can effectively capture the localized to delocalized transition. With the archetypal P3HT-$FeCl_3$ polymer-dopant system, we measure the temperature dependent electrical conductivity, Seebeck coefficient, quantify the extent of oxidation using XPS, and show that the transport function prefactor and the localization activation energy are functions of the charge carrier concentration ratio (i.e., the ratio of oxidized thiophene rings to total thiophene rings). From these observations, we develop a semi-localized transport (SLoT) model, which captures both localized and delocalized transport effects with broad application in describing the electro-thermal transport of many chemically doped polymers. By applying the SLoT model to published data on semiconducting polymers and carbon nanotube systems we demonstrate its broad applicability and utility. We are able to determine system dependent parameters such as (i) the maximum localization energy of the system in the low doping limit, (ii) how this localization energy changes with doping (iii) the amount of dopant required to achieve metal-like conductivity, and (iv) the hypothetical conductivity a system could have in the absence of localization effects. Ultimately, for the first time, this proposed SLoT model captures both localized and delocalized transport, and thereby improves our ability to predict and tailor electronic properties of doped-semiconducting polymers.

Structural Transformations in Conjugated Polymers Upon Electrochemical Doping from Aqueous Electrolytes
Connor G. Bischak and David Ginger; University of Washington, United States

Electrochemically-driven ion insertion into conjugated polymers causes molecular structural changes that impact how ionic and electronic charge carriers move through the polymer matrix. Couplings between structural changes, ion motion, and electronic transport affect the performance of devices that rely on the mixed ionic electron conductivity of conjugated polymers, such as electrochemical capacitors, bioelectronics, and neuromorphic computing. Typically, the crystal structures of conjugated polymers change continuously upon

ion insertion. Yet, using *in situ* X-ray scattering, we find that conjugated polymers can undergo reversible first order structural phase transitions upon electrochemically-driven ion insertion. We also use nanoscale infrared imaging to characterize phase separation between ion-rich and ion-poor regions of the polymer during electrochemical doping. We find that structural phase transitions have important implications for the charging mechanism of conjugated polymers for electrochemical capacitors.

12:10 PM EL01.07.07
Designing Dopants to Produce Highly Mobile Carriers in Chemically Doped Conjugated Polymers Taylor Aubry, KJ Winchell, Jonathan Axtell, Alexander Spokoyny, Benjamin Schwartz and Sarah Tolbert; University of California, Los Angeles, United States

Doping conjugated polymers is an effective way to tune their electronic properties for thin-film electronics applications. Chemical doping of semiconducting polymers involves the introduction of a strong electron acceptor or donor molecules that can undergo charge transfer with the polymer. The charge transfer reaction creates electrical carriers on the polymer chain (usually positive polarons a.k.a. holes) while the dopant molecules remain in the film and serves as a counterion. Unfortunately, strong electrostatic attraction between counter-anions and most dopants will localize the polarons and reduce their mobility. Here, we employ a new strategy, utilizing substituted icosahedral dodecaborane (DDB) clusters as molecular dopants for conjugated polymers. DDBs provide a unique system in which the redox potential of the dopant can be rationally tuned via modification of the substituents without significant change to the size or shape of the dopant molecule. These clusters thus allow us to disentangle the effects of energetic offset on the production of free and trapped carriers in DDB-doped poly-3-hexylthiophene (P3HT) films. We find that the propensity for charge transfer is directly proportional to the energetic offset between P3HT and the DDB dopant. More importantly, by designing DDB clusters to have a high redox potential and good steric protection of the core-localized electron density, highly delocalized polarons with mobilities equivalent to films doped with no anions present are obtained. P3HT films doped with these boron clusters have conductivities and polaron mobilities roughly an order of magnitude higher than films doped with conventional small-molecule dopants such as 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F_4TCNQ) at the same doping level. The spectral shape of the IR-region absorption for our DDB-doped polymer film closely matches the calculated theoretical spectrum for the anion at infinite distance from the polaron. At the same time, grazing incidence diffraction indicates that, despite their large size, DDB clusters can intercalate within the polymer crystallites to create highly crystalline dope polymer films. We therefore conclude that these DDB clusters are able to effectively spatially separate polarons and counterion, and that this separation is a critically important aspect for producing high carrier mobilities in doped conjugated polymers.

Morphology Control to Realize Multi-Functionalities in Skin-Inspired Electronic Materials Zhenan Bao; Stanford University, United States

Skin-inspired electronic materials need to combine excellent electronic properties with additional requirements, such as stretchability, biodegradability and self-healability. In order to satisfy all the requirements, controlling multi-scale morphology through material design and processing is crucial. In this talk, I will present examples of such material systems.

1:25 PM *EL01.08.02
Plasmonics for Bright and Long-Lived Light Emitting Devices Michael Fusella, Renata Saramak, Rezlind Bushati, Vinod Menon, Michael S. Weaver, Nicholas J. Thompson and Julia J. Brown; Universal Display Corporation, United States

In this seminar, we introduce a new light emitting device combining the benefits of organic semiconductors, such as defect tolerance and chemical diversity, with the enhanced optical properties of plasmonic systems. Excitons formed in the organic layers of our novel LED architecture are intentionally coupled to the surface plasmon mode of a nearby metal electrode for decay rate enhancement and subsequently converted to photons in free space via a nanoparticle-based out-coupling scheme. Our architecture achieves a two-fold increase in operational stability at a given brightness compared to a conventional OLED while simultaneously outcoupling 8% of photons from the device. Our innovative approach augments materials design allowing for parallel development of increases in efficiency and stability and is applicable to all commercial applications of OLEDs, which include lighting panels, televisions, and mobile displays.

1:50 PM EL01.08.03
Late News: Pseudo-Self-Aligned Organic Field-Effect Transistors Jörn Vahland, Karl Leo and Hans Kleemann; TU Dresden - Institut für angwandte Physik, Germany

The gap in performance between organic and inorganic transistors is getting closer due to continuous improvements in charge carrier mobility and device designs. With record cutoff frequencys exceeding 150 MHz, organic transistors become increasingly attractive for high-frequency applications on flexible substrates, e.g., wireless communication.
However, a severe disadvantage of the state-of-the-art organic thin-film transistor (OTFT) technology is the lack of a self-aligned transistor architecture as routinely employed in silicon-based technology. In consequence, organic thin-film transistors suffer from large overlap capacitances reducing the frequency of device operation and causing large device-to-device variation due to the required alignment step. Hence, the development of a self-aligned organic transistor architecture based on a scalable and reliable process bears great potential for the improvement of printed and flexible circuits.
Here we propose a pseudo-self-aligned OTFT in a coplanar top-gate configuration in order to reduce parasitic capacitances originating from the source-gate and drain-gate overlap. Furthermore, these device are fabricated by conventional photolithography and etching processes and do not require unreliable processes such as lift-off. The self-alignment is achieved by employing a spacing layer between the source and drain and the gate electrode. This spacer reduces the specific capacitance in this overlap region by about a factor of 10 from around 15nF/cm^2 to 0.13nF/cm^2. While maintaining the overlap length L_{OV}, required for alignment during lithography, this reduces the total gate capacitance. A total device capacitance reduction from 1.34fF/µm to 0.4578fF/µm (normalized by channel width) for a channel length and overlap of $L=L_{OV}=3$µm can be estimated.

2:05 PM EL01.08.04
Late News: Amplification of External Quantum Efficiency by Photomultiplication in Organic Photodetectors Jonas Kublitski[1], Axel Fischer[1], Shen Xing[1], Johannes Benduhn[1], Lucasz Baisinger[1], Donato Spoltore[1], Koen Vandewal[2] and Karl Leo[1]; [1]Technische Universität Dresden, Germany; [2]Hasselt University, Belgium

Photodetectors (PDs) find their applicability in several technological fields. In medical applications low signals need to be amplified, requiring external circuits, which increases the final price. In addition to low cost, flexibility and lightweight devices provided by organic materials, photomultiplication has been achieved in organic PDs, leading to remarkable external quantum efficiencies (EQEs). Drawbacks of such systems are the high dark currents (J_D), lack of spectral selectivity and high operation voltages, due to large injection barriers in reverse direction. By controlling the acceptor amount and with the aid of appropriated blocking layers, we force electrons to accumulate in the acceptor phase of ZnPc:C_{60} blends, close to the cathode interface. Due to the increased field caused by the accumulated photocharges in this region a band bending arises, effectively

increasing the injection rate across the barrier. Under reverse bias, holes are able to tunnel through it, allowing for high hole injection. Because they can easily cross the device through the ZnPc phase, while electrons cannot easily reach the contact, an EQE of 200% is achieved in the visible range, under -5V. Simultaneously, under dark conditions, the band bending is absent and the J_D follows that of common photodiodes with values of 10^{-4} mA.cm^{-2}. Switching injection only by illumination leads to an on/off ratio of 10^5. Controlling the trapping character of the acceptor phase allowed us to achieve photomultiplication in vacuum processed devices, leading to EQE higher than 100%. This results open the possibility to explore high responsivity controlled by the applied bias in the visible range for future applications in organic PDs.

2:20 PM EL01.08.05
Controlling Polymer-Dopant Interactions Through Molecular Design Christian Nielsen; Queen Mary University of London, United Kingdom

Polythiophenes are among the most studied organic semiconductors and they have found widespread use as the active material in organic field-effect transistors, bioelectronic sensors and as the electron donor component in organic photovoltaic devices. Here, we investigate how subtle structural modifications of archetypical polythiophenes such as poly(3-hexylthiophene) affect the optical, structural and electrical properties of the resulting polymer thin films. We furthermore discuss the implications of these structural modification for binary systems incorporating molecular dopants and outline molecular design strategies for controlling doping efficiency and electrical conductivity.

2:35 PM EL01.08.06
Late News: A Reassessment of the Characterization and Performance of Low-Noise Large-Area Organic Photodiodes Canek Fuentes, Wen-Fang Chou, Victor A. Rodriguez-Toro, Youngrak Park, Yi-Chien Chang, Oliver Moreno, Felipe A. Larrain and Bernard Kippelen; Georgia Institute of Technology, United States

Silicon photodiodes (SiPDs) are the foundation of light-detection technology but emerging applications such as wearable biometric monitoring, biomedical imaging, distributed ionizing-radiation detection, and others, require photodetectors with mechanical properties and form factors that are beyond those physically possible with SiPDs. Novel organic and hybrid semiconductors processed from solution at low temperatures have the potential to overcome current limitations of traditional SiPDs and to enable next-generation photodetector technology. Although the performance of photodiodes (PDs) based on these novel semiconductors has been reported to be similar or better than that of low-noise SiPDs, the claimed performance is in question because the approximations used to estimate relevant metrics are often not verified (*1,2*).
Questions in the characterization of PDs arise because the noise equivalent power (*NEP*) is seldom measured directly. Instead, it is extrapolated from responsivity values commonly measured with a low measurement bandwidth and at a high optical power that is much larger than the *NEP*. In addition, the electronic noise is not measured directly either. In this work, we present a reassessment of the characterization of PDs including direct measurements of the responsivity as a function of optical power, electronic noise, and a detailed derivation of the parameters that are relevant for the accurate estimation of a photodetector's performance.
Insights derived from a detailed characterization, enable optimization of organic photodiodes (OPDs) based on polymeric bulk heterojunctions achieving a level of performance that within the visible spectral range, rivals that of low-noise SiPDs in all metrics, except response time. A comparison between small-area SiPDs and OPDs yields comparable median electronic noise currents of 37 fA, yielding comparable median noise equivalent power (*NEP*) values at 525 nm of ca. 200 fW and median specific detectivity (D^*) values of 2.1×10^{12} cm Hz$^{1/2}$/W at a low measurement bandwidth of 1.5 Hz. Champion OPDs show a D^* value as high as 8×10^{12} cm Hz$^{1/2}$/W. Detailed measurements of the electronic noise yields a reassessment of the physical origin of the different electronic noise contributions in OPDs, potential paths for optimization, and suggest that these OPDs could reach an extrapolated white-noise limited $NEP_{ex,wn}$ of 2 fW and a $D^*_{ex,wn}$ of $1.6\times B^{1/2}\times10^{14}$ cm Hz$^{1/2}$/W. This remarkable performance arises from the selection of photoactive layer materials and by the optimization of a device-geometry that does not make use charge-blocking layers.
The superior design possibilities of OPDs in terms of area, form factor, weight, and custom shapes are also

demonstrated by fabricating on glass devices with an area of 0.9 cm^2 that achieve a D^* of 2×10^{12} cm $Hz^{1/2}$/W and flexible OPDs with an area of 1 cm^2 that yield a D^* of 1.1×10^{12} cm $Hz^{1/2}$/W, both of which are comparable to small area OPDs on glass. Advantages of OPDs are further illustrated and quantified in a biometric monitoring application that uses ring-shaped, large-area, flexible OPDs, while maintaining low-noise SiPD-level performance.

Development of Benzodithiophene-Based Copolymers with Conjugated Indolin-2-One Side Chains as Wide Band Gap Donor Polymers for Efficient Non-fullerene Organic Solar Cells with a Large Open Circuit Voltage Marwa Abdellah, Wuqi Li and Yuning Li; University of Waterloo, Canada

We report the syntheis and develpoment of benzodithiophene-based copolymers with conjugated indolin-2-one side chains (PTIBDT), and its fluorine derivetive (PTIFBDT) with a donor backbone and acceptor side chains (Type II D-A polymer) as wide band gap donor polymers for efficient non-fullerene organic solar cells with a large open circuit voltageas up to (1 eV) opposed to the conventional D-A polymers having both donor and acceptor units on backbone (Type I D-A polymers) with limited open circuit voltage values. PTIBDT and the flourinated derivative PTIFBDT having a backbone consisting of benzodithiophene donor units and side chains containing indolin-2-one acceptor units were synthesized in a simple inexpensive route with a low-lying HOMO energy level of -5.59, -5.60 eV and a wide band gap of 1.91, 1.89 eV, respectively. In addition, both PTIBDT and PTIFBDT showed typical p-type semiconductor performance with ITIC were used as donor and acceptor to form a blend active layer, the best OSC device showed a short circuit current density (J_{sc}) of 15.60 and 13.70 $mAcm^{-2}$, a an open voltage (V_{oc}) of 0.97 and 1.00 V, and a fill factor of 0.60 and 0.59, resulting in a power conversion efficiency (PCE) of up to 8.00 and 7.70 %, respectively.

4:03 PM EL01.09.02
Separating the Active Region from the Edges—Bulk Quantum Efficiency in Organic Photovoltaics Kan Ding[1], Xiaheng Huang[1], Yongxi Li[1] and Stephen Forrest[1,1,2]; [1]University of Michigan, United States; [2]University of Michigan–Ann Arbor, United States

We introduce a convenient method for analyzing bulk heterojunction (BHJ) organic photovoltaics (OPVs) by calculating its “bulk quantum efficiency” (BQE), a quantity related to the recombination losses only within the BHJ, from device *J-V* characteristics. By testing the method against experimental results for both vacuum- and solution-processed OPVs with various BHJ, buffer layers and interface layers compositions, we show that direct measurement of BQE isolates the properties of the BHJ from device edges (i.e., buffer layers, interfaces and electrodes). The BQE analysis is then applied to study different degradation mechanisms in OPVs with various active layer materials and device structures. In solution-processed OPVs with non-fullerene acceptors (NFAs), we show that the primary mechanism for degradation is externally induced by the ZnO buffer layer. By inserting a self-assembled monolayer at the BHJ/ZnO interface, the degradation is significantly suppressed and the solution-processed NFA BHJs are stabilized. We also introduce an equation to quantitatively describe the degradation of BQE.

4:06 PM EL01.09.03

Late News: Probing the Role of Lateral Charge Transport in Organic Solar Cell Active Layers Pravini S. Fernando, Jeremy Mehta, Detlef M. Smilgies and Jeffrey M. Mativetsky; Binghamton University, United States

Solution processed organic bulk heterojunction (BHJ) solar cells offer a promising route towards lightweight, cost-effective, and flexible photovoltaics. Although the BHJ's nanoscale interpenetrating donor-acceptor network results in efficient charge photogeneration, it also creates complex three-dimensional pathways for collecting charge. Despite the three-dimensional nature of the charge transport, the importance of lateral pathways is generally ignored. In this work, we examine the extent of lateral current spreading during out-of-plane charge transport across BHJ active layers for insight into the impact of lateral pathways on charge collection. We first introduce a procedure, using conductive atomic force microscopy, to quantify lateral current spreading during out-of-plane charge transport. This method was used to study the dependence of lateral spreading on molecular orientation (face-on versus edge-on), molecule type (small molecule versus polymer), and film type (single component versus BHJ). Generally, charge transport is favored along the pi-pi stacking direction; hence, a face-on (edge-on) orientation normally favors vertical (lateral) charge transport. We observed in P3HT:PCBM active layers that lateral hole spreading was proportional to the edge-on to face-on population ratio of the P3HT, as determined by grazing-incidence X-ray diffraction. Interestingly, BHJ films with the greatest content of face-on P3HT did not have the highest out-of-plane current. Instead, an intermediate edge-on to face-on ratio exhibited a 20% higher out-of-plane current. We expect that the edge-on P3HT stacking plays an essential role in allowing holes to circumvent acceptor domains in which hole transport is excluded, enabling three-dimensional charge percolation. Predominantly edge-on P3HT, however, led to excessive lateral spreading and inefficient out-of-plane charge transport. We also observed that the polymer donor P3HT led to more lateral current spreading than the small molecule donor *p*-DTS(FBTTh$_2$)$_2$, owing to charge transport along the polymer backbone of P3HT. Less lateral current spreading was observed in BHJs compared to pure films, due to a disruption of lateral hole transport by the acceptor domains. These experiments provide insight into the effects of film morphology on charge percolation in BHJs, which will help promote efficient charge collection in organic solar cells.

4:09 PM POSTER Q&A

4:17 PM EL01.09.04

Morphological Origins of Non-Langevin Recombination to Realize Thick Yet Efficient Polymer-Fullerene Solar Cells Obaid Alqahtani[1,2], Seyed Hosseini[3], Ardalan Armin[4], Safa Shoaee[3], Vicotr Murcia[1], Thomas Ferron[1], Terry McAfee[1], Kevin Vixie[1], Brian A. Collins[1] and Fei Huang[5]; [1]Washington State University, United States; [2]Prince Sattam bin Abdulaziz University, Saudi Arabia; [3]University of Potsdam,, Germany; [4]Swansea University, United Kingdom; [5]South China University of Technology, China

Scaling-up and commercialization of organic solar cells (OSC) using high throughput deposition techniques requires thicknesses >500 nm for reproducibility. Yet most OSC materials rapidly lose efficiency as thickness increases due to the recombination prior to extraction of charges. A novel electron-donating polymer NT812 exhibits efficient, micron thick solar cells when paired with a fullerene acceptor due to highly suppressed bimolecular recombination relative to diffusion-limited Langevin rate. In this system, bimolecular recombination depends on the blend ratio and solvent additives, pointing towards the role of nano-morphology. We investigate the morphological origins of the bimolecular recombination in blends of NT812. By combining results from a suite of X-ray techniques, we are able to quantify not only the crystallinity, domain size and purity but also the sharpness of the donor-acceptor interfaces, which are found to sharpen when introducing a plasticizing solvent additive. We find that all the investigated devices possess pure domains of polymer fibrils and fullerene aggregates regardless of the recombination reduction factor. This indicates that pure phases are insufficient for non-Langevin recombination. However, large well-ordered conduits free of molecular mixing and in particular, sharp interfaces help to maintain opposite charges away from one another and keep percolation pathways clear for enhanced charge transfer (CT) state dissociation rate. This structure-morphology relationship will be key to the successful commercialization of printed OSCs at scale.

4:20 PM EL01.09.05
Role of the Blend Ratio in Polymer:Fullerene Phototransistors Cinthya K. Trujillo Herrera, John G. Labram and Min Ji Hong; Oregon State University, United States

Because of their ability to combine detection and processing into a single element, phototransistors have the potential to be a disruptive optical detection technology. The complexity of commercial applications (as defined by number of vertical processing steps) can be reduced significantly when using phototransistors compared to photodiodes, for example. In addition, phototransistors have a gate-voltage-tunable responsivity (something for which there exists no analog in 2-terminal devices), with high gain from small changes in incident optical power density.

Organic phototransistors (OPTs) in particular offer the opportunity to develop devices with well-defined, tailored, optical response spectra. One of the most significant drawbacks to OPTs however is the complexity of the relationship between photocurrent and incident optical power density. In addition to the choice of two applied voltages (drain and gate), optically induced shifts in threshold voltage often lead to behavior that is difficult to predict and quantify.

In this work we have varied the composition of polymer:fullerene bulk heterojunction (BHJ) OPTs, in order to identify the respective role played by direct charge generation and optically induced shifts in threshold voltage. The current-voltage behavior of blends of poly(3-hexylthiophene-2,5-diyl) (P3HT) and phenyl-C_{61}-butyric acid methyl ester (PCBM) were studied under illumination at various intensities. It is demonstrated that even one percent (by weight) of P3HT in PCBM produces an appreciable response while remaining highly optically transparent to the excitation wavelength, making these organic phototransistors highly attractive for optically transparent detectors.

4:23 PM POSTER Q&A

4:35 PM EL01.09.07
Late News: Engineering Solution Processable N-Type Silicon and Tin Phthalocyanines for Organic Thin-Film Transistors Rosemary R. Cranston, Mário C. Vebber and Benoit Lessard; University of Ottawa, Canada

P-type organic semiconductors typically demonstrate higher mobilities and better chemical and environmental stability compared to n-type materials which are often air sensitive and insoluble. The development of soluble, stable, high performing n-type materials is critical for the fabrication of organic electronic devices for many of the novel applications organic semiconductors allow for. Due to their high degree of intermolecular stacking, crystallinity, chemical and mechanical versatility, and compatibility with solution processed fabrication technique, axially-substituted metal phthalocyanines (MPcs) are promising materials for applications in organic thin-film transistors (OTFTs). MPcs contain multiple functional sites, including the core, periphery and axial positions, allowing to chemically tune molecules to improve device performance. MPcs with tetravalent metal centers, such as silicon and tin phthalocyanines (SiPcs and SnPcs), are among the highest performing materials in this family, however remain relatively unexplored compared to commonly used divalent metal MPcs. Seven varying lengths of branched chain alkyl silane groups were incorporated into SiPc or SnPc at the axial positions to create fourteen solution processable n-type organic semiconductors, ten of which are novel materials never before used in OTFTs. Atomic force microscopy (AFM) images of the films show that variations in alkyl chain length and metal center result in drastic changes in film morphology and corresponding OTFT performance. OTFTs fabricated with the SnPc derivatives exhibited average mobilities in the range of $0.02 – 0.70 \times 10^{-2}$ cm^2 V^{-1} s^{-1}, with four of the seven compounds outperforming their SiPc counterparts whose mobilities ranged from $0.01 – 2.8 \times 10^{-2}$ cm^2 V^{-1} s^{-1}. The relationship between two key fabrication parameters, thermal annealing and spin time, on thin-film microstructure and OTFT performance was investigated through the electrical characterization of the highest performing material, bis(tri-*n*-butylsilyl oxide) SiPc, and related to grazing-incidence wide-angle x-ray scattering (GIWAXS) and x-ray diffraction (XRD) data. Thermal annealing

increased film crystallinity and altered the orientation of the SiPc molecule relative to the substrate, whereas spin time solely effected film crystallinity, thus exhibiting how these fabrication parameters can be used to change different aspects of the thin-film microstructure and modify device performance. The results of this work show the effectiveness of axial substitution as a strategy to control crystal packing and charge transport properties of SiPcs and SnPcs, and the potential of these materials as solution processable low cost n-type semiconductors.

4:50 PM EL01.09.08

Operando Scattering Reveals the Structural Origins of Regio-Chemistry Driven Improvements in Mixed Conducting Polymers Bryan D. Paulsen[1], Rawad K. Hallani[2], Christopher J. Takacs[3], Micaela Matta[4], Ruiheng Wu[1], Joseph Strzalka[5], Qingteng Zhang[5], Wonil Sohn[1], Alexander Giovannitti[3], Anthony J. Petty II[1], Iain McCulloch[6] and Jonathan Rivnay[1,1]; [1]Northwestern University, United States; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]Stanford University, United States; [4]University of Liverpool, United Kingdom; [5]Argonne National Laboratory, United States; [6]University of Oxford, United Kingdom

Conjugated polymers with oligoethylene glycol side chains are excellent mixed ionic-electronic conductors, and through volumetric capacitive coupling can efficiently interconvert ionic and electronic currents. These phenomena have been exploited for electrochromic, charge storage, biological sensor, neuromorphic, and organic electrochemical transistor (OECT) applications, amongst others. The polythiophene pg2T-TT, poly(2-(3,3′-bis(2-(2-(2-methoxy ethoxy)ethoxy)ethoxy)-[2,2’-bithiophen]-5-yl)thieno[3,2-b]thiophene), with its high capacitance (C*), high hole mobility (μ), and high transconductance in OECTs (ionic-to-electronic transduction gain), has become a benchmark material for this emerging class of mixed conductors. Surprisingly, simply switching the side chain position on the bithiophene repeat unit from 3,3' to the 4,4' positions (producing pgBTTT) results in a marked improvement in mixed conducting properties. The product of pgBTTT’s electronic mobility and volumetric capacitance (μ x C*), which is the source of OECT transconductance, is double that of pg2T-TT, and represents a record high intrinsic figure of merit for enhancement mode OECT channel materials (μ x C* = 563 ± 33 F cm^{-1} V^{-1} s^{-1}).

The source of this improvement is not immediately obvious. Traditional characterization methods typically carried out on dry polymer films do not reflect the operating conditions of these polymers in OECTs or other devices that exploit their mixed conducting properties, where they are swollen by a contacting electrolyte. Therefore, in situ and operando techniques are required. While X-ray scattering has become ubiquitous for structure determination, in situ or operando scattering of films emersed in aqueous electrolyte is severely limited by electrolyte scattering and absorption. This is especially critical for conjugated polymers which are weak scatterers and most often employed in (sub-micron) thin films. To overcome these challenges, we employ a new frit-based electrochemical cell that allows electrolyte contact of the thin film from below and incident X-rays to impinge from above, separating the electrolyte and x-ray path to provide unparalleled resolution of polymer microstructure in aqueous operando conditions. Leveraging this cell we compare the grazing incidence wide angle scattering (GIWAXS) patterns of dry, hydrated, electrolyte exposed, and electrochemical potential cycling pg2T-TT and pgBTTT, monitoring both molecular d-spacing and molecular packing coherence lengths. These operando measurements deviate markedly from equivalent ex situ measurements, highlighting the limited utility of ex situ experiments in elucidating the structure of electrolyte swollen polymer mixed conductors.

While pg2T-TT and pgBTTT show similar lamellar d-spacing expansions (~0.7 Å) with hydration, upon electrolyte exposure further expansion of pg2T-TT lamellae (9.4 Å) is over four times that of pgBTTT (2.1 Å). This represents a fundamentally different degree of polymer electrolyte interaction that depends solely on the side chain regio-chemistry and gives rise to the difference in mixed conducting properties. Electrochemically doping pg2T-TT and pgBTTT produces similar pi-stack d-spacing contractions and relative lamellar expansions. UV-Vis and Raman spectroelectrochemistry was carried out to verify the similar degree of charging and nature of dopant induced charge carriers in pg2T-TT and pgBTTT.

These results highlight the sensitivity of mixed conducting properties to side chain architecture and the crucial

necessity of operando measurements to establish synthetic design rules for polymer mixed conductors. Further, the frit-based operando cell provides a new powerful tool to probe the previously inaccessible structure of solvent and electrolyte swollen polymer thin films with controlled electrochemical potential. This characterization capability is key for advancing the field of polymeric mixed conductors and likely other fields as well.

5:05 PM EL01.09.09
Stable Organic Electronic Devices Achieved Through the Characterization of Charge Carrier Traps in Organic Semiconductors Hamna Haneef[1], Qianxiang Ai[2], Karl Thorley[2], Hu Chen[3], Iain McCulloch[3,4], Chad Risko[2], John Anthony[2] and Oana Jurchescu[1]; [1]Wake Forest University, United States; [2]University of Kentucky, United States; [3]King Abdullah University of Science and Technology, Saudi Arabia; [4]University of Oxford, United Kingdom

Given their low-cost processing, light weight, chemical versatility, and compatibly with flexible and biological systems, organic semiconductors (OSCs) are gradually becoming an integral part of our lives as active components of various optoelectronic devices. These systems undergo considerable electronic and structural transformations during device fabrication and operation which can profoundly impact their performance and stability. Characterization techniques that can elucidate the mechanisms of the time-dependent transformations occurring in these materials and devices are necessary to guide the processing and design of high performance and stable organic devices. For example, in organic field-effect transistors (OFETs), the basic building block of applications such as displays, radio frequency identification tags, and conformable sensors, identifying the sources and mechanisms leading to operational instabilities are crucial in eliminating their impact to ultimately achieve the much-needed stability to make these devices components in real-life applications. In this presentation, we describe an efficient characterization technique that serves as a quick and reliable diagnostic tool to identify with high accuracy the environmental and operational degradation pathways occurring in OFETs during device operation. Charge carrier trapping in electronic states generated in the bandgap of the OSC during operation has been identified as the main culprit for device instabilities. Therefore, by monitoring the energetic distribution and time evolution of trap states during OFET operation, and with guidance from density functional theory (DFT) calculations, we gained access to the sources of device degradation, clarified the nature of the traps generated during operation, and the parameter space that gives rise to these traps. This information guided the development of efficient design rules for device processing and delivered robust OFETs with unparalleled operational stability in both staggered and coplanar configurations regardless of the active material (small molecule and polymeric OSCs), as confirmed by the constant mobility and exceptionally low threshold voltage shift of ΔV_{th} = 0.1 eV achieved under aggressive bias stress conditions for 500 min in ambient air.

EL01.10.02
Heavy-Duty Flexible and Transparent Organic Solar Cells Wallace C. Choy[1,2] and Jinwook Kim[1]; [1]The University of Hong Kong, Hong Kong; [2]Guangdong-Hong Kong-Macao Joint Laboratory for Photonic-Thermal-Electrical Energy Materials and Devices, China

While it is highly desirable to simultaneously achieve the features of good electrical/optical properties, low

surface roughness, robust mechanical flexibility under continuous operation bias for practical flexible electrodes, we demonstrate an outperformed a new class of Ag nano-network composite based transparent flexible electrode by a new one-step multifunctional chemical treatment. The robust electrical stability loaded with simultaneously continuous operation bias and mechanical bending is confirmed on the treated composite electrode. The organic solar cells based on our newly developed flexible composite electrode offer impressive performances as compared to the untreated device [1].
In details, we demonstrate a flexible transparent electrode showing the figure-of-merit value over 1000 (5.4 ohm/sq sheet resistance and >94% diffused transmission at 550 nm wavelength) via the new synthesis approach, simultaneously achieving selective welding at nanowires cross junctions to form Ag nano-network, removing PVP surfactants from Ag nanowires and PSS from PEDOT:PSS. In addition, with our proposed chemical treatment, the composite electrode can be completely detached from the supporting rigid substrate with no remained residues on the substrate, exhibiting extremely smooth topography (<1 nm root-mean-square roughness and <3 nm peak-to-valley roughness). Remarkably, we demonstrate robust electrical stability under simultaneously continuous operation bias and mechanical bending for the treated electrode for the first time. The OSC device with our proposed chemical treatment has achieved the best PCE of 15.41%, which is the best performance among ITO free flexible OSCs so far.

EL01.10.05
High Performance Indoor Photovoltaic Cells Using Main Chain Conjugated Copolymer Having Donor-Acceptor Heterojunctions Na Yeon Kwon, Su Hong Park, Hungu Kang, Young Un Kim, Hyo Jae Yoon, Min Ju Cho and Dong Hoon Choi; Korea University, Korea (the Republic of)

In general, the active layer of a high-performance polymer solar cell (PSC) has been fabricated by mixing a polymer donor and a low molecular acceptor. On the other hand, for future flexible photovoltaics, many studies are being conducted on *all*-PSCs that contain blend film of donor polymer and acceptor polymer to produce an active layer. However, despite the recent high power conversion efficiency(PCE) achievements of *all*-PSCs, the miscibility control and morphology reproducibility between the donor and acceptor polymers of the photoactive layer using two polymers remain a concern. This problem directly affects the stability of the device efficiency. Therefore, in order to overcome these shortcomings, studies have been conducted on polymers that can have heterojunctions in the internal structure of a main chain conjugated copolymer synthesized by covalent bonding between a donor and an acceptor unit.

And indoor photovoltaic (IPV) cells receive increasing attention because of their promising applications as power sources for devices of the Internet of Things ecosystem. The essential requirement for active materials of IPVs is that their absorption spectrum should overlap with the emission spectrum of light-emitting diodes (LEDs) that are often used as indoor lamps. Since IPVs require high harvesting efficiencies mainly in the visible range, the corresponding active material must be designed and applied differently from the molecular structure of the active material used in outdoor PVs. For this reason, photoactive materials for IPVs must display a narrow absorption spectrum in the visible wavelength range and a medium bandgap.

In this study, we successfully synthesized a crystalline main chain conjugated copolymer, P(BDBT-*co*-NDI2T), having BDBT donor-NDI2T acceptor heterojunctions in film states. Interestingly, the polymer exhibited a strong absorption band from 500 to 650 nm, which is overlapped well with the emission spectrum of white LED used as an indoor light source. IPV produced by using the P(BDBT-*co*-NDI2T) synthesized in this study as an active layer, showed a high power conversion efficiency of 12.70% (@500 lux) with a short circuit current density of 49.89 mA cm^{-2}. The PCE of the P(BDBT-*co*-NDI2T) film-based IPV was twice as high as that of the blend film-based IPV and showed excellent operational stability. This result was thought to be due to a smoother surface/internal morphology of the P(BDBT-*co*-NDI2T) films. Additionally, kelvin probe force

microscope(KPFM) data also indicated a relatively uniform distribution of the surface charge in the P(BDBT-*co*-NDI2T). These results may explain why P(BDBT-*co*-NDI2T)-based devices exhibit higher efficiency and very high operational stability compare to the blend film-based device. This study is the first time that the P(BDBT-*co*-NDI2T) has been applied to IPV, which suggests the potential for their widespread use in the development of indoor organic PVs in the future.

EL01.10.06
Tunable Light-Harvesting Property of Conjugated Terpolymers for Realizing High-Performing Indoor Photovoltaics Su Hong Park, Na Yeon Kwon, Young Un Kim, Diem H. Chau, Chai Won Kim, Seoung Uk Cho, Dong Won Lee, Min Ju Cho and Dong Hoon Choi; Korea University, Korea (the Republic of)

In addition to sunlight, we can see buildings (hospitals, shops, airports, offices, factories) illuminated for 24 hours, and artificial lighting is beginning to be recognized as a source of energy that needs to be harvested. Indoor light sources such as white light-emitting diodes (LEDs) can provide enough energy to operate most small wireless and low power consumption indoor electronics. Therefore, if organic photovoltaics (OPV), which are very sensitive to indoor light, are developed, they can be an ideal power source for indoor Internet of Things (IoT) wireless sensor networks due to their lightweight and mechanical flexibility. Thus, OPV has great potential to harvest energy that cannot be realized with powerful silicon-based inorganic photovoltaic cells. However, high-performance OPVs are typically fabricated using highly toxic solvents such as chlorinated aromatic solvents. These solvents can cause serious concerns about the side effects of human health in terms of germ cell mutagenicity, skin corrosion, and serious eye damage. From this point of view, the OPV material must be processed with a solvent that is harmless to the human body, and it must be designed to absorb indoor lighting to achieve high power conversion efficiency.
In this study, we introduced the fluorine-substituted benzotriazole (BTA) as a third monomeric unit into the benzo[1,2-*b*:4,5-*b′*]dithiophene (BDT-Cl)-benzo[1,2-*c*:4,5-*c′*]dithiophene-4,8-dione (BDD) alternating polymer, PM7 to increase electron-accepting property. PM7 is a famous donor polymer that shows very high performance in OPV cells. However, PM7 is only soluble in halogenated solvents such as CF, CB, and 1,2-dichlorobenzene but not soluble in a non-halogenated solvent such as toluene due to the highly rigid π-conjugated polymer with a strong aggregation effect. By introducing the BTA moiety into the PM7 as a relatively ductile unit, the terpolymer PM7-J52 (50) is successfully synthesized and it is well soluble in non-halogenated solvents, enabling environmentally friendly processing. When terpolymer was used as a donor polymer for indoor photovoltaics and processed using a non-halogenated solvent, PCE was measured as high as 11.34% in outdoor PV(AM1.5G) and 17.41% (500 lux) in indoor PV, respectively. Besides, the absorption spectrum of the blend film can be adjusted by changing the third monomer composition, which can improve the performance of PV devices using outdoor and indoor light sources. Our research has proposed a new ternary copolymer structure that can be used for fabricating outdoor or indoor PVs. In addition, the use of terpolymer has the advantage of being able to use non-halogenated solvents when fabricating PV devices.

8:13 PM Q&A

EL01.10.09
Introducing Oxide-Metal-Oxide Electrode with Heat Dissipating Thin Substrate to Geometrically Stretchable Organic Light-Emitting Diodes with Stable Color Coordinate Dong hyun Choi, Jun Su Yang, Dong Hyun Kim, Changmin Lee, Hyung Ju Chae, Geon Woo Jeong, Tae Wook Kim, Subrata Sarker and Seung Yoon Ryu; Korea University, Korea (the Republic of)

We implemented the geometrically stretchable organic light-emitting diodes (OLEDs) by breaking the stereotype that it is impossible to implement stretchable devices with a fragile oxide-type electrode under intense 2-dimensional random area strains with molybdenum trioxide (MoO_3)/gold (Au)/MoO_3 (MAM). The devices were fabricated on the pre-strained NOA63/3M elastomer and encapsulated with NOA63 for the waterproof sandwiched structure. The transmittance of the electrode was high enough to replace the semi-transparent silver (Ag) electrode, while the resistance was still lower than that. The work function of the

electrode could also be tuned through the MoO_3 dipole layer for excellent charge injection. Also, it was shown that the color coordinate did not change according to the angle. By comparing the glass- and the thick NOA63 film-based devices, it was found that the triplet-triplet annihilation was reduced through the heat sink mechanism that facilitated achieving a high exciton density. Also, significantly enhanced out-coupling was achieved by inserting silicon dioxide nanoparticles into NOA63. Consequently, the high current efficiency of ~82.5 cd/A and external quantum efficiency of ~22.6% were achieved by the horizontal emitter with a minimum efficiency roll-off.

EL01.10.10

Rational Design of Boron-Oxygen Bridged Acceptor Based Copolymer Host Materials for High Performance Solution-Processed Thermally Activated Delayed Fluorescent OLEDs Jinhyo Hwang, Chai Won Kim, Dong Won Lee, Seung Uk Cho, Min Ju Cho and Dong Hoon Choi; Korea University, Korea (the Republic of)

Organic polymers those exhibit features pertinent to functioning as host materials for thermally activated delayed fluorescence (TADF) emitters have considerable potential in solution-processable organic light-emitting diodes (OLEDs), allowing simple, low-cost, and large-area applications. In particular, polymer hosts have superior characteristics, including facile functionality to introduce various electron donor and acceptor entities, ability to uniformly disperse and contain small molecular dopants, and ability to produce more smooth and homogeneous films, compared to those of their small-molecule counterparts. This research describes the design and development of three new styrene-based copolymers (ABP91, ABP73, and ABP55) bearing diphenylacridine (DPAc) as the electron donor and 2,12-di-*tert*-butyl-7-phenyl-5,9-dioxa-13b-boranaphtho[3,2,1-de]anthracene (TDBA) as the electron acceptor.
In particular, the three polymers were synthesized via variations in the ratio of donor (DPAc) and acceptor (TDBA) monomers. A homopolymer (DHP) containing only DPAc units was also synthesized for comparison. Non-conjugated styrene backbone was employed as a linker between the donor and acceptors to restrict the conjugation length and thus accomplish a high E_T. Subsequently, the resulting copolymers featured E_Ts values in the range of 2.73–2.75 eV.
We fabricated OLEDs via solution processing, employing a familiar t4CzIPN as TADF emitter using the following configuration: ITO/PEDOT:PSS (40 nm)/PVK (10 nm)/Host:t4CzIPN (20 nm, *x* wt %)/TPBi (40 nm)/LiF (0.8 nm)/Al (100 nm). The devices based on ABP91:t4CzIPN, ABP73:t4CzIPN, and ABP55:t4CzIPN achieve EQE/CE/PEs as high as 21.8%/71.4 cd A^{-1}/ 44.9 lm W^{-1} (with CIE color coordinates of (0.29, 0.60)), 22.2%/70.1 cd A^{-1}/48.9 lm W^{-1} (with CIE color coordinates of (0.27, 0.57)), and 19.7%/61.7 cd A^{-1}/43.1 lm W^{-1} (with CIE color coordinates of (0.27, 0.56)), respectively. In contrast, the DHP-based devices were limited to only 14.5%/47.3 cd A^{-1}/27.4 lm W^{-1} (with CIE color coordinates of (0.30, 0.59)) because of charge imbalance, attributed to its unipolar nature. Among the three hosts, ABP73 delivered the best performance, which is attributed to the high k_{RISC}, high PLQY, well-balanced charge-carrier transport ability, and homogeneous film formation with a small value of RMS roughness.
These results suggest that the development of copolymers, which consist of donor and acceptor entities in the side chain or pendent groups, is more suitable for highly efficient solution processing of TADF OLEDs. To our knowledge, this is, to date, the best performance that has ever been reported for polymer host materials in the area of TADF OLEDs. We strongly believe that this work will make a significant contribution through the introduction of a variety of copolymers that function as hosts for the development of proficient solution-processable TADF OLEDs.

EL01.10.11

Late News: Tetrabranched Photocrosslinker Enables Micrometer-Scale Patterning of Light-Emitting Super Yellow for High-Resolution OLEDs Wooik Jang, Hyewon Park, Jeehye Yang, Seunghan Kim, Hyunwoo Jo and Moon Sung Kang; Sogang University, Korea (the Republic of)

Development of a simple and effective patterning method applicable to solution-processible organic luminophores over a large area is critical for cost-effective production of organic light-emitting-diode (OLED)

displays. Here, we demonstrate high-resolution patterning of light-emitting polymer active layers using a highly efficient photocrosslinker (4Bx). The photocrosslinker is structured in a tetrabranched geometry, wherein a photocrosslinkable azide moiety is present at each of the four corners of the molecule, and each of these moieties can form a chemical bond with light-emitting polymer semiconductors under UV irradiation. Due to the high crosslinking efficiency of 4Bx, the use of an unprecedentedly small amount of 4Bx (0.1 wt%) allows fully crosslinking light-emitting Super Yellow polymer without degrading their photoluminescence and electroluminescence characteristics. Furthermore, precisely-defined photocrosslinked patterns of Super Yellow with feature sizes of 5 μm are formed by using p-xylene as the developing solvent that was carefully selected according to Hansen solubility parameter analysis.

EL01.10.12

A Comparison of Measurements of Organic Light-Emitting Diode with the Spectroradiometer and the Integrating Sphere Measurements Dong Hyun Kim, Changmin Lee, Hyung Ju Chae, Geon Woo Jeong, Dong hyun Choi, Tae Wook Kim, Subrata Sarker and Seung Yoon Ryu; Korea University, Korea (the Republic of)

There are two main ways to measure the performance of organic light-emitting diodes (OLEDs). One way is using a spectroradiometer (CS-2000) through the viewing angle and the other is the most widely used technique that involves an integrating sphere. In this study, we present a comparison of measuring the performance of OLEDs using the spectroradiometer and the integrating sphere. To improve the measurement accuracy of spectroradiometers, the viewing angles were set between -70° and +70° to avoid the out of focusing area. As the external quantum efficiency (EQE) estimated using the spectroradiometer was not coincident with that obtained using the integrating sphere method, we applied a mean estimation protocol to convert the EQE values obtained from the spectroradiometer by integrating the EQE values extracted from different viewing angles. The results were summarized for four different kinds of angular emission patterns. The data obtained from the conversion of EQE and electroluminescence (EL) of OLEDs measured with a spectroradiometer from all different angular emission patterns were similar to that measured with the integrating sphere with a small deviation. This study and the mean estimation protocol should help in understanding the accuracy of OLED measurements at a laboratory scale. As such, it is possible to reduce the recurring costs and the required time for these two measurement techniques by bypassing the integral sphere measurement

EL01.10.13

Ultrasensitive, Selective and Fast Recovered Chemoreceptors Based on Interpenetrating Polymer Semiconductor Nano-Networks Hyukmin Kweon, Pureunsan Go, Han Wool Park, Chaeyoung Lee, Sang Jun Park, Joonseok Lee, Seon-Jin Choi and Do Hwan Kim; Hanyang University, Korea (the Republic of)

As air pollution has become an urgent issue worldwide, effective chemodetection and *in situ* monitoring of hazardous gases have been desired for public health. In this regard, high-performance of chemosensor have been demonstrated continuously based on conventional semiconducting materials, such as oxide semiconductors, 2-dimentional materials, and organic semiconductors (OSCs). Although oxide semiconductors based chemosensor possess high sensitivity and selectivity due to their high mobility and versatile surface functionalization, high temperature operation is a prerequisite for desired high sensitive chemodetection. On the other hand, OSCs can obtain high sensitive chemodetection at room temperature because of effective contact with target chemicals. However, OSCs cannot serve functionalization sites for selectivity, and exhibits poor recovery property by penetration of chemicals into an OSCs film. Therefore, in order to secure high sensitivity, selectivity, and ideal recovery property simultaneously, novel material design and scientific breakthrough in the field of chemosensors are strongly required.
Herein, we demonstrate an ultrasensitive, selective, and fast recovered NO_2 chemodetection based on interpenetrating polymer semiconductor nano-networks functionalized with amine based artificial chemoreceptors (NH_2-IPSNs), in which polymer semiconductor chains are interpenetrated into a ladder-like organosilica network. The IPSNs serves unreacted silanol (Si-OH) groups acting as functional points on its

surface; by carefully manipulating the Si-OH groups, the NH_2-IPSNs film can be designed by simple solution process without a degradation of electrical performance. This surface engineering has been considered to be available in oxide semiconductor materials, however, through a novel approach of the IPSNs, it also could be allowable in OSCs . Consequently, the NH_2-IPSNs based chemosensor exhibited ultrahigh sensitivity (990% ppm^{-1} at NO_2 5 ppm) and superior selectivity in room temperature operation, even the sensing performance persisted in ambient environment. This is because the surface anchored NH_2 groups can build strong dipole moment interaction with NO_2 molecules. Furthermore, the surface NH_2 groups can suppress penetration of NO_2 molecules into the NH_2-IPSNs film effectively, so that fully recovery capability with fast recovery rate (240 s) was achieved. As a result, the NH_2-IPSNs based chemosensor can develop ultrasensitivity, selectivity, and ideal recovery property at room temperature simultaneously, which is attributed to our conceptual novelty to reconcile the characteristics of oxide and organic semiconductors. We believe that our rational design of new concept of semiconductor material represents a big step towards next-generation chemical monitoring system for various industry and public health.

EL01.10.14
Late News: Ionically Connected Floating Electrodes for Long-Distance (> 1 mm) Coplanar-Gating Graphene Transistors Hyunwoo Jo and Moon Sung Kang; Sogang University, Korea (the Republic of)

Exploiting the long-range polarizability of an electrolyte based on ion migration, electric double-layer transistors (EDLTs) can be constructed in an unconventional configuration;[1] here, the gate electrode is placed coplanarly with the device channel. For example, the current density of a transistor channel can be modulated using a gate electrode that is not located directly on top/below the channel but placed apart from the channel as long as the electrode is bridged with the channel through the electrolyte– which we refer to as the remote gating. In this paper, we demonstrate the influence of the distance factors of the electrolyte layer on the operation of EDLTs with a coplanar gate. As the promptness of the electric double-layer formation depends on the distance between the channel and the gate, the dynamic characteristics of a remote-gated transistor degrade with long distance. To suppress this degradation, we suggest using multiple coplanar floating gates bridged through ionic dielectric layers. Unlike remotely gated EDLTs that utilizes a single extended electrolyte layer, the devices with multiple segmented electrolyte layers operate effectively even when they are gated from a distance longer than 1 mm. The new device architecture provided here shows new opportunities to exploit graphene transistors.

Late News: Synthesis and Characterization of an Open-Shell Conjugated Polymer Containing a Quinoid Building Block with Diradical Yunseul Kim, Dongseong Yang, Yeon-Ju Kim and Dong-Yu Kim; Gwangju Institute of Science and Technology, Korea (the Republic of)

Quinoid platforms have attracted much attention because of their unique optical, electrical and magnetic properties, and can be applied to various organic electronics, such as organic field-effect transistors (OFETs), organic photovoltaics and organic spintronics. They exhibit low band-gap and redox amphoterism arising from stable quinoid-aromatic resonance structure and high structural planarity due to double bond formation between each ring. This quinoid structure often result in high and n-type charge carrier mobilities in OFETs. We also demonstrated high performance OFETs using quinoidal polymers recently. Interestingly, the quinoidal structure stabilizes the open-shell form with diradical upon recovery of aromaticity. The open-shell diradicaloids via introduction of quinoid building blocks into polymer require the experimental and theoretical analysis to comprehensively describe their unique optical and magnetic properties.
In this research, we will present our recent results on the investigation of structure-property relationship of an open-shell conjugated polymer embedded with stable diradicals. We designed and synthesized an azaisatin-terminated quinoid building block, azaquinoidal-bithiophene (azaQuBT), which has pyridine replacing benzene in the end of terminal isatin unit. This can lead to better coplanar conformation of polymer backbone due to

suppressing the rotation between quinoid-comonomer counterpart. Therefore, diradical occurred by open-shell form of azaQuBT could be well-delocalized into the polymer backbone, leading to stable ground-state diradical characters. An open-shell conjugated polymers, PazaQuBT-T, was successfully synthesized by Stille-polymerization. We characterized material properties by UV-Vis-NIR absorption, Raman spectroscopy and electron spin resonance (ESR) and discussed.

EL01.10.17
Artificially Intelligent Tactile Ferroelectric Neuromorphic Skin Kyuho Lee, Chanho Park, Hyeokjung Lee, Seung Won Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Lightweight and flexible tactile learning machines can simultaneously detect, synaptically memorize, and subsequently learn from external stimuli acquired from the skin. This type of technology holds great interest due to its potential applications in emerging wearable and human-interactive neuromorphic electronics. In this study, an integrated intelligent tactile learning electronic skin (e-skin) based on arrays of ferroelectric field-effect transistor memories with dome-shape tactile top-gates, which can simultaneously sense and learn from a variety of tactile information, is introduced. To test this device, tactile pressure is applied to a dome-shaped top-gate that measures ferroelectric remnant polarization in a gate insulator. This results in analog conductance modulation that is dependent upon both the number and magnitude of input pressure-spikes, thus mimicking diverse tactile and essential synaptic functions. Specifically, our device exhibits excellent cycling stability between long-term potentiation and depression over the course of 10,000 continuous input pulses. Additionally, it has a low variability of only 3.18 %, resulting in high-performance and robust tactile perception learning. Our 4 × 4 device array is also able to recognize different handwritten patterns using 2-dimensional spatial learning and recognition, and this is successfully demonstrated with a high degree accuracy of 99.66 %, even after considering 10 % noise.

EL01.10.18
Electropolymerized One-Dimensional Growth Coordination Polymer for Hybrid Electrochromic Aqueous Zinc Battery Wei Church Poh, Xuefei Gong and Pooi See Lee; Nanyang Technological University, Singapore

Conjugated polymers are attractive for rechargeable batteries owing to their reversible electrochemical redox reactions and/or intercalation abilities. However, conventional conjugated polymers are generally consisting of only organic backbones which tend to form highly reactive redox species during an electrochemical process or under light excitation, leading to undesirable side reactions. These side reactions such as irreversible oxidation occurred on the polymer backbones and its physical properties will be permanently altered, leading to degradation. This problem can be alleviated by incorporating redox-active transition metals into the conjugation system, helping to stabilize the generated redox species via coordination, or having itself undergoing a stable redox process.
Over the years, there has been an increasing interest focusing on nanostructured conjugated polymers as green and renewable electrodes for energy conversion and storage devices. Realizing an optically modulated energy storage device could unlock new applications including but not limited to variable optical attenuator, optical switches, displays, and smart windows for energy-efficient buildings. Herein, a rationally designed nanostructured coordination polymer has been prepared with the aim of realizing electrical modulated light transmission with stable electrochemical cathodic reactions. By utilizing the coordination conjugated polymer as the cathode and a zinc anode, an integrated hybrid electrochromic zinc battery device can be demonstrated with promising endurance.
From the electrochemical and optical analysis, the $\Delta E_{(HOMO\text{-}LUMO)}$ of the polymer was found to be *ca.* 1.5 eV, suggesting that the polymer is behaving like an organic semiconductor with decent conductivity even with interrupted conjugation system due to metal inclusion. Based on the classical Johnson–Mehl–Avrami–Kolmogorov (JMAK) interpretation, the coordination polymer has undergone a one-dimensional growth process

which can be attributed to the judicious design of the monomeric transition metal complexes. During the designing of materials, the interplay between metal and ligands has been carefully considered from both thermodynamic and kinetic aspects in order to attain coordination systems with stable and robust redox process that is critical for both electrochromism and energy storage. Unlike the intercalation-deintercalation mechanism exhibited by metal oxides, the movement of ions flux in and out of the polymer could occur rapidly during the electrochemical reaction, offering a fast charge transfer process that is not possible in inorganic materials. The polymer-bound electrode has been configured into a hybrid device which is able to operate in an aqueous Zn electrolyte, achieving high color contrast of *ca*. 60 %, fast response time of <1s, and good stability for over 1000 consecutive charging-discharging cycles.

8:00 AM EL01.11.01
Late News: In Situ and In Operando Scattering Studies on Organic Solar Cells Based on Organic Semiconductors Peter Muller-Buschbaum; Technische Universität München, Germany

Based on novel organic semiconductors, organic solar cells are an interesting alternative to conventional silicon based solar cells as they feature new possibilities. Using wet chemical processing, they can be manufactured with large-scale production methods such as roll-to-roll printing. Consequently, the production of organic solar cells has the potential to become very cheap and easy. With in-situ grazing incidence small- and wide-angle X-ray scattering (GISAXS and GIWAXS) studies, we gain information on the kinetics of morphology formation of electrodes, blocking layers and active layers of the solar cells during processing.
In terms of large-scale usability, one of the major challenges for organic solar cells is to overcome their relatively short lifetime, as compared to their inorganic counterparts. To gain a deeper understanding of organic solar cell degradation with respect to changes in the active layer nano-morphology, we present in-situ studies on model donor-acceptor organic semiconductor based solar cells during the first hours of operation. The in-operando studies reveal information on both, its evolving current-voltage characteristics and the active layer nano-morphology. For that purpose, GISAXS / GIWAXS measurements and current-voltage (IV) tracking of the operating solar cell are performed simultaneously to gain fundamental understanding. Starting from an optimized morphology of the active layers in terms of highest efficiencies for organic solar cells, depending on the donor-acceptor organic semiconductor system, a mixing or demixing process are identified to cause changes of the morphology. The altered morphology is less optimal for charge transport through the active layer due to poor percolation in a too fine morphology or poor splitting of excitons in a too coarse morphology.

Late News: Phase Segregation Driven Ultra-Low Dark Currents in Organic-Inorganic Hybrid X-Ray Detectors Maheshani Prabodhi Alwis Nanayakkara[1], Lidija Matjacic[2], Andrew Nisbet[3], Imalka Jayawardena[1] and S. Ravi P. Silva[1]; [1]University of Surrey, United Kingdom; [2]National Physical Laboratory, United Kingdom; [3]University College London, United Kingdom

Organic-inorganic hybrid semiconductors have been identified as an emerging class of novel materials for direct conversion X-ray detection[1,2]. Their success is attributed to a number of characteristics such as sensitivity over a broad energy range including high sensitivity for hard X-rays, low voltage operation, and conformability to complex shapes. However, previous generations of such detectors displayed dark currents that are ×1000 -

10,000 higher than the industry standard of 10 pA mm^{-2}, therefore hindering their potential for commercialization. Herein, we introduce a new route to achieve ultra-low dark currents that are below 10 pA mm^{-2} even at electric fields as high as ~4 V μm^{-1} in hybrid detectors fabricated by incorporating high atomic number bismuth oxide nanoparticles into an organic bulk heterojunction consisting of p-type Poly(3-hexylthiophene-2,5-diyl) (P3HT) and n-type [6,6]-Phenyl C71 butyric acid methyl ester ($PC_{70}BM$). Such ultra-low dark currents are achieved through the enrichment of the hole selective p-type polymer near the anode contact, induced via vertical phase segregation within the hybrid film. The resulting hybrid detectors display broadband response with a record high sensitivity of ~1.5 mC Gy^{-1} cm^{-2} and less than 6% variation in angular dependence response when tested under 6 MV X-rays from a clinical linear accelerator. Therefore, we anticipate that the above characteristics in combination with excellent dose and dose rate linearity, reproducibility, and long-term stability would stimulate further interest towards implementing such detectors for applications in dosimetry for medical and industrial applications.

Enhancing Long-Term Device Stability Using Thin-Film Blends of Small Molecule Semiconductors and Insulating Polymers to Trap Surface-induced Polymorphs Tommaso Salzillo[1,2], Antonio Campos[1], Adara Babuji[1], Raul Santiago[3], Stefan Bromley[3,4], Carmen Ocal[1], Esther Barrena[1], Remi Jouclas[5], Christian Ruzie[5], Guillaume Schweicher[5], Yves H. Geerts[5,6] and Marta Mas-Torrent[1]; [1]Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Spain; [2]Weizmann Institute of Science, Israel; [3]Universitat de Barcelona, Spain; [4]Institució Catalana de Recercai Estudis Avanzats (ICREA), Spain; [5]Faculté des Sciences Université libre de Bruxelles, Belgium; [6]Université Libre de Bruxelles, Belgium

The 2,7-dioctyloxy[1]benzothieno[3,2-b]benzothiophene (C_8O-BTBT-OC_8) molecule, one of the most promising organic semiconductors, presents two different crystalline phases: a co-facial structure (bulk phase) and a herringbone structure also defined as surface-induced phase (SIP phase).[1] From solution deposition on Si/SiO_2 always the SIP phase has been detected so far and previous works have reported that with aging at ambient conditions or by solvent vapor annealing it transforms to the thermodynamically stable bulk structure.[2] The Bulk C_8O-BTBT-OC_8 phase crystallizes in a triclinic P-1 system with two molecules per unit cell presenting a displaced cofacial stacking, while the SIP phase has a monoclinic $P2_1/c$ structure with a herringbone packing.[1,3]
In this work we report the stabilization of the SIP phase by blending the C_8O-BTBT-OC_8 with an insulating polymer and preparing the thin film transistors (TFTs) by the bar-assisted meniscus shearing (BAMS) technique. All the TFTs based on C_8O-BTBT-OC_8 with polystyrene (PS) of low molecular weight (i.e., 3K) and high molecular weight (i.e., 100K) present the SIP structure and display good electrical properties with a field-effect mobility close to 1 cm^2/V s, a threshold voltage around 0 V and an on/off current ratio of 10^7-10^8. However, after 3 months in ambient conditions the C_8O-BTBT-OC_8:PS100K film retain the same morphology, while the film based on the lower molecular weight PS presents the formation of different crystal domains on top of the pristine layer. The structural inhomogeneity of the C_8O-BTBT-OC_8:PS3K was investigated by micrometric spatially resolved Lattice phonon Raman spectroscopy.[4]
In order to compare the hole transport tendencies in the Bulk and SIP polymorphs of C_8O-BTBT-OC_8, we analyzed all independent pairwise HOMO-HOMO (Highest occupied molecular orbital) intermolecular electronic couplings (J_{HOMO}) in the two crystal structures using density functional theory (DFT) based calculations. Bulk phase show a highly anisotropic one dimensional (1D) electronic structure with only a single dominant J_{HOMO} value of 42 meV in a direction parallel to the *a*-axis of the crystal with all other J_{HOMO} values being $\leq$ 6 meV. In contrast, the SIP polymorphic phase has two main independent intermolecular couplings with

moderate J_{HOMO} values of 12-13 meV, which span over three different directions in the *ab* plane of the material, indicative of a more 2D electronic isotropy. Thus, although a larger electronic coupling is found in the Bulk phase, the electronic dimensionality in the SIP phase is enhanced.
Using the polymer blend we demonstrate the possibility to stabilize, during the time period studied of one year and a half, of the metastable SIP phase which present a 2D electronic isotropy compared with the 1D π-stacking arrangement of the bulk structure and thus to be preferred for thin film devices fabrication.[5]

Monitoring Ionic-to-Electronic Conduction in Bioelectronic Devices Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

Organic mixed conductors and electrochemical phenomena at solid-liquid interface have garnered significant attention for applications in bioelectronics, electrochromics, energy storage/generation, neuromorphic computing, and thermoelectrics. These devices operate in electrolytes that render ions mobile in the film, making the coupling between electronic and ionic charges crucial. A prime example of such devices is the organic electrochemical transistor (OECT), a transducer used commonly to monitor bioelectronic signals. In this work, I will introduce the class of materials that have been used in OECT channels. Using *in operando* techniques, we find that the ions enter the semiconducting polymer channel hydrated and the excess swelling of the material has a significant effect on device characteristics, which can be traced back to changes in the overall structural order. [1,2] We show that the infiltration of the hydrated dopant ions into the polymer film irreversibly changes the polymer structure and negatively impacts the OECT mobility, as well as the efficiency, reversibility, and speed of charge generation. We conclude that minimizing swelling of the polymer films during doping is a key parameter to design fast and highly efficient ion-to-electron transduction devices. Our work highlights the importance of characterizing the properties of these films *in-situ* (in their electrolyte swollen state) for drawing conclusions related to materials properties/device performance, which has a tremendous impact on the performance of biosensors. Lastly, I will show an n-type conjugated polymer that, against all the current design rules, shows high device performance, and introduce a new direction for the design of mixed conductors.

Controlled and Reversible Volume Change in Conjugated Polymers via Electrochemical Addressing—An Experimental and Theoretical Study Johannes Gladisch[1], Sarbani Ghosh[1], Maximilian Moser[2], Iain McCulloch[3], Magnus Berggren[1], Igor Zozoulenko[1] and Eleni Stavrinidou[1]; [1]Linköping University, Sweden; [2]University of Oxford, United Kingdom; [3]King Abdullah University of Science and Technology, Saudi Arabia

Controlled volume change of soft materials is of interest for a wide range of applications, from actuators, microfluidics and drug delivery. Conjugated polymers can transform electrical energy into volume change when included in electrochemical devices via the exchange of ions and solvent. Recently we demonstrated a

glycolated polythiophene that reversibly expands by 300% upon addressing, relative to its previous contracted state, while the first irreversible actuation can achieve values of 10000%, outperforming any other conjugated polymers. Here I will present a study on a series of polythiophenes that differ in the length and/or in the distribution of the ethylene glycol side chains and how this impacts the volume change upon electrochemical addressing. In order to get insight on how the structure and morphology affect the volume change and reveal the mechanisms involved at the nanoscale we preformed Molecular Dynamics. Finally, I will present how we can apply these materials for dynamic microfiltration.

SESSION EL01.12: Organic Ionic Conductors II

Next-Generation Organic Mixed Ionic-Electronic Conductors—A Dynamic Study on Copolymers for Faster Electrochemical Devices Olivier Bardagot[1], Sanne Govaerts[2], Gonzague Rebetez[1], Priscila Cavassin[1], Frederic Schneider[1], Julien Réhault[1], Wouter Maes[2] and Natalie Banerji[1]; [1]University of Bern, Switzerland; [2]Hasselt University, Belgium

Improving the performance of organic mixed ionic-electronic conductors (OMIECs) favors not only the development of bioelectronic devices for healthcare and neuroscience applications, but also of optoelectronic and energy storage devices.[1] The performance of OMIECs can be explored using organic electrochemical transistors (OECTs). OMIECs bearing ionic side chains (called conjugated polyelectrolytes) present promising doping/dedoping cycling stability for applicative use.[2] Higher transconductance can be reached for copolymers bearing both alkyl and ionic side chains.[3] Nonetheless, the use of polar, glycolated, side chains remains to date the most effective strategy to concomitantly enhance the transconductance and response time of OECTs.[4] In this work, we compared P3HT-like polymers composed of: 100% alkyl, 100% ionic, 100% glycolated, and 50/50% ionic/glycolated side chains. Using *in operando* time-resolved UV-Vis-NIR absorption spectroscopy, with a time-resolution of a few milliseconds, and multivariate curve resolution (MCR) analysis, we elucidated the underlying processes driving the electrochemical doping kinetics of these OMIECs. Our findings suggest that introducing ionic side chains in glycolated polymers is an effective and easily transferable strategy to further enhance the response time of OECTs.

Late News: Aqueous Formulation of Concentrated Semi-Conductive Fluid Using Polyelectrolyte Complexation My Linh Le[1], Dakota Rawlings[1], Scott Danielsen[2], Rachel Segalman[1] and Michael Chabinyc[1]; [1]University of California, Santa Barabara, United States; [2]Duke University, United States

There has been a growing interest in aqueous formulation of conjugated polymers to achieve more environmentally benign processing routes and to widen the utilization of these polymers in bioelectronics. The widely studied conducting polymer poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) has

high electrical conductivity and aqueous processability, but suffers from ill-defined structure, poor synthetic tunability, and heavily post-processing dependent performance. Here, we demonstrate how coacervation of oppositely charged polymers can be used for formulating and processing conjugated polymers in aqueous media. By sampling a wide range of polymer concentrations and dielectric media, we obtained the mixing phase diagram of a PEDOT derivative substituted with alkoxysulfonate groups (PEDOT-S) with a polymeric ionic liquid (PIL). Using this phase diagram, we were able to find compositions that enabled the formation of a complex coacervate of these 2 polymers. This coacervate is a viscous fluid with extremely high polymer content (up to 60 wt%), and can be readily blade-coated to produce films of around 5 μm in thickness. Subsequent doping of the film with a strong acid increased the electrical conductivity of the coacervate to values that were higher than those of the neat PEDOT-S polymer. Optical spectroscopy showed that acid treatment led to a lower doping level in the coacervate than in neat PEDOT-S, suggesting a smaller charge carrier density and thus a higher carrier mobility within the coacervate. We postulate that in the coacervate, the conjugation length of PEDOT-S was enhanced due to the reduction in torsional disorder along the polymer chain upon the complexation. This work shows that polyelectrolyte complexation is a promising route to formulate conjugated polymers in aqueous media at high concentrations and that the resulting material is compatible with large-scale industrial processing protocols like blade coating. The complexation can also have beneficial impacts on charge transport through the improved control of the conformation of the conjugated polymer.

12:15 PM EL01.12.03

Late News: Characterizing Mixed Ionic-Electronic Conductors Using Grazing-Incidence Wide-Angle X-Ray Scattering (GIWAXS) with *In Situ* Potential Control Lucas Flagg[1], Maximilian Moser[2], Iain McCulloch[3,2], Dean DeLongchamp[1] and Lee Richter[1]; [1]National Institute of Standards and Technology, United States; [2]University of Oxford, United Kingdom; [3]KAUST, Saudi Arabia

Organic mixed ionic-electronic conductors (OMIECs) are a class of materials that have recently drawn interest as materials for next generation biosensors, energy storage, neuromorphic computing and other organic electronic applications. This class of materials rely on counterions from an electrolyte solution to penetrate the volume of the organic layer in order to compensate injected electronic charges. Measuring the microstructure of these materials is uniquely challenging due to the essential role the electrolyte plays during operation of these types of devices. Traditional microstructure measurements are rarely performed in contact with liquid electrolytes, and therefore fail to fully characterize the most device relevant microstructure. Additionally, many of these materials are electrochemically unstable in the presence of air which limits the understanding we can gain from traditional *ex-situ* scattering techniques. These challenges motivate *in-situ* scattering experiments with both potential control and solvent present. Here we develop an *in-situ* grazing-incidence wide-angle x-ray scattering (GIWAXS) procedure based upon a “rolling drop” electrode, that allows us to interrogate the crystallite lattice while fully hydrated AND electrochemically doped. We explore a model series of polymers that display distinctly different swelling based upon the distribution of ethylene glycol in their side chains. Using this technique, we separate the active swelling of the polymer crystallites due to electrochemical oxidation/reduction from the passive swelling due simply to the hydration of the polymer lattice. Additionally, we use the identity of the dopant ion to change the hydrophobicity of the electrochemically doped polymer to further probe the role of hydration in this series of polymers.

12:30 PM EL01.12.04

Late News: Effect of Morphology, Composition and Mobile Anion on the Electronic Performance of Polyelectrolyte Block Copolymers Samantha Brixi, Alexander Peltekoff and Benoit Lessard; University of Ottawa, Canada

The growing demand for flexible, lightweight, and stretchable electronics has led to significant interest in printed electronics such as thin-film transistors (TFTs), which are used as foundational components in many emerging organic electronic devices such as displays and sensors. These applications require TFTs that can both operate at low voltages to minimize power utilization and be effectively produced by large scale printing methods to reduce cost.

Polyelectrolyte materials produce a large electrical double-layer capacitance (EDL) that is independent of layer thickness. This large EDL capacitance is exploited to produce TFTs that operate at low voltages. These materials are also compatible with large scale production methods that have less control over layer thickness. However, the resulting devices are typically slow-responding due to the slow ion migration during electrical double-layer formation. To improve this, the material's ionic conductivity must be improved. Ideally, an optimal polyelectrolyte gating material must insulate charge, have a high conductivity for fast switching speeds, and produce a large double-layer capacitance required for reduced operating voltages.

Our study investigates structure-property relationships between polymeric structural elements, such as morphology, polymer composition, anionic salt, and the materials' physical properties of interest: double-layer capacitance and conductivity. We synthesized a matrix of diblock copolymers consisting of insulating polystyrene first block followed by a second copolymer block consisting of an ionic liquid (IL) conductive monomer and soft PEGMA monomer. We varied the IL/PEGMA composition of the second block, the length of the second block, as well as the mobile anion associated with the ionic liquid monomer. Each material was tested in capacitors to determine the EDL capacitance and conductivity of each material to investigate structure-property relationships.

We found that microphase separation is critical for increased conductivity. Also, we found that increasing the PEGMA loading of the second block greatly improved conductivity. However, PEGMA loadings over 75% solubilized the first block eliminating the microphase separation and thus the nanochannel domains essential for conductivity. The double-layer capacitance can be changed by an order of magnitude depending on the anionic salt. We have identified structural design rules showing what chemical handle influences a specific material property.

Incorporating the dielectrics into top-gate top-contact TFTs with n-type semiconductor P(NDI2OD-T2), we found the devices could be operated at exceptional low voltages (< 1 V) while maintaining mobility values comparable to literature. We have also performed frequency-dependent measurements of the TFTs to compare the properties of the polyelectrolytes with different mobile anions, finding these results correlated well with observed TFT performance.

12:45 PM EL01.12.05
Quantitative Composition and *Operando* Structure Determination of Organic Mixed Ionic-Electronic Conductors Ruiheng Wu[1], Christopher J. Takacs[2], Maximilian Moser[3], Bryan D. Paulsen[1], Joseph Strzalka[4], Qingteng Zhang[4], Iain McCulloch[5,6] and Jonathan Rivnay[1,1]; [1]Northwestern University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Imperial College London, United Kingdom; [4]Argonne National Laboratory, United States; [5]University of Oxford, United Kingdom; [6]King Abdullah University of Science and Technology, Saudi Arabia

Organic mixed ionic-electronic conductors (OMIECs) are organic conjugated materials with the ability to uptake ions from aqueous electrolyte and transduce between ionic and electronic currents. The unique properties of OMIECs make them highly attractive in range of biological, energy and neuromorphic computing applications. For these materials operating in electrolyte emersed situations, the structure and composition is non constant during operation, and is difficult to characterize. This has become a major impediment to elucidation of structure property relationships that further the development of new materials. Here, we have filled these gaps of understanding that have been neglected in previous studies by quantifying the composition with ex situ X-ray fluorescence spectroscopy (XRF) and probing the device relevant structure with ex situ and operando grazing incident X-ray scattering. PEDOT:PSS and pg2T-TT were selected as model materials representing polyelectrolyte/conjugated polymer blends and homogeneous glycolated conjugated polymers, respectively. XRF studies of doped and dedoped PEDOT:PSS revealed the effect of Donnan exclusion due to the presence of PSS poly anions, preventing anion uptake and resulting in cation-only transport. Additionally, charge and mass balances revealed that the equilibrium between the polyanion and the proton contributed

significantly to the doping processes. XRF studies of doped and dedoped pg2T-TT quantified the dopant-anion concentration modulation, directly measured the minority role of cation transport, and revealed an unaticipated massive amount of charge trapping (>10^{20} anions cm^{-3}) when exposed to electrolyte, that persists when reductively dedoped. The low conductivity of the reductively dedoped state confirmed the localized nature of the electronic charge counterbalancing the trapped anions. The pH dependence of dopant composition was investigated in both systems.

Ex situ grazing incident small-angle X-ray diffraction (GISAXS) confirmed the compositional homogeneity of both pg2T-TT and PEDOT:PSS polymer films. Operando grazing incident wide-angle X-ray diffraction (GIWAXS) of PEDOT:PSS, revealed the degree of polymer-electrolyte interaction resulting moderate lamellar expansions (1.6 Å) with electrolyte exposure, following a lamellar spacing relaxation upon ionic doping. Operando GIWAXS of pg2T-TT showed a moderate lamellar expansion (0.6 Å) with DI water exposure, but a much larger lamellar expansion (~10 Å) upon electrolyte exposure. The potential dependent pi stack and lamellar d-spacing were quantified from the diffraction patterns. In contrast to PEDOT:PSS, the lamellar spacing of pg2T-TT was clearly increased during doping process.

Combining these multimodal results gives new insight into these systems. For instance, the XRF and GISAXS reveal that cations are evenly distributed in PEDOT:PSS contrary to common assumptions about the heterogenous composition of PEDOT-rich and PSS-rich domains. Only when phase separation is driven by processing in strong acids, is an inhomogeneous distribution of cations observed. XRF and operando GIWAXS reveal the permanent structural modification that accompanies the high degree of charge trapping in pg2T-TT. As confirmed by GISAXS, this implies that anions must be present in both the amorphous and the crystalline regions of the polymer. These results represent the first quantitative compositional determination of OMIECs and the first operando scattering studies of weakly scattering homogenous OMIECs in aqueous conditions, and establish quantitative techniques necessary to produce meaningful structure-property relationships to drive the rational design of next-generation OMIECs.

1:00 PM EL01.12.06
Predicting Mechanical Properties from Molecular Parameters of Conjugated Polymers Abigail M. Fenton, Ralph H. Colby and Enrique D. Gomez; The Pennsylvania State University, United States

Conjugated polymers are used in many organic electronic devices such as organic photovoltaics, organic light emitting diodes, organic field effect transistors and bioelectronics. However, fundamental characteristics of these materials, such as mechanical properties and phase behavior, and their correlation with chemical structure, are not well understood. Nevertheless, controlling mechanical properties of conjugated polymers is crucial to enabling flexible and stretchable electronics. The plateau modulus G_N°, which is inversely related to the entanglement molecular weight M_e, can be used to predict the mechanical response of polymers for many orders of magnitude in frequency (along with the molecular weight distribution and relaxation time). The relationship between structural parameters (Kuhn length b and Kuhn monomer volume v_0) and mechanical stiffness (plateau modulus G_N°), initially proposed by Graessley and Edwards and experimentally investigated by Everaers, while well-studied for flexible and stiff polymers, has a large gap in experimental data between the flexible and stiff regimes. This gap prevents the validation of the crossover between flexible and stiff polymers and therefore, the prediction of mechanical properties from chain structure of any polymer in this region. Given the chain architecture, including a semiflexible backbone and side chains, conjugated polymers are an ideal class of material to study this cross-over region. Using small angle neutron scattering, oscillatory shear rheology, in-situ polarized optical rheology, along with the freely rotating chain model we have shown that twelve polymers with aromatic backbones, including conjugated polymers, populate a large part of this gap. We also have shown that a few of these polymers exhibit nematic ordering which explains a lower experimental G_N° than predicted using Everaers' plot, as nematic polymers have fewer entanglements than isotropic polymers. Nevertheless, when isotropic, these polymers follow the proposed relationship between b, v_0, and G_N°.

1:15 PM EL01.12.07

High-Performance and Temperature-Resilient Redox Memories with Linear 20 ns Switching for Integrated Neuromorphic Computing Armantas Melianas[1], Tyler J. Quill[1], Garrett LeCroy[1], Yaakov Tuchman[1], Hilbert v. Loo[2,1], Scott Keene[1], Alexander Giovannitti[1], Hye Ryoung Lee[1], Iuliana Petruta Maria[3], Iain McCulloch[3,4] and Alberto Salleo[1]; [1]Stanford University, United States; [2]Technische Universiteit Eindhoven, Netherlands; [3]Imperial College London, United Kingdom; [4]King Abdullah University of Science and Technology, Saudi Arabia

Synaptic devices with linear resistance tuning are highly sought after for parallel programming of artificial neural network (ANN) weights in neuromorphic arrays. Conventional resistive memories however suffer from nonlinear and asymmetric conductance tuning and excessive write noise that are detrimental for accelerating learning in hardware ANNs. To address these challenges, we have recently introduced electrochemical random-access memories (ECRAMs), where resistive switching is controlled by ion insertion from the electrolyte into a semiconductor channel, enabling linear resistance tuning and parallel array programming [1]. However, state-of-the-art organic ECRAMs have not yet demonstrated stable and efficient operation at elevated 20-100 ºC temperatures required for large scale integration with Si logic.

Here, we show that semiconducting polymers in combination with ion gels enable solid-state organic ECRAMs with stable and temperature-independent operation up to 110 ºC. With a judicious choice of materials we demonstrate ECRAMs with linear conductance tuning (over 100x distinct states), fast switching (20 ns), rapid write-read cycles (<1 µs), low voltage (±1 V) and low energy (~100 fJ/write) operation, and excellent endurance (>10^9 write-read operations at 90 ºC). The use of novel polymers also improves the dynamic range to >2x. We use a series of photolithographically patterned devices and quantitative modelling to demonstrate that further scaling would lead to faster than 1 GHz switching. This shows that organic ECRAMs are temperature-resilient and meet the stringent device requirements for efficient neuromorphic computing. Demonstration of such high-performance solid-state ECRAMs [2] is a fundamental step towards their integration into synaptic arrays amenable to learning and inference.

2:15 PM *EL01.13.01
Assessment of Molecular Dynamics Force Fields for Conjugated Polymers Using Neutron and X-Ray Scattering Caitlyn M. Wolf and Lilo D. Pozzo; University of Washington, United States

Conjugated polymers can be ideal materials for the design of efficient photovoltaic devices, batteries, thermoelectric cells, light emitting diodes and many new technologies. Moreover, a large flexibility in organic synthesis methods enables the efficient application of molecular design principles to produce superior materials. Yet, the use of computational methodologies for conjugated polymers is still limited by a lack of properly validated simulation force fields that can be used to model structures and temporal fluctuations through molecular dynamics simulations. This presentation motivates the use of neutron and x-ray scattering techniques for the development of improved molecular simulation force fields and structural parameters specifically for poly-3-alkyl-thiophene, a model conjugated polymer. Quasi-elastic neutron scattering (QENS) experiments are used along with MD simulations to quantitatively compare proposed force fields to extensive sets of experimental data. X-ray and polarized neutron diffraction are also used to correlate experimental and model-

generated polymer structures. QENS validation of MD force fields presents a unique opportunity to increase the accuracy of highly uncertain parameters that are used in the simulation of conjugated polymers, including partial charges, Lennard-Jones and backbone torsion parameters. Many of these parameters are estimated from quantum mechanical calculations such as density functional theory but, unlike for force fields designed for small molecules, they are not often parameterized to experimental data. High variability is also observed in parameters for the small number of simulation force fields that have been proposed in the literature. A vision for the accelerated development of accurate force fields for these classes of materials is also proposed.

2:40 PM *EL01.13.02
What is the Assembly Pathway of Conjugated Polymers from Solution to the Solid State? Ying Diao; University of Illinois at Urbana-Champaign, United States

The hierarchical assembly of conjugated polymers has gained much attention due to its critical role in determining the optical/electrical/mechanical properties. The hierarchical morphology encompasses molecular scale intramolecular conformation (torsion angle, chain folds) and intermolecular ordering (π-π stacking), mesoscale domain size, orientation and connectivity, and macroscale alignment and (para)crystallinity. Such complex morphology in the solid state is fully determined by the polymer assembly pathway in the solution state, which in turn is sensitively modulated by molecular structure and processing conditions. However, molecular pictures of polymer assembly pathways remain elusive, due to the lack of detailed structural characterizations in the solution state and lack of understanding on how various factors impact the assembly pathways. In this talk, we discuss pre-aggregation and liquid-crystal mediated assembly pathways and their relationship. We develop SAXS models for in-depth analysis of the complex solution state structure of conjugated polymers complemented by imaging and spectroscopy. Further we discover a chiral, helical liquid crystal mediated assembly pathways from achiral conjugated polymers. We elucidate a hierarchical helical structure spanning the molecular scale to micron scale. We further trace the molecular origin of chiral liquid crystal assembly pathways. These studies change the way we perceive structure of conjugated polymers and may bring forth exciting new optoelectronic properties not imagined before.

3:05 PM EL01.13.03
Chiral Emergence in Multistep Hierarchical Assembly of Achiral Conjugated Polymers Kyung Sun Park and Ying Diao; University of Illinois at Urbana-Champaign, United States

Hierarchical structures are inherent to various soft material systems including biomolecules, mesogens and conjugated polymers. Structural chirality commonly results from the hierarchical organization of chiral building blocks, e.g., amyloids, M13 phage and chiral mesogen [1, 2]. Recently, it has been discovered that achiral mesogens/nanostructures can also form chiral, twisted structures due to symmetry breaking or topological defects [3-5]. This new finding can open a new degree of freedom for tuning electrical and optical properties and provide a fundamental understanding of complex supramolecular assembly and phase transition behaviors. In this work, we demonstrate chiral emergence from achiral donor-acceptor (D-A) conjugated polymers, a high-performance organic semiconductor. Our previous work demonstrated that the morphology of printed isoindigo-bithiophene-based conjugated polymer (PII-2T) films results in chiral, zigzag twinned domains despite the inherent molecular achirality [6]. We anticipate that the chirality is responsible for the multistep hierarchical assembly of achiral, torsional molecular structures. Still, several aspects regarding the nature of its multiscale organization and behavior remain a mystery. In conjugated polymers, the main intermolecular forces are π-interactions between the backbones and dispersion forces among the alkyl side chains. Such interaction often results in the presence of solution-phase aggregates and/or liquid crystalline phase. Given the importance of solvent in mediating these interactions, we also demonstrate how a solvent influences the development of mesophase and the relationship between pre-aggregation and mesophase formation. This study provides a clear map for the multiscale assembly pathway of conjugated polymers as we explore the possible hierarchical mesophase structures that can be used to enhance device performance

Late News: Crystallization of Organic Thin Films and the Role of Thermal Properties and Molecular Structure Jordan Dull[1], Yucheng Wang[1], Holly Johnson[1], Komron J. Shayegan[2], Ellie Shapiro[1], Rodney Priestley[1], Yves H. Geerts[3] and Barry P. Rand[1]; [1]Princeton University, United States; [2]California Institute of Technology, United States; [3]Université libre de Bruxelles, Belgium

A group of organic small molecules, selected for small differences in molecular structure, are investigated for their ability to crystallize as a thin film. Each material is vapor deposited in a range of thicknesses between 20 - 80 nm and subsequently thermally annealed. The annealed films are categorized into three groups based on the crystal morphology as determined by polarized optical microscopy: platelet-forming, spherulite-forming, and those that resist crystallization. Differential scanning calorimetry is utilized to determine bulk thermal properties of these materials. We demonstrate that these thermal properties provide a reliable indicator of a material's crystallization motif. Platelet-forming materials tend to be characterized by high melting points (T_m) and a large crystallization driving force at the material's crystallization temperature (ΔG_c). The materials that resist crystallization as a thin film have small ΔG_c. These guidelines can help determine which organic molecules have a greater likelihood of growing into large-scale crystalline frameworks, a key step for improving charge carrier mobility and exciton diffusion length in organic semiconductors.

Late News: Using the High-Resolution ac-Hall Effect to Investigate the Effects of Grain Boundaries, Strain and Photoexcitation on the Charge Transport in Crystalline Organic Semiconductors. Vitaly Podzorov; Rutgers, The State University of New Jersey, United States

An exciting recent progress has been made in our understanding of fundamentals of charge carrier transport and photoconductivity of crystalline and polycrystalline organic semiconductors, largely achieved thanks to high-sensitivity *ac*-Hall effect measurements. This talk will cover one or more examples. For instance, we have elucidated the effect of grain boundaries on the Hall effect in high-performance, polycrystalline organic transistors, where it was found that capacitively charged grain boundaries may lead to an underestimated Hall mobility and an overestimated Hall carrier density [1]. In another example, the *intrinsic* mobility-strain relationship has been measured for the first time in organic semiconductors (here, in single crystalline rubrene). It became possible thanks to the *ac*-Hall effect and Raman measurements as a function of uniaxial mechanical strain applied to ultra-thin, flexible single-crystal rubrene OFETs. The study reveals a very strong, anisotropic and reversible modulation of the intrinsic (trap free) charge carrier mobility of these OFETs with strain, showing that an effective mobility of organic circuits can, in principle, be enhanced by up to ~ 80% with only 1% of compressive strain [2]. Finally, a photo-Hall effect has been measured in organic semiconductors for the first time [3]. These measurements have allowed us to directly access the mobility and density of charge carriers photogenerated at the surface and in the bulk of (ungated) organic crystals under *cw* photoexcitation. Our data reveal some unexpected properties of photoexcitation process, including the generation of mobile carriers of only one type (holes) and unconventional power exponents in photoconductivity. The data are also consistent with the mechanism of photoconductivity in rubrene based on an interaction of long-lived, mobile triplet excitons with surface electron traps, leading to a release of mobile holes [3].

Late News: Application of Structure-Property Relationships of Silicon Phthalocyanines to Achieve Low Threshold Voltage N-Type Organic Thin-Film Transistors Benjamin King and Benoit Lessard; University of Ottawa, Canada

Metal and metalloid phthalocyanines (MPcs) are a large class of thermally stable organic semiconductor materials which can be manufactured with relatively inexpensive reagents and that have easily accessible synthetic routes. A wide variety of MPcs containing different metal cores have been incorporated into incorporated into organic light-emitting diodes (OLEDs), organic solar cells (OPVs) and organic thin-film transistors (OTFTs), including copper (CuPc) and zinc (ZnPc), trivalent MPcs (one axial group) including aluminum (AlPc-Cl) and tetravalent MPcs (two axial groups) including silicon (SiPc-Cl_2) and tin (SnPc-Cl_2). To date, the greatest reported mobility for an MPc-based OTFT incorporates titanyl phthalocyanine (TiOPc) as the semiconductor, which exhibits a hole mobility (μ_h) on the order of 10 $cm^2V^{-1}s^{-1}$. Although MPcs are generally p-type, examples of n-type derivates of these materials exist including SiPcs, SnPcs and peripherally-fluorinated F_{16}-CuPc.

SiPcs have recently shown promise as n-type or ambipolar organic semiconductors with various derivatives. The highest reported electron mobility (μ_e) of SiPcs is ≈0.5 $cm^2V^{-1}s^{-1}$ using pentafluoro-phenoxy silicon phthalocyanine (F_{10}-SiPc), indicating that high-performance SiPcs not only compare to but exceed other metal phthalocyanines (MPcs) in n-type OTFTs and can rival state-of-the-art organic organic semiconductors. Despite this excellent potential, only a few structure-property relationships have been established to determine the impact of the axial substituent on the electrical performance of SiPc-based OTFTs. For example, previous density functional theory (DFT) modelling data indicated that μ_e and other charge transport properties in fluorophenoxy SiPcs are dependant on the axis of transport and the number of substituted fluorine atoms on the axial pendant. Additionally, the choice of axial group affects SiPc packing in the single crystal, often changing the π-π stacking distance, herringbone angle, and degree of molecular overlap.

In this work, structure-property relationships for phenoxy-SiPcs were developed by fabricating bottom-gate top-contact OTFTs employing 11 derivatives. Characterization of thin-film properties in addition to electrical performance in devices was completed. Thin-film characterization techniques included x-ray diffraction (XRD), atomic force microscopy (AFM) Grazing-Incidence Wide-Angle X-ray Scattering (GIWAXS) and DFT modelling. One significant trend observed from electrical characterization was that increasing the electron-withdrawing character of axial pendant groups as characterized by their Hammett Parameter led to a reduction in threshold voltage, indicating that these substituents play a role beyond solid state packing and influencing morphology of thin-films. It was also determined that low molecular weight pendant groups contributed to a greater degree of crystalline order of SiPc materials in thin-films. These findings dictated the design of three additional novel SiPcs with phenoxy pendant group Hammett Parameters in the range of +0.66 to + 0.997. These materials exhibited threshold voltages as low as 4.8 V, exceeding the record low threshold voltage of 7.8 V reported for F_{10}-SiPc-based OTFTs fabricated in an identical architecture.

EL01.14.01
Atom Probe Tomography of Molecular Organic Materials Matthew B. Jaskot, Andrew P. Proudian and Jeramy D. Zimmerman; Colorado School of Mines, United States

Many organic electronic devices, such as organic light-emitting diodes (OLEDs) and organic photovoltaics (OPVs), contain blends of molecules. The morphology, interface structure, impurities, and degradation pathways are all of great interest in improving device performance. Conventional analysis techniques, such as transmission electron microscopy, often provide critical but limited information in these materials. Atom probe tomography (APT) collects the mass-to-charge state of every ion detected with nanometer-scale resolution, providing previously inaccessible information that enables evaluation of nanometer-scale morphology, impurity analysis, and understanding degradation pathways in molecular organic electronic materials blends.

A wide variety of molecules can be analyzed with APT, ranging from fullerenes (e.g., C_{60}) to metalorganics (e.g., tris(2-phenylpyridine)iridium or $Ir(ppy)_3$) without indication of fragmentation. Sub-nanometer spatial resolution, sub-Dalton mass discrimination, and the ability to identify impurities or degradation products below 0.01 atomic% have been demonstrated [1,2]. We will introduce the APT technique, discuss techniques for creating APT samples, typical analysis conditions for organic small molecules, and highlight structure-property relationships in OLED and OPV devices enabled by APT analysis.

EL01.14.02
Late News: Flexible Blade Coated Devices—Dual Functionality with Simultaneous Deposition Jasmine M. Jan, Juan Zhu, Jonathan Ting and Ana C. Arias; University of California, Berkeley, United States

Advances in printing techniques have given rise to low-cost, large-area, flexible electronics and systems. These printing methods have been used to fabricate organic electronics including light-emitting diodes (OLEDs), photodiodes (OPDs), solar cells (OSCs), and thin-film transistors (OTFTs) for various applications such as flexible displays, imagers, photovoltaics, smart tags, and logic circuits. However, in applications that require dual functionality, such as optoelectronic sensors with a combination of light sources and detectors, devices are fabricated separately in multiple processing steps. Additionally, the devices are often stacked together, reducing the mechanical flexibility of the overall system. To address these limitations, we utilize blade-coating in conjunction with surface-energy-patterning (SEP) to simultaneously deposit OLED and OPD films side-by-side on a single flexible substrate. This printing technique allows us to manufacture functionally distinct devices, while retaining the ability to individually optimize each device via ink parameters. The film thickness and device performance are compared and characterized for concentrations of 8, 10, and 12 mg/ml for OLEDs and 20, 35, and 50 mg/ml for OPDs. We chose the optimal ink concentration for the blade-coating process based on desired device performance – luminance for OLEDs and EQE for OPDs. The optimized OLEDs exhibit an average turn-on voltage of 3.4 V, and average luminance of 7000 cd/m^2 at 8 V. At 1000 cd/m^2, the current density, EQE and luminous efficacy of the OLEDs is 60.8 mA/cm^2, 1.35% and 9.5 lm/W with peak emission at 612 nm. OPDs exhibit EQEs of over 30% over the visible spectrum, and up to 45% in the near infrared region. The OPDs have a low dark current of 65.5 pA/cm^2, a cutoff frequency of 300 kHz, and LDR of over 120 dB.

EL01.14.03
Advanced Infrared Nanospectroscopy for Polymer Blend Characterization Nathaniel L. Prine[1], Zhiqiang Cao[1], Song Zhang[1], Tianyu Li[2], Kunlun Hong[2], Sarah Morgan[1] and Xiaodan Gu[1]; [1]The University of Southern Mississippi, United States; [2]Center for Nanophase Materials Sciences, United States

Characterizing the morphology of polymer blends is critical for improving the performance of next-generation sensors, photovoltaics, and pharmaceuticals. Unfortunately, blends containing materials that share similar chemical composition remain challenging to measure by traditional scanning probe microscopy due to poor topographical contrast. Coupling infrared spectroscopy with atomic-force microscopy, infrared nanospectroscopy (AFM-IR) overcomes this contrast barrier by distinguishing blended components by their unique infrared absorption response. While AFM-IR remains a robust technique for measuring surface morphology, the versatility of the technique has been largely unexplored. Herein, AFM-IR is used to determine blend composition using fundamental infrared spectroscopy theory for a series of immiscible and miscible blends. Second, nanoscale phase separation in isotope blends is explored using AFM-IR and confirmed by resonant soft X-ray scattering and small angle neutron scattering. These investigations highlight the widely unexplored potential of AFM-IR and its application for probing low-contrast, polymer blend morphology.

EL01.14.04
Engineering π-Stacking of an Anthracene Organic Semiconductor Through Cocrystallization Gonzalo Campillo-Alvarado and Ying Diao; University of Illinois at Urbana-Champaign, United States

Organic semiconductors (OSCs) are a rapidly emerging field in molecular electronics. Specifically, single-crystalline OSCs have received considerable attention due to the unique properties associated with long-range order, solution processing, absence of grain boundaries, and extremely low defect density [1] leading to a wide range of multi-functional materials (e.g., field-effect transistors, light-emitting diodes, photovoltaics). However, the lack of strategies to control and promote π-stacking in single crystals of OSCs has limited their diversification, property tunability, and application. While covalent modification of OSCs has arguably received the most attention [2], supramolecular modification of OSCs through weak, non-covalent interactions with additional molecules (i.e., coformers) has been largely unexplored [3]. The resulting single-phase multicomponent solids (i.e., cocrystals) typically display enhanced or modulated properties compared to the parent OSC.

In this contribution, we introduce the use of halophenols as coformers to promote π-stacking of a pyridyl-containing anthracene through hydrogen-bonding. Specifically, solution cocrystallization of the anthracene OSC results in single crystals with modulated π-stacking and is accompanied with significant changes in the photophysical properties. We envisage the supramolecular control of π-stacking in single crystals of OSCs with suitable coformers could lead to a rapid diversification of multicomponent and multifunctional crystalline electronics with enhanced and tailored properties (e.g., flexible electronics).

EL01.14.05
Nanoscale Mapping of Morphology of Organic Thin Films Jongchan C. Kim; University of Michigan–Ann Arbor, United States

Understanding morphology is fundamental to revealing the structure-property relationships of solids.

Disordered materials are of particular interest since their morphology is rarely in the lowest energy, equilibrium state, and hence can be complex and metastable, or even unstable over time. Organic molecular solids are particularly important disordered materials since they are bonded by relatively weak van der Waals (vdW) forces. Here, we reveal the detailed nanoscale morphology within archetype organic electronic thin films using Fourier plane imaging microscopy (FIM). By depositing phosphorescent dye molecules at strategic positions within a host organic thin film, their luminescence provides high resolution, depth and area-dependent structural maps of the host. In this work, the FIM-plus-dye molecule combination is used to create 3D morphological maps of changes arising from thermal annealing in a stacked bilayer film comprising CBP (4,4′-Bis(N-carbazolyl)-1,1′-biphenyl) and TPBi (2,2',2"-1,3,5-Benzinetriyl)-tris(1-phenyl-1-H-benzimidazole), and at the interfaces. The volume resolution of the measurements is at the Ångstrom scale in the direction normal to the film plane that is limited only by the flatness of the predeposited film and the ability to accurately determine layer thickness during deposition, and has a resolution of approximately half the visible wavelength (~200 nm) within the plane. Our results provide a powerful tool for the high-resolution 3D morphological imaging of materials employed in a wide range of optoelectronic applications.

EL01.14.06
Conformally Vapor-Printed PEDOT on Fabrics for Foldable and Breathable Wearable Device Application Michael Clevenger[1], Han Wook Song[2] and Sunghwan Lee[1]; [1]Purdue University, United States; [2]Korea Research Institute of Standard and Science, Korea (the Republic of)

Wearable electronics are a growing branch of technology that can have a large impact on various types of applications. The potential for the creation of new wearable devices from the most important medical applications to ones for novel enjoyment are extreme. In order to develop these wearable electronic devices, traditional inorganic conductive materials do not lend themselves to this type of application due to their mechanically brittle nature. Instead, polymeric materials with better mechanical flexibility are more advantageous to the development of wearable electronic components. Poly(3,4-ethylenedioxythiophene) (PEDOT) is one of the most promising conjugated polymers due to its high electrical conductivity as well as the environmental stability. PEDOT has been integrated in many electronic and optoelectronic devices such as organic thin film transistors (TFTs), solar cells and sensors. Due to these demonstrated performance together with mechanical flexibility, PEDOT has been garnering much attention more recently for potential use in wearable electronic applications.

For the development of wearable electronic devices with PEDOT, challenges remain particularly for clothing applications. Sustainable mechanical flexibility should be achieved over repeated folding and bending cycles as naturally occur in our daily use of clothing. Further, breathability, one of the principle functions of clothes should not be sacrificed after the coating of PEDOT.

In this presentation, in order to mitigate the challenges, oxidative chemical vapor deposition (oCVD) will be utilized, which uses mild thermal energy to generate a polymerization between a vaporized source material and an oxidizer in a vacuum chamber. We have investigated the electrical and structural stability of oCVD PEDOT and other thiophene-based polymers[1-3] and these polymers have been integrated in electrochromic devices[4]; TFTs[3, 5]; organic solar cells[6-8]; and chemical sensors[9-11]. In comparison to more conventional solution-based processes, oCVD lends itself to certain traits that are more beneficial when applied to the creation of wearable electronic devices and thin film deposition on fabric substrates. Films deposited from the use of oCVD better conform to the target fabric substrate. With the achieved excellent conformality, the fabric coated with oCVD PEDOT is still able to maintain its flexible properties as well as breathability, and can effectively be used in next generation devices on fabrics that work as clothing as well as electronics. In addition, no solvents are required for the oCVD deposition and therefore substrate distortion or damage is minimized.

What will be presented is a comparison of various properties of PEDOT thin films on both glass and fabric substrates as well as Si and glass substrates. Thin film deposition on Si and glass substrates is used as a control to compare the performance of oCVD PEDOT on fabrics. Specifically performance in regard to electrical,

mechanical, surface, and chemical properties will be discussed. To mimic daily use in clothing, mechanical bending tests of oCVD PEDOT were conducted and excellent performance stability was observed over 150 times bending cycles. General electrical properties include an analysis of conductivity, carrier density, and carrier mobility utilizing Hall Effect measurements system and four-point probe. AFM and SEM are used to determine and compare surface and cross-sectional microstructures. FTIR and UV-Vis spectroscopy are used to compare optical properties and chemical bonding information. Our findings on vapor-processed conjugated polymers on fabrics with high conductivity and mechanical flexibility is expected to significantly contribute to the realization of high performance and sustainable wearable clothing electronic devices that require enhanced uniformity, flexibility, and breathability.

EL01.14.08

Nanowire Morphologies Can Improve Ion Uptake Kinetics in Organic Electrochemical Transistors Rajiv Giridharagopal, Jiajie Guo, Jessica Kong and David Ginger; University of Washington, United States

Organic electrochemical transistor materials face a design tension between optimizing for ion mobility and for electronic mobility. These devices transduce ion uptake into electrical current, thereby requiring high ion mobility for efficient electrochemical doping and rapid turn-on kinetics, and high electronic mobility for maximum transconductance. Here we explore one method to improve operational kinetics in a high hole mobility conjugated polymer (poly[2,5-(2-octyldodecyl)-3,6-diketopyrrolopyrrole-alt-5,5-(2,5-di(thien-2-yl)thieno [3,2-b]thiophene)], DPP-DTT) by using a nanowire morphology. For equivalent thicknesses, the DPP-DTT nanowire films exhibit consistently faster spectroelectrochemical kinetics in KPF6 solution (~6-10X faster) compared to a standard DPP-DTT film. Nanowire devices also exhibit favorable shifts in the threshold voltage, making the nanowire architecture both faster and energetically easier to dope compared to neat films. We use nanoinfrared imaging via photoinduced force microscopy to show that these films exhibit ion diffusion throughout the film, suggesting there is a volumetric benefit to the nanowire architecture. We propose that, for higher-mobility materials that are often hydrophobic, casting the active layer in nanowire form may offer faster kinetics and possibly lower threshold voltage while maintaining desirable device performance, thereby providing one method to optimize ion mobility without sacrificing electronic mobility.

EL01.14.09

Simulation-Guided Design of Organic Devices for Cost-Effective and Scalable Electronics Matthew C. Waldrip[1], Hamna Haneef[1], Iain McCulloch[2,3] and Oana Jurchescu[1]; [1]Wake Forest University, United States; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]University of Oxford, United Kingdom

Interest in organic electronics is driven in large part by the applications they can address, yet a complete set of design rules is still absent for devices intending to fulfill those roles. Progress is assisted by general guidelines such as minimizing the Schottky barrier at injection interfaces or reducing defect states in the semiconductor layer, but improvements are achieved mainly through experimental trial-and-error, which is time, cost, and material intensive. Here we use physically-based numerical simulations to explore a vast parameter space with a high throughput in order to generate rules for material processing and device design, and optimize charge mobility and injection. For this purpose, the organic field-effect transistor (OFET) was selected as an experimental platform since current densities in OFETs (~10^4 A cm^{-3}) are much higher than in other organic devices, thereby allowing the exploration of charge injection and transport in the most extreme case. We have investigated the impact of the density of trap states and the injection barrier on the charge carrier mobility for both thick- and thin-dielectric devices, in a co-planar and staggered architecture. The simulations revealed that the performance of thin-dielectric devices (10 nm) is insensitive to large changes in the density of traps, while an injection barrier has a significant impact on mobility: only a 15% decrease in mobility was observed when raising the trap density by an order of magnitude in both architectures, but 60% and 95% decreases were observed when a 0.5 eV injection barrier was introduced in the staggered and co-planar devices, respectively. On the other hand, employing a thick dielectric (1000 nm) had the opposite trend: changes in the density of traps produced large reductions in mobility (by 60%), but the same 0.5 eV injection barrier decreases mobility by only 20% and 40% in the staggered and co-planar structures, respectively. Our results suggest that the

staggered structure and the thick dielectric are more tolerant to injection barriers. All these effects were also found to scale with the intrinsic mobility of the semiconductor. To test these predictions, we have fabricated and characterized a variety of OFETs and tuned the injection barrier via self-assembled monolayers (SAMs), oxide interlayers, and contact material selection, while the density of states was modified through altering film microstructure by processing. Notably, the experimental results agree well with the simulations, validating its use to predict and guide device design. With regards to the quality of the semiconductor and the contact/semiconductor interface, these results reevaluate the requirements necessary for optimizing OFETs. For example, given a good quality semiconductor with a low trap density, improving the injection barrier is not essential if a sufficiently thick dielectric is employed in the staggered architecture, allowing the selection of a more cost-effective and scalable contact material. Further parameter exploration combining both simulation and experiment will fine-tune the model and expand its predictive power.

EL01.14.10

Dynamic Modulation of Charge Transport Properties Enabled by Cooperative Structural Transitions

Daniel Davies[1], Sangkyu Park[1], Prapti Kafle[1], Yuan Dafei[2], Hyunjoong Chung[1], Stefan Mannsfeld[3], Danielle Gray[1], Ralph Weber[4], Xiaozhang Zhu[2] and Ying Diao[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Institute of Chemistry, Chinese Academy of Sciences, China; [3]Technische Universität Dresden, Germany; [4]Bruker Corporation, United States

Cooperativity has long been used by living systems to circumvent energetic and entropic barriers to yield highly efficient molecular processes. Cooperative structure transition involves simultaneous, concerted displacement of molecules in a crystalline material, in stark contrast to the typical nucleation and growth mechanism occurring in a molecule-by-molecule fashion that often disrupt the material structural integrity. Cooperative transitions have acquired much attention in the research community for its low transition barrier, ultrafast kinetics, and structural reversibility. On the other hand, cooperative transition is rarely observed in molecular crystals and its molecular origin is not well understood. In 2-dimensional quinoidal terthiophene (2DQTT-o-B), a high-performance n-type semiconductor our research has shown prolific diversity in polymorphism and transition behavior resulting in 5 obtainable polymorphs showing large variations in electronic and optical behaviors. Along with the diversity of structure, both a cooperative and nucleation and growth transition has been reported simultaneously in the same system through 2 different thermally activated phase transitions. In situ microscopy, single crystal and grazing incidence X-ray diffraction, and Raman spectroscopy suggest a reorientation the alkyl side chains results in a cooperative transition behavior. While in stark contrast, we find the nucleation and growth mechanism occurs through a combination of side chain melting and increased core interactions resulting from a sudden increase in biradical nature of 2DQTT-o-B and is confirmed through in situ electron paramagnetic resonance. This is the first time, to our knowledge, that biradical interactions result in a structural change. Finally, we harness the cooperative phase transition behavior for a novel thermally actuated switching device. Through studying these fundamental mechanisms, we may establish design rules to rationally obtain polymorphic behavior for novel electronic applications.

EL01.14.12

High Anisotropic Self-Assembled Multilayered Films Used Simultaneously as Dielectric and Conducting Channel Material—A Novel Approach to Fabricate Solid-State Organic Field Effect Transistors

Gabriel Gaal[1,2], Maria L. Braunger[1], Varlei Rodrigues[1], Antonio Riul Jr.[1] and Henrique L. Gomes[2,3]; [1]Universidade Estadual de Campinas, Brazil; [2]Universidade do Algarve, Portugal; [3]Universidade de Coimbra, Portugal

The next generation of organic-based electronic devices will require composite materials synergistically engineered to exploit novel and multi functionalities in a single device structure. Such multifunctional organic materials are attractive for various applications, including electronic skin, smart textiles, and self-healing batteries. Organic Field Effect Transistors (OFETs) have historically suffered from the lack of a single seamless material acting as both dielectric and channel. Typical OFET devices have defects and active electrical

impurities due to the quality of the dielectric/semiconductor interface critical for the device operation, which is the primary source of electrical instabilities and reliability issues. Such lack of quality control in the dielectric/semiconductor interface has until now, prevented, the commercialization of solid-state organic transistors. Here, we report a comprehensive investigation of process-friendly multilayered organic transistors without material discontinuities between dielectric and channel. The transistor design makes use of the high anisotropic electrical behavior of multilayered polyethylenimine/poly(acrylic acid) (PEI/PAA) composite thin films doped with reduced graphene oxide (rGO) and poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS). The films were fabricated by self-assembled layer-by-layer (LbL) deposition technique, exploiting the spontaneous physical interactions that allow for the natural combination of various materials in a multilayered structure. Conductive layers formed by rGO nanosheets and the PEDOT:PSS nanofibers are dynamically ordered in a specific direction due to electrostatic interactions in the LbL film fabrication, creating highly anisotropic pathways. The in-plane film conductivity is 7 orders of magnitude higher than the conductivity normal to the multilayered planes. Temperature dependent measurements confirm the strong anisotropic electrical behavior. The charge transport mechanism is weekly thermal activated (E_A = 33.4 meV) along the aligned conductive phases while the charge transport normal to the plane is fitted with variable ranging hopping having an activation energy of 1.0 eV. The LbL films' high anisotropic electrical conduction is used to fabricate a novel field effect transistor where the same multilayered structure operates simultaneously as both dielectric and conductive channel. The transistor presents a low power consumption as it operates at the sub voltage regime. The dielectric part shows a high specific capacitance of 18 μF/cm^2, and the semiconductor presents an *n*-type carrier transport having a field effect mobility of 4.0 cm^{2}V^{-1}s^{-1}. Moreover, the transistor threshold voltage (V_{th}) is zero, which shows that electrical active traps, which can charge upon the applied gate field and shield the external applied voltage are not active or do not exist. The entire applied gate field contributes to an increasing channel current, as expected in trap free devices. The results point to the development of a simple and efficient approach to fabricate solid-state OFETs relying on the high anisotropy of the LbL films, enhancing its potential for commercial applications.

Excitons and Phonons in 2D Perovskites Paulina Plochocka[1,2]; [1]Laboratoire National des Champs Magnetiques Intenses, CNRS-UJF-UPS-INSA, France; [2]Department of Experimental Physics, Faculty of Fundamental Problems of Technology, Poland

High environmental stability and surprisingly high efficiency of solar cells based on 2D perovskites have renewed interest in these materials. These natural quantum wells consist of planes of metal-halide octahedra, separated by organic spacers. Remarkably the organic spacers play crucial role in optoelectronic properties of these compounds. The characteristic for ionic crystal coupling of excitonic species to lattice vibration became particularly important in case of soft perovskite lattice. The nontrivial mutual dependencies between lattice dynamics, organic spacers and electronic excitation manifest in a complex absorption and emission spectrum which detailed origin is subject of ongoing controversy. First, I will discuss electronic properties of 2D perovskites with different thicknesses of the octahedral layers and two types of organic spacer. I will demonstrate that the energy spacing of excitonic features depends on organic spacer but very weakly depends on octahedral layer thickness. This indicates the vibrionic progression scenario which is confirmed by high magnetic fields studies up to 67T. Finally, I will show that in 2D perovskites, the distortion imposed by the organic spacers governs the effective mass of the carriers. As a result, and unlike in any other semiconductor, the effective mass in 2D perovskites can be easily tailored.

8:40 AM EL02.01.02
Late News: Vertically Aligned CsPbBr3 Nanowire Arrays with Template-Induced Crystal Phase Transition and Stability Zhaojun Zhang, Klara Suchan, Jun Li, Crispin Hetherington, Alexander Kiligaridis, Eva Unger, Ivan Scheblykin and Jesper Wallentin; Lund University, Sweden

All inorganic Metal halide perovskite (MHP) $CsPbBr_3$ nanowires (NWs) arrays have shown excellent performance in various optoelectronic applications such as laser, LED, and photodetection, *etc*. owing to its special properties have, such as one-dimensional photon/electron transport, enhanced light absorption, larger active surface area and higher charge injection efficiencies, *etc*.
The growth of $CsPbBr_3$ NWs and their various optoelectronic applications have been explored, e.g. for lasing, multicolor displays, control of emission anisotropy, and light guiding, as well as photodetection. However, most of these studies used unprotected in-plane NWs with horizontal alignment. A few studies have investigated vertically aligned MHP NW arrays, which have been proven to have high light extraction capability for LED devices and high resolution for pixel image sensors. So far, studies on vertically aligned $CsPbBr_3$ NWs arrays are limited.
Here, we report a low temperature solution growth of vertically aligned $CsPbBr_3$ NWs arrays with excellent stability, using anodized aluminum oxide (AAO) templates. AAO template is commonly used for nanocrystals synthesis, and it has also been used for MHP nanocrystals synthesis. However, the growth behavior and mechanism of micrometer length $CsPbBr_3$ NWs in AAO from a solution precursor have not been clearly investigated.
In this work, the growth behavior of $CsPbBr_3$ NWs in 5 μm thick AAO template from solution is clearly elucidated. Owing to the low concentration of precursor, the growth of micrometer length pure phase $CsPbBr_3$ NWs in AAO is different from the common way used for growing other MHP NWs such as $MAPbI_3$. The low solubility of its precursors makes it more challenging to fill the nanopores with $CsPbBr_3$, but it can be overcome by supplying sufficient solution as shown by our results. The NW diameter (10-250 nm) and the length (tens of nm to few μm) can be independently controlled. With decreasing diameter, the $CsPbBr_3$ NWs show a gradual photoluminescence blue-shift from 250 nm to 10 nm and crystal structure change from orthorhombic to cubic phase below 20 nm. This is the first observation of physical confinement induced phase transition for $CsPbBr_3$. The physical confinement of the $CsPbBr_3$ NWs in the AAO gives a remarkable stability to long term air storage.

Any significant degradation of these structures is not observed within 4 months, despite storing the sample in ambient air. Additionally, the $CsPbBr_3$-NWs/AAO composite shows good resistance to X-ray exposure, which makes it promising for applications in X-ray scintillation. The growth method proposed in this work should be viable for a wide range of MHP materials. The demonstrated stability makes the vertically aligned $CsPbBr_3$-NWs a promising foundation for a wide range of applications in many fields of optoelectronics.

Late News: Exciton Diffusion in Two-Dimensional Metal-Halide Perovskites Michael Seitz[1,2,3], Alvaro Magdaleno[1], Marc Meléndez[1], Nerea Alcázar-Cano[1], Tim Lubbers[1], Sanne W. Walraven[1], Sahar Pakdel[4], Elsa Prada[1], Daniel N. Congreve[2,3], Rafael Delgado-Buscalioni[1] and Ferry Prins[1]; [1]Universidad Autonoma de Madrid, Spain; [2]Harvard University, United States; [3]Stanford University, United States; [4]Aarhus University, Denmark

There is an increasing interest in two-dimensional (2D) Ruddlesden-Popper perovskites for solar harvesting and light-emitting applications due to their superior chemical stability as compared to bulk perovskites.[1,2] Both, purely 2D and blends of 2D/3D phases have been successfully employed in solar cells with efficiencies of >18% and >21%, respectively.[3,4] As with earlier advances in the field of perovskites, these technological improvements are advancing at a pace that far exceeds our understanding of the physical mechanisms underlying their performance. Particularly, the reduced dimensionality in 2D perovskites results in excitonic excited states which dramatically modify the dynamics of charge collection. While the carrier dynamics in bulk systems is increasingly well understood, a detailed understanding of the spatial dynamics of the excitons in 2D perovskites is lacking.[5]

Here, we present direct measurements of exciton transport in single-crystalline layered perovskites. Using transient photoluminescence microscopy, we can follow the temporal evolution of a near-diffraction-limited exciton population with sub-nanosecond resolution revealing the spatial and temporal exciton dynamics. We observe two distinct temporal regimes: For early times excitons undergo unobstructed normal diffusion, while at later times exciton transport becomes subdiffusive as excitons get trapped. Interestingly, the diffusivity at early times depends sensitively on the choice of the organic spacer which can yield diffusion lengths that differ by up to an order of magnitude. We find a clear correlation between lattice stiffness and diffusivity, suggesting exciton–phonon interactions to be dominant in the spatial dynamics of the excitons in perovskites, consistent with the formation of exciton–polarons. Our findings provide a clear design strategy to optimize exciton transport in these systems.[6] In addition, we show that the complex exciton dynamics observed at later times can be leveraged to provide a detailed map of the trap-state landscape in 2D perovskites, in particular when used in combination with transient photoluminescence spectroscopy and a rigorous diffusion model that accounts for a distribution of radiative shallow trapping sites.[7]

Exciton-Phonon Coupling in 2D Perovskites—Role of Organic Spacer, Halide Cage Composition and Quantum Well Thickness Michal Baranowski[1] and Paulina Plochocka[2]; [1]Wroclaw University of Science and Technology, Poland; [2]LNCMI, France

High environmental stability and surprisingly high efficiency of solar cells based on 2D perovskites have renewed interest in these materials. This natural quantum wells consists of planes of metal-halide octahedra, separated by organic spacers. Remarkable the organic spacers plays crucial role in optoelectronic properties of these compounds. Despite the bandedge states are composed from metal and halide orbitals the organic spacer imposes octahedral distortion and in this way controls band structure and carriers-phonon coupling. The characteristic for ionic crystal coupling of excitonic species to lattice vibration became particularly important in case of soft perovskite lattice. The nontrivial mutual dependencies between lattice dynamics, organic spacers and electronic excitation manifest in a complex absorption and emission spectrum which detailed origin is subject of ongoing controversy, because observed multiple sidebands are attributed to phonon replicas or distinct excitonic states.
Here we address this issue by systematic studies of 2D perovskites of different thickness of octahedral layer, different organic spacer, (namely phenethylammonium $C_6H_5C_2H_4NH_3$ (PEA) and long aliphatic chains (AC) $C_nH_{2n+1}NH_3$ (with n=4,6,8,10,12)) and halide cage composition. We found that energy spacing of excitonic feature depends on organic spacer but very weakly depends on octahedral layer thickness and metal ion. This support the vibrionic progression scenario originating from coupling to organic spacer or halide cage motion. Our results show that in case of PEA spacer exciton couple dominantly to PEA vibration, while in case of AC excitons are coupled to octahedral layer vibration. We found that exciton-phonon coupling can be tuned by the quantum well thickness. The phonon related origin of complex spectral feature is additionally supported by high magnetic fields studies up to 67T. In all cases the equally spaced features exhibit identical shifts in magnetic field as can be expected for phonon replicas. The observed difference in exciton-phonon coupling can be consistently explained taking in to account mutual dependence between organic spacer, octahedral distortion and dielectric screening.

9:30 AM EL02.01.05
Strong Coupling Between Photon-Exciton Fano Resonances and Plasmonic Silver Nanoparticles in 2D Perovskites Franziska E. Muckel[1], Kathryn N. Guye[2], Shaun Gallagher[2], Yun Liu[2] and David Ginger[2]; [1]University Duisburg-Essen, Germany; [2]University of Washington, United States

As easy-to-grow quantum wells with direct bandgaps, two dimensional Ruddleson-Popper perovskites carry great potential as excitonic components in strongly coupled polaritonic applications. Their combination of narrow excitonic features at room temperature and enhanced collective effects (i.e., coupling with multiple excitons) enable the observation of various regimes of light-matter interaction, including evidence of strong coupling with dielectric cavities or plasmonic nano-arrays.

Here we demonstrate that in $(C_4H_9NH_3)_2PbI_4$, butylammonium lead iodide (BAPI) thin films prepared via spin coating, the geometric morphology of the perovskite emitters needs to be considered to understand the excitonic spectrum and the light-matter interactions with localized cavities, in our case plasmonic silver nanoparticles. Specifically, we provide proof that a distinct exciton-photon Fano resonance in dark field scattering emerges from the coupling between the band edge exciton and the geometry-driven Rayleigh-like scattering background of the BAPI material itself, supported by finite-difference time-domain (FDTD) simulations and a classical coupled-oscillator model.
Through sequential spin coating, we combine the BAPI thin films with individual plasmonic silver nanocavities. Combining single particle dark field scattering spectroscopy and FDTD simulations, we demonstrate that the

BAPI Fano resonance exhibits strong coupling to the plasmon resonance of colloidal silver nanoparticle plasmonic cavities, although the total dark field scattering of the combined system is still dominated by the perovskite Fano resonance. We estimate a Rabi splitting of ~ 300 meV -- amongst the highest values ever reported for comparable material systems.

By adding a gold layer beneath the perovskite, we formed particle-on-mirror cavities, allowing us to access the out-of-plane excitonic component of the 2D perovskite. Due to the higher energy dissipation rate of the combined cavity, the combination of BAPI and particle-on-mirror cavity is found to exhibit intermediate coupling.
Our work not only highlights the potential of Ruddleson-Popper perovskites for polariton applications, but in addition provides new and unexpected insights into the principles governing the light matter-interaction of 2D halide perovskites.

Late News: Critical Role of Additive-Induced Molecular Interaction on the Operational Stability of Perovskite Light-Emitting Diodes Chaoyang Kuang, Sai Bai and Feng Gao; Linkönping University, Sweden

In spite of rapid improvements in efficiency and brightness of metal halide perovskite light-emitting diodes (PeLEDs), the poor operational stability remains a critical challenge hindering their practical applications. Herein, we demonstrate greatly improved operational stability of high-efficiency PeLEDs, enabled by incorporating dicarboxylic acids into precursor for the deposition of perovskite emissive layers. We reveal the critical role of carboxyl groups in enhancing the device stability through converting the active organic ingredients in perovskite emissive layers to stable amides, a process catalyzed by the alkaline zinc oxide substrate. The formed inert amides prohibit detrimental interfacial reactions between the perovskites and the charge injection layer underneath, greatly improving the thermal stability of the perovskite emissive layers and ensuring the long operational stability of the resulting PeLEDs. Through rationally optimizing the amidation reaction in the perovskite emissive layers, we achieve efficient PeLEDs with a peak external quantum efficiency of 18.6% and an outstandingly long half-life time of 682 h at 20 mA cm^{-2}, presenting an important breakthrough in PeLEDs.

Organic-Inorganic Metal Halide Hybrids Beyond Perovskites—From Material Development to Device Integration Biwu Ma; Florida State University, United States

Organic-inorganic metal halide hybrids have attracted great research attention for their remarkable and useful optical and electronic properties with applications in a variety of areas, ranging from photovoltaic cells to light emitting devices, sensors, and detectors. In addition to the well-known 3D ABX_3 perovskite structure, organic-inorganic metal halide hybrids can have many other crystallographic structures, in which inorganic metal halide units, for instance, metal halide octahedrons, form 2D, 1D, and 1D structures surrounded by organic cations. These low dimensional materials exhibit unique and remarkable properties that are completely different from those of 3D ABX_3 perovskites. For instance, corrugated-2D and 1D organic metal halide hybrids exhibit broadband emissions from both direct and self-trapped excited states, and 0D organic metal halide hybrids exhibit broadband emissions from the reorganized excited states with high photoluminescence quantum efficiencies of up to 100 %. In this talk, I will present our recent efforts on the development and study of

organic-inorganic metal halide hybrids beyond perovskites. From 3D to 2D, 1D, and 0D structures at the molecular level, from mononuclear molecular metal halide species to multinuclear metal halide clusters, and from single-component homogeneous systems to multi-component heterogenous systems, I will discuss how we can achieve synthetic control of this class of hybrid materials to realize desired properties with applications in various types of optoelectronics.

12:25 PM *EL02.02.03
Halide Perovskite-Polymer Composites for Fully Printed and Stretchable LEDs Zhibin Yu; FAMU-FSU College of Engineering, United States

Recently, astounding optoelectronic properties have been discovered in a group of halide perovskite materials. In this talk, our recent work of developing perovskite-polymer composites towards the realization of fully printed and stretchable light-emitting diodes (LEDs) will be presented. The perovskite-polymer composites possess all the remarkable optoelectronic characteristics of pristine perovskites. For instance, we have demonstrated their use for blue, green, and red LEDs. In addition, the device efficiencies are compatible to those of pristine perovskite LEDs. The perovskite-polymer composites have shown advantages in improving the processability and quality of the perovskite thin films; and enhancing the structural stability of the perovskites especially at humid fabrication and service environments. By embedding the perovskite crystals inside a polymer matrix, the perovskites can be less toxic and more environmentally benign compared to pristine perovskites; moreover, to enable new mechanical properties of perovskite LEDs.

12:50 PM EL02.02.04
All-Solution-Processed, Fully Inkjet-Printed Organometal Halide Perovskite Light-Emitting Diodes on Flexible Substrate Junyi Zhao[1], Li-Wei Lo[1,1], Haochuan Wan[1], Zhibin Yu[2,2] and Chuan Wang[1,1]; [1]Washington University in St. Louis, United States; [2]Florida State University, United States

Organometal halide perovskite has already attracted extensive research attention owing to its great potential for ubiquitous optoelectronic applications. However, most hybrid perovskite-based optoelectronic devices are fabricated on rigid indium-tin-oxide (ITO) glass substrate inside the glove box with a vacuum-evaporated metal top electrode, which is a tedious and time-consuming process. In this work, we demonstrate an all-solution-processed perovskite light-emitting diodes (PeLEDs) fabricated entirely by inkjet printing in ambient conditions for high-resolution flexible display applications. The PeLEDs were constructed with an extremely simple 4-layer sandwich structure, consisting of a composite transparent bottom electrode of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and poly(ethylene oxide) (PEO), a composite light-emissive layer of methylammonium lead tribromide ($CH_3NH_3PbBr_3$) and poly(ethylene oxide) (PEO), and a silver nanowire (AgNW) top electrode, all directly printed onto an ultrathin polydimethylsiloxane (PDMS) substrate. In addition, a printed polyethyleneimine (PEI) buffer layer inserted between the emissive layer and the top electrode was found to be effective in protecting the perovskite crystals from being attacked by the solvent in AgNW ink during the top electrode printing step. The device exhibits bright green emission with a turn-on voltage of 3.18 V, a maximum luminance intensity of 10 227 cd m^{-2}, and a peak current efficiency of 2.01 cd A^{-1}. By optimizing the ink formulation and printing recipe and taking full advantage of direct printing, we have also achieved scalable patterning of PeLEDs with resolution down to 250 μm. The printed PeLEDs also exhibit good flexibility and can be conformably bent to a 3.5 mm radius convex curvature for over 100 bending cycles without degradation in performance. The combination of superior optical performance, simplified device structure, all-solution processibility, and low-cost printing strategy is promising to pave way for emerging flexible display and wearable electronics applications.

2:15 PM *EL02.03.01
Organic-Inorganic Perovskites—Highly Diverse and Tunable Semiconductors David B. Mitzi; Duke University, United States

Hybrid perovskites offer an unprecedented degree of tunability through mixing and matching of diverse functionalities for inorganic and organic components [1]. The interfaces among organic cations and between the organic and inorganic components (mediated by hydrogen bonding and steric interactions) play an essential role in determining emergent properties within this semiconductor family. In this talk, we will examine how organic cation choice can profoundly impact spin, optical and thermodynamic properties, with a goal towards understanding how these characteristics can be rationally controlled. As an example, selection of appropriate chiral organic cations can lead to a transfer of chirality between the organic and inorganic components and an associated breaking of symmetry within the inorganic layer, which in turn provides a large Rashba-Dresselhaus splitting of the conduction band and associated control over spin texture [2]. Alternatively, organic cations with controlled HOMO and LUMO position can offer unique opportunities to fabricate self-assembling quantum well structures with distinct alignment of the energy levels [3]. Appropriate choice of the organic cation also leads to hybrids with melting temperature well below the decomposition point [4]. These examples of structure-property versatility yield new opportunities for fundamental science and prospective device applications.

2:40 PM *EL02.03.02
Low-Dimensional Metal Halide Hybrid Perovskite Semiconductors for Light Emitting Devices Wanyi Nie; Los Alamos National Laboratory, United States

Metal halide perovskites are emerging class of semiconducting materials that make high performance photovoltaics. Recently, low dimensional perovskites, such as 2D perovskites and nanocrystals, show unique carrier transport and recombination processes. Low dimensional perovskites are thus demonstrated as ideal candidate for high efficiency light emitting diodes.

In my talk, I will discuss both 2D perovskites and perovskite nanocrystals and their applications in light emitting devices and radiation detectors. Firstly, the charge transport properties and surface properties will be discussed by scanning photocurrent microscopy measurement, where we found a long carrier diffusion length in 2D perovskite single crystals along in-plane direction. Secondly, we observed large degree of charge localization in the bromide 2D perovskite which yielded strong emission properties. Finally, I will introduce new perovskite nanocrystal structure that show stable and bright emission properties. Using low dimensional perovskite materials, we demonstrate bright light emitting diodes with external quantum efficiency of 10%~15% with stable operational lifetime.

3:05 PM *EL02.03.03
Structural and Electronic Impact of an Asymmetric Organic Ligand in Diammonium Lead Iodide Perovskites Antoine Kahn; Princeton University, United States

Reduced dimensionality forms of perovskites with alternating layers of organic ligands are a promising class of materials for achieving stable perovskite solar cells. Most work until now has focused on phases utilizing two ammonium terminated ligands per formula unit. However, phases utilizing a single diammonium ligand per formula unit are advantageous in that they can potentially have a thinner insulating organic layer between Pb-halide layers, yet the structural effects on their optoelectronic properties remain to be well understood. In this talk, we first rapidly summarize our recent work on the energetics of 2D Ruddlesden-Popper phase metal halide perovskites (MHP). We then turn to two Dion-Jacobson *n*=1 MHPs formed with butane 1,4- diammonium (BDA) and N,N–dimethylpropane diammonium (DMPD) spacers. Using ultraviolet and inverse photoelectron spectroscopies, $BDAPbI_4$ is shown to have a larger transport gap by 350 meV and a larger exciton binding energy by 140 meV than $DMPDPbI_4$. Through density functional theory calculations, the cause of this difference is traced to the out-of-plane tilting of the Pb-halide octahedra provoked by the asymmetric ligand in DMPDPbI4. Parallel channels of nearly straight Pb-I-Pb bonds are formed in one direction, leading to enhanced electronic coupling and higher band dispersion in that direction. In $BDAPbI_4$, no such channels exist, resulting in greater electronic confinement and a larger band gap and exciton binding energy.

3:30 PM EL02.03.04
Long Periodic Ripple in a 2D Hybrid Halide Perovskite Structure Using Branched Organic Spacers Justin M. Hoffman[1], Christos Malliakas[1], Siraj Sidhik[2], Ido Hadar[1], Rebecca McClain[1], Aditya Mohite[2] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Rice University, United States

Two-dimensional (2D) halide perovskites have great promise in optoelectronic devices because of their stability and optical tunability, but the subtle effects on the inorganic layer when modifying the organic spacer remain unclear. Here, we introduce two homologous series of Ruddlesden-Popper (RP) structures using the branched isobutylammonium (IBA) and isoamylammonium (IAA) cations with the general formula $(RA)_2(MA)_{n-1}Pb_nI_{3n+1}$ (RA = IBA, IAA; MA = methylammonium n = 1-4).[1] Surprisingly, the IAA n = 2 member results in the first modulated 2D perovskite structure with a ripple with a periodicity of 50.6 Å occurring in the inorganic slab diagonally to the [101] direction of the basic unit cell. This leads to an increase of Pb-I-Pb angles along the direction of the wave. Generally, both series show larger in-plane bond angles resulting from the additional bulkiness of the spacers compensating for the MA's small size. Larger bond angles have been shown to decrease the bandgap which is seen here with the bulkier IBA leading to both larger in-plane angles and lower bandgaps except for n = 2, in which the modulated structure has a lower bandgap because of its larger Pb-I-Pb angles. Photo-response was tested for the n = 4 compounds and confirmed, signaling their potential use in solar cell devices. We made films using an MACl additive which showed good crystallinity and preferred orientation according to grazing-incidence wide-angle scattering (GIWAXS). As exemplar, the two n = 4 samples were employed in devices with champion efficiencies of 8.22% and 7.32% for IBA and IAA, respectively.

Stability of 2D Hybrid Lead Halide Perovskites: Perspective from Bulk Crystals and Thin Films Eugenia S. Vasileiadou[1], Ido Hadar[1], Bin Wang[2], Ioannis Spanopoulos[1], Mikaël Kepenekian[3], Jacky Even[4], Alexandra Navrotsky[5] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]University of California, Davis, United States; [3]University of Rennes, France; [4]INSA Rennes, France; [5]Arizona State University, United States

Two-dimensional (2D) hybrid organic-inorganic halide perovskites are a promising class of environmentally stable semiconductors. Their inherent structural tunability and technological features provide a vast compositional space to engineer new materials for optoelectronic applications. Within this compositional space, several different homologous series and structure types of 2D perovksites have been developed for their successful fabrication in solar cells, light-emitting diodes and radiation detectors with attractive efficiencies.

Although 2D lead iodide perovskites exhibit superior stability over their 3D parent structures, a systematic understanding of their observed stability is missing. Herein, we actuate a comprehensive study on the relative stability of several distinct families of 2D halide perovskites in bulk crystal and film form. Thermochemical evaluation of the representative 2D structure types of Ruddlesden-Popper (RP) and Dion-Jacobson (DJ) perovskites was undertaken based on calorimetric measurements that reveal that the enthalpy of formation for the RP perovskites is negative while for the DJ perovskites is positive. Film stability tests demonstrate consistent observations with the thermochemical findings, where RP lead iodide perovskites are both thermodynamically and environmentally stable candidates for optoelectronic applications. Additionally, the methodical tailoring of the 2D perovskite structure's composition (organic and inorganic component), unveils trends in the comparison of 2D lead iodide and bromide perovskites, for the acquisition of halide perovskites with enhanced stability. Structural – crystallographic analysis of bulk, layered perovskites provides atomistic insight to control these materials' stability. Our work highlights the importance of the rational assessment of stability in 2D hybrid halide perovskites for the optimal synthetic design and engineering of environmentally robust perovskite materials for next-generation optoelectronic devices.

8:15 PM EL02.04.01
Late News: Highly Efficient Halide Perovskite Light-Emitting Diodes via Molecular Passivation Kang Wang, Aihui Liang and Letian Dou; Purdue University, United States

Metal halide perovskites are promising for applications in light-emitting diodes (LEDs), but still suffer from defects-mediated nonradiative losses, which represent a major efficiency-limiting factor in perovskite-based LEDs (PeLEDs). Here, we synthesized a series of new phenyl and thienyl-based molecular passivators with ammonium, formamidinium and imidazolium terminal groups, to examine the effects of different anchoring groups on defect passivation. After introducing the passivators, the as-prepared perovskite thin films display improved optoelectronic properties with low nonradiative recombination rate and high PLQY as well as reduced grain size and surface roughness. On this basis, we demonstrate highly efficient PeLEDs with an EQE of 15.6% using a novel imidazolium terminated passivator. Employing grazing incidence wide-angle X-ray scattering technique and single-crystal analysis, we further confirm that the in-situ formation of low-dimensional perovskite phase on the surface of 3D perovskite nanograins is responsible for the surface defects passivation, which lead to significantly enhanced device performances. This work not only provides us a deep insight into the interaction of organic molecules with perovskite lattice for defects passivation, but also guides the beginning of a new realm of molecular engineering for the development of high-performance perovskite-based optoelectronic devices.

8:30 PM *EL02.04.02
Comprehensive Defect Suppression of Halide Perovskite Nanoparticles for High-Efficiency Light-Emitting Diodes Young-Hoon Kim[1], Sungjin Kim[1], Arvin Kakekhani[2], Andrew Rappe[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]University of Pennsylvania, United States

Metal halide perovskite nanocrystals (PNCs) are regarded as promising light-emitters due to their high photoluminescence quantum efficiency and color purity. However, the electroluminescence efficiencies of perovskite light-emitting diodes (PeLEDs) based on PNCs are limited by lack of comprehensive materials design strategy both to suppress formation of defects causing non-radiative recombination and to enhance charge carrier confinement for more radiative recombination inside PNCs. In this work, we report a

reproducible method for producing PeLEDs based on PNCs that leads to unprecedentedly high current efficiency (CE) of 108 $cd \times A^{-1}$ (external quantum efficiency (EQE) of 23.4 %) in the PeLEDs and even higher CE of 205 $cd \times A^{-1}$ (EQE of 45.5 %) with a hemispherical lens. To accomplish this, we design a simple materials alloying strategy that generates smaller, monodisperse colloidal particles (improving charge carrier confinement) with fewer surface defects (suppressing non-radiative recombination). The governing concept is elegant only with one type of large organic cation dopant in colloidal PNCs. Doping of larger guanidinium (GA) into formamidinium (FA) lead bromide PNCs yields limited bulk solubility, above which extra GA segregates to the surface and stabilizes the under-coordinated sites. In bulk of PNCs, a small concentration of GA creates an entropy-stabilized phase. Increasing GA concentration requires higher surface/volume, leading to smaller PNCs for more carrier confinement inside PNCs. Additionally, the one dopant alloying strategy in PNCs was combined with a surface stabilizing a 1,3,5-tris(bromomethyl)-2,4,6-triethylbenzene overcoat which acts as a Br vacancy healing agent. Our world-leading efficiencies demonstrate that this design strategy provides a clear pathway to translate PNCs into PeLEDs for a new generation of high-efficiency display applications.

Achieving Bright and Stable Perovskite Light-Emitting Diodes via Surface Engineering Ni Zhao and Yuwei Guo; The Chinese University of Hong Kong, Hong Kong

In recent years metal halide perovskite based LEDs (PeLEDs) have attracted increasing research attention due to their solution processability and extraordinary electroluminescence performances. However, many PeLEDs exhibit significantly degraded radiance or shifted emission wavelength within hours of operation, thus limiting the practical applications of this technology. In this talk I will introduce our recent efforts in addressing the stability issues in high-efficiency PeLEDs. Firstly, the importance of eliminating iodide residues in the perovskite emissive layer will be discussed. Applying extensively excess ammonium halides in forming perovskites is a widely used approach to achieve high-performance PeLEDs. However, most of these PeLEDs suffer from severe external quantum efficiency (EQE) roll-off at high current densities, thereby restricting the realization of high-brightness PeLEDs and laser diodes. By combining voltage-dependent electrical stress measurements and *ex-situ* ion distribution analysis of the PeLEDs, we found that the electric-field driven diffusion of excess iodide ions, originated from the non-stoichiometric precursors, plays a dominant role in the EQE roll-off. Based on this discovery, we introduced a simple wash-off treatment with chloroform to remove the excess iodides from the perovskite surface and demonstrated that the treatment is highly effective in suppressing the roll-off behavior. Secondly, we further explored surface treatment of the $FAPbI_3$ perovskite films with phenylalkylammonium iodide molecules of varying alkyl chain lengths. Combining experimental characterization and theoretical modelling, we show that these molecules stabilize the perovskite through suppression of iodide ion migration. The stabilization effect is enhanced with increasing chain length due to the stronger binding of the molecules with the perovskite surface, as well as the increased steric hindrance to reconfiguration for accommodating ion migration. The passivation also reduces the surface defects, resulting in a high radiance and delayed EQE roll-off. Using the optimized passivation molecule, phenylpropylammonium iodide, we achieved a high radiance of 1282.8 $W/(sr \times m^2)$, a high critical current density (the current density corresponding to half of the EQE_{max}) of 2400 $mAcm^{-2}$ and a record T_{50} half-lifetime of 130 hrs under a high bias current density of 100 mA/cm^2.

10:00 PM *EL02.04.05
Dimensional, Interface and Optical Engineering for Efficient Blue and White Perovskite Light-Emitting Devices Hin-Lap Yip; South China University of Technology, China

Metal halide perovskite light-emitting diodes (PeLEDs) show great potentials to be the next-generation lighting technology, with external quantum efficiencies (EQEs) exceeding 20% for infrared, red and green LEDs. However, the efficiencies of blue and white devices severely lag behind. To improve the performance of blue

PeLEDs, we employed an integrated strategy combining dimensional engineering of perovskite film and recombination zone modulation in the LED device to obtain an EQE up to 5 %.[1] While further incorporating the strategy of interfacial engineering, highly efficient blue PeLEDs with EQEs over 10% have been successfully realized in our group, establishing an excellent platform for white-light emission. In our latest work, we demonstrated efficient white PeLEDs by optically coupling a blue PeLED with a red emitting perovskite nanocrystal layer in an advanced device structure, which allows to extract the trapped optical modes (waveguide and SPP modes) of blue photons in the device to the red perovskite layer via near-field effects. As a result, a white PeLEDs with EQE over 10% is achieved, which represents the state-of-the-art performance for white PeLEDs.

A Mechanistic Study on the Spectral Instability of Light-Emitting Diodes Based on Layered Mixed Halide Perovskites Yoonseo Nah[1], Omar Allam[2,2], Han Seul Kim[3], In Soo Kim[4], Seung Soon Jang[2] and Dong Ha Kim[1,1]; [1]Ewha Womans University, Korea (the Republic of); [2]Georgia Institute of Technology, United States; [3]Korea Institute of Science and Technology Information, Korea (the Republic of); [4]Korea Institute of Science and Technology, Korea (the Republic of)

Quasi-2D layered halide perovskites have been demonstrated as a promising class of materials for light-emitting applications. The interests in this class of materials derives from its attractive features including strong light absorption, narrow emission and unprecedented defect tolerance. Furthermore, halogen alloying offers an effective way for the finetuning of bandgap energy, hence a wide range of emission colors can be achieved by using mixed halide perovskites (MHPs). However, light-emitting diodes based on MHPs exhibit significant spectral shifts during the operation, which suggests that the fundamental understanding of the effects of mixed halide compositions should be preceded. Here, we report a novel mechanism of the spectral instability of layered mixed halide perovskites containing bromide and iodide. X-ray diffraction and absorption measurement indicate the uniform distribution of anions in the ambient environment. However, strong electric field which is applied during the device operation is found to drive the systematic migration of halides. The quantum mechanical density functional theory calculations reveal that slow equatorial-to-apical diffusion of bromide is responsible for the halide redistribution. In-depth analysis on the electroluminescence spectra also confirm that the spectral instability is responsible for the anion migration. Finally, we suggest that the dominant red electroluminescence from layered MHPs is attributed to the thermodynamically favored hole injection process. It is envisioned that our comprehensive study will provide new insights into the mechanism of spectral instability of multilayer electroluminescence devices based on MHPs.

Late News: Synergistic Effect of A-Site Engineering and Surface Treatment in Tin Halide Perovskite Solar Cells Muhammad Akmal Kamarudin[1], Shahrir Razey Sahamir[1], Daisuke Hirotani[2], Kohei Nishimura[1], Kenji Yoshino[3], Takashi Minemoto[4], Qing Shen[1] and Shuzi Hayase[1]; [1]The University of Electro-Communications, Japan; [2]Kyushu Institute of Technology, Japan; [3]University of Miyazaki, Japan; [4]Ritsumeikan University, Japan

Tin halide perovskite solar cells have attracted attention due to the less toxic nature of tin compared to lead compound. Currently, the efficiency of tin-based perovskite solar cells now reaching more than 13 % slowly catching up with that of lead-based perovskite solar cells showing the promise of tin-based perovskites. However, there are several issues with tin-based perovskites that need to be addressed in order for these materials to compete with lead-based perovskites. The susceptibility of Sn^{2+} to oxidize into Sn^{4+} upon exposure to air reduces the long-term device stability and this phenomenon also caused major surface recombination which will result in low open-circuit voltage. In addition, the energy levels in tin halide perovskites are shallow compared to that of lead-based perovskites which result in large energy mismatch when common charge transport carriers are used. In this work, we performed simultaneous A-site substitution and surface treatment on tin-halide perovskites to achieve efficiency of more than 10 % and device stability of more than 300 h. Upon partial A-site substitution, the energy barrier has been effectively reduced especially at the hole transport layer/perovskite interface leading to efficient hole carrier injection. While the surface passivation suppressed the formation of unreacted Sn species and hence surface recombination issue has been addressed successfully. Our hypotheses have been supported using Mott-Schottky and Electrochemical Impedance Spectroscopy measurements showing reduced intrinsic carrier density and enhanced carrier recombination resistance. Using X-ray Photoelectron Spectroscopy measurements, we confirmed the suppression of under-coordinated Sn species and oxidized Sn^{4+}.

Controlling Orientation of VLS-Grown Lead Iodide van der Waals Nanowires Leeku Huh and Naechul Shin; Inha University, Korea (the Republic of)

Lead iodide (PbI_2) with van der Waals (vdW) layered crystal structure is widely used as a precursor to prepare lead halide perovskites (LHPs) for diverse applications such as photovoltaics (PVs) or optoelectronics. Although the recent advances in the LHPs-based device applications are mainly based on the thin film-based technologies, fabrication of low-dimensional structures in precise manner would be beneficial for the enhancement of their physical properties. 1D nanowire is of particular interest since its structure intrinsically allows the increase in the light absorption, carrier lifetime, and mobilities, compared to its bulk counterpart. Furthermore, the ability to engineer the structure of 1D nanowires (e.g., phase, orientation, and heterojunction) promises advanced exploitation of the properties, as previously demonstrated for group VI or III-V semiconductor material system.
Here, we demonstrate that PbI_2 nanowires grown *via* vapor – liquid – solid (VLS) method, originally composed of vdW layers stacked along [0001] axis, can switch their orientation (i.e., kinking) by introducing $PbBr_2$ during the growth. Specifically, we can control two different types of kinking modes: (1) orientation with twin boundary (TB) formation, (2) orientation without TB, by differing the Br exposure time. Our systematic study controlling VLS growth parameters indicates that the incorporation of Br to the catalytic Pb seeds disturbs the triple-phase-line (TPL) and change interface energy, which determines the mode of kinking according to the Br concentration. Our kinked PbI_2 nanowires having different vdW stacking in a single domain exhibit interesting optical property such as localized photoluminescence and waveguide effect, suggesting their potential use in photonics or optoelectronics.

Late News: Formation Thermodynamics, Stability, and Decomposition Pathways of Perovskite Halides APbX3 (A = methylammonium, Cs; X = Cl, Br, I) and Their Solid Solutions Dmitry S. Tsvetkov, Maxim Mazurin, Vladimir Sereda, Ivan Ivanov, Dmitry Malyshkin and Andrey Zuev; Ural Federal Univ, Russian Federation

Standard enthalpies of formation of $APbX_3$ (A = methylammonium, Cs; X = Cl, Br, I) perovskites and their solid solutions $APb(X_{1-z}X'_z)_3$ from halides and from elements at 298 K were measured using solution calorimetry. Standard entropies of $CsPbX_3$ (X = Cl, Br, I) at 298 K were determined using the results of EMF measurements of galvanic cells. Intrinsic and extrinsic stabilities of studied halides were analyzed and

compared with each other. The main difference between the stabilities of $CsPbX_3$ and $CH_3NH_3PbX_3$ halides was found to stem from the different chemical nature of cesium and methylammonium cations. Indeed, the enthalpies of formation of $CsPbX_3$ from binary constituent halides, $\Delta_fH_{hal}^\circ$, are only slightly more negative than those of $CH_3NH_3PbX_3$. Small values of $\Delta_fH_{hal}^\circ$ imply that the entropic contribution to the Gibbs free energy of formation of $CsPbX_3$ and $CH_3NH_3PbX_3$ is significant and, hence, of utmost importance for understanding the intrinsic stability of these compounds and their analogs. Regarding the extrinsic stability, the presence of gaseous O_2, H_2O, and CO_2 was shown to be crucial for the stability of the iodide, $CsPbI_3$, for which several decomposition reactions, exergonic at 298 K, were identified. At the same time, chloride, $CsPbCl_3$, and bromide, $CsPbBr_3$, are much less sensitive to these chemical agents. However, liquid water should degrade all the $CsPbX_3$ halides.

Tin-Halide Perovskite Semiconductors—Defects Photophysics and Optimized Devices Architectures
Annamaria Petrozza; Center for Nano Science and Technology, Italy

Here, I will summarize our understanding of the nature of defects and their photo-chemistry in tin-halide perovskites thin films. We show that, in inert conditions, tin, p-doped, and lead (intrinsic) based perovskite thin film show comparable photoluminescence quantum yield, at comparable morphology. The thin film is also extremely stable under light soaking. On the other hand, photovoltaic devices, showing comparable device architecture show a dramatic reduction in power conversion efficiency for tin based devices. While so far, most of the community effort has been focused on the optimization of the perovskite thin film, very little work has been done on the design of the solar cell architecture. Here we will show new architectures for making tin based solar cells a competitive solution.

Dependence of Phase Transitions on Halide Ratio in Inorganic $CsPb(Br_xI_{1-x})_3$ Perovskite Thin Films Obtained from High-Throughput Experimentation
Hampus Näsström[1,1], Pascal Becker[1,1], Jose Marquez Prieto[1], Oleksandra Shargaieva[1], Roland Mainz[1], Eva Unger[1,2] and Thomas Unold[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Lund University, Sweden

Inorganic Cs-based lead halide perovskites have recently experienced a surge in interest, in part due to their enhanced stability compared with hybrid perovskites. The mixed $CsPb(Br_xI_{1-x})_3$ is especially interesting due to the tunable bandgap in the optimal range suitable for tandem solar cells as well as light emitting devices. However, in contrast to the pure $CsPbI_3$ and $CsPbBr_3$, there has been very few investigations on the crystal phase dynamics of the halide mixture. In this work, we present the phase diagram of $CsPb(Br_xI_{1-x})_3$ ($0 \leq x \leq 1$, 300–585 K) obtained by high-throughput in situ GIWAXS measurements of a combinatorial thin film library[1]. The thin film library is produced by combinatorial inkjet printing and measured at a high-flux liquid metal jet source. After synthesis, the films with lower Br/I ratio exhibit the non-photoactive delta-phase at room temperature, whereas the films with higher I/Br ratios are present in the metastable perovskite gamma phase. We find that during heating all compositions convert to the cubic perovskite phase at high temperature and that the presence of bromide in the films stabilizes the metastable perovskite phases upon cool down. In accordance with recent predictions from DFT-calculations, the phase transition temperatures are found to monotonically decrease with increasing bromide content.

Late News: Glass Formation in Metal Halide Perovskites
Akash Singh, Manoj K. Jana and David B. Mitzi; Duke University, United States

Crystalline metal halide perovskites (MHPs) have shown tremendous significance in the past decade, leading to momentous advancement in the interdisciplinary fields of materials, electronics and photonics. So far, these studies heavily focused on crystalline MHPs. Though crystallinity offers numerous advantages, the ability to induce glass formation in such semiconductors could provide unique opportunities to extend the associated structure-property relationships and broaden their application space. Despite significant efforts to amorphize MHPs under high pressure, an immediate reversal to a crystalline state upon pressure removal has so far impeded the study of the glassy MHP state and associated practical application, thus necessitating alternative routes. Further, the ability to melt-quench hybrid MHPs has largely been limited due to (i) degradation/loss of the organic component upon heating above 200°C and (ii) super-fast ordering kinetics of these melts. Herein, we demonstrate the first example of glass formation at ambient pressure and reversible switching between glassy and crystalline states in hybrid MHPs. Drawing inspiration from structure-property studies of chiral vs. racemic organic systems, we exploit bulky aromatic chiral organic cations to modify the bonding and packing characteristics and thereby enable an exceptionally low melting temperature (T_m = 175°C) below the degradation point ($T_d \approx$ 205°C), as well as slow ordering kinetics in the exemplary 2D S-(-)-1-(1-naphthyl)ethylammonium lead bromide chiral MHP. These factors provide facile access to a stable glassy state of the said chiral MHP by melt-quenching both in thin-film and monolith configurations. Furthermore, the components of the melt can recrystallize (at $T_x \approx$ 100°C) upon heating above the glass-transition temperature ($T_g \approx$ 67°C), allowing reversible switching between the glassy and crystalline states with characteristic temperatures obeying the atypical sequence for MHPs, $T_g < T_x < T_m < T_d$. Formation of a semiconducting MHP glass, along with the demonstration of thermally-induced reversible switching between the glassy and crystalline states, each offering distinct semiconducting properties, unlocks a new research domain for MHPs with numerous prospective applications spanning the research fields of memory, computing, photonics, catalysis, batteries and meta-surfaces.

Understanding Function of Extrinsic Metal Ions in Perovskites Jinsong Huang; University of North Carolina at Chapel Hill, United States

Successful application of metal halide perovskites in different technologies stems from their demonstrated exceptional optoelectronic properties such as a long charge carrier diffusion length, tunable bandgap, low mid-bandgap trap density, high absorption coefficient, and efficient photoluminescence. However, one question still to be answered is whether these properties, particularly for those polycrystalline films used in most optoelectronic devices, are of intrinsic or extrinsic nature. For example, among all the intriguing optoelectronic properties of the polycrystalline thin perovskite films, the long carrier recombination lifetime is most attractive as it enables efficient perovskite solar cells. I will present some intriguing observation of how extrinsic metal ions affect the materials Morphology, optoelectronic properties and stability.

Nonradiative Energy Transfer and Long-Range Exciton Diffusion in Thickness-Controlled Halide Perovskite Nanoplatelets Andreas Singldinger, Michael Lichtenegger, Jan Drewniok, Moritz Gramlich, Carola

Lampe and Alexander Urban; Ludwig-Maximilians-Universität München, Germany

Despite showing great promise for optoelectronics, the commercialization of halide perovskite nanostructure-based devices is hampered by inefficient electrical excitation and strong exciton binding energies. To counteract these problems, an understanding of energy- and charge transfer processes in this material is crucial. Here, we study Förster resonance energy transfer (FRET) and charge carrier diffusion processes in quantum-confined two-dimensional $CsPbBr_3$-based nanoplatelets (NPls). In thin films of NPls with two predetermined thicknesses, we observe an enhanced acceptor photoluminescence (PL) emission and a decreased donor PL lifetime. This indicates a FRET-mediated process, benefitted by the structural parameters of the NPls and with efficiencies of nearly $\eta_{FRET} = 70\%$.[1] Additionally, films comprising NPls of one thickness show signs of FRET-enabled long-range exciton diffusion with diffusion lengths of several hundred nanometers. Ultimately, a tailored energy funnel, in combination with a high diffusion length for perovskite NPls could substantially improve the efficiency of blue-emitting nanostructure-based optoelectronic devices.

11:10 AM EL02.06.03
Late News: Assessing Charge Carrier Extraction Rates in Halide Perovskite Heterojunctions Using Ultrafast THz and Optical Spectroscopies Edward Butler-Caddle[1], Imalka Jayawardena[2] and James Lloyd-Hughes[1]; [1]University of Warwick, United Kingdom; [2]University of Surrey, United Kingdom

Lead halide perovskites are one of the leading candidates as the light absorbing layer for new photovoltaic devices[1]. As the fabrication of high quality perovskite layers has matured, the optimisation of the charge selective contacts has become increasingly important[2].

In a solar cell, the device asymmetry necessary to generate a photocurrent and photovoltage is provided by electron or hole selective transport layers (TLs) on either side of the light absorbing layer. At each interface, carrier selectivity may be provided by the relative band alignment, and can also be affected by any built-in fields at the interface. Built-in fields can also affect the interfacial recombination that competes with current extraction, so can have an important role in device performance. Together the two TLs may provide a built-in field throughout the perovskite layer which aids charge separation in the bulk.

Here we report time-resolved measurements of charge extraction into commonly used charge transport layers, by using the terahertz photo-conductivity, transient optical absorption and photoluminescence as non-contact spectroscopic probes. In order to isolate the carrier dynamics at a single interface, experiments were performed on bilayers consisting of the perovskite layer and a single transport layer. By investigating each transport layer in isolation, bulk fields were avoided and the behaviour of each interface was isolated independently.
In this work we studied bilayers consisting of commonly used transport layers (Spiro-OMeTAD, PCBM and C60) deposited on top of a high-performance triple cation mixed halide perovskite[3] layer $(FA_{0.79}MA_{0.16}Cs_{0.05})Pb(I_{0.83}Br_{0.17})_3$. The ground-state bleach of the interband transitions (observed via transient absorption spectroscopy) probed the carrier density change, while the THz photoconductivity probed the product of the carrier density and mobility. By comparing the two techniques, the relative mobility of electrons and holes can also be observed, with holes found to have higher mobility. The optical techniques used here avoided the need for additional contacts, which may influence the data or confuse the interpretation of the results.

By tuning the optical excitation wavelength we created different initial carrier distributions in the perovskite. When using a short excitation wavelength to generate carriers close to the interface with the transport layer, rapid carrier extraction (within a picosecond) was observed, whereas when photogeneration was concentrated on the far side, negligible carrier extraction was observed over the first 3ns. Conversely, when using longer wavelengths to generate carriers more uniformly through the depth of the perovskite layer, very little extraction was observed over the first few nanoseconds. Therefore, concentrating carriers near the transport layer interface

gave extraction rates that were order of magnitudes faster than expected from diffusion alone.

We identify band bending near the interface as a potential route by which rapid charge extraction can occur. We explored the possible scenarios of drift-limited and diffusion-limited transport through a numerical solution to the drift-diffusion and Poisson equations. The importance of band bending (built-in fields) at the interface in perovskite heterojunctions was assessed.

Long-Range Hot Carrier Transport in Hybrid Perovskites Visualized by Ultrafast Microscopy Libai Huang; Purdue University, United States

The Shockley-Queisser limit for solar cell efficiency of ~ 33% can be overcome if hot carriers can be harvested before they thermalize. Recently, carrier cooling time up to 100 picoseconds was observed in hybrid organic-inorganic lead halide perovskites, but it is unclear whether these long-lived hot carriers can migrate long distance for efficient collection. We report direct visualization of hot carrier migration in $CH_3NH_3PbI_3$ thin films by ultrafast transient absorption microscopy, demonstrating three distinct transport regimes. Quasi-ballistic transport was observed to correlate with excess kinetic energy; resulting in up to 230 nanometers transport distance in 300 fs that could overcome grain boundaries. The nonequilibrium transport persisted over tens of picoseconds and ~ 600 nanometers before reaching the diffusive transport limit. These results suggest potential applications of hot carrier devices based on hybrid perovskites.

11:55 AM EL02.06.05
Light-dependent Impedance Spectra and Transient Photoconductivity in a Ruddlesden–Popper 2D Lead-Halide Perovskite Revealed by Electrical Scanned Probe Microscopy John A. Marohn[1], Ali Tirmzi[1], Ryan P. Dwyer[2] and Fangyuan Jiang[3]; [1]Cornell University, United States; [2]University of Mount Union, United States; [3]University of Washington, United States

We recenlty used electric force microscopy to discover persistent light-induced conductivity in a range of 3D lead-halide perovskite semiconductors. Here electric force microscopy was used to record the light-dependent impedance spectrum and time-resolved photoconductivity of a film of butylammonium lead iodide, BA_2PbI_4, a 2D Ruddlesden--Popper perovskite semiconductor. The impedance spectrum of BA_2PbI_4 showed modest changes as the illumination intensity was varied up to 1400 mW/cm^2, in contrast with the comparatively dramatic changes seen for 3D lead-halide perovskites under similar conditions. BA_2PbI_4 's light-induced conductivity had a rise time and decay time of 100 microseconds, 10^4 slower than expected from direct electron-hole recombination and yet 10^5 faster than the conductivity-recovery times recently observed in 3D lead-halide perovskites and attributed to the relaxation of photogenerated vacancies. What sample properties are probed by electric force microscope measurements remains an open question. A Lagrangian-mechanics treatment of the electric force microscope experiment was recently introduced by Dwyer, Harrell, and Marohn which enabled the calculation of steady-state electric force microscope signals in terms of a complex sample impedance. Here this impedance treatment of the tip-sample interaction is extended, through the introduction of a time-dependent transfer function, to include time-resolved electrical scanned probe measurements. It is shown that the signal in a phase-kick electric force microscope experiment, and therefore also the signal in a time-resolved electrostatic force microscope experiment, can be written explicitly in terms of the sample's time-

dependent resistance (*i.e.*, conductivity).

I will discuss the resultant photophysics and how the materials can be deployed in devices such as narrow-linewidth LEDs.

1:25 PM *EL02.07.02
***In Situ* Visualization of Ferroic-Ionic Interaction in Hybrid Organic Inorganic Perovskites** Olga S. Ovchinnikova; Oak Ridge National Laboratory, United States

Understanding the relationship between structure and functionality is particularly important for the future development of energy devices such as photovoltaics, batteries, catalysts, supercapacitors, optoelectronics, among a myriad of other important applications. In virtually all cases, it is the local inhomogeneities and defects that ultimately control macroscopic behavior and device performance by acting as nucleation centers for new phases, interactions, or failure sites. It is only by understanding the local mechanisms that we can hope to address these problems, and in doing so understand how to improve and enable the next generation of high conversion efficiency and long lifetime for optoelectronic materials. Hybrid organic-inorganic perovskites (HOIPs) such as methylammonium lead iodide (CH3NH3PbI3) have attracted broad research interest due to their outstanding optoelectronic performance. However, fundamental understandings of the origin of high PCE and the anomalous current-voltage (I-V) hysteresis of HOIPs optoelectronic devices has proven elusive, even controversial. Although ferroelectricity has been suggested as the reason for this hysteric behavior, convincing evidence supporting this hypothesis is still incomplete. This is due in part to the strong ion motion in HOIPs that complicates the ferroic characterization. Here, using multi-modal functional and chemical imaging methods, we unveil the interaction between ferroic behavior and ion distribution in methylammonium lead iodide (CH3NH3PbI3 or MAPbI3). We demonstrate *in-situ* interaction of ions under the effect of local fields by introducing a new in-situ imaging mobility for time-of-flight secondary ion mass spectrometry (ToF-SIMS). By combining x-ray diffraction and ToF-SIMS we show that the ion redistribution is accompanied by a change in lattice strain, which is reversible. Additionally, Kelvin Probe Force Microscopy (KPFM) demonstrated a screening effect of the electric field and polarization in CH3NH3PbI3 caused by ion migration. Overall, we demonstrate that local ion distribution can manipulate the formation of ferroelastic twin domain, providing a pathway to manipulate ferroelastic twin domains and hence optimize optoelectronic properties of HOIPs. This work offers an understanding of ferroic-ionic interplay in HOIPs, providing a pathway to develop novel devices based on HOIPs.

1:50 PM EL02.07.03
Tunable Broad Light Emission from 3D Bromide Perovskites Through Defect Engineering Ioannis Spanopoulos[1], Ido Hadar[1], Weijun Ke[1], Peijun Guo[2], Eve Mozur[3], Emily Morgan[3], Shuxin Wang[3], G. N. Manjunatha Reddy[4], Ram Seshadri[3], Richard Schaller[1] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States; [3]University of California, Santa Barbara, United

States; [4]University of Lille, France

Hybrid halide perovskites have proven to be prominent candidates for many commercial applications, and despite their solution processable synthetic protocols, the resulting films and single crystals demonstrate a combination of optoelectronic properties which are not found to their fully inorganic semiconductor competitors. These features are attributed partly to their inherent defect tolerance.
In this work we take advantage of their defect tolerance to engineer a new family of 3D highly defective "hollow" bromide perovskites with general formula $(FA)_{1-x}(en)_x(Pb)_{1-0.7x}(Br)_{3-0.4x}$ (FA = formamidinium, *en* = ethylenediammonium, x = 0-0.44). The corresponding materials were characterized by a battery of techniques, including single crystal X-ray diffraction (XRD), high resolution powder X-ray diffraction (PXRD), and solid state nuclear magnetic resonance (NMR) measurements. Pair distribution function (PDF) analysis shed light on the local structural coherence, revealing a wide distribution of Pb-Pb distances in the crystal structure, validating further that the corresponding materials are lead deficient and that *en* inclusion has the same structural effect as in the case of the "hollow" iodide analogs.
By manipulating the number of defects, we finely tuned the optical properties of the pristine $FAPbBr_3$, by blue shifting the band gap from 2.20 eV to 2.60 eV for the 42% *en* sample. A most unexpected outcome was the fact that above 40% *en* incorporation the material exhibits strong broad light emission with 1% photoluminescence quantum yield (PLQY), that is maintained after exposure in air for more than a year. This is the first example of strong broad light emission from a 3D hybrid halide perovskite and is a clear demonstration that defect engineering can be utilized in our favour to add unusual, exotic optoelectronic properties to this versatile class of materials.

Subgrain Structure and Ionic Segregation in Metal Halide Semiconductors Yongtao Liu[1,2], Patrick Trimby[3], Liam Collins[1], Mahshid Ahmadi[2], Bin Hu[2], Sergei Kalinin[1], Roger Proksch[4] and Olga S. Ovchinnikova[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oxford Instruments Nanoanalysis, United Kingdom; [4]An Oxford Instruments Company, United States

Metal halide perovskites (MHPs) solar cells have shown great potential for optoelectronic applications. Although it has been well established how grain, grain boundary, and grain facet affect MHPs optoelectronic properties, less is known about subgrain structures. Recently, a sub-grain feature, twin domain, in MHPs has stimulated extensive discussion. Numerous calculation works have indicated that both domains and domain walls can significantly influence the optoelectronic properties of MHPs, while related experimental results are still missing. In this work, using electron backscatter diffraction (EBSD) and multiple advanced piezoresponse force microscopy (PFM) we studied the crystallographic and ferroic properties of twin domains in MHPs, respectively. Using EBSD, we identified the orientation relationship across the twin boundaries in $CH_3NH_3PbI_3$ and the directions parallel to the surface normal. Then, we performed multiple advanced PFM measurements to investigate whether the origin of PFM signals of these twin domains is ferroelectricity. We also investigated the behavior of twin domains and domain walls in polarization switching measurement and discovered nonferroelectric contributions to polarization switching measurement. Combining EBSD and PFM study, we found that the PFM signal in $CH_3NH_3PbI_3$ in the directions parallel to the surface normal (identified by EBSD) is not originated from piezoelectricity/ferroelectricity. These measurements were also carried out to study low-dimensional (2D) metal halide materials. A number of interesting phenomena have also been observed in 2D metal halide materials, including ferroic twinning, ion segregation, photoinduced strain, etc. This work offers a

picture describing the crystallographic orientation, twin domains, domain walls in MHPs, which is crucial for understanding the influence of subgrain structure on the optoelectronic properties of metal halide semiconductors.

Donor Doping of $CsPbBr_3$ John L. Lyons; U.S. Naval Research Laboratory, United States

The inorganic lead halide perovskite $CsPbBr_3$ exhibits many outstanding properties, in addition to possibly offering environmental stabilities better than their hybrid perovskite counterparts. The full utilization of these materials in optoelectronic applications would be aided by gaining the ability to control the electrical conductivity via impurity doping. One possible donor, bismuth, has been found to enhance solar cell efficiency, and an increase in the position of the Fermi level upon doping. Here I examine how bismuth incorporates into $CsPbBr_3$ using first-principles hybrid density functional theory. The stability of different configurations is considered as a function of chemical potential and Fermi level. Although bismuth prefers to substitute for lead under most conditions, it introduces a deep donor level ~500 meV from the conduction-band minimum, indicating it will not efficiently generate free carrier concentrations. Based on these results, doping strategies for $CsPbBr_3$ are reconsidered.

Late News: Surface Energy-Driven Preferential Grain Growth of Metal Halide Perovskites—Effects of Nanoimprint Lithography Beyond Direct Patterning Jiyoung Moon[1], Sunah Kwon[1], Masoud Alahbakhshi[1], Yeonghun Lee[1], Kyeongjae Cho[1], Anvar Zakhidov[1,2], Moon J. Kim[1] and Qing Gu[1]; [1]University of Texas at Dallas, United States; [2]ITMO University, Russian Federation

Hybrid organic−inorganic lead halide perovskites have attracted much attention in the field of optoelectronic devices because of their desirable properties such as high crystallinity, smooth morphology, and well-oriented grains. In addition, they can be easily implemented in many platforms using deposition techniques such as spin coating, methylamine gas vapor annealing, and vapor-assisted/gas-assisted solution processing.[1] However, direct patterning of perovskites is known to be challenging because they degrade when exposed to polar solvents and to UV and high electron energies that are used in photo- and e-beam lithography.[2] Recently, it was shown that thermal nanoimprint lithography (NIL) is an effective method not only to directly pattern but also to improve the morphology, crystallinity, and crystallographic orientations of annealed perovskite films.[3,4] However, the underlining mechanisms behind the positive effects of NIL on perovskite material properties have not been understood. In this work, we study the kinetics of perovskite grain growth with surface energy calculations by first-principles density functional theory (DFT) and reveal that the surface energy-driven preferential grain growth during NIL, which involves multiplex processes of restricted grain growth in the surface-normal direction, abnormal grain growth, crystallographic reorientation, and grain boundary migration, is the enabler of the material quality enhancement. Moreover, we develop an optimized NIL process and prove its effectiveness by employing it in a perovskite light-emitting electrochemical cell (PeLEC) architecture, in which we observe a fourfold enhancement of maximum current efficiency and twofold enhancement of luminance compared to a PeLEC without NIL, reaching a maximum current efficiency of 0.07598 cd/A at 3.5 V and luminance of 1084 cd/m^2 at 4 V.

Deep Levels in Cesium Lead Bromide from Native Defects and Hydrogen Michael W. Swift and John L. Lyons; U.S. Naval Research Laboratory, United States

Lead halide perovskites such as CsPbBr3 have attracted widespread attention as optoelectronic materials, due in large part to their good performance despite high defect densities. This “defect tolerance” has often been explained by hypothesizing that there is negligible trap-assisted nonradiative recombination in these materials because none of the dominant defects give rise to deep levels in the gap. We refer to this as the “shallow defect hypothesis” (SDH). In this work, we reject the SDH for CsPbBr3. Via a thorough first-principles inventory of native defects and hydrogen impurities, we show that a number of relevant defects do in fact have deep levels, most notably the bromine interstitial and hydrogen interstitial. This adds to a growing body of evidence against the SDH, suggesting that the observed defect tolerance may be due instead to relatively low recombination rates at deep levels. Guided by the theoretical identification of these defects, experiments can take steps to mitigate trap-assisted non-radiative recombination, further boosting the efficiency of lead halide perovskite optoelectronics.

Late News: Ultraflexible Perovskite X-Ray Detectors Interface Engineering Stepan Demchyshyn[1,1], Matteo Verdi[2], Laura Basirico[2,3], Andrea Ciavatti[2,3], Bekele Heilegnaw[1,1,1], Daniela Cavalcoli[2], Markus Scharber[1], Niyazi Serdar Sariciftci[1], Martin Kaltenbrunner[1,1] and Beatrice Fraboni[2,3]; [1]Johannes Kepler Universität Linz, Austria; [2]Università di Bologna, Italy; [3]National Institute for Nuclear Physics, Italy

The world around us consists of a myriad of objects with curved geometries and complex surfaces, yet the majority of sensors and detectors that we use to study them are rigid and planar. While state-of-the-art X- and gamma-ray detectors based on Si, a-Se, HgI_2 and CdZnTe have tremendously advanced the field of digital X-ray radiography, their mechanical stiffness, high thickness, and mass impose limits on their application and ultimate performance. Here we present first ultraflexible, lightweight, and highly conformable perovskite X-ray detectors, showing excellent performance that was achieved by means of thorough interfacial engineering study [1]. Our devices with an active area of 0.05 cm^2 show sensitivity of 9.3 ± 0.5 $\mu C\ Gy^{-1}\ cm^{-2}$ operated at 0 V (passive mode operation) with limit of detection down to 0.58 ± 0.05 $\mu Gy\ s^{-1}$ setting a current record for passive thin film perovskite detectors. Moreover, these ultraflexible detectors allow for isotropic operation, reliably

detecting X-rays impinging either on the back or the front side of the device. Ultraflexible, low-cost, and highly sensitive high energy radiation detectors are of great interest to the fields of medical diagnostics, dosimetry, industrial inspection,security, and defense. Low weight and high conformability of X-ray wearable dosimeters are appealing features for astronauts, nuclear power plants, and laboratory workers, as well as for imagers used in structural inspection and cultural heritage preservation.

Performance Losses in Perovskite Solar Cells Under Reverse Bias Due to Electrochemical Halide Reactions Jay Patel[1,2], Luca Bertoluzzi[3], Kevin Bush[3], Caleb Boyd[3,1], Ross Kerner[1], Brian O'Regan[4] and Michael McGehee[2,1]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States; [3]Stanford University, United States; [4]Sunlight Scientific, United States

Metal halide perovskite solar cells are now nearly as efficient as the best silicon solar cells but could cost less and be made with a less energy-intensive fabrication process. One of the most significant, but frequently overlooked challenges that must be addressed to allow commercialization of perovskite devices is their degradation under partial shading. When a solar cell is shaded in a module, the photogenerated current drops and a negative voltage (reverse bias) builds up as the other illuminated cells in series try to drive current through, leading to undesired efficiency losses.(*1*, *2*) Moreover, metal-halide perovskite-based photodetectors are showing real potential as x-ray detectors for medical imaging purposes. X-ray detectors are mainly operated in reverse bias for fast extraction of charge carriers.(*3*)However there have been very few studies, investigating the behavior of devices under prolonged reverse bias. (*2*, *4*, *5*)

It is imperative to understand how these devices behave under reverse bias. Applying -1 V to -5 V (reverse bias) for a few seconds on perovskite devices with metal contacts induces irreversible device shunting and significant device degradation.(*2*) Additionally, reports have shown some semi-transparent device architectures display substantial "s-kink" behavior in their *J-V* scans after placed under extended reverse bias.(*4*) However, the "s-kink" behavior is only one particular case of the reverse bias behavior. Many devices generally undergo short circuit, open circuit voltage and/or fill factor losses. Additionally, there have been observations of reverse bias induced halide phase segregation.(*2*, *4*) Consequently, while several processes may be occurring at reverse bias, the mechanisms provided do not entirely explain the severe efficiency losses (>50%) measured after reverse bias.

Here, we use an advanced drift-diffusion approach incorporating an electrochemical term to elucidate the short-circuit, open circuit and fill factor losses we experimentally measure after prolonged reverse bias. We show that holes can tunnel into the perovskite due to sharp band bending near the contacts, accumulate within the bulk of the perovskite absorber, and trigger the oxidation of halides. The density of the oxidized halide species is much higher in reverse bias as there are scarcely any electrons available to reduce the halogens. The resultant halogens act as bulk recombination centers. While the interstitial halogen density does decay when the cell is operated in forward bias, permanent degradation can occur if the iodine diffuses out of the perovskite layer. Our theory shows the significance of the mobile ions in controlling device performance and stability and suggests that reverse bias could be used to perform accelerated tests to quickly assess the robustness of perovskite devices to halide reactivity.

Tunable Perovskite-Based Photodetectors in Optical Sensing Ruth Shinar; Iowa State University, United States

There is a continued and growing need for miniaturization of sensors to enable their integration into technologies, such as wearable electronics in medical testing and (bio)chemical analyses. Perovskite-based photodetectors (PPDs) are of special interest for integration with optical sensor components due to their thin structure and exceptional attributes of high responsivity and fast response. In this presentation we demonstrate the suitability and advantage of PPDs for optical analyte sensing by monitoring not only dose-dependent changes in the photoluminescence (PL) intensity of analyte-sensitive dyes, but also by measuring the PL decay times following an excitation pulse, which is a preferred monitoring approach. Two types of highly responsive PPD structures are described: (1) PPDs with wide band responsivity that are suitable for light detection over a broad spectral range, and (2) PPDs sensitive only over a tunable narrow spectral band, which makes them suitable for multi-analyte compact sensors arrays, with analytes that are detected in different spectral ranges. We show the functionality of such PPDs for monitoring gas-phase and dissolved oxygen (DO), as well as glucose. The effect of the PPDs attributes, e.g., size, response time, and responsivity spectrum on the sensors' components, mode of operation, and characteristics, including dynamic range, sensitivity, and limit of detection will be discussed. Advantages of such PPDs in comparison to Si photodiodes, thin film amorphous and nano-crystalline Si, as well as all-organic photodetectors will also be presented.

5:00 PM EL02.08.04
Revealing Electrical Poling Induced Polarization Potential in Hybrid Perovskite Photodetectors Haiyang Zou, Zhiqun Lin and Zhong Lin Wang; Georgia Institute of Technology, United States

Despite recent rapid advances in metal halide perovskites for use in optoelectronics, the fundamental understanding of the electrical poling induced ion migration, accounting for many unusual attributes and thus performance in perovskite based devices, remain comparatively elusive. Herein, the electrical poling promoted polarization potential is reported for rendering hybrid organic inorganic perovskite photodetectors with high photocurrent and fast response time, displaying a tenfold enhancement in the photocurrent and a twofold decrease in the response time after an external electric field poling. First, a robust meniscus assisted solution printing strategy is employed to facilitate the oriented perovskite crystals over a large area. Subsequently, the electrical poling invokes the ion migration within perovskite crystals, thus inducing a polarization potential, as substantiated by the surface potential change assessed by Kelvin probe force microscopy. Such electrical poling induced polarization potential is responsible for the markedly enhanced photocurrent and largely shortened response time. This work presents new insights into the electrical poling triggered ion migration and, in turn, polarization potential as well as into the implication of the latter for optoelectronic devices with greater performance. As such, the utilization of ion migration produced polarization potential may represent an important endeavor toward a wide range of high performance perovskite based photodetectors, solar cells, transistors, scintillators, etc.

5:15 PM EL02.08.05
Perovskite-Based Sensing Scheme for Detecting Volatile Organic Compounds (VOCs) at Room Temperature Mohammad Shakhawat Hossain and Arash Takshi; University of South Florida, United States

Volatile Organic Compound (VOC) gases can contribute to the environmental pollution, leading to difficulty in breathing, nausea, eye irritation, and even damage of the central nervous system, specially in indoor environment. Sensing these gases plays a crucial role in environmental monitoring. This study aims to test the sensitivity and selectivity of methylammonium lead iodide ($MAPbI_3$) perovskites to various different VOC gases. Here, at first, microchannels were created on indium tin oxide (ITO) coated plastic substrates. The microchannels were filled with the perovskite precursor solution using the capillary motion force. After crystallization, the current-voltage (I-V) characteristic responses of the perovskite before and after the exposure to the gasses were studied, both under dark and light conditions. The variation of the photocurrent in response to ethanol, methanol, and acetone have been studied. While the sensor showed a negligible I-V changes in response to ethanol and acetone, the photocurrent was decreased by 25% when the device was exposed to methanol at 2.0 V voltage bias. The experimental results of detecting VOCs at room temperature are promising for the development of an array of low-cost and low-power perovskite-based gas sensors that can be integrated in lab-on-a-chip devices.

5:30 PM EL02.08.06
Late News: Multispectral Image Sensor Beyond Tristimulus Color Vision with Perovskites Md Wayesh Qarony[1,2] and Mohammad I. Hossain[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]The Hong Kong Polytechnic University, Hong Kong

In this study, optical multispectral sensors based on perovskite semiconductors have been proposed, simulated, and characterized. The perovskite material system combined with the 3D vertical integration of the sensor channels allows for the realization of sensors with high sensitivities and a high spectral resolution. The sensors can be applied in several emerging areas, including biomedical imaging, surveillance, complex motion planning of autonomous robots or vehicles, artificial intelligence, and agricultural applications. The sensor elements can be vertically integrated on a readout electronic to realize sensor arrays and multispectral digital cameras. In this study, three- and six-channel vertically stacked perovskite sensors are optically designed, electromagnetically simulated, and colorimetric characterizations to evaluate the color science. The proposed sensors allow for the implementation of snapshot cameras with high sensitivity. The proposed sensor is compared to other sensor technologies in terms of sensitivity and selectivity.

Influence of Charge Transport Layers on Capacitance Measured in Halide Perovskite Solar Cells Yanfa Yan; The University of Toledo, United States

To further improve the powder conversion efficiency of halide perovskite solar cells (PSCs), it is highly preferred to understand the electrical properties of the perovskite absorbers, since the PCE is determined by the electrical properties of PSCs, such as defect activation energy and density, carrier concentration, and dielectric constant. Capacitance–based techniques, such as thermal admittance spectroscopy (TAS) and capacitance–voltage (C–V), have been the choice of method for measuring electrical properties of semiconductor devices and have played important roles in the development of thin-film solar cell technologies. These techniques have been used to measure the electrical properties of PSCs such as defect activation energy and density, carrier

concentration, and dielectric constant, which provide key information for evaluating the device performance. We show that charge-transport layers can have significant influence on the measured capacitance, affecting the interpretation of the results. For example, the hole-transport layers (HTLs) can introduce high-frequency capacitance signature due to the response of charge carriers in HTLs. In literature, the so-called D1 signature was attributed to defects in perovskite defects. However, we found that the D1 signature is due to HTLs. For HTL-free PSCs, the D1 signature disappears and the high-frequency capacitance can be considered as the geometric capacitance for analyzing the dielectric constant of the perovskite layer.

8:40 PM EL02.09.02

Anisotropic Lattice Deformations Control Photocarrier Relaxation Dynamics in 2D Halide Perovskites

Hao Zhang[1,1], Wenbin Li[1,1], Joseph Essman[1], Claudio Quarti[2], Siraj Sidhik[1], Jin Hou[1], Isaac Metcalf[1], Jared Crochet[3], Mercouri G. Kanatzidis[4], Claudine Katan[2], Jacky Even[5], Jean-Christophe Blancon[1] and Aditya Mohite[1]; [1]Rice University, United States; [2]Univ Rennes, France; [3]Los Alamos National Laboratory, United States; [4]Northwestern University, United States; [5]Fonctions Optiques pour les Technologies de l'Information, France

Understanding hot-carrier cooling processes in hybrid (organic-inorganic) halide perovskites is crucial in photovoltaic applications. The dynamics of carrier-lattice interactions in perovskites strongly affect carrier lifetimes and diffusion lengths, which are key factors in device efficiency. Studies of 2D perovskite systems have revealed unique physics in terms of electron-lattice interactions, such as light-induced phonon coherences, phonon dynamical lattice disorder, and electron-phonon scattering through deformation potentials. Besides spectroscopic studies, we have performed direct structural probing of 2D perovskites using ultrafast electron diffraction (UED), and have shown multiple electron-phonon interactions during non-thermal carrier relaxation. Those electron-phonon scattering dynamics are dominated by structural deformation related to low-frequency phonon modes, induced by in-plane rotation of perovskite octahedra. Compared with the structural responses of 3D perovskites ($MAPbI_3$), our results on 2D crystals show distinct behavior in terms of both anisotropy and anharmonicity. These understandings could provide deeper insight in the dynamics of carrier-lattice interactions in 2D perovskites, and will bridge the knowledge gap of hot-carrier dynamics between 3D and 2D perovskite systems.

8:55 PM EL02.09.03

Direct Visualization of Large Polaron Formation in Hybrid Lead Halide Perovskites via Femtosecond Diffuse X-Ray Scattering

Burak Guzelturk[1], Thomas Winkler[2], Tim van de Goor[2], Matthew Smith[3], Sean Bourelle[2], Sascha Feldmann[2], Mariano Trigo[4], Samuel Teitelbaum[4], Hans-Georg Steinrück[4], Gilberto de la Pena[4], Roberto Alonso Mori[4], Diling Zhu[4], Takahiro Sato[4], Hemamala Karunadasa[3], Michael Toney[4], Felix Deschler[2] and Aaron Lindenberg[3,4]; [1]Argonne National Laboratory, United States; [2]University of Cambridge, United Kingdom; [3]Stanford University, United States; [4]SLAC National Accelerator Laboratory, United States

Lead halide perovskites uniquely offer long carrier diffusion lengths and high resilience against electronic defects, which are highly surprising for a solution-processed semiconductor. The microscopic mechanisms behind such favorable properties have not been fully understood to date. Main hypotheses revolved around dynamic structural responses and formation of large polarons in order to explain the slower carrier recombination and defect tolerances. Nevertheless, these dynamic structural aspects have not been monitored before mainly due to lack of available techniques that can track atomic-scale motions after photoexcitation. In this work, we perform optical pump / femtosecond diffuse x-ray scattering probe measurements using an x-ray electron free laser, the so-called LCLS at SLAC/Stanford [1]. The experiments clearly show that localized expansive strains build up following photoexcitation. It takes ~20 ps for the local distortions, on average, to reach about 5 nm in diameter. These lattice distortions then relax over the time window of the carrier recombination. Our finding undoubtedly demonstrates that the charge carriers in the perovskites strongly distort the atomic structure transiently while the distortion size extending over many unit cells, hence forming large polarons. In this experiment, we resolve the spatio-temporal evolution of the polarons for the first time enabled by phonon-momentum-resolved measurements in our experiment based on time-resolved diffuse x-ray

scattering.

9:15 PM EL02.09.04
Determination of Semiconductor Diffusion Coefficient by Optical Microscopy Measurements Dane W. deQuilettes[1], Roberto Brenes[1], Madeleine Laitz[1], Brandon Motes[1], Mikhail Glazov[2] and Vladimir Bulovic[1]; [1]Massachusetts Institute of Technology, United States; [2]Ioffe Institute, Russian Federation

Energy carrier transport and recombination in emerging semiconductors can be directly monitored with optical microscopy, leading to the measurement of the diffusion coefficient (D), a critical property for design of efficient optoelectronic devices. D is often determined by fitting a time-resolved expanding carrier profile after optical excitation using a Mean Squared Displacement (MSD) Model, where $D = [\sigma^2(t) - \sigma^2(0)]/2t$, *with* $\sigma^2(t)$ *being the Gaussian variance as a function of time. Although this approach has gained widespread adoption, its utilization can significantly overestimate D due to the non-linear recombination processes that artificially broaden the carrier distribution profile. Here, we simulate diffusive processes in both excitonic and free carrier semiconductors and present revised MSD Models that take into account second-order (bimolecular) and third-order (Auger) processes to accurately recover D for various materials. For perovskite thin films, utilization of these models can reduce fitting error by orders of magnitude, especially for commonly deployed excitation conditions where carrier densities are >* $5x10^{16}$ cm^{-3}*. Contrary to what is generally accepted, we find that photon recycling does not have a significant impact on carrier profiles and that differences in grain size and boundary behavior, present in most polycrystalline films, can lead to distinct profiles that are not captured by MSD Models. Finally, we present clear strategies to investigate energy transport in disordered materials for more effective design and optimization of electronic and optoelectronic devices.*

9:30 PM EL02.09.05
Modulating Charge Carrier Dynamics and Transfer Via Surface Modifications in Organometallic Halide Perovskite Quantum Dots William G. Delmas[1], Evan Vickers[2], Albert Dibenedetto[1], Calista Lum[1], Isaak Hernandez[3], Jin Zhang[2] and Sayantani Ghosh[1]; [1]University of California, Merced, United States; [2]University of California, Santa Cruz, United States; [3]Massachusetts Institute of Technology, United States

Controlled functionalization of colloidal quantum dot surfaces is key to the manipulation of their optoelectronic properties. Applying this principle to the study of organometallic halide perovskite quantum dots (PQD's), we investigate temperature-dependent optical and energy transfer properties of four PQD species, all functionalized with variations of benzoic ligands. These include benzoic acid (BA), phenylacetic acid (PAA), benzylamine (BZA), and isopropyl benzylamine (IPBZA). While the chemical structure of BZA/BA and IPBZA/PAA differ by just a few carbon atoms, this difference manifests as a significant variation in PQD properties. Charge transfer efficiency in PQD films comprising BA-ligated samples varies between 12- 95% as dot density is tuned from $10^2 – 10^5$ dots/μm^2 but is consistently ~ 92% over that entire range for PAA-ligated PQDs. As temperature T decreases, initially, recombination is dominated by bound or trapped excitons, but for $T < 80$ K, spectral broadening accompanied by free excitonic behavior is observed. Our results indicate enhanced charge delocalization at lower T, which reduces exciton confinement and recombination decay rates, underlining the importance of investigating PQD-ligand interactions at the fundamental level given the significant effect minute changes in ligand structures have on optoelectronic properties of quantum dots.

9:45 PM *EL02.09.06
On the Degradation and Self-Healing Mechanism in Perovskite Solar Cells Sai Wing Tsang; City University of Hong Kong, China

Ion dissociation in perovskite lattices has been recently identified to determine the intrinsic stability of

perovskite solar cells (PVSCs), the underlying degradation mechanism is still elusive. In this work, we demonstrate that by combining highly sensitive sub-bandgap external quantum efficiency (s-EQE) spectroscopy, impedance analysis as well as theoretical calculations, the evolution of defect states in PVSCs during the degradation can be monitored. It is found that the degradation of PVSCs can be divided into three steps: (1) dissociation of iodine ions (I^-) from perovskite lattices, (2) migration of I^- to interfaces, and (3) consumption of I^- by reacting with the metal electrode. Importantly, step (3) is found to be crucial as it will accelerate the first two steps and lead to continuous degradation. By replacing the metal with more chemically robust indium tin oxide (ITO) as the electrode, we find that the dissociated I^- under light soaking will only saturate at the perovskite/ITO interface without being consumed. Importantly, the dissociated I^- will subsequently restore to the iodine vacancies under dark condition to heal the perovskite and photovoltaic performance. Such shuttling of I^- without consumption in the ITO-contact PVSCs results in Harvest-Rest-Recovery (HRR) cycles in the natural day/night operation. We envision that the mechanism of the intrinsic perovskite material degradation reported in this work will lead to clearer research directions towards highly stable PVSCs.

Lead-free perovskite-inspired materials (PIMs) are receiving ever-growing attention in photovoltaics, optoelectronics, and beyond, due to their similarity to mainstream lead-based perovskites while being free of the toxicity concerns associated with the latter.[1–3] Specifically, antimony- and bismuth-based PIMs have been identified as particularly promising. Nonetheless, the efficiencies of such PIMs in single-junction outdoor solar photovoltaics are yet to approach the levels of the lead-based counterparts. An important limiting factor lies in the bandgaps of these materials, which are in the region of 1.9 eV or greater, thereby preventing the optimal absorption of solar light for single-junction operation.
Going beyond the mainstream view of solely considering lead-free PIMs for outdoor solar photovoltaics, herein we show that these materials have considerable potential for indoor photovoltaics (IPV),[4] a rapidly growing sector in energy harvesting for smart devices of the Internet of Things (IoT) ecosystem.[5] With a focus on two representative lead-free PIMs with high photoconversion efficiencies, $Cs_3Sb_2Cl_xI_{9-x}$[6] and BiOI,[7] we show that their IPV efficiencies are up to ~5%, i.e., four times higher than under outdoor solar illumination and already within the performance range of mainstream commercial IPV based on hydrogenated amorphous silicon (a-Si:H).[4] Further, based on power-dependent measurements and optical loss analyses, we provide insight into the current performance bottlenecks and identify strategies for future improvements toward the ultimate IPV efficiencies of these materials. Finally, by combining millimeter-scale $Cs_3Sb_2Cl_xI_{9-x}$ and BiOI IPV devices with ultralow-power printed electronics,[8] we present the first-ever demonstration of printed thin-film-transistor electronics powered by IPV.[4] By revealing the capability and potential of lead-free PIMs for indoor photovoltaics, our findings point to the opportunity provided by such environmentally-friendly semiconductors to sustainably power the growing IoT ecosystem.

New Kid on the Block—An Emerging Quaternary Chalco-Halide for Stable High-Performance Solar Cells Seán R. Kavanagh[1,2,2], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

The exceptional optoelectronic performance of lead-halide perovskites (LHPs) has motivated enormous research efforts toward the discovery of 'perovskite-inspired materials' – compounds which aim to replicate the astonishing performance of LHPs while avoiding the infamous stability and toxicity pitfalls of these materials.[1–3] Recently, quaternary chalcogen halides of group IV / V elements have begun to attract attention, due to the presence of valence ns^2 lone pairs, a performance-defining feature of LHPs.[4]
Following the first experimental report of stable, solution-grown tin-antimony sulfoiodide ($Sn_2SbS_2I_3$) solar cells,[5] with power conversion efficiencies above 4% (exceeding the first reported solar efficiency of methylammonium lead-iodide (MAPI)),[6] we comprehensively characterize the structural and electronic properties of this emerging material. We find that the experimentally reported (non-ferroelectric) *Cmcm* crystal structure is in fact an equipment artefact, representing an average over multiple (ferroelectric) $Cmc2_1$ configurations. The resemblance of this dynamic crystal structure and ferroelectric behavior to that of MAPI begs the question of its importance in high-performance defect-tolerant solar materials.
Moreover, using state-of-the-art *ab-initio* methods (hybrid Density Functional Theory including spin-orbit coupling effects), we rigorously assess the efficiency limits of this material on the basis of its electronic structure and predicted defect behavior.
Our work provides valuable insight regarding both the potential success of this emerging class of optoelectronic materials and structure-property relationships in perovskite-inspired materials, guiding design strategies and expanding the compositional space of candidate materials.

High-Efficiency Light Emission from Lead-Free Metal Halides Bayrammurad Saparov[1], Tielyr Creason[1] and Mao-hua Du[2]; [1]The University of Oklahoma, United States; [2]Oak Ridge National Laboratory, United States

The emergence of lead halide perovskites for optical and electronic applications has been one of the most important discoveries of materials science and chemistry of the past two decades. To accelerate the industrial use of metal halide perovskites, there is a global search for alternative non-toxic, lead-free halides that demonstrate higher environmental stability and similarly outstanding optoelectronic properties while preserving the advantageous properties of lead halides. In this talk, our recent discoveries of brand-new families of lead-free high efficiency light-emitting materials will be summarized. These include all-inorganic copper(I) halides demonstrate low-dimensional non-perovskite structures, and consequently, very flat bands around the band gap, leading to very localized charges. Such charge localization and low-dimensional structures typically result in the presence of high stability self-trapped excitons at room temperature producing record high photoluminescence efficiencies approaching unity. On the other hand, families of low-dimensional hybrid organic-inorganic halides prepared in our show very diverse crystal structures and optical emission properties, including controllable emission form organic or inorganic components, or simultaneous emission from both. The talk will be concluded with a few examples of the potential practical applications of the luminescent metal halides mentioned in this talk.

Late News: Emergence of Qualitatively Different Anharmonic Expressions in the Structural Dynamics of Halide Perovskites Adi Cohen[1], Thomas M. Brenner[2], Johan Klarbring[3], Rituraj Sharma[1], Douglas H. Fabini[4], Roman Korobko[1], Bettina Lotsch[4,5], Pabitra Nayak[6], Olle Hellman[3] and Omer Yaffe[1]; [1]Weizmann Institute of Science, Israel; [2]Weizmann institute of science, Israel; [3]Linköping University, Sweden; [4]Max Planck Institute for Solid State Research, Germany; [5]Ludwig-Maximilians-Universität München, Germany; [6]Tata Institute of Fundamental Research, India

Lead-based halide perovskite crystals have unique structural dynamics in that they exhibit, an-harmonic, liquid-like thermal fluctuations. This type of structural dynamics, that can not be treated within the classic framework of semiconductor physics, is intimately to the beneficial electronic properties of the lead based perovskites. In recent years, the double perovskite Cs2AgBiBr6, was studied as part of an effort to find a lead-free perovskite for optoelectronic applications. While the electronic properties of Cs2AgBiBr6 were extensively studied, little is known about its structural dynamics. We investigate the structural dynamics of Cs2AgBiBr6 and compare it to CsPbBr3 which is its lead-based analog. By using temperature-dependent Raman measurements we found that both materials are strongly anharmonic. However, the expression of their anharmonic behaviour is markedly different. Cs2AgBiBr6 shows a soft-mode and a displacive phase transition similar to archetypical oxides perovskites. In contrary, CsPbBr3 show an increase of acentral Raman component, related to a large amplitude, relaxational motion. These differences area result of different evolution with temperature of the tilting instability that exists in both crystals at low temperatures. This difference is important because it may explain why Cs2AgBiBr6 is not an effective material for optoelectronic applications compared to the lead-perovskites. In the course of our investigations, we also discovered a new phase of Cs2AgBiBr6 below35 K.

A Direct Comparison of BiI_3, BiOI and Ag_3BiI_6 Layered Semiconductors for Optoelectronics Andrea Crovetto, Alireza Hajijafarassar, Ole Hansen, Brian Seger, Ib Chorkendorff and Peter Vesborg; Technical University of Denmark, Denmark

The bismuth-based (oxy)iodides BiI_3, BiOI and Ag_xBiI_{x+3} share similar layered crystal structures, optimal band gaps for top absorbers in tandem solar cells, and moderate growth temperatures. Similarly to halide perovskite absorbers, they contain a heavy cation with a lone pair of electrons (Bi^{3+}) which has been proposed as one of the features enabling defect tolerance in perovskites.

We have grown and characterized BiI_3, BiOI, and Ag_3BiI_6 absorbers and solar cells in a systematic manner by employing a consistent synthesis method ((oxy)iodization of metallic precursor) and a consistent analysis

routine [1]. In this way, the individual strengths and weaknesses of the three absorbers, as well as their common challenges, can be outlined.

The radiative efficiency of the three materials is within the same order of magnitude, indicating a similar degree of defect tolerance. Apart from that, each material has its own advantages and drawbacks, which will be outlined in this presentation.

Control of growth orientation should be a priority for all three materials in view of their anisotropic properties. P-type bulk doping and selection of alternative hole transport layers with deep valence bands would also be desirable to improve performance. At the device level, we report an improved open circuit voltage of BiI_3 solar cells with respect to the state of the art, and we report a proof-of-concept Ag_3BiI_6/silicon tandem cell.

Finally, we have observed at least one unusual, exciting property in each material: BiI_3 diodes have a very low dark ideality factor, on par with the highest-quality silicon solar cells. BiOI has a very convenient mix of moderate growth temperature and air stability. Ag_3BiI_6 is a mixed electronic-ionic conductor with fast ionic diffusion, which may find applications in neuromorphic, memory, or battery devices.

A_2MX_3 (A=Rb, K, NH_4; M=Cu, Ag; X= Cl, Br, I): High Stability, Nontoxic Group 11 Halides with Near-Unity Photoluminescence Quantum Yield Tielyr Creason[1], Hadiah Fattal[1], Timothy M. McWhorter[1], Mao-hua Du[2] and Bayrammurad Saparov[1]; [1]The University of Oklahoma, United States; [2]Oak Ridge National Laboratory, United States

All-inorganic group 11 halides have recently gained interest in the optical materials community as viable, relatively non-toxic alternatives to luminescent lead halides. Bulk powder samples and single crystals of A_2MX_3 (A=Rb, K, NH_4; M= Cu, Ag; X= Cl, Br, I) were prepared using high temperature solid-state and solution techniques. The all-inorganic group 11 halides have been investigated through an in-depth optical characterization, including diffuse reflectance, photoluminescence, and radioluminescence. A_2CuX_3 are found to exhibit narrow blue photoluminescence peaks with record-high efficiencies as evidenced by the measured photoluminescent quantum yields up to unity (100 %). Conversely, A_2AgX_3 displays broad, white emission with tunability in color temperature. Through variation in the A^+ cation site, the stability of the material can be dramatically increased, while retaining similar optical performance. For A_2CuX_3 the bright emission in this family has been attributed to self-trapped excitons localized on $[CuX_3]^{2-}$ anionic substructure based on exhaustive photoluminescence studies supported by the density functional theory (DFT) calculations. Our combined experimental and computational study suggests strong potential of A_2MX_3 as phosphors for radiation detection and solid-state lighting applications.

Late News: Factors Influencing the Temperature-Dependent Amplified Spontaneous Emission (ASE) Threshold in Phase-Stable 3D Perovskite Films Isabel Allegro, Yang Li, Bryce S. Richards, Ulrich W. Paetzold, Uli Lemmer and Ian A. Howard; Karlsruhe Institute of Technology, Germany

Room-temperature continuous-wave (CW) lasing in quasi-two-dimensional perovskites was just recently demonstrated in thin films on a distributed feedback grating. However, CW lasing and amplified spontaneous emission (ASE) in three-dimensional (3D) perovskites was so far, only achieved at cryogenic temperatures. Factors limiting the 3D materials to sustain CW gain at higher temperatures include the temperature dependence of the charge carrier distribution in energy; the build-up of photo-induced non-radiative recombination channels; and the rates of bimolecular and Auger recombination. We investigate the latter in a phase-stable triple cation perovskite, by performing transient reflection measurements to determine the charge carrier dynamics from 80 K up to 290 K.

To accurately determine the Auger rate coefficient, we vary the initial carrier density reaching up to very high carrier concentrations where the Auger recombination plays a significant role. These carrier concentrations are above the ASE threshold for thin films prepared on conventional substrates, such as glass or sapphire. Therefore, we use a silicon substrate with a higher refractive index to completely suppress ASE in the film and its associated carrier depletion. Based on the power and temperature-dependent carrier dynamics measurements, we implemented a global fitting of the rate equation across the considered temperature range to extract the bimolecular and Auger recombination coefficients.

The results show that the bimolecular recombination rate decreases with increasing temperature (from 6.4×10^{-10} cm^{-3} s^{-1} at 80 K to 1.1×10^{-10} cm^{-3} s^{-1} at 290 K), as expected due to increased phonon scattering, whereas the Auger rate coefficient stays approximately constant across the entire temperature range (at approximately 3×10^{-29} cm^{-6} s^{-1}). Based on these results, we consider the carrier density at which the Auger recombination will dominate over the bimolecular recombination and discover that above 250 K, the ASE threshold density is lower than the carrier density at which the non-radiative Auger recombination dominates over the radiative bimolecular recombination. This means, that above 250 K, the ASE performance is limited by the Auger recombination and the threshold carrier density is in the roll-off region of the radiative emission efficiency due to Auger losses. At lower temperatures, the ASE threshold density is below the point at which Auger recombination starts dominating and the increase in ASE threshold is mainly determined by two factors: the rapid decrease in the bimolecular rate coefficient with temperature, and the energy dilution of the charge carriers. This energy dilution results in a reduced fraction of radiative emission in the ASE band, compared to the total photoluminescence spectrum. Both effects lead to a necessary increase in carrier density (and therefore pump rate) to maintain the same total emission rate in the ASE band. To increase the temperature at which CW ASE (and lasing) can be achieved in 3D perovskite films, strategies to increase the bimolecular recombination coefficient and keep a narrow emission bandwidth at higher temperatures should be investigated.

12:25 PM EL02.11.03
Late News: A New Photophysics for 2D and 3D Lead Halide Perovskites—Polaron Plasma in Equilibrium with Bright Excitons Michele Saba; Università di Cagliari, Italy

Rapid advances in perovskite photovoltaics have produced efficient solar cells, with stability and duration improving thanks to variations in materials composition, including the use of layered 2D perovskites. A major reason for the success of perovskite photovoltaics is the presence of free carriers as majority optical excitations in 3D materials at room temperature. On the other hand, the current understanding is that in 2D perovskites or at cryogenic temperatures insulating bound excitons form, which need to be split in solar cells and are not beneficial to photoconversion. Here we apply a tandem spectroscopy technique that combines ultrafast photoluminescence and differential transmission to demonstrate a plasma of unbound charge carriers in chemical equilibrium with a minority phase of light-emitting excitons, even in 2D perovskites and at cryogenic temperatures. We validate the technique with 3D perovskites and investigate 2D compounds basded on both Pb and Sn as metal cation. The underlying photophysics is interpreted as formation of large polarons, charge carriers coupled to lattice deformations, in place of excitons. A conductive polaron plasma foresees novel mechanisms for LEDs and lasers, as well as a prominent role for 2D perovskites in photovoltaics.

Late News: Large-Grain Double Cation Perovskites with 18 µs Lifetime and High Luminescence Yield for Efficient Inverted Perovskite Solar Cells Emilio Gutierrez-Partida[1], Hannes Hempel[2], Sebastian Caicedo Davila[2], Meysam R. Raoufi[1], Carlos Peña-Camargo[1], Max Grischek[2,1], René Gunder[2], Pietro Caprioglio[1,2], Kai O. Brinkmann[3], Hans Kobler[2], Steve Albrecht[2], Thomas Riedl[3], Antonio Abate[2], Daniel Abou-Ras[2], Thomas Unold[2], Dieter Neher[1] and Martin Stolterfoht[1]; [1]University of Potsdam, Germany; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [3]University of Wuppertal, Germany

Recent advancements in perovskite solar cell performance were achieved by stabilizing the α-phase of $FAPbI_3$ in *nip*-type architectures. However, these advancements could not be directly translated to *pin*-type devices. Here, we fabricated a high-quality double-cation perovskite ($MA_{0.07}FA_{0.93}PbI_3$) with low bandgap energy (1.54 eV) using a two-step approach on a standard polymer (PTAA).**[1]** The perovskite films exhibit large grains (1 µm), high external photoluminescence quantum yields of 20% and outstanding Shockley-Read-Hall carrier lifetimes of 18.2 µs without further passivation. The exceptional opto-electronic quality of the neat material was translated into efficient (up to 22.5%) *pin*-type cells with improved stability under illumination. The low-gap cells stand out by their high fill factor (83%) due to reduced charge transport losses and short-circuit currents 24 $mAcm^{-2}$. Using intensity dependent QFLS measurements, we quantify an implied efficiency of 28.4% in the neat material which can be realized by minimizing interfacial recombination and optical losses.

[1]Gutierrez-Partida, et al. Large-grain double cation perovskites with 18 µs lifetime and high luminescence yield for efficient inverted perovskite solar cells. *ASC Energy Letters.***2021,** https://dx.doi.org/10.1021/acsenergylett.0c02642

1:00 PM EL02.11.05

Novel Absorption Feature Due to Intrinsic Quantum Confinement in $FAPbI_3$ Adam D. Wright[1], George Volonakis[1,2], Juliane Borchert[1], Christopher Davies[1], Feliciano Giustino[1,3,3], Michael Johnston[1] and Laura Herz[1]; [1]University of Oxford, United Kingdom; [2]Institut des Sciences Chimiques de Rennes, France; [3]The University of Texas at Austin, United States

Perovskite nanostructures have been engineered for LEDs, lasers and photodetectors[1], their reduced dimensionality resulting in quantum confinement of charge carriers which yields dramatically different optoelectronic properties, including enhanced photoluminescence quantum yield[2] and lower thresholds for amplified spontaneous emission[3]. Although the creation of such perovskite nanostructures has clear advantages, it often relies on challenging top-down fabrication methods. It would therefore be highly advantageous if instead nanoscale domains were found to form intrinsically through self assembly in the perovskite.

In this study[4], I report the discovery of intrinsically-occurring nanostructures in $FAPbI_3$, which exhibit quantum confinement effects manifested as an oscillatory absorption feature above the band gap. These features are present at room temperature but sharpen and become more apparent as the temperature is lowered towards 4 K. I demonstrate that the energetic spacings and temperature-dependence of the peaks vary in a manner consistent with quantum confinement intrinsically associated with the lattice of the material. I suggest the origin of this confinement to be nanodomains with an extent of approximately 10-20 nm. This interpretation is supported by correlating absorption spectra against *ab initio* calculations based on the bandstructure of $FAPbI_3$ in the presence of infinite barriers, and simulations for superlattices with moderate barrier heights. I further explore ferroelectricity/ferroelasticity and delta-phase twin boundaries as two possible causes of these domains. Altogether, such absorption peaks present a novel and intriguing quantum electronic phenomenon in a nominally bulk semiconductor, offering intrinsic nanoscale optoelectronic properties without necessitating cumbersome additional processing steps.

1:15 PM EL02.11.06
Antisolvent Processing Dependent Photon Upconversion Performance in Perovskite-Sensitized Triplet-Triplet Annihilators Karunanantharajah Prashanthan[1,2], Boris Naydenov[1], Klaus Lips[1], Eva Unger[1,3] and Rowan W. MacQueen[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]University of Jaffna, Sri Lanka; [3]Lund University, Sweden

Organolead halide perovskite thin films are an emerging class of triplet sensitizer for photon upconversion applications, with favourable semiconductor properties such as strong and broad optical absorption, large carrier diffusion lengths and pronounced spin-mixing. Our study aimed to identify connections between key properties of the perovskite film and the upconversion efficiency achieved in a standard bilayer upconverter structure. The perovskite film properties were deliberately altered by changing film processing conditions such as spin-coating speed, antisolvent type and antisolvent dripping time, while triplet-triplet annihilation photon upconverters were prepared in a bilayer structure consisting of thin film methaylammonium lead iodide perovskite (MAPI) combined with a DBP-doped rubrene annihilator layer.

Photoexcitation of the perovskite film at 715 *nm* lead to delayed photoluminescence at 605 *nm* from the annihilator layer, with triplet formation in the rubrene layer sensitized by photogenerated charge carriers in the MAPI film. A stronger upconversion effect was observed for films which displayed brighter and more uniform perovskite photoluminescence. These attributes were highly sensitive to antisolvent dripping time, and were optimized at 20 *seconds*, measured relative to the start of the spinning process. Further, the choice of antisolvent also had a significant contribution in upconversion performance. Two different antisolvents, anisole and chlorobenzene, were utilized in the MAPI formation process. Films treated with anisole had on average a 10-fold increase in upconversion efficiency compared to the chlorobenzene-treated films.

Time-resolved photoluminescence measurements of the two MAPI variants revealed a stark difference in carrier lifetimes, which were 52 *ns* and 306 *ns* in the chlorobenzene and anisole-treated films, respectively. Owing to the near-identical appearance of the two films in a range of bulk-sensitive measurements, we proposed that the difference in carrier lifetime is due to a changing defect density at the MAPI/rubrene interface induced by the two antisolvent treatments. This may itself explain the pronounced difference in upconversion performance, since triplet exciton formation is driven by charge carrier interactions across the same interface, and presumably competes with defect-mediated electron-hole recombination.

1:30 PM EL02.11.07
Late News: Unconventional Scaling of Photoconductivity and Photoluminescence in Lead-Halide Perovskites and Novel Field-Effect Transistor Devices for Photoluminescence Control Vitaly Podzorov; Rutgers, The State University of New Jersey, United States

We have recently performed several fundamental magneto-transport (Hall effect), photoconductivity (PC) and photoluminescence (PL) studies of lead-halide perovskite single crystals, leading to a better understanding of the important charge transport and recombination properties of these materials [1,2,3]. Among these are the first reliable measurements of the dark- and photo-Hall effects in perovskites [1,2], revealing the intrinsic charge carrier mobilities and recombination parameters, as well as the first proposal of large polarons being an important type of carrier in these materials [4]. In this talk, I will focus more on the discovery of unconventional power exponents in photoexcitation flux dependence of PC and PL (including the “strange” power 3/2 in PL) in perovskite single crystals [3], and the demonstration of a novel type of an optoelectronic field-effect transistor device, where PL (rather than electric current) is modulated by a gate voltage [5].

Formation of High-Temperature Giant Quantum States in Hybrid Perovskites Kenan Gundogdu and Franky So; North Carolina State University, United States

Optical excitation creates excitons in semiconductors. These quasiparticles most commonly exist in incoherent states. In extremely rare situations under critical conditions, these excitons might gain a collective electronic coherence through a process called spontaneous synchronization. This process is a symmetry breaking, i.e., second-order quantum phase transition, similar to Bose-Einstein condensation and superconductivity. When this happens, all oscillators form a giant dipole and radiate collectively, and act like a giant atom. This process was first proposed by Dicke and hence called Dicke superradiance. Since the electronic quantum phase is extremely fragile due to thermal phonon interactions, Dicke superradiance is only observable in a handful of solid state systems at cryogenic temperatures. In this presentation, we will present the results of our recent discovery of high-temperature Dicke superradience in hybrid perovskites, and discuss the fundamental mechanism leading to such a macroscopic quantum phenonomena in hybrid perovskites. Observation of superradient phase transition in hybrid perovskites is important for developing emerging quantum applications using this versatile material family. Specifically, quantum sensing, communication, and computation applications require robust quantum oscillators. Observation of superfluorescence in hybrid perovskite can pave the way for such applications.

5:40 PM EL02.12.02
Distance Dependence of Förster Resonance Energy Transfer in 2D Perovskite Quantum Wells Shobhana Panuganti[1], Lucas V. Besteiro[2], Eugenia S. Vasileiadou[1], Alexander Govorov[3], Stephen Gray[4], Mercouri G. Kanatzidis[1] and Richard Schaller[4]; [1]Northwestern University, United States; [2]Institut National de la Recherche Scientifique-Énergie, Matériaux et Télécommunications, Canada; [3]Ohio University, United States; [4]Argonne National Laboratory, United States

Two-dimensional (2D) materials are outstanding candidates for a variety of optoelectronic applications but are inhibited by low carrier mobilities and high exciton binding energies compared to their bulk counterparts. To that end, rapid Förster resonance energy transfer (FRET) presents an opportunity to quickly and purposefully direct energy through devices, which could improve the efficiency of existing applications and establish new

types of energy-funneling devices. The exciting observation of fast energy transfer that outcompetes other multiexcitonic effects, on the order of picoseconds, has been experimentally observed in 2D materials with requisite spectral overlap and electronic coupling between donor and acceptor, but high quality, clear data in such systems is sparse. Predictive models for FRET in 2D systems, particularly with respect to the distance between states, are underdeveloped.

In this work, we approach FRET in 2D perovskite quantum wells; these materials, in which layers of perovskite are electronically decoupled by organic spacer cations into 2D quantum wells of *n* octahedra in thickness, provide ideal systems for studying FRET given the precision with which various electronic and optical parameters may be synthetically adjusted. Though research into devices fabricated from such materials has skyrocketed, as they present ambiently stable and highly tunable alternatives to well-known hybrid organic inorganic perovskites, synthetic control for desired mixtures of *n* phases in thin-films that would enable a reliable energy transfer study are non-existent. Few studies exist that aim to discern energy transfer processes in these materials, and each suffers from a complete lack of control over sample composition, resulting in reported lifetimes of energy transfer that are orders of magnitude apart. In order to provide insights regarding FRET in this material class, we prepare thin-films with controlled mixtures of specific *n* phases of 2D perovskite quantum wells for the first time and use them to investigate binary arrangements of quantum well thicknesses to reveal fundamental behavior.

We examine rates of Förster resonance energy transfer in binary mixtures of 2D perovskites as a function of the distance between layers by incorporating alkylammonium cations of increasing chain length. Energy transfer is observed using transient absorption spectroscopy in each case. Evaluated rates in some instances outpace biexcitonic Auger recombination, and lifetimes become slower with increasing separation. We model these systems computationally, obtaining results in agreement with our empirically obtained lifetimes, and expand upon the model to survey effects of other influencing factors on energy transfer in 2D materials that may be, in principle, synthetically controlled. Our work begins building the necessary foundation for predictive models of FRET in 2D PQWs and further guides design principles for employing FRET in devices fabricated from 2D materials.

The Stark Effect as a Measure of Surface Passivation in Growing $MAPbI_3$ Perovskite Nanocrystals.

James C. Sadighian, Kelly Wilson, Michael Crawford and Cathy Wong; University of Oregon, United States

Organic-inorganic halide perovskite (OIHP) semiconductors are currently the focus of significant research interest due to their potential optoelectronic device applications. Quantum-confined nanocrystals (NCs) of these materials emit with high photoluminescence quantum yields and a narrow, tunable spectrum. These properties, coupled with the potential for low-cost, facile solution-based syntheses, make these NCs ideal for LEDs, lasers, and optical sensors. Due to their high surface area-to-volume ratio, the surface plays a critical role in determining the excited state dynamics, and thus optoelectronic properties, in these materials. In particular, the evolution of NC surface quality and the mechanisms by which surface states become bound by ligands during growth is still poorly understood. Under-coordinated surface atoms act as traps for charge carriers and can promote unwanted non-radiative recombination. The goal of this work is to understand how the NC surface becomes passivated during NC synthesis.

The fate of photogenerated species in NCs is typically studied using non-linear optical spectroscopies, such as transient absorption (TA), but these techniques have inherently long measurement timescales of up to several hours. OIHP NCs are traditionally formed through either a hot-injection or ligand-assisted reprecipitation synthesis. These reactions are typically complete withing a few minutes, and nascent NCs are highly unstable and difficult to kinetically trap, precluding in situ investigation of dynamics with non-linear optical spectroscopies. This has limited our understanding of nucleation and growth processes in these systems. To overcome these limitations, we have developed a TA spectrometer that reduces the timescale required for measurement by spatially encoding the time delay in a tilted-pulse geometry. This allows collection of an entire broadband transient spectrum with a 60 ps time delay in just a few laser shots, and spectra with a good signal-to-noise ratio can be acquired within seconds. In this work we apply this novel instrumentation to a NC

synthesis whose reaction kinetics are limited by the solvation of precursors in a highly nonpolar solvent. Coupling this solvation-mediated synthesis to a rapid sampling technique has enabled the first-ever characterization of exciton dynamics in growing methylammonium lead triiodide NCs.

We observe the appearance of unique TA spectral features in newly formed NCs that slowly disappear over the remainder of the synthesis. Comparison to first and second order derivatives of the linear absorbance spectrum shows that photogenerated charge carriers become localized at surface trap states in nascent NCs, inducing a Stark effect that manifests in the TA measurements. The amplitude of the lineshape arising from this Stark effect declines as NC growth continues, suggesting that intermediate NCs possess unpassivated surface sites that can trap charge carriers and hamper optoelectronic performance. These sites are slowly passivated by capping ligands over the course of the synthesis. Our results contribute to a growing body of evidence suggesting that surface passivation occurs toward the end of NC growth in a final surface ligation stage of the reaction. This experimental technique provides researchers with a new tool to report on surface quality in growing NCs and has the potential to yield fundamental insights into the mechanism of nanocrystal nucleation and growth. A full understanding of these processes would allow for further synthetic control of NC properties by providing researchers the ability to tune reaction conditions *in situ* to target desired properties.

Late News: The Role of Dopant Ions in Tuning the Optical Properties of Inorganic Lead Halide Perovskite Lijia Liu; University of Western Ontario, Canada

Inorganic lead halide perovskite ($CsPbX_3$, X=Cl, Br, and/or I) have fascinating optical properties. By tuning the halide composition, the luminescence of $CsPbX_3$ can be tuned across the entire visible spectrum. The optical property of $CsPbX_3$ can also be modified upon the introduction of a new cation species, either a divalent or a trivalent metal ion. Depending on the type of cation, the synthesis strategy, and the nature of the perovskite host, how the introduced cations influence the optical property of the pristine perovskite could be entirely different. In this presentation, I am going to discuss three systems: (1) Mn-doped $CsPbX_3$, in which the introduction of Mn results in dual-band emission, (2) Pr^{3+}-doped $CsPbX_3$, in which heterovalent doping drastically enhance the perovskite bandgap emission, and (3) Eu^{2+}-doped $CsPbBr_3$, in which Eu^{2+} induces a phase transformation of the perovskite host and producing a blue-emission band. The electronic structure of the doped perovskite and the luminescence mechanism is investigated using synchrotron-based X-ray absorption fine structure (XAFS) and X-ray excited optical luminescence (XEOL). These characterization techniques provide detailed structural information and energy transfer processes in these doped perovskites, and the information obtained is valuable for designing $CsPbX_3$ light-emitters with desired properties.

6:30 PM EL02.12.05
Light-Activated Contraction in Organic-Inorganic 2D Perovskites Enables High-Efficiency Photovoltaics
Wenbin Li[1], Siraj Sidhik[1], Boubacar Traore[2], Reza Asadpour[3], Hao Zhang[1], Jin Hou[1], Joseph Strzalka[4], Esther Tsai[5], Justin M. Hoffman[6], Ioannis Spanopoulos[6], Muhammad A. Alam[3], Claudine Katan[2], Mercouri G. Kanatzidis[6], Jacky Even[2], Jean-Christophe Blancon[1] and Aditya Mohite[1]; [1]Rice University, United States; [2]Institut National des Sciences Appliquées, France; [3]Purdue University, United States; [4]Argonne National Laboratory, United States; [5]Brookhaven National Laboratory, United States; [6]Northwestern University, United States

Understanding and tailoring the structure-induced physical behavior of materials under practical environments is critical for designing efficient and durable optoelectronic devices. Here, we report a new phenomenon - a sunlight-activated anisotropic lattice contraction in organic-inorganic 2D perovskites, which is reversible and strongly dependent of the specific structural phase and the organic interlayer cation bridging the perovskite octahedra. Modeling suggests that light-generated charge accumulation results in the build-up of a bulk compressive strain, which induces a continuous lattice contraction over minutes. In-situ structural

measurements on photovoltaic devices directly correlate the light-induced lattice contraction to an increase in the photovoltaic efficiency of Dion-Jacobson 2D perovskite solar cells from 13.8% to 16.4%. The increase in efficiency results from a combined increase in the open circuit voltage and fill factor, arising from the reduction of the potential barrier heights upon light-induced contraction

6:45 PM EL02.12.06
Multiplexed Nanocrystal Arrays of Halide Perovskites Jingshan S. Du, Donghoon Shin, Vinayak P. Dravid and Chad A. Mirkin; Northwestern University, United States

Halide perovskites have exceptional optoelectronic properties, making them attractive for photovoltaics, light-emitting technologies, and radiation detection. However, a poor understanding of the relationship between crystal dimensions, composition, and properties limits their use in integrated devices. In this presentation, we will discuss a multiplexed cantilever-free scanning probe method for synthesizing compositionally diverse halide perovskite nanocrystals spanning cm^2 areas. Single-particle photoluminescence studies reveal multiple independent emission modes due to defect-defined band edges with relative intensities that depend on crystal size for a fixed composition. Smaller particles, but ones with dimensions that exceed the quantum confinement regime, exhibit blue-shifted emission due to the reabsorption of higher-energy modes. The method reported herein is generalizable and has been used to synthesize six different halide perovskites, including a layered Ruddlesden-Popper phase. Importantly, it also enables the preparation of functional solar cells based upon a single nanocrystal. Additionally, the ability to pattern arrays of multi-color light-emitting nanocrystals opens avenues towards the development of sophisticated optoelectronic devices, including a wide variety of optical displays.

Chalcogenide Perovskites for Electronics and Optoelectronics Shengbai Zhang; Rensselaer Polytechnic Institute, United States

Most conventional semiconductors are covalent materials with four-fold coordination. The recent emergence of semiconducting perovskites, with six-fold coordination metal atoms in the skeleton framework and an exceptional success in photovoltaics, however, represent a different type of semiconductors distinctly different from any existing ones. For example, $BaZrS_3$ (a chalcogenide perovskite) has a direct band gap in the visible close to that of GaAs, but its ionicity, on average, is close to that of AlN. In other words, conventional semiconductors and perovskites represent two extremes in the ionicity spectrum. In this talk, I will discuss our recent theoretical efforts in advancing the knowledge on various forms of chalcogenide perovskites as a new class of semiconductors for electronic and optoelectronic applications [1-4]. Noticeably, a chalcogenide perovskite often exhibits a significantly higher density of states near the band gap than a conventional semiconductor due to the presence of transition-metal *d* states [1]. While the d bands are usually flatter than the (*s, p*) bands which is undesirable for carrier transport, their hybridizations exhibit noticeable anisotropy to resulting in favorable conduction channels with reasonably small effective masses. Also, indirect gap materials are often perceived as poor optoelectronic materials. However, due to these *d* bands, high optical absorption in indirect chalcogenide perovskites can take place at energies only a few tenth of an eV higher than the fundamental band gap [3], which could be beneficial for photovoltaic applications requiring both high absorption in the visible and long carrier lifetimes.

10:55 AM *EL03.01.02
Electron Count and Ferroelectricity in Complex Oxides From First Principles Karin M. Rabe; Rutgers, The State University of New Jersey, United States

The electron count in complex oxide compounds can be controlled during growth via compositional substitution or formation of defects such as oxygen vacancies. Reversible control can be achieved through gating in heterostructures or through introduction of H or alkali metal interstitials. In this talk, I will present first-principles investigations of the effects of added charge on the crystal structure and bandstructure of illustrative systems, including BaTiO3, ZnSnO3, SmNiO3, La1/3Sr2/3FeO3 and perovskite titanate superlattices. In some systems, the added electrons or holes become free carriers, their mobility and concentration determining the resulting conductivity. When the system is ferroelectric, for example BaTiO3 and ZnSnO3, key questions include the effect of the free carrier concentration on the polar distortion, and the switchablity of ferroelectrics with free carriers. Alternatively, the added charges can localize on transition metal ions and order, breaking translational and/or point symmetries. Combining the symmetry-breaking of the charge order with other symmetry-breaking factors, such as cation layering, epitaxial strain or the arrangement of the added interstitial ions, can produce charge-order-driven ferroelectricity. In these systems, coupling of charge order to the lattice is a key consideration in determining switchablity between states of different polarization. Connections to experimental observations in the literature and to ongoing experiments will be discussed.

11:20 AM *EL03.01.03
Prediction of Novel Quinary Layered Oxychalcogenides Daniel W. Davies, Benjamin A. Williamson and David O. Scanlon; University College London, United Kingdom

N-type transparent conductors (TCs) are key materials in the modern optoelectronics industry. Despite years of research, the development of a high-performance p-type TC has lagged far behind that of its n-type counterparts, delaying the advent of “transparent electronics” based on transparent p-n junctions.[1] Here, we computationally investigate three layered oxychalcogenide structural motifs to try to predict new p-type TCs, namely the $[Cu_2Ch_2][A_3B_2O_5]$ (325), $[Cu_2Ch_2][A_4B_2O_6]$ (426) and $[Cu_2Ch_2][A_2BO_2]$ (212) structural motifs.

Specifically, we have used a materials informatics approach (SMACT) to screen through the search space using low-cost heuristic tools.[2] This reduces the potential combinations from 1800 to a more computationally tractable 228, which then undergo DFT calculations to assess thermodynamic and dynamic stability. In this talk, I will present an update on how our search has predicted >50 novel semiconductors with potential applications ranging from TCs,[3] to photocatalysts,[4] solar absorbers and thermoelectrics.

11:45 AM *EL03.01.04
Data-Enabled Discovery of New Semiconductors for Energy Generation and Energy Storage Joseph W. Bennett; University of Maryland Baltimore County, United States

The interplay of first-principles density functional theory and experiments has led to the optimization of well-known families of oxides and chalcogenides whose members display a range of tunable band gaps, polarizations, and compositions. Here we combine crystallographic database mining and high-performance computing to discover and design new semiconductive functional materials that could be readily synthesized and potentially operate in different regimes of temperature, pressure, humidity, etc. Ultimately, we would like to examine a family of materials whose compositions span a wide set of cations and anions, specifically oxide and chalcogenides, to complement well-established materials like the ABX_3 perovskites and Ruddlesden-Popper phases. We focus on finding new examples of functional materials called ferroelectrics and antiferroelectrics since semiconductive ferroelectrics can find use as photovoltaics and antiferroelectrics are proposed to find use as materials capable of energy storage. Our work explores a candidate family of materials with a general formula of A_2BX_3, where members have been assigned nonpolar, antipolar, and polar structure types. We use density functional theory to map out the potential energy landscape of this family by including both known and as-yet to be identified structure types. The results of our analysis show several known members to be either ferroelectric or antiferroelectric. We present a targeted set of oxide and chalcogenide semiconductors, and their compositionally tuned variants, that warrant further investigation as new functional materials.

12:10 PM EL03.01.05
Search for Inorganic Ternary Oxide-Nitrides Abhishek Sharan[1,2] and Stephan Lany[1]; [1]National Renewable Energy Laboratory, United States; [2]Khalifa University, United Arab Emirates

Materials design from first principles enables exploration of uncharted chemical spaces. Broad computational searches have been reported for ternary mixed-cation oxides and nitrides. More recently, mixed-anion systems are gaining interest for computational discovery studies. Within this class, oxide-nitrides are particularly intriguing, because the two constituent systems exhibit remarkable commonalities (e.g., bond strength, elastic properties) and differences (e.g., formation enthalpies, electronic structure). A common limitation of computational discovery approaches is the reliance on prototype structures for total energy calculation which can miss the lowest energy structure. In addition, some known ternary oxide-nitrides form an ordered or disordered configuration derived from the crystal structure of a binary oxide, which may not be captured by prototypes selected from ternaries. We approach this challenge by letting two complementary structure sampling approaches compete. We use the Kinetically Limited Minimization (KLM) approach for high-throughput unconstrained crystal structure prediction in smaller cells up to 20 atoms, and, on the other hand, a configurational sampling on larger binary prototype structures. Using this approach, we searched 65 different

charge-balanced oxide-nitride stoichiometries, where 6 known systems were included as control sample. Within this set, we predict 8 new stable ternary oxynitrides, and an additional 5 new oxynitrides that are expected to be stable under activated Nitrogen conditions. The control sample was correctly recovered, providing confidence in the approach and clearing the path for future studies in a more extensive search space.

Metavalent Bonding in Solids—Provocation or Promise? Matthias Wuttig[1,2]; [1]RWTH Aachen University, Germany; [2]FZ Jülich, Germany

Scientists and practitioners have long dreamt of designing materials with novel properties. Yet, a hundred years after quantum mechanics lay the foundations for a systematic description of the properties of solids, it is still not possible to predict the best material in applications such as photovoltaics, superconductivity or thermoelectric energy conversion. This is a sign of the complexity of the problem, which is often exacerbated by the need to optimize conflicting material properties. Hence, one can ponder if design routes for materials can be devised. In recent years, the focus of our work has been on designing advanced functional materials with attractive opto-electronic properties, including phase change materials, thermoelectrics, photonic switches and materials for photovoltaics. These materials are typically discussed as unconventional semiconductors, often but not always, with appreciable charge transfer. Phase Change Materials have provided a special challenge for materials optimization. They possess a remarkable property portfolio, which includes the ability to rapidly switch between the amorphous and crystalline state. Surprisingly, in PCMs both states differ significantly in their properties. This material combination makes them very attractive for applications in rewriteable optical and electronic data storage, as well as photonic switches. In this talk, the unconventional material properties will be attributed to a unique bonding mechanism (metavalent bonding). Further evidence for this bonding mechanism comes from a quantum-chemical map, which separates the known strong bonding mechanisms of metallic, ionic and covalent bonding. The map reveals that metavalent bonding is a new, fundamental bonding mechanism, which differs substantially from metallic, covalent and ionic bonding. This insight is subsequently employed to design phase change as well as thermoelectric materials. Yet, the discoveries presented here also force us to revisit the concept of chemical bonds and bring back a history of vivid scientific disputes about ‘the nature of the chemical bond’.

Computational Screening of Light-Absorbing Materials for Tandem Devices Karsten W. Jacobsen; Technical University of Denmark, Denmark

In the talk I shall discuss recent efforts to computationally identify light-absorbing materials for use in solar cells and water splitting devices in particular with a tandem configuration. A range of materials are considered including sulfide perovskites, quartenary chalcogenides, and more broadly experimentally synthesized compounds, which have been structurally characterized. Key descriptors such as structure, stability, band gap, band structure, and defect states will be addressed. The possibilities of using machine learning to improve the efficiency of computational screening and structure determination will also be discussed.

1:50 PM EL03.02.03

$K_{1-x}Na_xAsSe_2$—New Low-Melting Noncentrosymmetric $AAsQ_2$ Semiconductors Abishek K. Iyer[1], Hye Ryung Byon[2], Jingyang He[3], Shiqiang Hao[1], Benjamin Oxley[1], Christopher Wolverton[1], Venkatraman Gopalan[3], Mercouri G. Kanatzidis[1] and Joon Jang[2]; [1]Northwestern University, United States; [2]Songang University, Korea (the Republic of); [3]The Pennsylvania State University, United States

Nonlinear optical (NLO) materials are used to convert the specific coherent wavelengths produced by lasers into wavelengths in other spectral regions such as UV-visible (0.2–2 μm) and infrared (IR) (3–20 μm), where lasers have poor efficiency. Metal chalcogenides with their smaller band gaps are appropriate for IR lasers, which are useful for visualization of tissue, environmental monitoring, and security applications. There are plenty of commercially available UV-visible NLO materials, but there only a few commercially available IR NLO materials. Even these materials suffer from problems such low laser damage threshold and two photon absorption, thus there is a need to search for new NLO materials in the IR-region. Alkali-metal chalcoarsenates (AAsQ_2) one such system that were discovered a decade ago which showed impressive NLO properties. AAsQ_2 (A = Li, Na and Q = S, Se) compounds are made up of 1-dimensional (1D) (1/∞) $[AQ_2]^-$ chains which are connected by pyramidal AQ_3 units as observed in β-LiAsQ_2 (*Cc*) and γ-$NaAsSe_2$ (*Pc*) structures (Q = S and Se). γ-$NaAsSe_2$ have one of the highest second harmonic generation (SHG) intensities observed (~ 75 x $AgGaSe_2$) while, adding Na to the β-LiAsQ_2 structures resulted in increased SHG response as observed in γ-$Li_{0.2}Na_{0.8}AsSe_2$ (~ 65 x $AgGaSe_2$) and β-$Li_{0.6}Na_{0.4}AsS_2$ (~ 30 x $AgGaSe_2$). Structurally, the substitution of the smaller Li ions with larger Na ions weakens the interactions between adjacent (1D) (1/∞) $[AQ_2]^-$ chains. A problem with γ-$NaAsSe_2$ (*Pc*) is a phase transition to the centrosymmetric δ-$NaAsSe_2$ (*Pbca*) upon melting, making it a challenge to grow large single crystals for NLO applications.
Here we have studied the effects of substituting γ-$NaAsSe_2$ (*Pc*) with the larger cation K to see if the interactions between the adjacent (1/∞) $[AQ_2]^-$ chains are further weakened, thereby, its effect on their NLO properties. Additionally, K containing chalcoarsenates are usually low melting making them attractive for crystal growth which are essential for their application as NLO materials.

2:05 PM *EL03.02.04
Surface Structure, Defects and Reactivity of Perovskite Oxynitrides Ulrich Aschauer; University of Bern, Switzerland

The smaller band gap compared to pure oxides yields a superior light-absorption efficiency of perovskite oxynitride photocatalysts. While the bulk structure and properties of these materials have been extensively studied by computational methods, significantly less is known about their surfaces and consequently their photocatalytic reaction mechanisms. In this talk, I will present results of our density functional theory (DFT) calculations, highlighting anion-ordering phenomena at perovskite oxynitride surfaces, the effect of defects on their oxygen-evolution reaction (OER) activity as well as the potential of strain engineering these materials to become ferroelectric photocatalysts.

2:30 PM EL03.02.05
A Theoretical Exploration of Earth-Abundant Bismuth Oxyhalides for Thermoelectric Applications Maud Einhorn and David O. Scanlon; University College London, United Kingdom

Thermal energy is an unavoidable by product of myriad processes, spanning the industrial, domestic and transportation sectors, and presents an abundantly available and largely untapped source of clean energy. Thermoelectric devices, which are able to convert thermal energy into electricity, provide a route to significantly increase the overall energy efficiency of existing process across a range of sectors via waste-heat harvesting and yield a supply of clean energy.[1] The effectiveness of a thermoelectric material is measured using the dimensionless figure of merit *ZT*, with the world record set at 2.6 for single-crystal SnSe along the through-plane direction.[2] Realising reasonable conversion efficiencies generally requires high electrical conductivity and low thermal conductivity, with the maximum *ZT* of a material often limited by the strong correlation between these properties.

Despite efforts in the past few decades to identify promising novel thermoelectric materials, the champion thermoelectric materials tend to rely on non earth-abundant and toxic elements, such as bismuth telluride (Bi_2Te_3) and the lead chalcogenides. Oxides generally present properties valuable for thermoelectric applications, including low cost, thermal and chemical stability and environmental benignity, but broadly thermoelectric performance has been hindered by the inherent high lattice thermal conductivities.[4] The performance of oxide thermoelectrics generally lagging behind the efficiencies achieved by chalcogenide-based materials, with poor carrier mobilities and high intrinsic thermal conductivities hampering progress.[3]

In this study, we predict the maximum theoretical ZTs of a range of novel mixed-anion quaternary systems using state-of-the-art methods based on density functional theory. We have identified three materials with complex crystal structures, Bi_2YO_4Cl, Bi_2YO_4Br and Bi_2YO_4I, which possess lower lattice thermal conductivities than usually seen in oxides, and excellent charge transport properties, calculated using methods superseding the traditionally used constant relaxation time approximation.[5] We conclude that these materials have the potential to achieve ZTs greater than many existing oxide thermoelectric materials, and have the potential to perform as high-performance thermoelectric components. Additionally, the effects of nanostructuring these materials is discussed, to guide potential synthesis methods.

Thin Film Growth of Chalcogenide Perovskites by Pulsed Laser Deposition Jayakanth Ravichandran; University of Southern California, United States

Chalcogenide Perovskites are a new class of semiconductors, which have tunable band gap in the visible to infrared part of the electromagnetic spectrum, large density of states with potentially high carrier mobility, and emergent photonic properties with anisotropy and non-linearity. In this talk, I will review the developments in thin film growth of perovskite chalcogenides and discuss some of the advances made in my research group on developing pulsed laser deposition as a growth method for chalcogenide perovskite thin films. We have successfully achieved textured growth of chalcogenide perovskite thin films on single crystalline oxide substrates. This advance presents new opportunities to probe the physical and chemical properties of this family

of novel electronic materials, their device implementations and applications, and also study the interfacial properties of oxides and chalcogenides. Specifically, I will outline the growth of model chalcogenide perovskite, $BaZrS_3$ and the quasi-1D hexagonal Perovskite-related sulfide, $BaTiS_3$ on compatible perovskite and other oxide single crystal substrates. Preliminary investigations on the physical properties accompanied by detailed structural and chemical characterizations and future outlook for the thin film growth of these materials will also be discussed.

4:25 PM EL03.03.02

Combinatorial Development of CaCuP Thin Films as P-Type Transparent Conductors Andrea Crovetto[1,2], Thomas Unold[2] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Despite long-standing research efforts to develop p-type transparent conductive materials (TCMs), the current generation of optoelectronic devices still relies exclusively on n-type TCM contacts due to their much better trade-off between conductivity and transparency. An important issue in oxide-based p-type TCMs is the deep energy and localized nature of the 2p oxygen states in the valence band, which has negative consequences on both hole dopability and hole mobility in most oxides.

Recent computational work has identified the mixed ionic-covalent compound CaCuP as a promising material that could potentially outperform the existing p-type TCMs. On the one hand, the covalent bond between Cu and P produces a highly dispersive valence band, which favors high hole mobilities. On the other hand, the presence of an electropositive cation (Ca) implies that more ionic Ca-P bonds are also present in CaCuP. This plays an important role in widening the band gap (thus ensuring high optical transmission in the visible) and making CaCuP potentially suitable as a p-type TCM.

Using a unique combinatorial sputter chamber equipped with reactive PH_3 gas, we have grown CaCuP thin films for the first time. We have mapped the compositional and thermal phase space of CaCuP and evaluated its potential as a p-type TCM using high-throughput methods. Due to the high concentration of copper vacancies, the electrical conductivity of CaCuP under optimized growth conditions is almost on par with the conductivity of state-of-the-art n-type TCMs such as ITO and FTO, even in the absence of any extrinsic dopant. However, CaCuP films are only moderately transparent in the visible region due to unexpectedly high absorption strength above its indirect band gap. We will discuss possible solutions to this problem, together with the general prospects of CaCuP as a p-type TCM.

4:40 PM EL03.03.03

Realization of $BaZrS_3$ Chalcogenide Perovskite Thin Films for Optoelectronics Xiucheng Wei[1], Haolei Hui[1], Mengjiao Han[2], Junhao Lin[2], Yi-Yang Sun[3], Shengbai Zhang[4] and Hao Zeng[1]; [1]University at Buffalo, The State University of New York, United States; [2]Southern University of Science and Technology, China; [3]Shanghai Institute of Ceramics, Chinese Academy of Sciences, China; [4]Rensselaer Polytechnic Institute, United States

Recently published work reveals that the ionic chalcogenide perovskite $BaZrS_3$ possesses suitable properties for PV application, such as direct band gap of 1.7 to 1.8 eV, high stability against moisture and pressure, and strong light absorption. However, the lack of thin films hinders further exploration of this material's fundamental properties. Here we report the first work on $BaZrS_3$ films, by sulfurization of precursor films deposited by pulsed laser deposition and magnetron sputtering. The films are n-type semiconductors with carrier densities in the range of 10^{19} to 10^{20} cm^{-3}. The hall mobility ranges from 2.1 to 13.7 cm^2/Vs depending on the sulfurization temperature. UV-Vis result shows an absorption coefficient of $>10^5$ cm^{-1} at a photon energy of >1.97eV. We further incorporate Ti to reduce the band gap of $BaZrS_3$ for better solar performance. Our thin film results pave the way to future device fabrication and validate $BaZrS_3$ as a viable candidate for optoelectronics.

4:55 PM EL03.03.04

Late News: Growth of BaZrS3 Thin Films by Molecular Beam Epitaxy Ida Sadeghi, Kevin Ye and Rafael Jaramillo; Massachusetts Institute of Technology, United States

Chemical intuition, first-principles calculations, and recent experimental results suggest that chalcogenide perovskites are an outstanding class of semiconductors [1]. Chalcogenide perovskites feature the large dielectric response familiar in oxide perovskites, but also have band gap in the VIS-IR and strong light absorption. Preliminary results suggest that chalcogenide perovskites feature excellent excited-state charge transport properties familiar in halide perovskites, while also being thermally-stable and comprised of abundant and non-toxic elements. Nearly all experimental results on chalcogenide perovskites to-date were obtained on powder samples and microscopic single crystals [2-7]. Realizing the full potential of chalcogenide perovskites for optoelectronic applications will require the availability of high-quality, single-crystal thin films.

Here we report synthesis of $BaZrS_3$ thin films by molecular beam epitaxy (MBE) on oxide substrates. The film composition is confirmed by X-ray fluorescence and X-ray photoelectron spectroscopy. The phase is confirmed by X-ray diffraction and Raman spectroscopy. Photoluminescence spectroscopy showed peaks at 1.8 and 1.95 eV, suggestive of pristine and partially-oxidized material. We use spectroscopic ellipsometry to measure optical properties, confirming strong band-edge light absorption. As time allows we will present results of scanning transmission electron microscopy, impedance spectroscopy, the growth of $BaZr(S,Se)_3$ alloys with tunable band gap.

5:10 PM EL03.03.05
$SrHfS_3$ Thin Films with Green Light Emission Haolei Hui[1], Xiucheng Wei[1], Zhonghai Yu[2], Yi-Yang Sun[3], Sen Yang[2] and Hao Zeng[1]; [1]University at Buffalo, The State University of New York, United States; [2]Xi'an Jiaotong University, China; [3]Rensselaer Polytechnic Institute, United States

$SrHfS_3$ belongs to the family of chalcogenide perovskite semiconductors with a bandgap of 2.43eV. Recently $SrHfS_3$ bulk crystals have been shown to exhibit strong green photoluminescence. It was also shown that it can be heavily doped to be both p- and n-type with strong emission, suggesting its bipolar doping capability and defect tolerance. It is thus a promising candidate to fill the green gap for solid
state lighting applications. In this work, we show that $SrHfS_3$ thin films can be prepared by magnetron sputtering and CS_2 sulfurization. Raman spectrum matches closely with the theoretical calculations of a distorted perovskite structure. The film quality such as PL intensity and carrier concentration is highly dependent on sulfurization temperature.

5:25 PM EL03.03.06
Structure and Electronic Properties of Mixed-Bonded PbSe Epitaxial Thin Films on III-V Substrates Kunal Mukherjee[1,2], Brian Haidet[2], Eamonn Hughes[2], Leland Nordin[3], Aaron Muhowski[3], Kevin Vallejo[4], Paul

Simmonds[4] and Daniel Wasserman[3]; [1]Stanford University, United States; [2]University of California, Santa Barbara, United States; [3]The University of Texas at Austin, United States; [4]Boise State University, United States

PbSe has emerged as a prototype for the study of unusual bonding in semiconductors. Recent work reveals the nature of bonding in PbSe and related IV-VI narrow band gap semiconductors as being distinct from covalent, ionic, and metallic.[1] We investigate the impact of such bonding on thin film growth, dislocation generation and dynamics, band-to-band carrier recombination, and field evaporation in epitaxial films grown directly on III-V substrates. These high quality engineered substrates serve as an excellent platform to probe and manipulate the properties of PbSe and its alloys.

We first demonstrate a route to prepare single crystal rocksalt PbSe films both on nearly lattice-matched and highly mismatched zincblende III-V substrates like InAs and GaAs using molecular beam epitaxy.[2] Our synthesis technique yields sharp heterointerfaces and we see clear structural distortions in the first few monolayers of PbSe mediating the significant bonding mismatch. These bare thin films strongly luminescence in the mid-infrared at room temperature even in the presence of threading dislocation densities exceeding $10^9/cm^2$, in sharp contrast to what may be expected from covalently bonded narrow bandgap III-V materials. We find minority carrier recombination lifetimes in our unintentionally doped PbSe films under low excitation in the 20–30 ns range and suggests a three carrier Auger process, although some very thin films deviate from this trend towards even longer lifetimes. Overall, these results are promising for the development of heterogeneously integrated mid-infrared light emitters.

Exploring this theme of unusual bonding further, the occurrence of elevated multi-atom evaporation events in atom probe tomography (APT) was recently hypothesized as a means to evaluate the nature of bonding in materials.[3] We indeed see high rate of events with multiple atoms evaporating at once in voltage-pulsed APT of PbSe, supporting this suggestion, and finding even more such events localized around dislocation cores. However, in the same experiment we also see a high rate of multi-atom evaporation events in epitaxial layered-structure SnSe, which should be a mix of conventional covalent intra-layer and Van der Waals inter-layer bonding, showing exceptions are possible.

Characteristics of Silicon Nitride Thin Film with Plasma Treatment Chanwon Jung, Seokhwi Song, Suhyeon Park, Byunguk Kim, Youngjoon Kim, Eunjong Lee, Sunggwon Lee, Taehun Park and Hyeongtag Jeon; Hanyang University, Korea (the Republic of)

As the device's feature sizes continue to shrink, traditional floating gate NAND flash memory faces reliability issues such as cell-to-cell interference, reduced charge loss tolerance, and susceptibility to stress-induced leakage currents. 3D NAND flash memory was developed to overcome the above-mentioned problem. In 3D NAND flash memory, the charge storage material is silicon nitride (SiN_x), and the main trend for increasing

memory density is not scaling shrinking but stacking layers. Low-pressure chemical vapor deposition (LPCVD) is one of the most popular deposition methods to deposit SiN_x thin films on semiconductors due to its low hydrogen content and excellent step coverage and thermal stability. However, as more layers are stacked to increase memory density, the device's aspect ratio increases. The 1st generation 3D NAND flash memory has 24 layers and has an aspect ratio of 40:1. And currently, devices with more than 100 layers are required. As above, with the continuous aspect ratio increase, there is a demand deposition technology with accurate thickness control and high step coverage. Among various deposition methods to apply at high step coverage device, atomic layer deposition (ALD) is one of the best solutions to satisfy above-mentioned requirements. Due to self-limited ALD reaction, it enables to deposit thin film with high step coverage and good thickness control. Particularly, remote plasma ALD (RPALD) was utilized to enhance the reactivity between precursor and reactant gas for high film density with minimizing plasma damage. In RPALD, the plasma generation section is remotely outside of the reaction chamber and the radicals in plasma generation region enter into the reaction chamber for deposition.
In this study, we developed low-temperature SiN_x using bis(dimethylaminomethylsilyl)-trimethylsilyl amine ($C_9H_{29}N_3Si_3$, DTDN-2H2) and N_2 reactant plasma as the precursor and reactant plasma. We studied the effect of plasma treatments that are 2 methods such as post plasma treatment and during deposition process plasma treatment. Various plasma processing processes were used in deposition processes to satisfy the defect density levels ($5x10^{19}$ /cm^3). We investigated the effect of plasma treatment on the properties of SiNx thin film. Auger electron spectroscopy (AES) was utilized to measure the stoichiometry. Samples treated by plasma treatment were stoichiometry thin film by 1:1.33 Si:N ratio. Because hydrogen content affects fault density, the hydrogen content of SiNx film deposited was measured using secondary ion mass spectrophotometry (SIMS). X-ray photoelectron spectroscopy (XPS) was utilized for chemical binding state. N1s peak of H_2 plasma treatment SiN film had low-binding shift to397.5eV from 397.7 eV (N-Si bond). The density of plasma-treated thin films was compared by X-ray reflectometry (XRR). In the case of thin film with plasma treatment, film density was higher than as deposition sample. And thin film with post H2 plasma treatment was the highest density of 2.9g/cm^3. In addition, studying defect properties of each thin film, we fabricated metal-Al_2O_3-silicon nitride-SiO_2-Si (MANOS) device. The trap density required by CTF device was satisfied by Ar plasma treatment during ALD process, post Ar plasma treatment, and post H_2 plasma treatment SiN thin film. Trap density of Post H_2 plasma treatment SiN films was increased to $7.65x10^{19}$ /cm^3

9:00 PM *EL03.04.04
Investigation on the Stability of Liquid-Like Thermoelectric Materials and Modules Pengfei Qiu;
Shanghai Institute of Ceramics, Chinese Academy of Sciences, China

Recently, the application of superionic conductors with liquid-like sublattice has been extended to the field of thermoelectrics. Extremely high thermoelectric figure of merit with the maximum $zT > 2.0$ have been observed and reported in a large family of novel Cu- and Ag-based liquid-like materials. However, despite the high performance, the stability and reliability of these liquid-like materials are key concerns for long-term service in the real applications. In this study, through systematically investigating the behavior of various liquid-like materials in an electric field or thermal gradient, we reveal the relations of atom migration, deposition, and material degradation. A general model is proposed to reveal the threshold for decomposition of liquid-like materials to prevent metal deposition upon atom migration. It is found that each liquid-like material has a threshold for metal deposition, named as the critical voltage. When the voltage stressed on the material is lower than the V_c, the mobile ions just form a steady concentration of gradient inside the material without any deposition. In this case, the liquid-like materials will demonstrate similar good stability with the traditional stable materials. With these understanding, a new strategy is proposed to design the stable and efficient TE modules based on liquid-like materials via geometry and interface optimization. By using this strategy, a TE module based on Cu_2Se with both good stability and high energy conversion efficiency up to 9.1% was successfully achieved.

9:25 PM EL03.04.06
Octahedron Rotation Evolution in 2D Perovskites and Its Impact on Optoelectronic Properties—The

Case of Ba–Zr–S Chalcogenides Chen Ming[1], Ke Yang[2,3], Hao Zeng[4], Shengbai Zhang[2] and Yi-Yang Sun[1]; [1]Shanghai Institute of Ceramics, Chinese Academy of Sciences, China; [2]Rensselaer Polytechnic Institute, United States; [3]Hunan University, China; [4]University at Buffalo, The State University of New York, United States

Perovskite materials can have self-passivated surfaces without resorting to reconstructions or other passivating agents. This feature renders perovskite materials intrinsically suited for making two-dimensional (2D) materials. Previous studies often considered the structure of 2D perovskites to be directly terminated from the bulk. However, octahedron rotation (OR), being the distinctive structural feature of perovskite materials, appears to be an unexplored degree of freedom in 2D.
In this work, the OR patterns in 2D perovskites are systematically studied for the first time by employing an adapted Glazer's notation. Taking 2D Ba-Zr-S system as an example, we establish the relation between the OR pattern and slab thickness. It is found that as the thickness decreases, the OR pattern undergoes a transition by suppressing out-of-plane rotations. The OR in 2D chalcogenide perovskites could result in an anti-confinement effect, i.e., reducing the band gap to even below that of the bulk by countering the quantum confinement effect. In addition, we show that the Ba-Zr-S 2D perovskites exhibit reasonable electron mobility of ~150 $cm^2 V^{-1} s^{-1}$ and large exciton binding energy of ~0.9 eV. Our results suggest that the structure of OR is worth attention in future studies on 2D perovskites, and it provides a novel tuning knob for enhancing the properties of 2D materials, which is absent in existing 2D materials, such as graphene and transition metal dichalcogenides.

9:40 PM EL03.04.07
Chalcogenide Perovskite $YScS_3$ as a Potential p-Type Transparent Conducting Material Han Zhang[1], Chen Ming[2], Ke Yang[3,4], Hao Zeng[5], Shengbai Zhang[3] and Yi-Yang Sun[2]; [1]Shandong University, China; [2]Shanghai Institute of Ceramics, Chinese Academy of Sciences, China; [3]Rensselaer Polytechnic Institute, United States; [4]Hunan University, China; [5]University at Buffalo, The State University of New York, United States

Transparent conducting materials (TCMs) have been widely used in optoelectronic applications such as touchscreens, flat panel displays and thin film solar cells. These applications of TCMs are currently dominated by n-type doped oxides. High-performance p-type TCMs are still lacking due to their low hole mobility or p-type doping bottleneck, which impedes efficient device design and novel applications such as transparent electronics. Here, based on first-principles calculations, we propose chalcogenide perovskite $YScS_3$ as a promising p-type TCM. According to our calculations, its optical absorption onset is above 3 eV, which allows transparency to visible light. Its hole conductivity effective mass is 0.48m_0, which is among the smallest in p-type TCMs, suggesting enhanced hole mobility. It could be doped to p-type by group-II elements on cation sites, all of which yield shallow acceptors. Combining these properties, $YScS_3$ holds great promise to enhancing the performance of p-type TCMs toward their n-type counterparts.

9:55 PM EL03.04.08
Late News: Single-Site of Pervoskite Unit Cell with d-d Transition in Electronic States Cong Wang; Beijing University of Technology, China

As one of low-cost and widely-utilized materials, pervoskite type metal oxides have been extensively investigated and applied in environmental remediation and protection, energy conversion and storage, etc.[1-7] Most of these diverse applications are results of a large diversity of the electronic states of metal oxides. Noticeably, however, many metal oxides present obstacles for applications in catalysis, mainly due to the lack of efficient active sites with desired electronic states. Continuous efforts and strategies have been devoted to create new structural units and functional activities of metal oxides. Single-site catalysis is one of most attractive solutions to explore new activities and enhance catalytic efficiencies.[8-10] Here, we demonstrate the fabrication of single tungsten atom oxide (STAO), in which the metal oxide's active site unit reaches its minimum and a new electronic state is created. The catalytic mechanism in the STAO is determined by a new single-site physics mechanism, which is fundamentally distinct from the traditional size effect, and is also in

contrast to the standard condensed matter physics. The photogenerated electron transfer process is enabled by an electron in the spin-up channel excited from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO)+1 state (both are largely tungsten atomic d-orbitals), which can only occur in STAO with W^{5+}. STAO results in a record-high and stable sunlight photocatalytic degradation rate of 0.24 s^{-1}, which exceeds the rates of available photocatalysts by approximately two orders of magnitude. The fabrication of STAO and its unique single-site photocatalytic mechanism lays a new ground for achieving novel physical and chemical properties using various single metallic atom oxides.

Structure and Physical Properties of Complex Chalcogenides—Fundamental Research with an Eye Towards Applications George Nolas; University of South Florida, United States

Complex chalcogenides have demonstrated a variety of unique physical properties that are directly related to specific bonding schemes, and therefore continue to be investigated for different applications of interest. In addition, new chalcogenide compositions expand our library of materials and provide potential new avenues for discovery. Research that not only allows for a continuity of ongoing work into new and novel chalcogenide material systems but can also provide pathways for the design of materials or processing techniques with targeted properties for specific applications is paramount. The intellectual merit of these investigations is very closely tied to the particular bonding and structure types these materials possess. Developing a fundamental understanding of the underlying physical properties and their structure-property relationships is also of interest. I will present some of our recent progress on the structure-property relationships of specific materials, including layered materials, lanthanide metal polytellurides and new quaternary chalcogenides, provide insight into the search for new materials, and present results that demonstrate strong electron-phonon coupling and atypical transport of new chalcogenide materials.

12:10 PM EL03.05.02
Configurational Order-Disorder Transitions in $ZnGeN_2$ Jacob Cordell[1,2], Jie Pan[2], Adele Tamboli[2,1], Garritt J. Tucker[1] and Stephan Lany[2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

The dependence of electronic structure on cation disorder in II-IV-V_2 materials with lattice parameters matched to their analogue III-V semiconductors makes these systems promising for tuning band gaps for use in energy-relevant devices such as LEDs and PV. Experimentally, however, properties do not always correlate with order as expected. In $ZnGeN_2$ specifically, the non-isovalent character of the disordered species (Zn^{2+} and Ge^{4+}) subjects the cation ordering to strong short-range order effects which influence band structure by decreasing the band gap relative to ordered $ZnGeN_2$. $ZnGeN_2$ exhibits pronounced discontinuities in enthalpy, entropy, and structural order parameters, which correspond to a first-order phase transition which is key to understanding the tunability of electronic properties. The steep nature of this transition suggests intermediate degrees of ordering are difficult or even impossible to obtain in single crystals or within crystalline grains. To model cation disorder, we use Monte Carlo (MC) simulations implementing a cluster expansion to approximate formation enthalpy. Representative configurations are relaxed in supercells containing 1,024 atoms using density functional theory calculations. From the Monte Carlo structures, we calculate the fractions of all possible

nitrogen coordination environments as a short-range order parameter and the Bragg-Williams and stretching parameters as long-range order parameters. We compare correlations between these order parameters as well as the mixing entropy and free energy of the system determined from thermodynamic integration to experimental literature on order in II-IV-V_2 materials.

12:25 PM EL03.05.03

Tuning the Electronic Properties of $LaFeO_3$ Thin-Films Photoelectrodes via Partial Cation Replacement

David J. Fermin[1], Xin Sun[1] and Devendra Tiwari[2]; [1]University of Bristol, United Kingdom; [2]Northumbria University, United Kingdom

Fe_2O_3 thin-films have been extensively investigated as photoanodes, with a variety of different strategies being proposed to mitigate key performance limiting factors, namely short carrier lifetimes and surface recombination kinetics.[1] On the other hand, significantly less is known about the properties of perovskite ferrite absorbers, including $LaFeO_3$,[2-4] $YFeO_3$,[5] $PrFeO_3$,[6] and $BiFeO_3$.[7] These materials exhibit a wide range of intrinsic defects, which often lead to p-type conductivity. Our recent studies have shown that highly crystalline $LaFeO_3$ nanoparticles can promote hydrogen evolution under illumination at potential as positive as 1.47 V vs RHE,[8] one of the highest photovoltages reported for a single p-type absorber layer. However, the performance of these perovskites is limited to quantum yields below 1%. In this contribution, we will examine the nature of the states involved in the loss of photogenerated carriers and the effect of partial substitution by alkaline-earth metal cations (AMC).

$LaFeO_3$ thin-film with a thickness of 95 nm were prepared by thermolysis (600 °C) of sol-gel precursors incorporating citric acid as chelating agent.[9] The ratio of AMC (Mg^{2+}, Ca^{2+}, Ba^{2+} and Sr^{2+}) to La^{3+} were adjusted in the range of 0 to 10% in the precursor solution, while keeping the Fe^{3+} concentration constant. XRD confirms the formation of single-phase cubic $LaFeO_3$ thin films across the whole composition range. Interestingly, we observe subtle trends in lattice constant variations which are closely correlated to shifts in the binding energies of Fe $2p_{3/2}$ and O 1s measured by XPS. These trends are the result of the complex interplay between differences in ionic radii of the cations and changes in the oxidation state of Fe sites. Indeed, we establish a scaling factor between these two photoemission peaks, revealing a direct correlation between Fe oxidation state and Fe–O covalency. Electrochemical impedance spectroscopy (EIS) confirms the p-type characteristic of pristine $LaFeO_3$ thin-films, as well as the presence of sub-bandgap electronic state (A-states) close to the valence band edge. Partial AMC replacement leads to: (i) a decrease in the density of A-states, (ii) an increase in density of majority carriers (shallow acceptor states), and (iii) a shift of the valence band edge toward more positive potentials. In addition, AMC-substituted films exhibit deeper states centered at 0.6 eV above the valence band edge (B-states). These sub-band gap states have contrasting effects on the photoelectrochemical responses towards the oxygen reduction and the hydrogen evolution reactions. These trends are rationalized in terms of the position of the sub-bandgap states, majority carrier mobility, charge transfer and recombination kinetics.

Challenges and Opportunities in Ionic Chalcogenide Semiconductors Mercouri G. Kanatzidis[1,1,2]; [1]Northwestern University, United States; [2]Argonne National Laboratry, United States

Metal chalcogenides define a large and important field of chemistry, and these materials continue to present appealing intellectual and scientific challenges. They are a large class with a broad set of chemical and physical properties involving diverse scientific phenomena and impact an astonishing variety of applications. The fields of science and technology impacted by chalcogenides continue to broaden. Some examples include nonlinear optics, thermoelectric energy conversion<!--[endif]---->, radiation detectors,<!--[endif]----><!--![endif]----><!--[endif]----> catalysis, topological insulators, science in two-dimensions, and unconventional superconductivity. Recently, the chemistry of these complex chalcogenides has witnessed the largest growth. We are in the middle of an impressive expansion in solid state chalcogenide chemistry with emphasis on materials with new compositions and structure types. In this regard, the development of novel synthetic methodologies is playing a major role in producing new materials, and this is a main objective in our program. We will highlight the general themes of synthesis science and structure-composition-property relationships with the following question being central: How does one develop the tools and concepts, both intellectual and experimental, to prepare new functional materials. There are several science drivers behind this research. Since crystal structure defines physical properties, of particular interest is learning to control structure dimensionality in complex systems. Another is learning how to incorporate two different metals in a single chalcogenide structure while avoiding phase separation. We will present relevant example in new materials with nonlinear optical properties and hard radiation and neutron detection capabilities and how they evolve as a function of composition and structure. <!--![endif]----><!--![endif]---->

1:05 PM EL03.05.05
Late News: Structure and Bonding of AM2Pn2 (A=Ca, Mg, Yb; Pn=Bi, Sb) Compounds at High Pressure
Mario R. Calderon Cueva[1], Wanyue Peng[1], Clarke Samantha[2], Megan Rylko[1], Jingxuan Ding[3], Allison Pease[1], Gill Levental[1], Benjamin Brugman[1], Susannah Dorfman[1] and Alexandra Zevalkink[1]; [1]Michigan State University, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Duke University, United States

Compounds in the structure type $CaAl_2Si_2$ have attracted great attention in recent years for their thermoelectric properties. In particular, $MgMg_2Sb_2$ and $MgMg_2Bi_2$ exhibit an impressive thermoelectric figure of merit zT due, in part, to their anomalously low thermal conductivity. In the present study, in situ high-pressure synchrotron X-ray diffraction was used to investigate the structure and bonding in binary and ternary AM_2X_2 compounds at pressures up to 50 GPa. Our results confirm prior predictions of isotropic in-plane and out-of-plane compressibility but reveal large disparities between the bond strength of the two distinct Mg sites. Using single-crystal diffraction, we show that the octahedral Mg–Sb bonds are significantly more compressible than the tetrahedral Mg–Sb bonds in $MgMg_2Sb_2$, which lends support to prior arguments that the weaker octahedral Mg bonds are responsible for the anomalous thermal properties of $MgMg_2Sb_2$ and $MgMg_2Bi_2$. Further, we report the discovery of a displacive and reversible phase transition (*C2/m*) in both $MgMg_2Sb_2$ and $MgMg_2Bi_2$ above 7.8 and 4.0 GPa, respectively. The transition to the high-pressure structure in these binary compounds involves a highly anisotropic volume collapse, in which the out-of-plane axis compresses significantly more than the in-plane axes. Further, we investigate the bond compressibility in ternary AM_2X_2 compounds using $CaMg_2Sb_2$ and $YbMg_2Bi_2$ to develop trends between bond compressibility and cation size and to study the stability of the $CaAl_2Si_2$ structure type.

Structure-Property Relationships in Complex Early Transition Metal Oxides for High-Rate Energy Storage Megan M. Butala[1], Kit McColl[2], Kent J. Griffith[3], Rebecca Dally[4] and Igor Levin[4]; [1]University of Florida, United States; [2]University College London, United Kingdom; [3]Northwestern University, United States; [4]National Institute of Standards and Technology, United States

As batteries are employed in larger numbers and for increasingly diverse applications, there is interest in electrode materials with improved safety, availability, and cost relative to commercial electrodes. Early transition metal oxides are one alternative material family showing promise, especially for high rate applications. However, we do not yet have a strong understanding of the role of composition, structure, and structural evolution with cycling for these materials, which tend to have large unit cells and complex structures.

To contribute to this fundamental understanding, we have studied the energy storage abilities and mechanism of complex niobate electrode materials KNb_3O_8 and $NaNb_3O_8$. Using *ex situ* and *operando* X-ray diffraction, complemented by nuclear magnetic resonance spectroscopy and first principles calculations, we identify local and average structure changes and relate them to cycling performance and properties, including electronic conductivity over a charge induced metal-insulator transition. We also reflect on the role of these results in establishing a more general understanding of the structure-property relationships of other early transition metal oxides, for energy storage and beyond. This understanding is a necessary step toward the selection and design of electrode materials for the quickly-evolving energy landscape and our fundamental understanding of complex oxide semiconductors.

Materials Chemistry of Ternary Nitride Semiconductors Andriy Zakutayev; National Renewable Energy Laboratory, United States

Nitride semiconductors is an interesting class of materials studied for diverse properties. Simple binary nitride semiconductors with wurtzite crystal structure such as GaN have been long used in many practical applications ranging from optoelectronic to telecommunication. The structurally related ZnGeN2 or MgSnN2 derived by cation mutation from the parent binary compounds have recently attracted attention for their disorder-tunable properties. However, these ternary nitride materials are mostly limited to II-IV-N2 composition closely related to parent III-N compounds.
This invited presentation will focus on chemistry-inspired material design of unconventional ternary nitride semiconductors. First, chemical trends in crystal structure and thermodynamic stability of ternary nitrides containing Mg or Zn, and Zr, Nb, Mo transition metals will be presented. Second, the results will be shown for thin film synthesis and optoelectronic properties for some of these new ternary nitrides semiconductors beyond II-IV-N2 family, such as Zn2NbN3 and Mg3MoN4. Finally, kinetically controlled synthesis of metastable ternary nitrides will be discussed as one of the important next steps in the field.

3:05 PM EL03.06.03
Exploring the Nitride Perovskites Composition Space with Chemical Heuristics and First-Principles Calculations Daniel W. Davies[1], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Oxide and halide perovskites of the form ABX_3 are a thoroughly studied class of material. They display a great breadth of interesting properties, which make them suitable for a variety of application areas from high-temperature superconductors to photovoltaic absorbers. More recently, the possibility of forming stable nitride perovskites have caught the interest of several research groups. While these are fairly illusive, which can be

understood in part due to the high oxidation states required on the A and B cations, the few that have been identified computationally and experimentally so far have shown interesting electronic properties.[1,2]

In this study, we apply a computational screening workflow to further probe the composition space of nitride perovskite materials. By combining filters based on chemical heuristics from data-mined oxidation states[3] we reduce the ABN_3 search space, were A and B are technologically relevant metals, from 3,906 to just 279 potentially feasible materials. We then carry out automated first-principles calculations to systematically investigate the stability of different octahedral tilting motifs in these materials. By mapping out the thermodynamic stabilities of the various tilts for each composition, we are able to provide the next level of resolution to the composition *vs* stability picture of this chemical space. Furthermore, we carry out phonon calculations on relevant subsections of the phase space to gain insight into dynamic stability and apply hybrid density functional theory (DFT) methods to determine accurate optoelectronic properties.

3:20 PM *EL03.06.04
Mg-IV-N_2 Semiconductors—Polymorphism and Cation Disorder Ann L. Greenaway[1], Amanda Loutris[1], Rekha Schnepf[1,2], Karen Heinselman[1], Allison Mis[1,2], Rachel Woods-Robinson[1,3], Celeste Melamed[1,2], Jesse Adamczyk[2], M Brooks Tellekamp[1], Rachel Sherbondy[1,2], Dylan Bardgett[1], Sage Bauers[1], Andriy Zakutayev[1], Steven Christensen[1], Stephan Lany[1] and Adele Tamboli[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States; [3]University of California, Berkeley, United States

As the search for new semiconductors expands, new paradigms for property control are emerging. Varying stoichiometry, polymorph, and alloying have, along with doping, enabled property control in binary semiconductors. Ternary and multinary compounds have additional degrees of freedom, such as lattice site disorder, which may enable unparalleled property control. In II-IV-N_2 compounds, which are analogs of the III-N semiconductors, cation site disorder can reduce the bandgap without substantially impacting lattice parameter,[1] but several members of this class are underexplored due to the historical difficulty in synthesizing nitrides. $MgSnN_2$ is a II-IV-N_2 with a predicted ~2.3 eV bandgap and wurtzite-derived ground state structure, making it of interest for optoelectronic properties and integration with existing III-N compounds. Here, we report on one of the first syntheses of $MgSnN_2$ and explore control of cation disorder and polymorphism in this material.

We first demonstrate combinatorial radio-frequency co-sputtering of $MgSnN_2$ across a range of cation compositions and up to 500 °C.[2] The predicted wurtzite-type polymorph forms across the explored temperature range, while a rocksalt-type polymorph not captured by previous predictions is found as a secondary phase at high Mg compositions below 200 °C. This phase is substantially metastable (>70 meV/atom) compared to the wurtzite-type ground state, and is predicted to be a wide bandgap, high dielectric constant material. Synchrotron x-ray diffraction confirms that both wurtzite- and rocksalt-type phases are cation-disordered, consistent with the reduced optical absorption onset of < 2 eV for the wurtzite-type phase *via* spectroscopic ellipsometry. We also demonstrate the heteroepitaxial growth of mixed wurtzite/rocksalt $MgSnN_2$ on GaN at 400 °C, where the close effective lattice match between GaN and the rocksalt-derived phase promotes its formation outside of the previously mapped temperature and cation composition range.

The existence of two accessible polymorphs of $MgSnN_2$, in addition to the possibility of cation ordering may enable additional control of materials properties. We exploit the ability to nucleate both polymorphs of $MgSnN_2$ on GaN in ongoing work investigating cation ordering in the rocksalt-derived $MgSnN_2$ using post-growth annealing, and further discuss related polymorph and cation order phenomena in the analogous compounds

$MgSiN_2$ and $MgGeN_2$. This work forms the basis for integrated materials control through both polymorph formation and lattice site disorder, bridging existing methods of manipulating semiconductor properties and emerging tools, while opening the door for a new set of semiconductors which can be integrated with well-established III-N compounds.

Controlled Synthesis and Electronic Structure Engineering of Metastable Ta_2N_3 via Oxygen Incorporation Chang-Ming Jiang, Laura Wagner, Johanna Eichhorn and Ian Sharp; Technische Universität München, Germany

The binary Ta-N chemical system includes several compounds with notable prospects in microelectronics, solar energy harvesting, and catalysis. Among these, metallic TaN and semiconducting Ta_3N_5 have garnered significant interest, in part due to their synthetic accessibility. However, tantalum sesquinitride (Ta_2N_3) possesses an intermediate composition and largely unknown physical properties owing to its metastable nature. Herein, Ta_2N_3 is directly deposited by reactive magnetron sputtering and its optoelectronic properties are characterized. Combining these results with density functional theory provides insights into the critical role of oxygen in both synthesis and electronic structure. While the inclusion of oxygen in the process gas is critical to Ta_2N_3 formation, the resulting oxygen incorporation in structural vacancies drastically modifies the free electron concentration in the as-grown material, thus leading to a semiconducting character with a 1.9 eV bandgap. Reducing the oxygen impurity concentration *via* post-synthetic ammonia annealing increases the conductivity by seven orders of magnitude and yields the metallic characteristics of a degenerate semiconductor, consistent with theoretical predictions. Thus, this inverse oxygen doping approach – by which the carrier concentration is reduced by the oxygen impurity – offers a unique opportunity to tailor the optoelectronic properties of Ta_2N_3 for applications ranging from photochemical energy conversion to advanced photonics.

4:00 PM EL03.06.06
Cation Disorder in Zn-IV-N_2—Does Intrinsic Disorder Exist Besides Effects of Composition and Oxygen Content? Joachim Breternitz[1], Zhenyu Wang[1,2] and Susan Schorr[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

Many of the materials considered for photovoltaic applications suffer from one or both of the barring arguments for truly sustainable materials: They contain elements that are either toxic (e.g. Pb, Cd) and/or scarce (e.g. Te, In, Ga). The use of more than 1000 ppm Pb in electrical devices is, for instance, banned in the European Union[1] and most other countries. Zinc-group IV-nitrides are being considered as promising candidates for photovoltaic absorber materials, containing uniquely elements of low toxicity and low resource criticality.[2] They can be formally related to binary III-V nitrides by replacing the trivalent cations of the latter with equimolar amounts of divalent and tetravalent ions. Further to band gap tuning by alloying group IV elements – in analogy to cation alloying in III-V's – it has been postulated based on DFT calculations that Zn-IV-N_2 compounds possess a second mechanism for bandgap tuning through cation disorder of the divalent and tetravalent species.[3]

The latter is unique to these ternary materials and marks the foundation of complex structure-property relationships in this class of materials, which need to be properly elucidated. Further, cation disorder is also

triggered by oxygen substiting nitrogen on the cation sites and the effects mimic each other in some way.[4] The latter is particularly important, since a degree of oxygen presence is hardly avoidable in most nitride syntheses. Understanding the different effects on the structural features of these materials is key to their performance as photovoltaic materials.

Herein, we present a systematic study of $Zn_{1+x}Ge_{1-x}(N_{1-x}O_x)_2$ as model system for oxygen containing Zn-IV-N_2 materials. While the oxygen rich oxide nitrides appear as completely cation disordered and crystallise in the wurtzite type,[4] oxygen poor compounds crystallise in the β-$NaFeO_2$-type that is also adopted by stoichiometric $ZnGeN_2$.[5] Both crystal structures are closely related to each other with the latter being a subgroup of the wurtzite-type. The β-$NaFeO_2$-type, however, consists of two crystallographically independent cation positions that allow ordered cations, as well as a quantifiable degree of disorder. Since Zn^{2+} and Ge^{4+} are isoelectronic, they are virtually indistinguishable using X-ray diffraction and hence neutron diffraction is used for the reliable determination of disorder in this class of materials.

Combining chemical analyses and both, X-ray and neutron powder diffraction, we endeavour to disentangle the different phenomena leading to cation disorder and find evidence for oxygen-content related disorder as well as for cation disorder that does not relate to oxygen. However, the effects of oxygen and sample composition are largely predominant. Finally, we relate these structural findings with the optical bandgaps of the materials obtained through diffuse reflectance UV-VIS spectroscopy.

Origin of Unexpectedly Low Thermal Conductivity in Mg_3Sb_2 and Mg_3Bi_2 Thermoelectric Materials
Alexandra Zevalkink; Michigan State University, United States

In the past five years, Mg_3Sb_2 and Mg_3Bi_2 alloys have emerged as exceptional room-temperature thermoelectric materials, threatening to overthrow the decades-long reign of Bi_2Te_3. The success of these compounds is thanks in large part to their surprisingly low lattice thermal conductivity, which is rarely observed in simple, lightweight compounds. This talk will explore the chemical and thermodynamic origins of the anomalously low thermal conductivity in the Mg_3Pn_2 system (*Pn* = Sb, Bi). Temperature-dependent measurements of the elastic moduli and first principles phonon calculations were used to investigate the bond strength, rate of softening, and mode Grüneisen parameters. Compared with other isostructural compounds, we find that both Mg_3Sb_2 and Mg_3Bi_2 have anomalously soft shear moduli and large mode Grüneisen parameters. We attribute this behavior primarily to the small size of the Mg cations: Mg is undersized with respect to the 6-fold octahedral coordination environment, leading to weak anharmonic interlayer bonding and high rates of Umklapp phonon-phonon scattering. This is corroborated by the phonon spectra obtained from inelastic neutron scattering of

Mg_3Bi_2 and $YbMg_2Bi_2$ single crystals, which show significant softening of the acoustic phonons when Yb is replaced by the smaller Mg cation. In addition, we used *in-situ* high-pressure synchrotron X-ray diffraction to investigate the structure and bonding in Mg_3Sb_2 and Mg_3Bi_2 at pressures up to 50 GPa. By extracting the pressure-dependent volume change of the polyhedra using Mg_3Sb_2 single crystal diffraction data, we show that the octahedral Mg-Sb bonds are significantly more compressible than the tetrahedral Mg-Sb bonds, lending further support to our argument that the octahedrally-coordinated Mg is responsible for the anomalous thermal properties of the Mg_3Pn_2 system. Further, we report the discovery of a reversible high-pressure phase transition in Mg_3Sb_2 and Mg_3Bi_2 to a monoclinic structure at 7.8 GPa and 4.0 GPa, respectively.

5:40 PM EL03.07.02
The Effect of Multi-Band Transport on Thermal Conductivity Seen in $Yb_{14}Mg_{1-x}Al_xSb_{11}$ Max Wood[1,2], Chris Perez[3], Francesco Ricci[4], Geoffroy Hautier[4], G. Snyder[2] and Susan Kauzlarich[3]; [1]NASA Jet Propulsion Laboratory, United States; [2]Northwestern University, United States; [3]University of California, Davis, United States; [4]Université Catholique de Louvain, Belgium

The lattice thermal conductivity of a material above its Debye temperature should either decrease with increasing temperatures, as in a crystal, or remain independent of temperature, as in a glass. However, multiple literature reports of the $Yb_{14}MgSb_{11}$ crystal indicate its lattice thermal conductivity increases with increasing temperature well above its Debye temperature. Herein we study the thermal conductivity and electrical transport of the $Yb_{14}Mg_{1-x}Al_xSb_{11}$ solid solution and show this increase in lattice thermal conductivity can be attributed to an electronic effect arising from multi-band transport. We go on to show the effect multi-band transport has on thermal conductivity is pervasive in literature but is often misattributed to the thermal conductivity arising from phonon transport.

5:55 PM EL03.07.03
Conversion of Electrospun Layered Perovskite Nanofibers to Perovskite Oxynitrides for Visible Light Absorption Anja Hofmann and Roland Marschall; University of Bayreuth, Germany

The wide bandgap layered perovskites $A_5M_4O_{15}$ (A = Ba, Sr; M = Ta, Nb) are shown do be very active in photocatalytic water splitting under UV-light, resulting from the additional reaction sites in the crystal structure.[1] The activity can be improved either by the formation of heterojunctions such as $Ba_5Ta_4O_{15}$-$Ba_3Ta_5O_{15}$ or $Ba_5Ta_4O_{15}$-$Ba_3Ta_5O_{15}$-$BaTa_2O_6$.[2,3] Preparation of nanofibers can additionally solve the problem of the large mismatch between the small charge carrier diffusion length and the much larger light penetration depth, resulting in higher photocatalytic activity.[4,5] Visible light activity can be gained by the formation of heterojunctions such as $Ba_5Ta_4O_{15}$-$AgVO_3$[6] and $Ba_5Ta_4O_{15}$-C_3N_4[7] and via ammonolysis[8].
We are combining the positive effects of the nanofiber structure and the ammonolysis by preparing (111) layered perovskites nanofibers of $Ba_5Ta_4O_{15}$ and $Ba_5Nb_4O_{15}$ and converting them into perovskite oxynitrides. The samples were characterized with XRD and the conversion degree was determined. SEM characterization was performed, and Kr physisorption measurements were done to determine the BET surface area before and after ammonolysis. UV-Vis spectroscopy as well as hydrogen evolution measurements in water/methanol were performed.
In first experiments, conversion degrees of nearly 100% were obtained, yielding in a decrease of the band from 4.0 eV down to 2.0 eV for the niobium compound and from 4.6 eV down to 1.9 eV for the tantalum compound; giving visible light absorption abilities. The surface area is slightly increased. Morphology changes will be discussed in detail.

6:10 PM *EL03.07.04
Divalent Ion Conductors Kimberly A. See; California Institute of Technology, United States

Materials that conduct ions have long been studied for a variety of applications from solid state lighting to energy conversion technologies. Room temperature ionic conductivity is especially useful for energy storage applications and notable examples conduct monovalent Li^{+}. Active materials in the cathode and anode must support facile ion diffusion and high electronic conductivity while solid-state electrolytes require high ionic conductivity but low electronic conductivity. Although Li-based systems work very well and have revolutionized energy storage, the desire to lower cost and increase availability motivates next-generation technologies based on new mobile ions including divalent Ca^{2+}, Mg^{2+}, and Zn^{2+}. We will discuss divalent ion conductivity in this context with a focus on Zn^{2+} conductivity in $ZnPS_3$. $ZnPS_3$ supports Zn^{2+} conductivity with unexpectedly low activation energies (~350 meV) enabled by the flexible $[P_2S_6]^{4-}$ polyanion that distorts into the Van der Waals gap at the transition state.

6:35 PM EL03.07.05
Investigation of Thermoelectric Properties of $Yb_{14-x}Na_xMgSb_{11}$ Naomi Pieczulewski, Max Wood, Michael Toriyama, James Male and G. Snyder; Northwestern University, United States

The $Yb_{14}MgSb_{11}$ structural system is a record-breaking high temperature p-type material with applications in radioisotope thermoelectric generators. However, the single parabolic band model that has guided previous optimization efforts, pointing toward decreasing carrier concentration, do not take into consideration a second valence band that alters effective mass and electronic transport in the $Yb_{14}MgSb_{11}$ system. Here we conduct the first investigation to increase carrier concentration by Na doping $Yb_{14}MgSb_{11}$ based on an improved multiband model. To understand defect-controlled carrier concentration, we apply density functional theory (DFT) to investigate equilibrium phases, defect formation enthalpies and band diagrams. We found that the enthalpy of formation was more favorable for Na as an interstitial rather than a substitutional atom. Furthermore, experimental transport data on $Yb_{14-x}Na_xMgSb_{11}$ (x =0, 0.05, 0.25 ,1, 2, 3) were prepared by mall milling and hot-pressing procedures. We show that Na increases Seebeck and resistivity leading to the conclusion that Na acts as a +1 electron donor interstitial atom decreasing carrier concentration.

6:50 PM EL03.07.06
Interplay Between Phononic and Electronic Properties in Determining Carrier Mobility in Heavily Donor-Doped CdO Thin-Films Zachary T. Piontkowski[1], Evan Runnerstrom[2,3], Angela Cleri[4], Anthony McDonald[1], Jon Ihlefeld[5,5], Jon-Paul Maria[4] and Thomas Beechem[1,1]; [1]Sandia National Laboratories, United States; [2]North Carolina State University, United States; [3]U.S. Army Research Office—Materials Science Division, United States; [4]The Pennsylvania State University, United States; [5]University of Virginia, United States

Advances in CdO donor doping have realized carrier concentrations exceeding 10^{20} cm^{-3} while maintaining carrier mobilities of up to 500 cm^2/Vs that together enable new mid-IR plasmonic applications. Despite this differentiating property combination, the underlying mechanisms dictating these properties remain incompletely understood. Unlike traditional semiconductors, mobility does not scale monotonically with carrier concentration in CdO as initial increases with dopant incorporation eventually level off and ultimately decrease. To explain these observations, we vibrationally resolve the lattice changes occurring upon doping and assess them in light with observed trends in mobility.
Raman spectroscopy, pre-resonant with the CdO band-gap, examined lattice strain, disorder, and exciton-impurity/phonon interactions occurring as a function of carrier concentration. Mobility is found to be inversely proportional to both the amount of strain and disorder that change with doping consistent with explanations for

dopant incorporation based on defect equilibria. Additionally, longitudinal optical phonon-plasmon coupled modes are identified and found to scatter by an impurity induced Fröhlich mechanism. Taken together, these coupling strengths also correlate linearly with the mobility, with decreased coupling associating with increased mobility. When viewed as a whole, the effects of strain, disorder and exciton-impurity/phonon interactions together dictate the carrier mobility, with phonon properties affecting the electronic properties and vice versa. These results have the potential to inspire new plasmonic materials which are engineered at the phonon level, revealing a new axis of device tunability.

Efficient Photocatalysts for Water Splitting to Produce Solar Hydrogen Kazunari Domen[1,2]; [1]Shinshu University, Japan; [2]The University of Tokyo, Japan

Sunlight-driven water splitting has received much attention as a means of large-scale renewable hydrogen production [1]. Both efficiency and scalability of water-splitting systems are essential factors for practical utilization of renewable solar hydrogen. Particulate photocatalyst systems do not involve any secure electric circuit and can be spread over wide areas by inexpensive processes potentially. Therefore, it is highly impactful to develop particulate photocatalysts and their reaction systems that efficiently split water.

The author’s group has studied various semiconducting oxides, (oxy)nitrides, and (oxy)chalcogenides as photocatalysts for water splitting [2]. The water splitting activity of a $SrTiO_3$ photocatalyst can be boosted by two orders of magnitude by doping Al [3]. The apparent quantum yield of overall water splitting using a $SrTiO_3$ photocatalyst has been improved to 95% in the near UV region via refining the photocatalyst and cocatalyst preparation [4]. This quantum efficiency is the highest yet reported, and indicates that particulate photocatalysts can drive the uphill overall water splitting reaction as efficiently as the photon-to-chemical conversion process in photosynthesis.

The author's group has also been developing panel reactors in view of large-scale applications [3]. A prototype panel reactor containing Al-doped $SrTiO_3$ photocatalyst sheets splits water and releases product hydrogen and oxygen gas bubbles at a rate corresponding to a solar-to-hydrogen energy conversion efficiency (STH) of 10% under intense UV illumination. A 1-m^2-sized photocatalyst panel reactor splits water under natural sunlight irradiation without a significant loss of the intrinsic activity of the photocatalyst sheets. A solar hydrogen production system with a greater size (100 m^2) was recently built and its performance and system characteristics are under investigation. Panel reactors can accommodate various kinds of photocatalyst sheets and are expected to be built using light and inexpensive materials, thus being ideal for large-scale solar hydrogen production from water.

It is essential to develop photocatalysts active under visible light irradiation for practical solar energy harvesting. Ta_3N_5 and $Y_2Ti_2O_5S_2$ photocatalysts show activity in overall water splitting via one-step excitation under visible light irradiation [5,6]. Particulate photocatalyst sheets split water into hydrogen and oxygen via two-step excitation, referred to as Z-scheme, efficiently regardless of the size. In particular, a photocatalyst sheet consisting of La- and Rh-codoped $SrTiO_3$ and Mo-doped $BiVO_4$ split water into hydrogen and oxygen O_2 via two-step excitation, referred to as Z-scheme, and exhibit STH exceeding 1.0% [7,8]. Some other (oxy)chalcogenides and (oxy)nitrides with longer absorption edge wavelengths are also applicable to Z-schematic photocatalyst sheets.

In my talk, the latest progress in the development of photocatalytic materials and their reaction systems will be presented.

Progress in Wide Gap Ionic Oxide Semicoinductors Hideo Hosono[1,2]; [1]Tokyo Institute of Technology, Japan; [2]National Institute for Materials Science, Japan

The nature of conduction band minimum is totally different from that of valence band maximum. Thus, the materials design concept different from the conventional covalent type semiconductors are required for these materials. In this talk we review our progress in materials and device application:
Material Design and Example of Transparent Bipolar Semiconductors
Ambipolar wide gap oxide semiconductors were restricted to CuInO2[1]and SnO2[2]. We reported ambipolar materials ZrOS based on new design concept[3] and Cu3N applying non-conventional doping approach[4].
Ultrawide gap amorphous oxide semiconductors and their TFTs
Ionic amorphous oxide semiconductors represented by IGZO is now widely used as the switching TFTs for high performance LCD and large-sized OLED TVs.[5] Here, ultra-wide gap(>3.5eV) amorphous oxide semiconductors[6] such as a-Ga2O3 [7] and their TFT characteristics are reported.
Crystal-amorphous nanocomposite semiconductors and their LED application
Nano-sized ZnO embedded in amorphous ZnO-SiO2 has low work function by ~1eV than bulk ZnO keeping mobility of ~1 cm2/Vsand can form ohmic contacts with a wide range of electrode materials [8]. These features make it possible to boost the performance halide perovskite LEDs [9]and OLEDs[10].

Panel Discussion: Why New Semiconductors? Hideo Hosono[1], George Nolas[2], Shengbai Zhang[3] and Andriy Zakutayev[4]; [1]Tokyo Institute of Technology, Japan; [2]University of South Florida, United States; [3]Rensselear Polytechnic University, United States; [4]National Renewable Energy Laboratory, United States

Recent decades have seen exciting explosions of research into new and lesser-studied semiconductors, including such broad categories as complex halides, nitrides, and chalcogenides, and layered and two-dimensional materials. Even so, silicon has further consolidated its position as the leading material for computing, solar energy conversion, and even for some optoelectronics. In light of this friendly but often overmatched competition with silicon, we will ask four of the world's leading researchers what motivates them to continue work on new semiconductor materials.

Panelists will be Hideo Hosono, George Nolas, Shengbai Zhang and Andriy Zakutayev. Moderated by Rafael Jaramillo.

SYMPOSIUM EL04

Ultrawide Bandgap Materials, Devices and Systems
April 18 - April 20, 2021

Symposium Organizers
Masataka Higashiwaki, National Institute of Information & Comm Tech
Robert Kaplar, Sandia National Laboratories
Julien Pernot, University of Grenoble
Hongping Zhao, The Ohio State University

AlN Nanowire pn Heterojunctions—A New Paradigm Towards UV-C LEDs Rémy Vermeersch[1,2], Alexandra-Madalina Siladie[1,2], Gwénolé Jacopin[3], Ana Cros[4], Nuria Garro[4], Eric Robin[1,5], D. Calliste[6], Pascal Pochet[6], Fabrice Donatini[3], Julien Pernot[3] and Bruno Daudin[1,2]; [1]Université Grenoble Alpes, France; [2]CEA, IRIG-PHELIQS "Nanophysics and Semiconductors" Group, France; [3]Institut Néel, Université Grenoble Alpes, CNRS, France; [4]Universidad de Valencia, Spain; [5]CEA, INAC-MEM, LEMMA, France; [6]CEA, INAC-MEM, L-SIM, France

The desired realization of efficient solid state deep UV emission devices is currently limited by the difficulty to achieve efficient p-type doping of AlGaN layers with high AlN molar fraction, due to the high ionization energy of single Mg impurity. However, if now using AlN nanowires (NWs), it will be shown that Mg/In codoping leads to an increased Mg solubility limit by more than one order of magnitude. Optimal electrical activation of acceptor impurities was achieved by electron irradiation [1]. Next, the formation of AlN NW p-n junction was

assessed by electron beam induced current (EBIC) experiments, putting in evidence the electrical field associated with the junction. Current-voltage characteristics in forward bias conditions have established that the current was varying as V^n, (with n larger than 6) before activation. By contrast, following acceptor activation, a space charge limited current regime was observed. Finally an AlGaN active region consisting of either a short period AlN/GaN superlattice or of an AlGaN section was inserted in the pn junction. The structural, electrical and electroluminescent properties of the resulting NW-based UVC LED will be discussed.

10:55 AM EL04.01.02
Growth of (Al,Ga)N/GaN Heterostructures at Temperatures Below 600 °C by Metalorganic Vapor Phase Epitaxy Caroline E. Reilly, Nirupam Hatui, Shuji Nakamura, Steven P. DenBaars and Stacia Keller; University of California, Santa Barbara, United States

As the role of the nitrides in electronic applications expands, integrating group-III nitrides with other materials such as silicon based integrated circuits is an attractive route. Although bonding processes exist, the ability to grow III-N materials directly on already processed wafers would greatly widen the design space, an approach which is currently hampered by the high temperatures associated with nitride growth by metalorganic vapor phase epitaxy (MOVPE). For GaN and AlN, typical growth temperatures can exceed 1000 °C – too high to be compatible with many processed wafers or other sensitive substrates. High quality material growth, with low impurity incorporation and good morphology, is then desirable at low growth temperatures for integration with other materials. In this work, the MOVPE growth of (Al,Ga)N layers at temperatures below 600 °C was explored using a flow modulation epitaxy (FME) scheme. The latter was applied in order to compensate for the lower surface mobility of adsorbed species at these very low deposition temperatures.
All experiments were conducted via atmospheric pressure MOVPE on semi-insulating GaN-on-sapphire templates. Low temperature (LT) layers were grown using a FME scheme consisting of pulsing the group III precursor(s), trimethylaluminum (TMAl) and triethylgallium (TEGa), while continuously flowing ammonia. The LT layers were analyzed by Hall measurements, atomic force microscopy (AFM), X-ray diffraction (XRD), secondary ion mass spectrometry (SIMS), and X-ray photoelectron spectroscopy (XPS).
The FME growth scheme used in this study was previously optimized for GaN deposition with TEGa to allow for step flow growth at 550 °C. Upon the addition of TMAl, however, the surface no longer showed steps and instead a layer by layer growth mode was observed via AFM. The transition into a layer by layer growth mode with the addition of TMAl is consistent with the known lower surface mobility of Al adatoms. Despite losing the step flow growth mode, the RMS roughness of the AlGaN layer was still sub-nanometer at 660 pm in comparison to 405 pm observed for the step-flow grown GaN, sufficiently smooth to be used for further studies. By using the same growth scheme exclusively with TMAl, layers with different thickness were grown varying the number of cycles between 94 and 563. The thinnest layer showed an RMS roughness of 470 pm and the thickest layer 535 pm. Layers with 282, 375, 469, and 563 cycles were additionally analyzed by XRD. The layer peak became sharper and shifted away from the substrate peak as the number of cycles was increased. This was the opposite trend of what may be expected if the shift in the XRD peak was solely due to increasing relaxation of the layer with increasing thickness. From SIMS and XPS data, it was confirmed that this shift was due to unintentional gallium incorporation, which was more pronounced in the thinner samples. Ga incorporation into AlN has been seen for higher temperature AlN growth on GaN following a similar trend to that seen herein.
Electrical characterization of the samples with varying thickness revealed that the two thinnest samples were too resistive to be measured. For all other samples, the sheet resistance decreased with increasing AlN thickness. The highest mobility measured was 400 $cm^2/(V\bullet s)$ with a sheet charge of 1.65 x 10^{13} cm^{-2} for the sample with 469 cycles. Additionally, a sample with 8 nm LT GaN underneath a LT (Al,Ga)N layer exhibited a mobility of 230 $cm^2/(V\bullet s)$ and a sheet charge of 1.60 x 10^{13} cm^{-2}. More details on the effects of growth temperature, thickness, and composition on the characteristics of the (Al,Ga)N layers will be presented at the conference. This work is partially supported by the Solid State Lighting and Energy Electronics Center and Intel Corporation.

Influence of Chemical Potentials on Strain Development in Si-Doped $Al_{0.7}Ga_{0.3}N$ Yan Guan[1], Shun Washiyam[1], Dolar Khachariya[1], Pegah Bagheri[1], Ji Hyun Kim[1], Pramod Reddy[2], Ramon Collazo[1] and Zlatko Sitar[1]; [1]North Carolina State University, United States; [2]Adroit Materials Inc., United States

AlGaN-based electronics and optoelectronics require Si doping for n-type conductivity. However, tensile stress is generated in AlGaN layers grown on foreign substrates with increasing Si concentration. High tensile stress could cause wafer bowing and cracking, which are detrimental to the device performance. Though several models have been proposed, the mechanism of the strain development by Si doping is still in debate. We have suggested that tensile stress is generated by dislocation climb. More vacancies and its complexes with Si are formed by the Fermi level shift brought by Si doping. Thus, the tensile stress is expected to be enhanced by lowering defect formation energy. This work reports the influence of chemical potentials on V_{III}-nSi complexes and the resulting strain development in Si-doped $Al_{0.7}Ga_{0.3}N$.

Si-doped $Al_{0.7}Ga_{0.3}N$ layers were grown on unintentionally doped $Al_{0.7}Ga_{0.3}N$ layers on top of c-plane AlN/sapphire substrates by MOCVD. Trimethylaluminum (TMA), triethylgallium (TEG), ammonia (NH_3), and SiH_4 were used as Al, Ga, N, and Si precursors, respectively. NH_3 flow rate was varied from 0.3 slm to 0.7 slm and 1.5 slm to control chemical potentials. SiH_4 flow rates were changed to control the Si concentration from 1E18 cm^{-3} to 1E19 cm^{-3}. TMA and TEG flow rates were adjusted to control the growth rate and composition. Growth temperature and pressure were kept constant at 1100°C and 20 Torr, respectively. X-ray diffraction (XRD) was employed to determine the composition and strain development. Photoluminescence (PL) and Hall measurements were performed to characterize the influence of V_{III}-nSi complexes on electrical and optical properties.

First, the influence of growth rate on strain evolution was characterized. Growth rate was varied by metalorganic flow rates while SiH_4 flow rate, Al composition and NH_3 flow rate were kept constant at 30 sccm ([Si]~1e19 cm^{-3}), 70% and 0.7 slm, respectively. Although strain increases linearly with thickness under the same growth condition (i.e., when growth time is varied), net strain was decreased from -0.19 % to -0.44 % (negative strain means compressive strain) as growth rate was increased from 600 nm/h to 900 nm/h for one hour growth. There are two possible reasons for the strain reduction by increasing growth rate: (1) as Si impurities are incorporated into the AlGaN layer in a mass transport limited process, [Si] is decreased at a higher growth rate; (2) metalorganic flow rate was increased to increase growth rate, and growth condition became more III-rich. Both lead to an increase in the formation energy of V_{III}-nSi complexes. Therefore, growth rate needs to be constant to characterize the role of chemical potentials in strain development.

When AlGaN layers were grown at a growth rate of 600±50 nm/h, an increase in strain towards a tensile state was clearly observed. Strain was increased from -0.41 % to -0.19 % and -0.04 % with increasing NH_3 flow rate. As the growth environment becomes more N-rich, the formation energy of V_{III}-related defects decreases, resulting in the increase in the V_{III}-related defect concentration. Under an equivalent growth rate, the Si concentration is constant for samples grown at different NH_3 flow rate. Thus, the observed high tensile strain at high NH_3 flow rate does not originate from the Si substitutional impurities by themselves, eg. formation of SiNx or lattice expansion. Under N-rich conditions, more V_{III}-related defects are expected to be involved in surface mediated dislocation climb. The increase in the [V_{III}-nSi] was also confirmed from an increase in the V_{III}-nSi peak PL intensity and an abrupt decrease in the carrier concentration by self-compensation. In summary, we demonstrate that tensile stress induced by dislocation climb is governed by vacancy concentration rather than Si concentration, supporting and adding further details to the mechanisms previously discussed for the observation of strain in Si doped III-nitride layers.

Late News: Assessment of N-Type and P-Type Doping in (Al,Ga)N Heterostructures by Scanning Probe Microscopy Techniques Albert Minj[1], Ming Zhao[1], Benoit Bakeroot[1,2], Lennaert Wouters[1], Kristof Paredis[1], Thomas Hantschel[1] and Stefaan Decoutere[1]; [1]imec, Belgium; [2]Centre for Microsystems Technology (CMST), imec and Ghent University, Belgium

The current state of dopant assessment for the optimization of the wide band gap (Al,Ga)N-based

heterostructures for high-frequency and high-power applications relies heavily on quantitative chemical analysis techniques such as secondary-ion mass spectrometry. In such heterostructures, the determination of P-type carrier density of the cap layer, control of background concentration and assessment of polarization-induced confined carriers are necessary for the realization of optimal working devices. None of these can be completely inferred from the chemical analysis owing to several material and growth issues including the poor activation of Mg, the presence of O impurities and the amphoteric nature of carbon impurities. Here, as regions of interest in a typical epitaxial stack for GaN electronic devices consist of multiple triangular quantum wells with electron/hole confinement and doped layers, it demands electrical characterization at a nanoscale. In this context, the exploitation of the Schottky behaviour of nano-size metal-semiconductor junction formed between a metallic scanning probe microscopy (SPM) probe and (Al,Ga)N-nitride surface can be promising for carrier assessment by SPM techniques.

The two scanning probe microscopy techniques, scanning capacitance microscopy (SCM) and Conductive-atomic force microscopy (C-AFM), which are today routinely used for the characterization of Si- and Ge-based semiconductor structures with nanometer spatial resolution are investigated for their applicability on (Al,Ga)N heterostructures with energy band gap values larger than 3.4 eV. Our experiments make use of rectifying property of the electrical conduction at the nanoscale in both the modes. In this paper, it will be shown that by combining the two techniques, the nature of free carriers originating from extrinsic n-/p-type dopants and polarization-induced confined carriers, two-dimensional electron gas (2DEG) and hole gas (2DHG), can be revealed across (Al,Ga)N/Silicon heterostructures consisting of n-/p-doped GaN and AlGaN transition layers (TLs) [1]. Here, a simple phase shift of approximately 180° consistently observed between all n-type and p-type regions in SCM phase maps verifies the absolute and correct determination of the type of carriers in accordance with TCAD band simulation. We also found that by fabricating Ti/Al-based low resistance back contacts, the issues related to back-to-back Schottky configuration and surface charging were mitigated and it concurrently allowed C-AFM measurements at low DC biases. Our back-contact methodology also aided the SCM signal enhancement at low magnitudes of AC bias comparable to that used in conventional semiconductors like Si and Ge. A large SCM signal strength for AC bias $\leq$ 1 V was seen on both extrinsically (Si, Mg) doped regions and on the polarization induced 2D carrier gases near the interface, while no signal was recorded otherwise on undoped regions such as unintentionally doped GaN and AlGaN regions in the transition layers. Because of the rectifying property of the tip-sample junction for both n-type and p-type doped (Al,Ga)N regions, the type of the carriers can also be determined from the C-AFM measurements through selection of the polarity of the DC bias. Thanks to the small tip-sample contact area, the C-AFM technique eventually allowed resolving the 2DHG and 2DEG regions separated by an only 5 nm AlN layer. As the contact area can be further reduced with the use of sharper probe tips [2], this analysis can be extended to even narrower barriers. Our paper illustrates the high potential of the two techniques to study device heterostructures for high power and RF applications and multi-quantum well heterostructures as in optoelectronic devices.

Late News: Hanbury Brown and Twiss Correlations in a SEM—Imaging Carrier Lifetime at the Nanoscale in Ultra Wide Band Gap Materials Sylvain Finot[1], Vincent Grenier[2], Vitaly Zubialevich[3], Catherine Bougerol[1], Pietro Pampili[3], Joël Eymery[4], Peter J. Parbrook[3], Christophe Durand[2] and Gwénolé Jacopin[1]; [1]University Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, France; [2]University Grenoble Alpes, CEA, IRIG, PHELIQS, NPSC, France; [3]Tyndall National Institute, University College Cork, Ireland; [4]University Grenoble Alpes, CEA, IRIG, MEM, NRS, France

In order to establish the relationship between luminous efficiency and material characteristics, it is essential to precisely measure the relative contribution of radiative and non-radiative recombinations. This is usually

obtained through the measurements of the luminescence decay time as a function of temperature. To do so, the commonly used technique is time-resolved photoluminescence spectroscopy [1]. However, this technique does not allow nanoscale resolution, which is the relevant scale for defect characterizations. In addition, when dealing with ultra-wide bandgap materials, it required expensive pulsed deep UV lasers.

To go beyond these limitations, fast electrons can be used as a highly localized excitation source for luminescence measurements. This technique is called cathodoluminescence (CL) spectroscopy. Recently, picosecond time-resolved CL technique has been developed to reach at the same time high spatial and high temporal resolutions [2,3]. However, it is difficult to obtain a high brightness pulsed electron gun, which leads to reduced spatial resolution, low CL intensity or photocathode aging issues.

In this work, to circumvent these limitations, we took advantage of the specific statistics of electron/hole pair generation by fast electrons. Indeed, in a secondary electron microscope, the interaction of the incident electron with the semiconductor generates almost instantaneously (< 1 ps) a bunch of electron/hole pairs (typically > 300). These electron/hole pairs can then radiatively recombine, according to their carrier lifetime. Hence, by studying the autocorrelation function of the CL intensity ($g_2(\tau)$), a strong bunching is expected at $\tau = 0$ ($g_2(\tau = 0) >> 1$). More importantly, by fitting $g_2(\tau)$, we access the local carrier lifetime without the need for an expensive pulsed electron gun [4].

Thus, to measure the $g_2(\tau)$ of the CL signal, we built a Hanbury Brown and Twiss (HBT) interferometer to analyze the CL photon statistics. As an illustration, we applied this technique to the study of AlGaN/GaN core-shell quantum wells on GaN microwires grown by metalorganic vapor phase epitaxy [5]. Due to the lattice mismatch between the GaN core and the AlGaN shell, there is a formation of cracks. These cracks locally affect the material properties (strain, energy shift, CL intensity change…). Therefore, to quantify the impact of cracks on the luminous efficiency at the nanoscale, we recorded the carrier lifetime in this region. As expected, we observe a reduction of carrier lifetime near the crack, which indicates the creation of dangling bonds and point defects in the crack region. The CL results are then compared with transmission electron microscopy.

UV-VIS Photodetectors Using AlGaN High Electron Mobility Transistors with GaN Nano-Dot Floating Gates

Andrew Armstrong[1], Alexandra Brianna Klein[1], Andrew Allerman[1], Albert Baca[1], Mary Crawford[1], Jacob Podkaminer[2], Carlos Perez[1], Michael Siegal[1], Erica Douglas[1], Vincent Abate[1] and Francois Leonard[1]; [1]Sandia National Laboratories, United States; [2]Current Address: 3M Corporate Research Laboratory, United States

Visible-blind and solar-blind photodetectors were demonstrated using AlGaN-channel high electron mobility transistors (HEMTs) with GaN nanodots as an optically-active floating gate. The effect of the photo-induced floating gate voltage was large enough to switch a HEMT from the off-state an on-state with illumination. Responsivity > 10^8 A/W was observed at room temperature with the HEMTs biased in the off-state in the dark for low dark current and low dc power dissipation. The absorption threshold was shown to be controlled by the AlN mole fraction of the HEMT channel layer, enabling the same device design to be tuned for either visible-blind or solar-blind detection. The influence of GaN nanodot position in the HEMT on the dynamic range of the photodetector was investigated. The responsivity and temporal response of the detectors as a function of optical intensity was investigated, and a gain-bandwidth product > 10^9 Hz was observed. The dependence of device performance on optical intensity was successfully modeled by treating the nanodots as a two-level system with

characteristic rates of carrier capture and recombination.

1:00 PM EL04.02.01
Late News: A Comprehensive Study of MOVPE Growth on 200 mm GaN-on-SOI for Monolithic Integrated GaN ICs Ming Zhao, Karen Geens, Xiangdong Li, Nooshin Amirifar and Stefaan Decoutere; imec, Belgium

With the mass production of discrete devices based on GaN-on-Si technology is just around the corner, the monolithic integrated GaN ICs (integrated circuits) has become a hot topic in recent years. This is largely attributed to its great potential in increasing the switching speed and efficiency, reducing the form factor and enabling a higher level of design flexibility, etc. We have proposed and experimentally validated the approach of using GaN-on-SOI combained with deep trench isolation as a technology platform to mainly eliminate the "back gating" effect which is associated with GaN-on-Si technology [1]. On the other hand, the MOVPE growth on SOI substrate, as a critical enabling technique, is far less studied compared to GaN-on-Si. In this work, we present a comprehensive study on multiple aspects of the MOVPE growth on 200 mm SOI substrates, including SOI substrate and buffer design. We further demonstrate the growth of HEMT device structures for voltage rating of 200 V, 650V and even beyond.

We found that the epitaxial growth on SOI substrates behaved very differently from the growth on regular Si substrate. The SOI wafer deformed much more strongly upon the lattice mismatch introduced stress. Further in-depth study pointed out that the phenomena is very likely associated with the strain partition effect. We have proven that the Si (111) device layer thickness is a tuning knob to alter the strain partition effect, which is in line with the strain partition thoery. In addtition, using Si (111) instead of Si (100) handling wafer can also to certain extent mitigate the strong wafer bowing of SOI substrate, which results from the higher stiffness of the Si (111) due to its higher biaxial modulus. Following our superlattice based GaN-on-Si buffer scheme but with dedciated modification, we have obtained a 200 mm GaN-on-SOI buffer platform with low wafer bow (<50 µm) and suitable for 200 V application. The vertical buffer breakdown voltagae (voltage at which the leakage current reaches 1 µA/mm2 at 25 °C and 10 µA/mm2 at 150 °C) is ~400 V at 25 °C and >300 V at 150 °C. A high operating voltage of ~440 V is extrapolated (corresponding to a lifetime of 10 years at 175 °C) based on time-dependent dielectric breakdown (TDDB) measurements. The buffer also shows a low buffer dispersion of < 10% at up to 150 °C using the "back-gating" method. This buffer platform has enabled the fabrication of E-mod p-GaN HEMT devices and the further demonstration of a functional 48V-to-1V buck converter with monolithic integrated half bridge and on chip drivers. However, it became extremely challenging to extend this buffer platform to a higher voltage, i.e. 650 V and beyond, by thickness scaling even using Si (111) handling wafer in the SOI substrate. It is very difficult to control the high in situ wafer deformation and to limit the post growth wafer bow <50 µm. We therefore proposed a novel buffer scheme by taking advantage unique properties of superlattice structure and the strain partition effect of SOI substrate. This buffer scheme consists of multiple superlattice blocks of different average Al% which allows to introduce alternatively the compressive and tensile stress along the buffer growth. Based on this buffer scheme we demonstrated a 4.8 µm buffer for 650 V application and a 6 µm buffer for a even higher voltage rating.

Characterization of III-Nitride Epitaxial Layers by Scanning Spreading Resistance Microscopy Sizhen Wang, Jinho Kang, Bingjun Li and Jung Han; Yale University, United States

Scanning spreading resistance microscopy (SSRM) is an AFM-based technique, it detects the resistance of current spreading layer just below the tip-semiconductor contact region. This innovative nanoscale characterization techniques find its wide application in 2D carrier mapping in semiconductor material and device characterization because of its high resolution and ease of quantification. Although SSRM has been used to study GaN carrier concentration, AlGaN-GaN heterostructure, AlN-GaN quantum well, and related defects in III-nitride, there is still lack of research on dopant calibration and quantification on GaN materials. Here we presented a systematic research on GaN dopant calibration under variable tip stress condition using SSRM and apply this technology to characterize the detail structure of distributed Bragg reflector (DBR) of vertical cavity surface emitting laser (VCSEL).
First, n-GaN sample with staircase doping of Si, Ge was used to calibrate with variable tip force (range from 0.32 μN to 6.40 μN). Although the measured resistance *log(R)* decreased with increased tip force, the *log(R)* decreased monotonically as the dopant concentration (Si, Ge) increased, almost four order of magnitude doping range (~$4x10^{16}cm^{-3}$ for UID to $1x10^{20}cm^{-3}$) can be distinguished for n-GaN thin film. And linear fitting curve was extracted to estimate the carrier concentration in heavy doping region. Then, the SSRM technology was used to reveal the fine DBR structure which consist of 25 pairs of Si-doped (43nm, $5x10^{18}cm^{-3}$) and Ge-doped GaN (55nm, $9x10^{19}cm^{-3}$), and the best contrast of 2D SSRM image of DBR structures was obtained with -0.1 V DC bias voltage and 2.56 μN tip force. Finally, the SSRM was applied to investigate the in-plane inhomogeneous incorporation of Ge dopants into GaN which was grown on Sapphire. 2D SSRM mapping results showed that as the Ge doping concentration was more than $3.0x10^{19}cm^{-3}$, Ge incorporation become inhomogeneous. It was estimated that the light doping zones had only $8.90x10^{18}/cm^3$ Ge dopant for sample with $6.0x10^{19}/cm^3$ intentional Ge doping, while for sample with $1.4x10^{20}/cm^3$ intentional Ge doping, the light doping zone was estimated only doped with $1.06x10^{19}/cm^3$ Ge dopants. Using the ratio of nominal doping concentration to the minimum doping concentration as an indicator, its value changed from 6.69 to 13.23 as Ge doping of GaN epitaxial layer increased from $6.0x10^{19}/cm^3$ to $1.4x10^{20}/cm^3$. The inhomogeneous doping became worse with heavy Ge doping. And this issue might be related to anisotropic dopant incorporation efficiency at different facets which were exposed during GaN epitaxial growth.

1:30 PM EL04.02.03
Structural and Piezoelectric Properties of $Sc_xAl_{1-x}N$-GaN Heterostructures Grown by Molecular Beam Epitaxy Joseph Casamento, Celesta S. Chang, Yu-Tsun Shao, John Wright, David A. Muller, Huili (. Xing and Debdeep Jena; Cornell University, United States

Alloying with Scandium (Sc) into the III-nitride platform of InN, GaN, and AlN has gained tremendous interest in recent years, from fundamental research to transformative changes in technological applications. This is because isoelectronic alloying with Sc has been demonstrated to increase the piezoelectric response and induce ferroelectric behavior in $Sc_xAl_{1-x}N$ alloys. [1,2] However, most studies of the fundamental properties $Sc_xAl_{1-x}N$ have been focused on sputter deposited materials, where challenges such as sub-optimal crystallinity, microstructural instabilities, and chemical inhomogeneities have been encountered. Molecular beam epitaxy (MBE) aims to enable solutions to these issues via epitaxial deposition on single crystalline substrates in an ultra-high vacuum environment and thereby better elucidate the fundamental properties of $Sc_xAl_{1-x}N$.

In this work, [3] we report on the epitaxial growth studies of $Sc_xAl_{1-x}N$ of various Sc compositions (x = 0.18 to 0.40) grown by MBE on n+ bulk GaN substrates and their corresponding structural and piezoelectric properties. Aluminum (Al) was supplied with a conventional Knudsen effusion cell and Sc was supplied via electron beam evaporation in a tungsten (W) crucible. Growth temperature was maintained at 600C, measured by a thermocouple. In-situ reflection high energy electron diffraction (RHEED) was used to assess the epitaxial nature of the films.

Phase purity and epitaxial relationship was further assessed using X-ray Diffraction (XRD). Films with a surface roughness of less than 1 nm were confirmed by atomic force microscopy (AFM). Out-of plane piezoelectric coefficients ($d_{33,eff}$) were analyzed with piezoresponse force microscopy (PFM) using a conductive AFM cantilever. High-angle annular dark field scanning transmission electron microscopy (HAADF-STEM) was utilized to study atomic level defects and to confirm the metal polar orientation of $Sc_xAl_{1-x}N$ grown on metal polar GaN.
Post-growth XRD measurements show a wurtzite 002 diffraction peak for the $Sc_xAl_{1-x}N$ layers at all Sc compositions studied (x = 0.18 to 0.40). XRD full-width-half maximum (FWHM) values ranged from 0.09 to 0.13 degrees (324-468 arcseconds) for x = 0.18 to x = 0.33, indicating superior crystalline quality. RHEED images suggested pure wurtzite phase $Sc_xAl_{1-x}N$ but decreasing crystallinity due to primary azimuthal streak broadening as Sc content increased. PFM results showed an increase in piezoelectric coefficient for $Sc_xAl_{1-x}N$ (x=0.18, 15 pm/V) relative to AlN (6 pm/V) and a decrease thereafter as Sc concentrations increased. Insight to this counterintuitive trend was given via HAADF-STEM, which showed the presence of zinc-blende inclusions bound by partial dislocations in the $Sc_xAl_{1-x}N$ (x=0.40) film. This contrasts with the RHEED images suggesting single-phase wurtzite crystals. The zinc-blende crystal structure is not thermodynamically stable and may arise from kinetic factors during the deposition process. The presence of zinc-blende inclusions likely hinders piezoelectric performance and is deleterious to potential ferroelectric behavior as zinc-blende point group prohibits ferroelectricity via symmetry arguments. This work gives insight into the fundamental behavior of epitaxial $Sc_xAl_{1-x}N$ and should provide guidance toward future optoelectronic applications based on these heterostructures. Future work will involve growth optimization and continued structural and electrical characterization to enhance piezoelectric performance and include ferroelectric behavior these epitaxial heterostructures.

Dielectric Properties, Electronic Transitions and Infrared Active Optical Phonon Modes of Molecular Beam Epitaxy $Sc_xAl_{1-x}N$ Determined by Spectroscopic Ellipsometry Alyssa L. Mock[1], Alan Jacobs[2], Eric Jin[1], Matthew Hardy[2] and Marko J. Tadjer[2]; [1]NRC Research Associateship Programs, United States; [2]U.S. Naval Research Laboratory, United States

Significant interest has grown recently in alloying ultra-wide bandgap AlN with ScN in order to obtain unique and tunable properties. Such alloys could have impactful applications in high electron mobility transistor structures potentially enabling more efficient, compact, and powerful amplifiers critical to global communications infrastructure. Other possible applications include high frequency and broadband acoustoelectric filters and resonators. Further, the ferroelectric behavior of ScAlN with high scandium content has begun to garner notable attention of late with potential in sensor applications.
In our work, we employ spectroscopic ellipsometry to investigate (0001) wurtzite $Sc_xAl_{1-x}N$ ($0.00 \leq x \leq 0.20$) thin films grown by molecular beam epitaxy on c-plane sapphire substrates. We present the dielectric function obtained in the spectral region from 4-6.4 eV and report on the thicknesses and extracted critical point parameters from our best match model analysis. We find that the critical points associated with electronic transitions shift to lower energy as a function of increasing ScN alloy fraction. This is particularly interesting for tunability of band offsets between ScAlN and GaN in heterostructures, for example, critical for the development of next generation RF devices as the conduction band offset impacts the confinement and electron density in the two-dimensional electron gas that forms the channel of the device.
We also present the infrared dielectric functions and dielectric loss functions in the spectral region from 400-1200 cm^{-1}. From these we obtain infrared active phonon mode properties, which are fundamental material properties important for future device design. We find that all phonons shift to lower wavenumber as a function of scandium incorporation and we also see evidence of a decrease in crystal quality which is confirmed by x-ray diffraction measurements. Further, we report the high frequency and static dielectric constants as well as their

evolution with scandium content. We calculate the Born effective charge for each composition and find an increase with scandium content. Thus, we attribute the softening of the phonon modes with increasing scandium content to an increase in the effective metal ion mass and a corresponding increase of the dynamic effective charge. This work elucidates fundamental properties of MBE grown ScAlN thin films and contributes to improved understanding of Sc-based alloys currently under development for electronic and optoelectronic devices.

Growth of High Quality MOCVD Aluminum Nitride Using N_2 as Carrier Gas Samiul Hasan, Abdullah Mamun, Kamal Hussain, Dhruvinkumar Patel, Mikhail Gaevski, Iftikhar Ahmad and Asif Khan; University of South Carolina, United States

High quality, low dislocation density, AlN is required for high efficiency, high power, and long lifetime of the III-nitride based electronic and photonic devices. Several techniques have been reported to improve the quality of AlN, including substrate patterning, pulsed lateral overgrowth, high-temperature annealing, and modulation of temperature and precursors. All these growth processes have been done using ultra high purity H_2 as a carrier gas. The impact of carrier gases on the growth of AlN has rarely been studied. The rationale to study N_2 as a carrier gas for AlN growth in this research is to explore another carrier gas than H_2, which is safer and economical. Previously, the use of N_2 as a carrier gas resulted in inferior quality AlN layers. Here, we report the growth of high-quality AlN using N_2 as carrier gas on a basal plane sapphire substrate using metal-organic chemical vapor deposition (MOCVD). A series of samples with N_2 as carrier gas were grown with thickness varying from 1µm to 4µm by employing a two-step growth process. The process includes the formation of a thin buffer layer grown at 950° C with a high V/III ratio and a thick high-temperature growth at 1180° C with a low V/III ratio without introducing any intralayer. AlN samples were characterized using scanning electron microscopy (SEM), atomic force microscopy (AFM), high-resolution x-ray diffraction (HR-XRD), and Raman spectroscopy. SEM images show the formation of air pockets in the AlN layers, which acts as strain relief centers, reducing the dislocation densities. The XRD analysis of these samples shows the full width at half maxima of 289 arcsec of the omega scan for (10-12) plane and total dislocation density of $1.1x10^9$ cm^{-2} for 4µm sample, which are the best-reported values for AlN on a sapphire substrate using N_2 as the carrier gas. Raman study of a 4µm AlN sample shows low compressive stress of 0.59 GPa. A systematic study of the evolution of the quality of AlN with thickness will be presented.

2:15 PM EL04.02.08

Late News: Polarization-Induced 2D Hole Gases in Undoped InGaN/AlN Heterostructures Grown on Single-Crystal AlN Substrates Jimy J. Encomendero Risco[1], Zexuan Zhang[1], Reet Chaudhuri[1], Masato Toita[2], Debdeep Jena[1] and Huili Xing[1]; [1]Cornell University, United States; [2]Asahi Kasei Corporation, Japan

We report, for the first time, the epitaxial growth, structural characterization, and transport properties of polarization-induced 2D hole gases (2DHGs) homoepitaxially grown on high-quality single-crystal AlN substrates. By harnessing the polarization discontinuity at the InGaN/AlN heterointerface, a high density of free holes ($p > 5x10^{13}$ cm^{-2}) is induced within AlN crystals without the need of acceptor impurities. This important feature, combined with the high structural quality of the homoepitaxial growth, results in the highest hole mobilities experimentally measured in bulk AlN substrates. The polarization origin of the 2D holes is experimentally confirmed by systematically increasing the Indium composition of the top InGaN layer, thereby inducing a higher density of free carriers at the InGaN/AlN heterojunction. Hole concentrations between $p = 5.2x10^{13}$ cm^{-2} and $p = 1.1x10^{14}$ cm^{-2} are measured at room temperature, as the indium composition is varied between 0% and 6%, showing a positive correlation with indium incorporation. X-ray diffraction reveals that over this composition range, the InGaN layers are coherently strained to the AlN lattice. Furthermore, the presence of strong interference fringes in the diffraction pattern and clear InGaN atomic steps indicates the presence of atomically smooth hetero-interfaces. Cryogenic Hall effect measurements show that hole concentrations are almost independent of temperature, ranging between $p = 2.5x10^{13}$ cm^{-2} and $p = 5.2x10^{13}$ cm^{-2} for indium compositions of 0% and 6%, respectively. These high hole densities, inaccessible by traditional

impurity doping at 77 K, attest to the electrostatic origin of the 2D holes. Our results constitute a pivotal step towards the manufacture of nitride-based p-type field effect transistors (FETs) that can take the advantage of the high thermal conductivity and high breakdown electric fields of single-crystal AlN substrates. As an added benefit, the simultaneous demonstration of complementary 2D electron gases (2DEGs) and 2DHGs in undoped heterostructures grown on single-crystal AlN substrates, enables an unmatched level of integration for high-power and high-frequency nitride-based electronics, raising hopes for all-nitride CMOS technology.

4:00 PM *EL04.03.01

Prospects of $LiGaO_2$ and $NaGaO_2$ as Ultrawide Band Gap Semiconductors Walter R. Lambrecht[1], Adisak Boonchun[2], Klichchukon Dabsamut[2], Dmitry Skachkov[3], Santosh K. Radha[1] and Amol Ratnaparkhe[1]; [1]Case Western Reserve University, United States; [2]Kasetsart University, Thailand; [3]University of Florida, United States

Inspired by the recent interest in β-Ga_2O_3 as ultra-wide-band-gap material, because of its combination of n-type dopability with a gap of about 4.9 eV, we propose two new even higher band gap materials and investigate their prospects for doping and transparent conducting applications in the ultraviolet range. We present a study of the phase stability, band structures, optical absorption and defect properties. $LiGaO_2$ is a material with a wurtzite derived orthorhombic structure with space group $Pna2_1$ at ambient conditions. It consists of an ordered arrangement of the Li and Ga cations on the wurtzite lattice and can be viewed as a I-III-VI_2 ternary derived from the binary II-VI compound ZnO. It has been considered in the past as ceramic material with piezo-electric properties and can be grown in bulk form by the Czochralsky method. Here we present quasiparticle self-consistent GW band structure calculations, showing that it has a direct gap of 5.6 eV (in agreement with experiment) when taking into account an estimated zero-point-motion correction of -0.2 eV. Furthermore, we find that transitions from the bottom of the conduction band to higher bands can only occur above 3.9 eV. The valence band maximum is split by crystal field splitting in three levels which leads to a polarization dependent absorption onset. The valence and conduction band effective mass tensors are determined. Defect calculations using the HSE hybrid functional show that the lowest energy of formation defect is the Ga_{Li} antisite, which is found to be a deep (negative U type) donor with a 2+/0 transition at 0.7 eV below the conduction band minimum. It is compensated by V_{Li}^{1-} or Li_{Ga}^{2-} depending on chemical potential conditions. These defects pin the Fermi level deep in the gap leading to insulating behavior in intrinsic $LiGaO_2$. However, Si and Ge dopants are shallow donors and have low energy of formation. Thus n-type doping should be feasible. Sn leads to a somewhat deeper donor. Prospects for p-type doping are less promising: N_O is a deep trap with amphoteric character and Zn doping leads to self-compensation between Zn_{Ga} and Zn_{Li}. Ga vacancies are found to have high energy of formation but can be created by high-energy particle irradiation, while Li vacancies are expected to occur in as grown material. Their EPR signals have been reported and we find excellent agreement between our calculated g-tensors and hyperfine splitting with the experiment. Finally, to avoid potential problems with Li diffusion, we also study $NaGaO_2$ and find it to have a gap of 5.5 eV and to also be stable in the $Pna2_1$ structure. Both $NaGaO_2$ and $LiGaO_2$ can undergo a phase transition under pressure of about 8-14 GPa to an octahedrally coordinated phase. Among those phases, we find the R-3m phase to have lower energy than a rocksalt type phase. Even in this R-3m phase, the gap is above 5 eV but it becomes slightly indirect.

4:25 PM EL04.03.02

Electron and Hole Mobility of Rutile GeO_2 from First Principles—An Ultrawide-Band-Gap Semiconductor for Power Electronics Kyle Bushick, Kelsey Mengle, Sieun Chae and Emmanouil Kioupakis;

University of Michigan, United States

Rutile germanium dioxide (r-GeO_2) is an ultrawide-band-gap semiconductor with potential applications in high-power electronic devices or transparent conductors. In these devices, understanding the carrier dynamics is paramount to evaluate the possible performance of a new material. In this work we use first-principles calculations based on density functional and density functional perturbation theory to investigate carrier-phonon coupling in r-GeO_2 and predict its phonon-limited electron and hole mobilities as a function of temperature and crystallographic orientation. Our findings show that r-GeO_2 has relatively high carrier mobilities, and in particular high hole mobility compared to other UWBG materials. We find the room temperature mobilities are $\mu_{elec,\perp c} = 244$ cm^2 V^{-1} s^{-1}, $\mu_{elec,\parallel c} = 377$ cm^2 V^{-1} s^{-1}, $\mu_{hole,\perp c} = 27$ cm^2 V^{-1} s^{-1}, and $\mu_{hole,\parallel c} = 29$ cm^2 V^{-1} s^{-1}, with carrier scattering dominated by low-frequency polar-optical phonons. While the electron mobility compares readily with other UWBG materials such as β-Ga_2O_3, the hole mobility is notably high. This finding is complimented by other recent work that reports r-GeO_2 can be ambipolarly doped, enabling access to both n- and p-type devices. Paired with a wide band gap around 4.68 eV, the high carrier mobilities lead to a predicted Baliga figure of merit that surpasses an array of more established semiconductors, including Si, SiC, GaN, and β-Ga_2O_3. Through this work, we show that r-GeO_2 is a promising UWBG semiconductor with desirable properties for both n- and p-type high-power electronic devices.

4:40 PM EL04.03.03

Extremely Sharp Free Exciton Emission in Heteroepitaxial Cuprous Iodide Thin Films Grown by MBE

Masao Nakamura[1], Sotato Inagaki[2], Yoshihiro Okamura[2], Makiko Ogino[2], Youtarou Takahashi[2,1], Licong Peng[1], Xiuzhen Yu[1], Yoshinori Tokura[1,2] and Masashi Kawasaki[2,1]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan

Triggered by the successful development of perovskite solar cells, halide semiconductors have gained extensive attention in the last few years. Cuprous iodide (CuI) is a representative wide-bandgap halide semiconductor with superior optical and electronic properties, such as direct bandgap and large exciton binding energy as well as high hole-mobility. In particular, the exciton binding energy and oscillator strength in CuI are comparable with or even surpassing those in well-known wide-bandgap semiconductors like GaN and ZnO. These prominent excitonic properties are of great advantage for future quantum optoelectronic applications, including ultraviolet lasers and quantum simulators utilizing the Bose-Einstein condensate of exciton-polariton. However, the studies towards such device applications have been of little progress in CuI due to the lack of high-quality thin films so far.

Recently, we have succeeded in a dramatic improvement in the quality of CuI thin films. Thin films were grown by the molecular beam epitaxy (MBE), which had been rarely employed for the fabrication of halide films but has a successful history in the growth of high-quality compound semiconductor films. As a substrate, we adopted InAs that is almost perfectly lattice-matched with CuI. The fabricated CuI film has a genuine single-crystalline structure with excellent lattice coherence and atomically-flat surface. The low-temperature photoluminescence spectra exhibit extremely-sharp luminescence peak assigned to the free-exciton emission, which has never been observed even in bulk single crystals. These results indicate that the optical quality of CuI film has reached to the level of much more extensively studied wide bandgap semiconductors.

The successful growth of the high-quality CuI film will facilitate the optoelectronic device applications of CuI. Moreover, the present result will open a new research direction to explore novel functionalities at the atomically-sharp heterointerface of halides.

4:55 PM EL04.03.04

Rutile GeO_2—An Ultra-Wide-Band-Gap Semiconductor for Power Electronics

Sieun Chae[1], Kelsey Mengle[1], Kyle Bushick[1], Hanjong Paik[2], Nguyen Vu[1], John Heron[1] and Emmanouil Kioupakis[1]; [1]University of Michigan, United States; [2]Cornell University, United States

Ultra-wide-band-gap (UWBG) semiconductors have tantalizing advantages for power electronics as their wider band gaps enable higher breakdown voltages. A handful of materials such as AlN/AlGaN, β-Ga_2O_3, and

diamond have been developed for UWBG semiconducting devices, however, they are still facing numerous challenges, such as doping asymmetry and/or inefficient thermal conduction. In our work, we have identified rutile GeO_2 (r-GeO_2) to be a promising, yet unexplored UWBG (4.68 eV) semiconductor. Our first-principles calculations predict shallow ionization energies for donors such as Sb, As, and F, a phonon-limited electron mobility of 289 $cm^2 V^{-1}s^{-1}$, and a breakdown electric field of 7.0 MV cm^{-1}, which lead to a higher Baliga figure of merit than β-Ga_2O_3. r-GeO_2 also has superior thermal conductivity (51 W m^{-1} K^{-1} (experiment)) and p-type doping property (the calculated ionization energy for Al acceptors is 0.45 eV and the calculated phonon-limited hole mobility is 28 $cm^2 V^{-1}s^{-1}$). Though the thin-film synthesis of r-GeO_2 has remained challenging due to its highly metastable amorphous phase, we demonstrate the first synthesis of single crystalline epitaxial thin films of r-GeO_2 on a sapphire substrate using ozone-assisted molecular beam epitaxy. Also, Sb-doping of r-GeO_2 was achieved for r-GeO_2 single crystal nanorods. Our work motivates further exploration of r-GeO_2 as an alternative UWBG semiconductor that can overcome the limitations of the current state-of-the-art UWBG materials.

5:10 PM EL04.03.05
Late News: Thermal Imaging of Ultrawide Bandgap Devices Using MoS2 Thermoreflectance Enhancement Coatings Riley C. Hanus[1], Samuel Graham[1] and Asif Khan[2]; [1]Georgia Institute of Technology, United States; [2]University of South Carolina, United States

Measuring the maximum operating temperature within the channel of ultrawide bandgap transistors is critically important, since thermal management often sets operational limits such as maximum power and lifetime. Thermoreflectance imaging is an optimal choice due to sub-micron spatial resolution, sub-microsecond transient characterization, and rapid data acquisition. Unfortunately, commercially available light sources are limited to energies less than ~3.9 eV and are therefore transparent to ultrawide bandgap materials. Here, we utilize an MoS_2 coating as a thermoreflectance enhancement coating which allows for the measurement of the surface temperature of (ultra)wide bandgap materials. This coating is a polycrystalline thin film with the c-axis preferentially aligned normal to the surface and is easily removable via sonication. The method is validated using electrical and thermal characterization of GaN and AlGaN devices. We demonstrate that this coating does not significantly influence the electrical and thermal behavior of the devices tested. A maximum temperature rise of 49 K at 0.59 W was measured within the channel of the AlGaN device, which is over double the maximum temperature rise obtained by measuring the thermoreflectance of the gate metal, demonstrating this methods value.

5:25 PM *EL04.03.06
Deep UV Optical Properties of High-Mg-Content Rocksalt-Structured MgZnO Takeyoshi Onuma[1], Kanta Kudo[1], Kyohei Ishii[2], Mizuki Ono[1], Yuichi Ota[3], Kentaro Kaneko[2,2,2], Tomohiro Yamaguchi[1], Shizuo Fujita[2,2] and Tohru Honda[1]; [1]Kogakuin University, Japan; [2]Kyoto University, Japan; [3]Tokyo Metropolitan Industrial Technology Research Institute, Japan

Deep and vacuum UV light emitters have a variety of applications, such as in ozone cleaners, UV sterilization, medical care, and photolithography. Recently, the alternative use of 222-nm-DUV-light instead of conventionally-used 254-nm-DUV-light is proposed to sterilize human skin with suppressing DNA lesions based on the UV effects on the epidermis of hairless albino. [1] Indeed, action spectra for producing DNA lesions exhibit a peak at around 260 nm and subsequent increase in a wavelength range shorter than 220 nm and VUV region. [2] Enhancement of light absorption by a protein in the human epidermis in a shorter DUV and VUV regions enables selective inactivation of virus in an atmosphere. An effective wavelength range of 190 nm to 220 nm can be proposed by a tradeoff between the action spectra and the air absorption. However, most of commercially available DUV and VUV light sources are discharge-type lamps or lasers. Therefore, demands are increasing for developing solid-state DUV and VUV emitters since their cost, environmental impact, energy consumption are expected to be drastically reduced compared to the discharge-type light sources.
AlGaN alloys are the most promising materials for DUV light emitters. [3,4] However, their shortest emission wavelength is limited to be around 210 nm for AlN. [5] In this study, we are focusing on high-Mg-content rocksalt-structured (RS) MgZnO alloys as alternative candidate materials for DUV and VUV emitters by virtue

of their wide variation of bandgap energy E_g from 4.5 eV for RS-ZnO to 7.8 eV for RS-MgO. Recently, successful growths of atomically-flat single crystalline RS-$Mg_xZn_{1-x}O$ films on (001) MgO substrates by the mist chemical vapor deposition (mist CVD) method [6,7] and observation of DUV emission [6-8] were demonstrated. Further improvements in its crystalline quality [9] has resulted in the predominate observation of cathodoluminescence (CL) peak at around 199-217 nm for x=0.92-0.95. [9,10] Excitation-current-density dependent CL spectra were measured, and analyses based on a rate equation model confirmed that the DUV luminescence band is attributed to the near-band-edge emission. [10] Electronic structure calculations suggested predominate contribution of Γ-Γ direct transition for the RS-$Mg_xZn_{1-x}O$ alloys with x>0.5. However, it is found that relatively broad tail-states expand toward deep UV spectral region. Consequently, CL peak energies show large Stokes-like shift of 0.7-0.8 eV. The E_g fluctuations and resultant exciton localization are possible origins of the large Stokes-like shift. Equivalent internal quantum efficiency is defined as spectrally integrated CL intensity at 300 K divided by that at 6 K. Relatively high values of 2-4% were obtained for the DUV NBE emission. The efficiencies were improved by employing the $Mg_xZn_{1-x}O$/MgO multi-layered structures. [11]

6:30 PM *EL04.04.01
Materials and Device Engineering for AlGaN and β-Ga_2O_3 UWBG Electronic Devices Nidhin K. Kalarickal[1], Towhidur Razzak[1], Hao Xue[1], Zhanbo Xia[1], Chandan Joishi[1], Hongping Zhao[1,1], Asif Khan[2], Wu Lu[1] and Siddharth Rajan[1,1]; [1]The Ohio State University, United States; [2]University of South Carolina, United States

This presentation will review recent and ongoing work on ultra-wide band gap (UWBG) semiconductor electronic devices based on AlGaN and β-Ga_2O_3. The high breakdown field strength of UWBG semiconductors such as AlGaN and Gallium Oxide have opened exciting opportunities for achieving improved performance over well-established materials such as Si, GaN, and SiC. While these materials have several unique properties, they also share common challenges, such as relatively low mobility (compared to conventional Si and GaN), and the need for managing extreme electric fields

The first part of the presentation will discuss the development of AlGaN-based transistors for RF and mm-wave applications. Device simulations show that despite the relatively low electron mobility, the high breakdown field in AlGaN could enable performance enhancement for high frequency transistors. We will then discuss key recent developments in AlGaN transistors that have enabled significant improvement in device performance. The use of electron affinity grading [1] and advanced epitaxial designs has enabled UWBG AlGaN transistors with cutoff frequency over 40 GHz [2], and current density over 900 mA/mm. Introduction of high-permittivity materials in lateral device structures prevents premature gate breakdown, while improving field uniformity in transistor gate-drain regions [3]. We will discuss the application of this idea in $BaTiO_3$/AlGaN lateral diodes,

where we achieved a breakdown field of 8.5 MV/cm [4] (breakdown voltage of 160 V), which represents the highest field achieved in a lateral device.

In the second part of the presentation, we will discuss recent work toward development of high-performance β-Ga_2O_3 lateral and vertical devices. We will discuss the growth of [endif]-->-$Ga_2O_3$and related alloys, and our investigation of fundamental electronic properties in these structures. The use of delta doping enables several key lateral electronic device structures. We will first give an outline of the relatively new mechanisms involved in Si delta doping using molecular beam epitaxy [5], and then discuss our work on growth of ��-$(Al,Ga)_2O_3$/��-Ga_2O_3 modulation-doped structures, including recent investigation into high sheet charge density modulation-doped structures [6]. We will then outline details of recent device demonstrations, including investigation of advanced passivation methods to reduce current collapse [7], scaled delta-doped transistors with cutoff frequency of 27 GHz [8], and modulation-doped field effect transistors state-of-art power switching figure of merit of 586 MW/cm^2.

Current Status of Deep Level Defects in β-Ga_2O_3 Steven A. Ringel[1], Hemant Jagannath Ghadi[1], Joseph McGlone[1], Rachel Adams[1], Aaron R. Arehart[1], Zixuan Feng[1], A F M Anhar Uddin Bhuiyan[1], Yuxuan Zhang[1], Hongping Zhao[1], Zhanbo Xia[1], Nidhin K. Kalarickal[1], Siddharth Rajan[1], Alexander Senckowski[2] and Man Hoi Wong[2]; [1]The Ohio State University, United States; [2]University of Massachusetts Amherst, United States

Beta phase gallium oxide (β-Ga_2O_3) is a strong contender as the basis for next generation high power and RF devices, and there has been significant progress and interest in developing this material system. Investigating the presence and properties of crystalline defects and their manifestation as bandgap states within the ~ 4.8 eV β-Ga_2O_3 bandgap has been paramount to improve material quality. With β-Ga_2O_3 rapidly advancing as a forward-looking semiconductor device technology, the exploration of deep level defect states has been extensive and is now broadening beyond initial baseline studies that continue to guide optimization of crystal growth and material quality. These directions include the characterization of the influence of high energy particle radiation, which represents envisioned applications of β-Ga_2O_3 devices used in harsh environments, direct investigations of deep level defect impacts on β-Ga_2O_3 transistor characteristics, and the characterization of intentional defect engineering such as using compensating deep acceptors for achieving semi-insulating layers that are needed in some device applications.

This presentation will first review the state of knowledge regarding deep level defect distributions in β-Ga_2O_3 based on the application of deep level optical spectroscopy (DLOS), deep level transient (thermal) spectroscopy (DLTS), and admittance spectroscopy to β-Ga_2O_3 materials and devices. This combination of techniques

enables quantitative characterization of defect states throughout the ultrawide β-Ga_2O_3 bandgap. A comparison of deep level distributions in energy and concentration will first be discussed based on materials grown using edge-defined film growth (EFG), metalorganic chemical vapor deposition (MOCVD), low pressure chemical vapor deposition (LPCVD), hydride vapor phase epitaxy (HVPE) and molecular beam epitaxy (MBE). Clear differences are observed depending on growth method, with the lowest total trap concentrations being found for MOCVD and HVPE materials. A deeper exploration of MOCVD materials reveal significant and inequivalent dependences of individual trap state concentrations on growth temperature, implying that the low total trap concentration in MOCVD material could be reduced further. Deep acceptor doping by Fe, Mg and N is also compared as a first step toward exploring the comparative efficacy of each impurity in enabling ideal semi-insulating behavior for β-Ga_2O_3, along with reviewing how Fe impacts the behavior of β-Ga_2O_3 transistors by virtue of its primary deep level position in the bandgap near E_C – 0.8 eV. Finally, the β-Ga_2O_3 response to proton irradiation will be discussed, detailing the dominant radiation-induced states that are formed and the subsequent radiation hardness.

CVD Diamond P-I-N Structures for High Temperature Electronics, Radiation Detection and Electron Emission Robert J. Nemanich[1], Franz Koeck[1], Mohamadali Malakoutian[2], Harshad Surdi[1], Jason H. Holmes[1], Manpuneet Benipal[3], Ricardo Alarcon[1], Srabanti Chowdhury[4] and Stephen Goodnick[1]; [1]Arizona State University, United States; [2]University of California, Davis, United States; [3]Advent Diamond Inc., United States; [4]Stanford University, United States

Diamond is a semiconductor with extreme and unique properties, which enable applications for high temperature electronics, radiation detectors, and electron emitters for ultra-high voltage vacuum switches and traveling wave tube cathodes. The fundamental structure for each of these applications is the p-i-n diode prepared from epitaxial, doped diamond layers. The availability of high-quality diamond substrates and the development of plasma CVD of epitaxial doped and undoped diamond have enabled fabrication of diodes with high breakdown field. CVD growth of high purity intrinsic diamond has shown room temperature mobility of both electrons and holes > 5000 cm^2/V-s. Boron and Phosphorus doped layers achieve p-type and n-type character, respectively. Highly doped layers > 10^{19} cm^{-3} demonstrate low resistance through hopping conduction, which supports low resistance contacts. Epitaxial diamond PIN diodes show high current density injection mode transport described as space charge limited current. The unipolar hole current density through a Schottky diode intrinsic drift layer shows a V^2 dependence as described by the Mott-Gurney expression where the differential resistance decreases as the voltage increases. Similarly, the differential resistance of a p-i-n diode shows a decrease of on-resistance with V indicative of bipolar conductivity modulation. At higher forward bias, velocity saturation is expected to limit the current in both unipolar Schottky and bipolar p-i-n diodes. The injection limited current transport of the undoped intrinsic diamond layer can enhance the predicted Baliga's figure of merit for diamond relative to other wide bandgap semiconductors. Results on diamond p-i-n alpha particle detectors show essentially 100 % charge collection efficiency at an applied bias of <20V. Moreover, background from x-ray and gamma photons does not substantially i,pact the count rate. Similalry, efficient electron emission is observed from forward biased diamond p-i-n diodes. Here, improved n-type contact structures substantially enhances the emission. The tremendous progress in diamond applications is limited by materials challenges. As materials research progresses, new device concepts are being developed based on the outstanding, extreme and unique properties of diamond materials.

Diamond Electronics for Quantum Sensing Mutsuko Hatano; Tokyo Institute of Technology, Japan

Diamond is an excellent host for spin-based qubits, and the spin in diamond has excellent properties. Nitrogen-vacancy (NV) center in diamond is one of the most promising candidates for quantum sensing. The energy levels of NV centers are sensitive to magnetic fields, electric fields, strain, and temperature, enabling scalable

applications from the atomic to the macroscopic range [1].
Core technologies on material, devices, quantum control technology, sensor systems, and applications for life science and energy electronics are introduced.
- Materials
Selectively-aligned NV ensemble formed by distinctive CVD-growth for scalable applications.
The heteroepitaxial growth of NV-contained diamond on Si substrate for large area and on-chip integration.
- Sensing devices using pn junctions.
- Multi-scale and multi-modal sensor systems for life-science and energy electronics applications [2-4].

UV-C Laser Diode with Distributed Polarization Doped P-Cladding Layer Maki Kushimoto[1], Ziyi Zhang[1,2], Tadayoshi Sakai[1], Naoharu Sugiyama[1], Leo J. Showalter[3], Yoshio Honda[1], Chiaki Sasaoka[1] and Hiroshi Amano[1]; [1]Nagoya University, Japan; [2]Asahi Kasei Corporation, Japan; [3]Crystal IS, Inc., United States

UV laser diodes are candidates for health care applications such as water and air sterilization, medical sensing, and curing. Especially AlGaN-based UV optical devices are compact, have a long lifetime, and is environmentally friendly compared with conventional UV light sources. Recently, UVC and UVB LDs [1,2] are realized a long time after the UVA LD is reported [3]. These were achieved by overcoming the several issues: low hole injection efficiency, high operation voltage, and optical loss caused by crystal defects. In particular, the the non-dopes distributed polarization doping (DPD) [4] structure of the p-clad layer contributes to the lasing by improving the hole injection efficiency. The average Al composition of 85% and hole concentrations in the mid-17th power range can be expected to be obtained by this method. The p-clad layer with a non-doped DPD structure has other advantages. The high Al composition in the region close to the active layer acts as an EBL layer that suppresses the electron overflow. Mg doping is not performed in this layer, so that absorption of light emission in the p-cladding layer can be suppressed. This mean that non-doped DPD is well matched method with the UVC-LD structure for p-type conductivity control.
The device structure we have prototyped consists of n, p-AlGaN cladding layer, guiding layer, single quantum well and p-contact layer. The p-type DPD cladding layer is constituted by continuously reducing the Al composition from AlN to AlGaN with 70% Al composition. From the evaluation of the optical properties, it was found that the internal loss could be reduced to less than 10 /cm with the appropriate DPD layer thickness [5]. After electrode formation, the wafer cleavage and the deposition of HfO_2/SiO_2 distributed Bragg reflector were carried out. As a result, a pulsed LD operation of a 270 to 280 nm was observed at the room-temperature. Lasing was observed at a forward current density of 14 kA/cm^2.
We also demonstrated LDs by the combined of dry and wet etching method as LD mirror facet fabrication. This method generally known to fabricate LDs grown on heterogeneous substrates, and it is attractive for mass production and monolithic integration. Since DBR formation was a major issue in this method, we focused on ALD with good coverage. As a result, the lasing was achieved with this combined method as well as the conventional cleaved method.

Wide Bandgap Semiconductor Based Power Electronic Devices for Energy Efficiency Isik C. Kizilyalli[1] and Eric P. Carlson[2]; [1]U.S. Dept. of Energy, United States; [2]Booz Allen Hamilton, United States

Abstract – Development of advanced power electronics with increased functionality, efficiency, reliability, and reduced form factor are required in an increasingly electrified world economy. Fast switching power semiconductor devices are key to increasing the efficiency and reducing the size of power electronic systems as a significant portion of the losses in the systems is dissipated in the power semiconductor devices. However, the prevailing power semiconductor devices, which are based on the semiconductor silicon, are fast approaching their operational limits due to the intrinsic Si material properties. Wide-bandgap (WBG) semiconductors, such as gallium nitride (GaN) and silicon carbide (SiC), with their superior electrical properties are enabling a new generation of power semiconductor devices that offer higher efficiency and higher power conversion densities in a wide range of applications. The U.S. Department of Energy's Advanced Research Project Agency - Energy (ARPA-E) has invested in WBG semiconductors to enable a new generation of power semiconductor devices that far exceed the performance of silicon-based devices. In 2017 ARPA-E launched the PNDIODES program to address a major barrier to fabricating GaN power electronic devices which is the lack of a viable selective area doping processes. At the launch of the program, the selective area doping processes commonly used for other semiconductor materials, such as ion implantation or solid state diffusion, had not produced satisfactory p-type regions or p-n junctions in GaN due to the thermodynamic decomposition of GaN at high temperatures which has limited the device fabrication processes. The selective area doping processes in GaN resulted in poor electrical performance not sufficient for power electronic applications. The goal of the PNDIODES program is to develop transformational advances and mechanistic understanding in the process of selective area doping in the group III-Nitride wide-bandgap semiconductor material systems in order to demonstrate arbitrarily placed, reliable, contactable, and generally useable p-n junction regions. The projects selected for funding as part of the PNDIODES program are developing innovative selective doping processes for GaN. These include cutting-edge high temperature annealing processes to activate implanted dopants and remove the damage caused by ion implantation while overcoming the thermodynamic limits of GaN decomposition, low temperature solid-state diffusion of dopants using pioneering mechanisms to increase the diffusion driving force, non-traditional selective area doping process using low damage patterned etching followed by GaN regrowth to form buried selectively doped regions, and nuclear transmutation techniques to convert host atoms to dopants *in-situ* through exposure to neutrons and/or high energy photons. The PNDIODES projects are using/developing advanced nanoscale characterization techniques to investigate the local optical, chemical, structural, and electrical properties of the selectively doped regions to gain a mechanistic understanding of the processes being developed. These include Photo and Cathodoluminescence, Raman Spectroscopy, Atom Probe Tomography, Secondary Electron Emission, X-ray Topography, Rutherford Backscattering Spectrometry/Channeling,

Electron Paramagnetic Resonance, Nuclear Magnetic Resonance, Scanning Spreading Resistance Microscopy, Scanning Capacitance Microscopy, Photoconductivity Spectroscopy, and Electron Holography. The progress and challenges of selective area doping processes being developed under the PNDIODES program is reviewed along with the mechanistic understanding being generated. Material and processing challenges, including reliability concerns, for GaN power devices are also described. A glimpse into the future trends in device development, system integration, and commercialization is offered.

Materials and Technology Issues of Vertical GaN Power FinFETs Ahmad Zubair, Joshua Perozek, John Niroula and Tomas Palacios; Massachusetts Institute of Technology, United States

By 2030, about 80% of all US electricity is expected to flow through power-electronic devices. To enable this vision, the next generation of power electronics will require much higher efficiency and smaller form-factor than today's silicon-based systems. III-Nitride semiconductors form an ideal material system for this thanks to the combination of excellent transport properties and the high critical electric field enabled by their wide bandgap.
Both lateral and vertical III-Nitride devices are being investigated. In this paper, we will study vertical GaN FinFETs, as the vertical fin channel offers excellent electrostatic and threshold voltage control, eliminating the need for epitaxial regrowth[1] or p-type doping[2] unlike other vertical power transistors. Vertical GaN FinFETs with 1200 V breakdown voltage (BV) and 5-A current rating have been demonstrated recently on free-standing GaN substrates[3]. Besides, the high current density of these devices, in combination with minimum parasitics, allow these devices to achieve beyond-state-of-the-art switching performance. This talk will discuss the recent progress of GaN vertical power FinFETs on native GaN substrates, highlighting the device and materials-level opportunities as well as some of the challenges to push the performance limits in these devices. In addition, the talk will review recent efforts on GaN vertical power FinFETs on non-GaN substrates[4]. In spite of their promising performance, the commercialization of vertical GaN FinFETs on native GaN substrates has been limited by the high cost ($50-$100/cm^2) and small diameter (2-4 inch) of free-standing GaN substrates. The use of Si or engineered substrates with a matched thermal expansion coefficient could potentially reduce the substrate cost by 1000×, although key trade-offs between leakage currents and performance need to be carefully studied.

Laser-Assisted MOCVD GaN Epitaxy for Vertical Power Device Applications Yuxuan Zhang, Zhaoying Chen, Zixuan Feng and Hongping Zhao; The Ohio State University, United States

GaN and its alloys have been widely utilized in optoelectronics, photonics, and electronics. Due to its large band gap (3.4 eV), strong critical electric field (3.4 MV/cm) and high electron mobility (>1000 cm^2/Vs), the Baliga's figure of merit (BFOM) of GaN is more than 500X and 3X higher than that of Si and SiC, exhibiting great potential for high power electronics. Vertical GaN PN diode with 5kV breakdown voltage has been demonstrated [1]. To further improve the device performance, thicker drift layer with lower controllable doping is desired. For MOCVD GaN growth, TMGa and NH_3 are typically used as Ga and N precursors. However, one of the challenges associated with current MOCVD technology is the low NH_3 cracking efficiency (<1%), due to its high chemical stability even under high temperature (1000 °C). Carbon is considered as the most common impurity which originates from TMGa precursor. It is most likely to be incorporated on nitrogen site to form a

deep acceptor (C_N) in n-type GaN [2], which compensates effective doping, thus increase on-resistance and leakage current in vertical GaN power devices. Traditionally, C can be suppressed by increasing growth temperature (increase NH_3 cracking efficiency) and V/III ratio (increase NH_3 partial pressure) [3]. Recent study [4] indicated that NH_3 can be efficiently cracked by CO_2 laser in which the photon energy is coupled with N-H wagging mode. With laser-assisted MOCVD (LA-MOCVD), GaN growth window is expected to be expandable to lower temperature regime with faster growth rate and lower impurity incorporation.

In this work, we performed a systematic study on the growth of GaN via LA-MOCVD growth technique. A tunable CO_2 laser with wavelengths between 9.201 to 10.365 μm was utilized as external excitation source in a commercial MOCVD system. From our studies, NH_3 has a strong interaction with the CO_2 laser, while neither N_2 nor H_2 has much absorption of the laser beam. The MOCVD GaN growth condition is widely tuned, including the growth temperature, chamber pressure, NH_3 flow rate, and type of carrier gas, to understand the effect of CO_2 laser beam on the GaN growth. The preliminary results indicate that LA-MOCVD growth can suppress C incorporation in GaN. Meanwhile, the CO_2 laser can also lead to strong gas phase reaction between precursors, which in turn leads to the reduction of GaN growth rate. LA-MOCVD growth of GaN at lower temperature regime indicates the suppression of V-pits formation as compared to the conventional GaN growth without the laser. Smooth surface morphology of LA-MOCVD GaN was observed under optical microscope, AFM and SEM, with low RMS of 0.34 nm measured by AFM. Therefore, LA-MOCVD can become a novel growth technique to grow high quality GaN suitable for high power vertical devices.

In summary, for the first time, we performed CO_2 based LA-MOCVD GaN growth in a commercial MOCVD system. LA-MOCVD growth conditions are systematically mapped and comprehensive material characterization is performed. Results from this work indicate the great potential of using the novel LA-MOCVD growth method to achieve GaN epitaxy for vertical power devices with high breakdown voltages.

GaN P-N Power Diodes with > 1.5 kV Breakdown Voltage Vishank Talesara, Zhaoying Chen, Yuxuan Zhang, Hongping Zhao and Wu Lu; The Ohio State University, United States

In this work, we report 1.5 kV GaN PN diodes on an HVPE substrate. The GaN layers were grown on a 2" HVPE GaN substrate using the Metal Oxide Chemical Vapor Deposition (MOCVD). The dislocation density of the substrate ranges between 2×10^6 cm^{-2} in the less dense regions to 1×10^7 cm^{-2} in regions that show the presence of dense dislocation clusters. The device structure consists of a 20 nm p+ GaN contact layer(Mg: 1×10^{20} cm^{-3}), followed by a 500 nm p-GaN layer (Mg: 1×10^{18} cm^{-3}), grown on an 8 μm n-GaN drift region (Si: 1.2×10^{16} cm^{-3}) and 1.6 μm n+ GaN buffer layer (Si: 1.5×10^{18} cm^{-3}) on a thick bulk HVPE GaN substrate. The hole concentrations in the p and p+ GaN layers are 1×10^{17} cm^{-3} and 5×10^{17} cm^{-3}, respectively, measured by Hall measurements. CV measurements show that the drift layer has an electron concentration of 5.1×10^{15} ~ 1.2×10^{16} cm^{-3}. According to the analytical calculations, this device structure design has a theoretical punch-through breakdown voltage value of ~ 2.0 kV. For electrical field management, three layers of guard ring structures were designed and implemented by nitrogen ion implantation at the dose of 3.2×10^{13} ions/cm^{-2} at five ion energies which results in a depth of ~520 nm. Based on numerical simulations, the electrical field peaks at the edge of each guard ring and this device design should result in a breakdown voltage of 1670 V at a critical

field of 3.4 MV/cm. For device fabrication, Ti/Al-based metal scheme was used to form the contact to n-GaN as the back cathode. Pt/Ni/Au anodes were annealed at 350 °C for p-contacts with a specific contact resistivity of 0.6 $m\Omega cm^2$. The devices were then passivated by a 500 nm SiN layer after nitrogen ion implantation. The device size varies from 100 to 600 μm. The devices exhibit a breakdown voltage of 1530 V due to a clear avalanche process. The measured breakdown voltage has a remarkable agreement with numerical simulations. This suggests that the devices have an excellent breakdown efficiency > 75%. The reverse leakage current density is in the $\mu A/cm^2$ range till 500 V. The turn-on voltage is 4.9 V at 100 A/cm^2 and the device exhibited 1 kA/cm^2 current density at 6.0 V. The specific on-resistance for this device is 1.2 $m\Omega\ cm^2$. This measured breakdown voltage and on-resistance lead to a figure of merit of 2.1 GW/cm^2. Considering the p-contact resistivity, this suggests that the n-drift layer has an electron mobility of 480 cm^2/Vs. The devices have an ideal factor of 2.7 at 2.3 V, likely due to a resistive layer at the bulk GaN substrate and epitaxy interface. More statistical analysis of device performance will be presented at the conference. Overall, this work represents the state-of-the-art device performances of GaN power diodes.

This material is based upon work supported by the U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy (EERE) under the Advanced Manufacturing Office, FY18/FY19 Lab Call.

9:10 AM DISCUSSION TIME

9:25 AM EL04.05.06
Low-Defect Etched-and-Regrown PN Diodes by *In Situ* Tertiarybutylchloride (TBCl) Etching Bingjun Li, Sizhen Wang and Jung Han; Yale University, United States

Gallium Nitride (GaN)-based devices are very attractive candidates for next-generation high-power applications, due to the intrinsic material properties. However, the lack of selective-area doping technique in GaN greatly limits the design flexibility and device performance. Due to the difficulty of post-ion-implantation annealing process in GaN material, selective-area etching (SAE), followed by selective area growth, is an alternative and promising approach to overcome this obstacle. Plasma-etching, as a well-developed technique to create smooth and high aspect-ratio trenches, induces serious optical and electronic defects and impurities on the treated surface. Therefore, we introduced a chlorine-based metal-organic (MO) precursor, tertiarybutylchloride (TBCl), into the MOCVD reactor to replace the role of plasma etching.

TBCl etching was also performed on 1.5μm unintentional-doped (UID) GaN templates grown on bulk GaN substrate to mitigate the effect of dislocation-mediated etching. Four samples are compared here. Sample A is a template. Sample B~D are templates etched by Cl-based plasma, TBCl and a combination of both, respectively. Photoluminescence (PL) showed strong near-band-edge emissions only from Sample A, C and D (Fig. 3(a)). And only Sample B had obvious Cl peak from x-ray photoelectron spectroscopy (XPS) (Fig. 3(b)). Both PL and XPS confirm that TBCl etching is able to remove the impurity (except Si and Al) and damage induced by plasma etching and does not introduce damage itself.

Besides, electrical properties were also evaluated. Four planar PN diodes were grown and fabricated. Device A is a continuous PN diode, while Device B~D were etched-and-regrown PN diodes. Three different etching were performed on 1.5μm UID drift layer grown on GaN substrate: plasma etching followed by AZ400K cleaning for Device B; plasma etching (ICP)+AZ400K cleaning+150nm TBCl etching for Device C; and 150nm TBCl etching for Device D. 300nm UID and 400nm p-GaN was regrown on the etched templates. Forward and reverse I-V characteristics were compared. No obvious difference is observed when they were forward biased. However, leakage behaviors are quite distinct. The TBCl-etched diode (Device D) shows the best leakage behavior among all three regrown devices, while ICP+TBCl-etched diode has the highest leakage current. From SIMS and CV measurement comparisons, Device C has the highest Si impurity concentration, which could explain the worst leakage behavior. On the other hand, a high concentration of deep traps was observed on ICP-etched diodes from CV measurement.

9:40 AM EL04.05.07
Scanning Capacitance Microscopy of GaN p-n Junction Through Planar and Selective Area Doping
Sizhen Wang, Bingjun Li and Jung Han; Yale University, United States

Scanning capacitance microscope (SCM) integrates a high-frequency capacitance sensor into the conductive atomic force microscope (C-AFM) to measure the change of capacitance of a well-known metal-oxide-semiconductor (MOS) or Schottky diode structure under an AC driving voltage. The dC/dV amplitude and phase of the output signal tells the doping type and carrier concentration, respectively. SCM has demonstrated the capability to delineate the p-n junction and form a 2-D dopant mapping on Si substrate accurately. In addition, doping characterization using SCM on GaN were also reported. Here, we demonstrated SCM characterization of a selective-area grown (SAG) lateral GaN p-n junction on bulk GaN substrate for the first time, which is a key building block of high-performance GaN-based high-power devices.
To quantify the doping concentration in a 2-D mapping, dC/dV amplitude and phase need to be calibrated with the known doping level at the beginning. Therefore, a sample consisting of multiple GaN layers with Si, Ge doping concentration ranging from unintentional doped GaN to $1x10^{20}/cm^3$ were used for the calibration. And the dC/dV amplitude peak was selected as parameter for calibration, which can reduce noise impact and eliminate the contrast reverse issue. By applying different AC driving voltage, near four order of magnitude doping of GaN can be calibrated on bulk GaN. Similarly, p-GaN layers with Mg concentration range from $1x10^{19}$ to $8x10^{19}/cm^3$ were also calibrated. Based on those calibration studies, we proposed an efficient operation procedure to characterize semiconductor samples with scanning capacitance microscopy and apply this procedure to investigate the continuously grown diodes, planar regrown diodes, and selective area regrown GaN diodes.
Several key results of applying SCM to characterize vertical GaN diode were summarized here: (1) to identify the p-n junction location, dC/dV phase is preferred to be used, because comparing to dC/dV amplitude, the dC/dV phase is much less susceptible to DC bias and AC driving signal. (2) SCM revealed that a thin n-type conducting layer existed at the regrown interface of planar regrown diode. This n-type layer, with increased conductivity comparing to UID-GaN, was related to ICP plasma damage. (3) For SAG regrown diodes, typical p-GaN layer was verified with SCM by applying proper DC bias condition, it was also found at the trench bottom (or regrowth interface), a typical n-type thin layer existed, which should not in ideal case. The possible n-type doping impurity might come from the out-gassing of the SiO_2 mask during the growth or other reactor parts made of quartz, which needs further investigation.

9:55 AM EL04.05.08
Late News: Surface Photovoltage Study of the Bulk Photovoltaic Effect in Carbon-Doped Gallium Nitride
Igal Levine[1], Ivan Gamov[2], Marin Rusu[1], Klaus Irmscher[2], Christoph Merschjann[1], Eberhard Richter[3], Markus Weyers[3] and Thomas Dittrich[1]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Leibniz-Institut für Kristallzüchtung, Germany; [3]Ferdinand-Braun-Institut GmbH, Leibniz-Institut für Höchstfrequenztechnik, Germany

Surface photovoltage (SPV) of carbon-doped gallium nitride single crystals (GaN:C) was investigated by Kelvin probe as a function of carbon doping.[1] GaN:C crystals are highly resistive due to compensating deep defect states. Depending on the carbon doping, SPV signals much larger than expected in relation to the band gap of GaN were detected setting on at photon energies of 2.5-2.6 eV due to excitation from defect states. Under constant illumination, the large SPV signals saturated at values above 20 V and even overshot abruptly by up to several volts above the saturation value when switching off the light source. The sign of the large SPV signals changed from positive to negative when flipping the crystal from the Ga-polar to the N-polar surface. Therefore, the large SPV signals on GaN:C are not related to a conventional Dember photovoltage, which is

based on different mobilities for photogenerated electrons and holes, but rather to a bulk photovoltaic effect (BPVE) caused by a structure dependence of directed momentum transfer. It is proposed that (tri)carbon complexes are key for directed momentum transfer in GaN:C and the resulting observed BPVE.

Design and Fabrication of Edge-Termination for Achieving Reliable GaN P-N Diodes for High Voltage Applications Srabanti Chowdhury[1], Andrew Allerman[2], Robert J. Kaplar[2], Andrew Armstrong[2], Jeramy Dickerson[2], Alan Jacobs[3] and Karl Hobart[3]; [1]Stanford University, United States; [2]Sandia National Laboratories, United States; [3]U.S. Naval Research Laboratory, United States

Electrification drives us closer towards our goal of a sustainable energy system. Highly efficient and reliable ways of converting, delivering and conditioning power calls for innovations at every level, from system to materials. Silicon's role in the electrification has led to exploring wide- bandgap (WBG) materials. SiC led power electronics have revealed the large scope of improvement that one can expect to see out of WBGs due to an enhancement of the critical electric field. GaN, originally pushed for medium voltage (650V-900V) devices using the well-known HEMT configuration, has a lot more to offer in power electronics through its vertical configuration. Over the last decade a tremendous amount of progress has been made with the support from ARPA-E and ONR which resulted in the improvement of the epitaxial material, understanding of the underlying physics, optimization of design and processing of the devices, accurate failure analysis, and finally, laying the groundwork for mass production.
Under the current ARPA-E Open plus program our team is developing high voltage (towards 20 kV) GaN PN diodes for use as devices to protect the electric grid against electromagnetic pulses [1]. A common goal shared by both DOD and DOE is to have a foundry component in the US to successfully scale and produce vertical GaN devices for circuit implementation. Under the current program, we are bringing together all the research components starting from material development and wafer metrology to reliability and failure analysis. These are the essential components for successful manufacturing of GaN devices leading to its transfer to the foundry. Achieving a reliable p-n junction definitely is the first step towards high voltage (1.2kV and up) power devices. In this talk we will focus on various approaches of edge termination to realize a robust p-n junction. Bevel and junction termination extension (JTE) approaches are being pursued on p-n diodes to study their efficacies in field mitigation. Using the bevel termination technique for 1.2kV diodes, we are studying the reverse blocking strength of these diodes, by closely monitoring their avalanche capabilities. The foundry effort is utilizing as a primary path various combinations of nitrogen-implanted isolation structures, guard rings, and JTEs.
The team, through a tight research collaboration, is working towards identification of the key challenges of edge- terminations and the best solution in GaN, to serve various voltage classes.

The authors gratefully acknowledge the support of ARPA-E's OPEN+ Kilovolt Devices Cohort managed by Dr. Isik Kizilyalli, and support of ONR managed by Mr. Lynn Petersen.

Variations in GaN Substrates and the Structural Evolution of Defects in Homoepitaxial GaN Layers
Yekan Wang[1], Michael E. Liao[1], Kenny Huynh[1], Andrew Allerman[2] and Mark S. Goorsky[1]; [1]University of California, Los Angeles, United States; [2]Sandia National Laboratories, United States

In this study, the structural defects in 40 mm homoepitaxial GaN grown on what is commonly referred to as dot-core GaN substrates were evaluated using synchrotron double crystal x-ray topography (XRT). 8.05 keV X-ray energy was used. The first crystal was an asymmetric Si (333) beam expander and the sample (2nd crystal) was oriented for diffraction of the (114) reflection. Films were obtained from single exposure at particular positions on the rocking curve and continuous exposure by rocking the sample (step size ~0.008°) about the [100] axis through the Bragg condition.
For as-received dot core substrates, regions of high distortion around the cores are observed. These defective regions are not confined within the core regions. The effect of tilt and distortion distribute to further affect regions between the cores as well. Meanwhile, variations in the substrates are observed. The substrates curvature for three as-received dot core substrates from the same vendor is quite different, with a radius of curvature of 25m, 17m, and 7m respectively. The defect structure surrounding the cores in the three substrates is also different. The distortions around the cores in two of the three substrates have a few hundred um white round (non-diffracting) regions around the cores while the other substrate shows irregular distorted regions. A few 'butterfly' shape patterns are present around some cores, which result from localized tilting of the lattice planes. Each side of the butterfly wing consists of contour lines representing regions of similar tilt. Rotating the sample every 60° and taking rocked images along different (11$\underline{2}$4) reflections, we found the 'butterfly' patterns follow the 60° rotation, suggesting that the lattice tilt around the cores occurs radially. The sample with 40 um epilayer grown on a dot core substrate shows a change in the defect structure around the cores. Defective regions after epitaxial growth are more concentrated in the core areas. A hypothesis is that defects observed on the bare substrate propagate into the overlaying epilayer. However, during epitaxial growth, structural distortions are redirected towards the centers of cores. The surface shows haze and specular regions with variation in AFM roughness (1.3 nm vs 0.4 nm). More defective regions observed using XRT appears to be correlated with haze on the surface. Variation of distortions across the wafer can also be identified. There are circular spot features with bright contrast, corresponding to highly defective regions of tilt after the epitaxial growth. Between cores and over some cores, there is undistorted, low dislocation density (~10^5 cm^{-2}) material with uniform grey contrast, corresponding to higher quality GaN (hundreds of um-size). Devices fabricated on such regions are expected to have better performance. In conclusion, the structural evolution of defects after the epitaxial growth is closely related to variations in the substrates. As a result, wafer screening and quality assessment using non-destructive techniques such as x-ray topography before and after the epitaxial growth are promised to help improve the overall quality of the homoepitaxial GaN structures.

The authors would like to acknowledge support through the ARPA-E PNDIODES program under contract DE-AR0001116 at UCLA. This research used resources of the Advanced Photon Source, a U.S. Department of Energy (DOE) Office of Science User Facility operated for the DOE Office of Science by Argonne National Laboratory under contract no. DE-AC02-06CH11357. The synchrotron X-ray topography measurements were carried out at 1-BM Beamline of the Advanced Photon Source, Argonne National Laboratory.

Application of Synchrotron X-Ray Topography to Characterization of Selective Area Doping Processes for the Development of Vertical GaN Power Devices
Yafei Liu, Hongyu Peng, Tuerxun Ailihumaer, Shanshan Hu, Balaji Raghothamachar and Michael Dudley; Stony Brook University, The State University of New York, United States

Selective area p-type doping of GaN is required for the development of vertical GaN devices that will help realize the potential of WBG semiconductor GaN in power electronics [1, 2]. Approaches being investigated include implantation followed by activation annealing by different methods, selected area etching and regrowth

of p-type regions [3], diffusion doping and neutron transmutation [4]. Using synchrotron X-ray topography [5] and complementary tools like HRXRD and Raman spectroscopy, the effect of substrate choice, implantation and annealing conditions have been evaluated on the structural quality and strain in the epilayers and regrown material. The choice of bulk GaN substrates plays an important role in the eventual extended defect configurations in the active layers. Ammonothermal-grown GaN substrate wafers show the best quality among all the wafers [6, 7]. These wafers, which are free of basal plane dislocations (BPDs), have low curvature and threading mixed dislocations (TMDs) dominant among the threading dislocations (TDs). Patterned HVPE GaN reveal a starkly heterogeneous distribution of dislocations with large areas containing low threading dislocation densities in between a grid of strain centers with higher threading dislocation densities and BPDs [8]. The strain level of HVPE GaN substrates is very high, and the dislocation density is around 10^5-10^6 cm^{-2}, which is much higher than 10^4 cm^{-2} of ammonothermal samples and dislocation-free areas in the patterned HVPE samples. During epitaxial growth by CVD for implantation purposes, defects in substrates are shown to replicate into the epilayer and typically no new defects are observed to be introduced at the interface. On implantation, damaged layers are generated in the epilayer as revealed by satellite peaks in double axis rocking curves. The radiation fluence and energy determine the extent of damage. Depending on annealing conditions most of the damage is healed. However, the annealing temperatures greater than 1100 C can result in introduction of inhomogeneous strains and dislocation generation. While etching by TBCl is shown to be sensitive to certain types of threading dislocations, any thermal treatment is shown to introduce basal plane dislocations. Further investigations are underway to analyze the regrowth interface for the nucleation of new defects. Results will be discussed with implications for vertical device fabrication and expected impact on device performance.

Late News: Microstructure Impacts on Performance of GaN Power Switching Devices Brett Setera and Aris Christou; University of Maryland, United States

GaN power switching devices with thick epitaxial layers (3-15 microns) suffer from a high density of crystal defects, and specifically threading dislocations(TDs) in the epi-layer. Presence of dislocations leads to non-ideal performance and higher costs manifested in device voltage derating, limited die sizes, poor wafer yields, operating parameter instability, and limited device types. Microstructure analysis of defect type and location is crucial to correlating structure with device performance.

Experimental results with 10 μm GaN epilayer grown on HVPE(hydride vapor phase epitaxy) + GaN indicate that threading dislocations can propagate through the epilayer to the contact, resulting in increased gate leakage current density. Cathodoluminescence (CL) imaging correlated with ECCI as well as AFM allow the conclusion to be reached that the main threading defects are the edge dislocations and dislocation loops which tend to be either tilted, exposing the edge dislocations, or parallel to the growth plane. Utilizing the three aforementioned non-destructive techniques allows measurement of as-grown defects before the device undergoes performance testing. Transmission x-ray topography analysis showed that the GaN is characterized by a nearly uniform

distribution of strain centers which are likely bundles of threading screw and edge dislocations. Strain free centers are then regions of relatively low dislocation densities. The threading dislocations are part of dislocation loops which are present in the GaN substrate and migrate through the interface. Cross-sectional TEM showed partial dislocation loops through the thickness of the GaN sample.
The two terminal GaN-on-GaN (HVPE) device was able to withstand 2.77 MV/cm before the contact to contact leakage current produced a gate – source short with an epilayer dislocation density of 10^6 cm^{-3}.

MOCVD GaN Epitaxy with Fast Growth Rates Yuxuan Zhang, Zhaoying Chen, Wenbo Li, Aaron R. Arehart, Steven A. Ringel and Hongping Zhao; The Ohio State University, United States

Gallium nitride (GaN) has been considered as a promising candidate for power electronic devices due to its wide bandgap (3.4 eV), high critical electric field (3 MV/cm), and high electron mobility (>1000 cm^2/V s). As a key parameter to evaluate the performance of power devices, Baliga's figure of merit (BFOM) of GaN is more than 500X higher than silicon (Si) and 3X higher than silicon carbide (SiC) [1]. Vertical GaN PN diode with 5kV breakdown voltage has been demonstrated [2]. Although tremendous progress has been made in the past few years, challenges still exist to achieve vertical GaN power devices with V_{BR}>10 kV, which requires the epitaxy of high quality GaN films with thick drift layer and low controllable doping with high mobility. Typical MOCVD GaN films with high mobilities were grown with growth rate of 2-3 μm/hr. Thus, it is important to develop and understand MOCVD GaN growth with fast growth rate, high crystalline quality, and controllable low carrier concentration.
In this work, the effect of increasing growth rate by increasing TMGa on the impurity incorporation, charge compensation, surface morphology and transport properties are systematically studied. Under optimized MOCVD GaN growth with a growth rate of 2 μm/hr, high quality GaN with stable low net charge density at 4×10^{15} cm^{-3} was demonstrated. [Si] and electron concentration (N_d-N_a) as a function of SiH_4 flow was studied. Stronger plummet of N_d-N_a was observed with reduction of SiH_4 flow when N_d-N_a is lower than 1×10^{16} cm^{-3}, due to prominent compensation effect at low doping range. According to capacitance-voltage (CV) and secondary ion mass spectroscopy (SIMS) analysis, the [C] level was at 7×10^{15} cm^{-3} (SIMS detection limit). Low N_d-N_a was achieved at 4×10^{15} cm^{-3} based on CV. Deep level transient spectroscopy / deep level optical spectroscopy (DLTS / DLOS) results show minimal electron trap concentration at 2.5×10^{15} cm^{-3}, mainly from carbon related deep level defects. By increasing the TMGa flow rate, GaN with fast growth rate at 5.2 μm/hr was achieved with stable N_d-N_a at 1.5×10^{16} cm^{-3} and [C] at 2×10^{16} cm^{-3}. Large area atomic force microscope (AFM) images on fast growth rate sample show smooth morphology with clear atomic strips and low surface roughness (RMS=0.647 nm). The Mn incorporation from the semi-insulating ammonothermal substrate into epilayer was observed. Controlled experiments show that Mn incorporation rate into epilayer is highly related to the growth rate, and Mn incorporation mechanism shares a similar behavior as Fe. SIMS showed that both Mn and Fe incorporation can be suppressed with faster growth rates. Room temperature Hall measurement showed that with electron concentration at around 1.5×10^{16} cm^{-3}, electron mobility decreased from 852 cm^2/Vs to 604 cm^2/Vs as growth rate increasing from 2 μm/hr to 5.2 μm/hr.
In summary, we studied the doping and compensation of n-type GaN as a function of growth rate. Low compensation level at 2 μm/hr was confirmed by both DLTS/DLOS and CV. Increasing GaN growth rate led to the increase of carbon concentration while suppressing Mn and Fe incorporation. In order to achieve high quality thick GaN drift layer with controllable doping concentration at low- to mid- 10^{15} cm^{-3} range for high voltage vertical power devices, the key challenge is to reduce carbon incorporation in the GaN epilayer. The results from this work provide insights for GaN vertical power electronics.

Influence of Surface Treatments on the Structure and Properties of GaN Layers Jiaheng He[1], Guanjie Cheng[1], Maggie Chen[1], Zhirong Zhang[1], Sam Frisone[1], Alexandra Zimmerman[1], Fabian Naab[1], Sizhen Wang[2], Bingjun Li[2], Jung Han[2] and Rachel Goldman[1]; [1]University of Michigan–Ann Arbor, United States; [2]Yale University, United States

Although silicon-based electronics are used to power light-emitting diodes and electric vehicles, their utility in high power applications is limited by slow switching and high on-state resistance. The most promising alternatives are vertical GaN devices, but these involve etching and selective-area re-growth which enhance the displacement of surface and near-surface Ga and N atoms. To understand processing-structure-property relationships relevant to vertical GaN devices, we are examining the influences of various surface treatments on the structure and properties of GaN layers. Utilizing ion beam analysis, we have examined the influence of ambient exposure and dry etching on the structure and properties of regrown p-i-n GaN structures. We show that dry etching improves the crystallinity of p-i interfaces, but also introduces interfacial H. In addition, we report on the influence of dry etching and metal-organic (MO) precursor treatment on the structure and properties of GaN substrates and epitaxial GaN layers. For these studies, we visualize the crystal symmetry and orientation using 2D planar ion channeling maps and angular yield profiles collected with a fully-automated 5-axis goniometer recently attached to the RC43 endstation of the 1.7 MeV Tandetron at the Michigan Ion Beam Laboratory. Our preliminary results suggest that the MO precursor reduces the density of displaced surface Ga atoms. To quantify the concentration and distribution of displaced atoms, we will compare 2D ion channeling maps with 2D Monte Carlo-Molecular Dynamics simulations using Flux 7.9.6. We will also present 2D maps of elastic recoil detection analysis spectra to evaluate the spatial distribution of H.

X-Ray Diffraction Studies of GaN p-i-n Structures for High Power Electronics Alexandra Zimmerman[1], Jiaheng He[1], Guanjie Cheng[1], Davide del Gaudio[1], Jordan Occena[1], Fabian Naab[1], Mohsen Nami[2], Bingjun Li[2], Jung Han[2] and Rachel Goldman[1]; [1]University of Michigan–Ann Arbor, United States; [2]Yale University, United States

Although silicon-based electronics are used to power light-emitting diodes and electric vehicles, their utility in high power applications is limited by a low breakdown voltage. The most promising alternative power devices consist of vertical GaN devices, which often require regrown active regions. Here, we report on x-ray diffraction studies of the crystallinity of the GaN p-i-n structures prepared with and without ex-situ ambient exposure and/or chemical etching. To quantify the mosaicity and threading dislocation (TD) densities at the p-i interfaces, we quantify and compare the full-width at half-maximum (FWHM) of both phi and omega x-ray diffraction scans. For the "in-situ" GaN structure, the screw-type TD densities are lowest, the edge-type TD densities are highest, and the interfacial near-band edge (NBE) and donor-acceptor pair (DAP) cathodoluminescence (CL) emissions are highest. Interestingly, elastic recoil detection analysis (ERDA) and Rutherford backscattering spectroscopy reveal minimal interfacial [H] but the highest fraction of displaced Ga atoms, suggesting efficient incorporation of Mg_{Ga}. On the other hand, for the ex-situ structures, minimal interfacial [H] is also observed, along with a high screw-type TD and low interfacial NBE and DAP CL emissions. Finally, for the etched/regrown structures, ERDA reveals the highest interfacial [H], along with moderate screw- and edge-type TD, moderate DAP CL, and significant yellow CL emission. The relationship between interfacial [H], displaced Ga, CL emission features, and screw- and edge-type TD densities will be discussed.
We gratefully acknowledge the support of ARPA-E through AWD0000191.

Defects in b-Ga_2O_3—An Ultra High-Resolution Scanning/Transmission Electron Microscopy Imaging and Spectroscopy Nasim Alem and Adrian Chmielewski; The Pennsylvania State University, United States

Group III wide band gap (WBG) oxides are considered ideal materials systems for power electronics at extreme conditions. Due to their high band gap, this family of materials has a high breakdown voltage and high resistivity to electric field and temperature. Among WBG oxides, β-Ga_2O_3 is considered an ideal candidate for high power electronics due to its high band gap and its high breakdown electric field compared with GaN and 4H-SiC. Yet, defects currently limit the high performance of β-Ga_2O_3 crystal in high power electronic applications. While there have been a number of studies on the characterization of the defects in β-Ga_2O_3, little is known about the underlying atomic scale physics and chemistry of such defect complexes within the crystal, at the interfaces, and how they can affect the macroscale electronic properties. In addition, little is known about the stability and transition dynamics of the crystal under extreme conditions, i.e. thermal or electrical biasing, ultimately leading to its failure.
In this work we use advanced scanning/transmission electron microscopy imaging and electron energy loss spectroscopy to understand the atomic and chemical structure of b-Ga_2O_3 and epi thin film of b-Ga_2O_3/b-$(Al_xGa_{1-x})_2O_3$. We present the atomic and chemical structure of the defects, interfaces, and its structural transformation in the bulk b-Ga_2O_3 and epi thin film of b-Ga_2O_3/b-$(Al_xGa_{1-x})_2O_3$. In addition, nanoscale modulations in the electronic structure and the band gap in the epi thin films of b-Ga_2O_3/b-$(Al_xGa_{1-x})_2O_3$ is discussed. This presentation will further cover the nanoscale transition dynamics of b-Ga_2O_3 lattice under extreme environments such as high temperature and electric field. This fundamental study can bridge the gap between atomic scale structural modifications and macroscale materials functionality not only in b-Ga_2O_3 but also in the family of WBG oxides.

1:25 PM EL04.07.02
Mg Acceptor Doping in MOCVD (010) β-Ga_2O_3 Zixuan Feng, A F M Anhar Uddin Bhuiyan, Nidhin K. Kalarickal, Siddharth Rajan and Hongping Zhao; The Ohio State University, United States

Metalorganic chemical vapor deposition (MOCVD) of β-Ga_2O_3 thin films have been demonstrated with record-high room temperature and low-temperature mobilities that approach the theoretically predicted limit. [1,2] The extracted low acceptor concentration ($N_a < 10^{15}$ cm^{-3}) is extremely encouraging for its potential application in high power electronics. Among various impurities in MOCVD grown β-Ga_2O_3, Si represents the dominant one that contributes to the conductivity in the unintentionally doped (UID) films. It is commonly observed the Si spike at the growth interface between Ga_2O_3 substrate and the epitaxial layer. The existence of interface charges not only severly impacts charge transport characteristics [2], but also detrimentally affects device performance, such as causing buffer leakage current in lateral power devices. [3] In addition, controllable charge compenstation serves as a key component in device designs, e.g., forming current blocking layer. Without effective p-type β-Ga_2O_3, an alternative route is to use semi-insulating layer to engineer the electric field in devices. Thus far, there are limited reports on the epitaxy of semi-insulating β-Ga_2O_3.

Among various acceptors in β-Ga_2O_3, Mg represents one of the most promising candidates with relatively shallow acceptor level and the lowest formation energy as compared to other cation-site acceptors from DFT calculation. [4] In this study, Mg in-situ doping in MOCVD β-Ga_2O_3 was conducted for the first time. Trimethylgallium (TEGa) and O_2 were used as Ga, O precursors and Ar as the carrier gas. Mg doping was introduced by using Cp_2Mg as precursor. Chamber pressure was set at 60 Torr in this study. The MOCVD growth temperature for β-Ga_2O_3 was expanded to the range from 650 °C to 900 °C. The growth was conducted

on commercial Fe-doped (010) β-Ga_2O_3 substrates. From secondary ion mass spectroscopy (SIMS), in-situ Mg doping concentration was tuned in the range of 10^{18} cm^{-3} to 10^{20} cm^{-3} by the variation of Cp_2Mg molar flow. H impurity concentration exhibits an obvious companion with Mg doping concentration, indicating possible Mg-H complex configurations in as-grown MOCVD Mg-doped β-Ga_2O_3.

In addition, we analyzed the SIMS diffusion characteristics of Mg acceptor under different growth temperature of 700 °C to 900 °C. Experimental results indicate Mg incorporation has a minimum dependence on the growth temperature. Instead, the Mg diffusion has a strong dependence on the growth temperature. The diffusion barrier energy of Mg in MOCVD β-Ga_2O_3 was estimated at ~0.9 eV based on numeric analysis of the SIMS profile. Capacitance-voltage (C-V) on lateral Schottky diode structures, with an Mg-doped buffer layer and a Si-doped channel layer, also verified the depletion of interface charge, demonstrating the effective charge compensation by in-situ Mg doping.

In summary, we demonstrated in-situ Mg acceptor doping in MOCVD growth of (010) β-Ga_2O_3 thin films. The growth conditions for Mg-doped MOCVD β-Ga_2O_3 were established with controllable doping between 10^{18} cm^{-3} to 10^{20} cm^{-3} and a wide growth temperature regime, ranging between 700 °C and 900 °C. The as-grown thin films were characterized to be electrically insulating despite the Mg-H chemical companion. Mg diffusion was observed strongly dependent on the growth temperature. With low growth temperature, Mg diffusion can be significantly suppressed while maintaining high crystalline quality. The demonstration of in-situ Mg-doping in MOCVD β-Ga_2O_3 can provide new routes for high-performance device design and device fabrication.

Acceptors in Gallium Oxide Jani Jesenovec, Jacob Ritter, Christopher Pansegrau, John McCloy and Matthew D. McCluskey; Washington State University, United States

Monoclinic gallium oxide (β-Ga_2O_3) is an ultra-wide bandgap semiconductor with potential applications in power electronics. Semi-insulating substrates are required for most practical devices such as metal-oxide-semiconductor field effect transistors. This presentation will discuss recent experimental studies on Czochralski-grown β-Ga_2O_3 single crystals doped with Mg or Zn acceptors. These dopants result in semi-insulating material and are likely compensated by oxygen vacancies and shallow donors. Ir impurities originating from the crucible form deep donors that also compensate acceptors. The Ir^{4+} oxidation state gives rise to an absorption threshold in the visible/UV part of the spectrum and an IR absorption peak at 5150 cm^{-1}. Acceptors are passivated by hydrogen, an omnipresent contaminant, resulting in IR absorption peaks corresponding to O-H vibrational modes near 3300 cm^{-1}.

1:55 PM EL04.07.04

High-Mobility Low-Temperature Metalorganic Vapor Epitaxy Grown (010) β-Ga_2O_3 Homoepitaxial Films and Its Application to Realize Low Resistance Ohmic Contacts Arkka Bhattacharyya, Praneeth Ranga, Saurav Roy and Sriram Krishnamoorthy; The University of Utah, United States

Metalorganic vapor phase epitaxy (MOVPE) has emerged as the leading growth technique that allows for the growth of high-quality β-Ga_2O_3 epitaxial films with mobility values closer to the theoretical limit (~ 200 cm^2/Vs). In the first part of this work, we report on the growth of high-mobility β-Ga_2O_3 homoepitaxial thin

films grown at a temperature **more than 200°C** less than the conventional growth temperature window for metalorganic vapor phase epitaxy [1]. Low-temperature β-Ga_2O_3 thin films **grown at 600°C** on Fe-doped (010) bulk substrates exhibit remarkable crystalline quality, which is evident from the measured room temperature **Hall mobility of 186 cm^2/Vs** for the unintentionally doped films. N-type doping is achieved by using Si as a dopant, and a controllable doping in the range of 2×10^{16}–$2\times10^{19}cm^{-3}$ is studied. Si incorporation and activation is studied by comparing the silicon concentration from secondary ion mass spectroscopy and the electron concentration from temperature-dependent Hall measurements. The films exhibit **high purity (low C and H concentrations)** with a very low concentration of **compensating acceptors (~$2\times10^{15}cm^{-3}$)** even at this growth temperature. Additionally, an abrupt doping profile with a forward decay of ~**5 nm/dec (10 times improvement compared to what is observed for thin films grown at 810°C)** is demonstrated by growing at a lower temperature due to suppression of Si dopant segregation [2].

In the second part of this work, we use this low-temperature growth regime to achieve degenerately n-type Si-doped (>$10^{20}cm^{-3}$) β-Ga_2O_3 layers to realize high-quality low resistance Ohmic contacts. We perform selective area regrowth of heavily-doped n^+ β-Ga_2O_3 Ohmic contacts to lightly doped channel layers using a novel Ni/SiO_2 mask which is patterned by a combination of dry and wet etching technique. The Ohmic metal stack of Ti/Au/Ni (20nm/100nm/30nm) was selectively evaporated using photolithography patterning and lift off process. The doping in the **n^+ β-Ga_2O_3 layers was estimated to be ~2×10^{20} cm^{-3}.** TLM measurements on the n^+ β-Ga_2O_3 layers show **R_{sh}, R_c and ρ_c** values to be **45 Ω/sq**, **0.08 Ω.mm** and **8.2 ×10^{-7} Ω.cm^2** respectively. These results indicate that these MOVPE-grown n^+ β-Ga_2O_3 layers were able to maintain good material quality even in this doping regime and is comparable to or better than that reported by other techniques such as MBE and PLD[3], [4]. **Fully MOVPE-grown FET** performance will be presented. The growth of high mobility films with an expanded growth window, MOVPE technique for Ga_2O_3 growths can now be considered more versatile. The ability to perform selective area regrowth of ohmic contacts expands the capability of the MOVPE technique in terms of device processing as well. This initial result of the low temperature growth and selective area regrowth using MOVPE shows the promise of this approach to realize high-quality channel layers as well as low resistance contacts for several lateral and vertical device topology.

MOCVD Epitaxy of β-$(Al_xGa_{1-x})_2O_3$ Films on (100) and (-201) β-Ga_2O_3 Substrates with Al Compositions up to 52% A F M Anhar Uddin Bhuiyan, Zixuan Feng, Jared M. Johnson, Hsien-Lien Huang, Jinwoo Hwang and Hongping Zhao; The Ohio State University, United States

β-Ga_2O_3 has gained a remarkable attention in high power electronic applications due to its higher bandgap energy (~ 4.85 eV), predicted high breakdown field strength (~ 8 MV/cm), and availability of high-quality native substrates with different orientations. β-$(Al_xGa_{1-x})_2O_3$ alloys, due to its bandgap tuning capability up to ~8.8 eV, can take advantage of its higher breakdown voltage in not only vertical power devices but also in high-performance lateral devices through device scaling. Recently, modulation doped field effect transistors have

been demonstrated with promising transport properties by forming 2-dimentional electron gas in β-AlGaO/GaO heterostructures with limited Al composition in β-AlGaO layer (x < 20%). High quality β-AlGaO epitaxy with higher Al compositions is required to form heterostructures with large band offset and thus high 2D electron density. While theoretical studies have predicted that the solubility limit of Al_2O_3 in β-Ga_2O_3 is as high as ~70%, very limited Al incorporation in (010) β-$(Al_xGa_{1-x})_2O_3$ films has been observed experimentally (x < 27%), as targeting for higher Al composition resulted in phase segregation [1].

In this work, for the first time, we have studied the growth of β-$(Al_xGa_{1-x})_2O_3$ thin films on (100) and (-201) oriented β-Ga_2O_3 substrates via metalorganic chemical vapor deposition (MOCVD). Trimethylaluminum (TMAl), Triethylgallium (TEGa), and pure O_2 were used as Al, Ga and O precursors, respectively. Argon (Ar) was used as the carrier gas. By the systematic tuning of TEGa/TMAl molar flow ratio, pure β-phase $(Al_xGa_{1-x})_2O_3$ films with Al compositions up to 52% were achieved on (100) β-Ga_2O_3 substrates [2]. X-ray diffraction (XRD) and X-ray spectroscopy (XPS) were used for determining the bandgaps and the Al compositions. Two-dimensional twin boundary defects in the β-$(Al_xGa_{1-x})_2O_3$ films with different Al compositions were investigated by utilizing atomic resolution scanning transmission electron microscopy (STEM) imaging. Coherent growth of high quality (100) β-AlGaO/GaO superlattice (SL) structures with abrupt interfaces and uniform Al distribution were observed with Al compositions as high as 50%. Step flow growth with lower RMS roughness values (< 1.2 nm) were observed for higher Al composition samples. A mechanism was proposed for the step-flow growth of high-Al content films by considering Al adatoms as preferred nucleation sites for $(Al_xGa_{1-x})_2O_3$ growths. The growth of β-$(Al_xGa_{1-x})_2O_3$ films on (-201) oriented β-Ga_2O_3 substrates also revealed higher Al incorporation in pure β-phase ($x \leq 48\%$) without causing phase segregations [3]. The bandgap energies for (-201) β-$(Al_xGa_{1-x})_2O_3$ films extracted from XPS spectra ranged between 5.20 ± 0.06 eV (x = 21%) and 5.72 ± 0.08 eV (x = 48%). The surface morphologies showed elongated features with granules along [010] direction, which were suppressed with the increasing Al content. The influence of the chamber pressure and temperature on Al incorporations and the surface morphologies were studied.

In summary, we have demonstrated MOCVD growth of (100) and (-201) β-$(Al_xGa_{1-x})_2O_3$ films with high-Al compositions. Results from this work provide great promises for future device technologies based on this emerging ultrawide band gap semiconductor material system.

Carrier Density in Ga2O3 Measured by Infrared Absorption Ernesto Gribaudo[1], Etienne Gheeraert[1] and Toshimitsu Ito[2]; [1]Université Grenoble Alpes, France; [2]AIST, Japan

Gallium oxide Ga2O3 is a very promising material for the next generation wide bandgap semiconductor devices. Even if impressive electronic devices have already been fabricated, demonstrating the high potential of this new semiconductor, the knowledge about its electronic properties is still weak. The purpose of this work is to explore dopants and carriers by infrared absoorption in gallium oxide. In regular semiconductor, such technique allows to identify at low temperature the ground level of dopants as shallow level centers, their excited states and photoionisation. At high temperature, when all the dopants are ionized, absorption by free carriers can by observed. All these information about the semiconductor electronic properties make infrared absorption a powerful technique.
In this work β-Ga_2O_3 crystals were grown by the floating-zone (FZ) method using no crucibles. By the zone-

refining that were executed by repeating the FZ procedure, very higher purity compared to that of regular growth method was obtained. Crystal were doped with Si with a concentration estimated from SIMS measurements from $2x10^{17}$ cm^{-3} to $1x10^{19}$ cm^{-3}. Infrared was recorded in transmission from 5K to 300K.
All the spectra exhibit a strong absorption continuum from 0.2 eV, with no mesurable transmission below this value, and extending beyond 1.2 eV for high doping values. No absorption peak, that could have been assigned to a transition from the dopant ground level to an excited state was observed, whatever the temperature and the doping level.
The absorption intensity in the continuum, at 0.5 eV, is clearely correlated to the Si concentration. A linear relation is proposed, allowing the measure of the Si concentration in Ga_2O_3 in a non destructive way. This continuum is assigned to free electron infrared absoprtion.
The fact that no absorption peak is observed, even at 5K, and that the free absorption is observed whatever the temperature, suggest that silicon is ionized without any ionization energy. This could be attributed to an impurity band formed by very shalow silicon centers.

Late News: Ge Doping of Epitaxial β-Ga2O3 Films by MOCVD Fikadu Alema, George Seryogin, Alexei Osinsky and Andrei Osinsky; Agnitron Technology Incorporated, United States

We report on Ge doping of epitaxial Ga_2O_3 films by MOCVD using germane (GeH_4) balanced in nitrogen as a Ge source. The incorporation efficiency of Ge into Ga_2O_3 films grown using triethylgallium (TEGa) and trimethylgallium (TMGa) sources was studied by varying substrate temperature, GeH_4 flow rate, growth rate, and oxygen flow rates using SIMS. As expected, Ge incorporation increased with GeH_4 flow rate, but it incorporated well into films grown using TEGa than that grown using TMGa despite similar growth conditions. Hall Effect measurement and SIMS showed a strong dependence of Ge incorporation on the growth temperature. By decreasing the substrate temperature over a range of ~200 ºC, the film's Ge concentration has increased by two orders of magnitude. The Hall Effect measurement also showed Ge doped films with RT electron mobilities ranging from ~40 to ~150 cm^2/Vs with the corresponding carrier concentration of $n=3x10^{19}$ to $n=2x10^{16}$ cm^{-3} for Ge doped films. Temperature-dependent Hall Effect measurement will be discussed to investigate the donor activation energy and compensation concentration in representative TMGa and TEGa grown films. The results will be compared with similar films doped by Si. In this talk, the effect of Ge doping on the surface roughness and the incorporation of carbon and hydrogen impurities into the films will be discussed.

Electro-Thermal Co-Design of a Gallium Oxide MODFET Sukwon Choi; The Pennsylvania State University, United States

To extend further the electrical performance envelope of wide bandgap (WBG) electronics based on gallium nitride (GaN) and silicon carbide (SiC), novel device structures based on ultra-wide bandgap (UWBG) semiconductors such as β-phase gallium oxide (Ga_2O_3) are being actively developed. While UWBG electronics target for higher power handling capabilities and smaller device footprints, the thermal conductivity of Ga_2O_3 is an order of magnitude lower than those for GaN and SiC. Therefore, device self-heating has become a major challenge to accomplish the successful transition from WBG electronics to the UWBG device technology. In this talk, the electro-thermal co-design process for a $(Al_xGa_{1-x})_2O_3/Ga_2O_3$ modulation-doped field-effect

transistor (MODFET) will be demonstrated. First, the steady-state and transient thermal response of an operational MODFET is characterized using a recently developed 2D material-assisted Raman thermography technique. Second, a multi-physics device modeling scheme is used to reproduce the temperature-dependent electrical output characteristics as well as the self-heating behavior in response to the electrical inputs. Finally, this coupled electro-thermal model is used to design a device-level thermal management solution, taking advantage of a low thermal resistance composite substrate.

Thermal Annealing of a-Ga_2O_3 on the Millisecond Time Scale and the Observation of γ-Phase Inclusions

Katie R. Gann, Ming-Chiang Chang, Aine B. Connolly, Duncan R. Sutherland, Maximillian Amsler, R. Bruce van Dover and Michael O. Thompson; Cornell University, United States

β-Ga_2O_3 has shown significant promise as a wide bandgap, high-breakdown field semiconductor with extensive device applications. While the β-phase is the thermodynamically stable phase, there are a variety of polymorphs in the system, including the hexagonal α-phase with the widest bandgap, a defect spinel γ-phase, and an -phase with predicted piezoelectric properties. These alternate polymorphs, while metastable, readily form under various processing conditions. Laser spike annealing (LSA), with heating times from 150 μs to 10 ms, has been shown to be effective in kinetically trapping metastable phases from a deposited amorphous phase. By varying the time and temperature, a processing-phase diagram for metastable phases can be rapidly developed using high throughput characterization methods.

The metastable phase formation sequence from amorphous Ga_2O_3, on a non-crystalline neutral substrate, was determined for annealing (dwell) times from 250 μs to 10 ms (τ_{dwell}), and peak annealing temperatures (T_{peak}) between ambient and 1400 ºC. Amorphous Ga_2O_3 films, 170 nm thick, were sputter deposited from a Ga_2O_3 target in an Ar(90%)/O_2(10%) ambient onto 100 mm oxidized (20 nm thermal SiO_2) Si wafers. Samples were annealed with 617 time/temperature conditions to fully characterize the time and temperature phase space using a CO_2 laser spike annealing system. The resulting thermally induced structural transformations were characterized with a variety of techniques, including optical imaging, reflectance spectroscopy, X-ray diffraction, and transmission electron microscopy. For temperatures below ~650 ºC, no transformations were observed. Between 650 and 800-850 ºC, and for all dwell times explored, the spinel γ-phase was observed in the quenched samples. At higher temperatures above 850-950 ºC, the equilibrium β-phase was observed in the quenched samples. No other phases were observed under any processing conditions. TEM micrographs show that the γ-phase nucleated near the center of the deposited film homogenously with minimal heterogenous nucleation at either the SiO_2 interface or surface. We postulate that this phase is always the first to nucleate, with β-phase only nucleating heterogeneously off of the γ-phase at higher temperatures. This is supported by observations of extremely large grains of the β-phase at short annealing times, suggesting nucleation is limited with significant grain growth during the subsequent heating and cooling times of the thermal process. The low surface energy implied by the homogenous nucleation also suggests a possible explanation for the widely observed γ-phase inclusions observed in MBE grown β- and α-phase films.

Thermal Transport Across Metal/β-Ga_2O_3 Interfaces

Jingjing Shi[1], Chao Yuan[1], Shangkun Wang[1], Riley Hanus[1], Zhe Cheng[1,2] and Samuel Graham[1,1]; [1]Georgia Institute of Technology, United States; [2]University of Illinois at Urbana-Champaign, United States

β-Ga_2O_3 is a very promising material to be applied in power and radio frequency devices because of its exceptional properties. However, the heat dissipation of its devices will be limited by its ultra-low thermal conductivity. Previous study showed that its device could achieve high power density with double-side cooling strategy and thin Ga_2O_3 layer. Therefore, the thermal transport across β-Ga_2O_3 interfaces becomes very important because the boundary resistance would be a main source of the total device resistance. In this work,

we study the thermal transport at β-Ga_2O_3/metal interfaces which play important roles in heat dissipation and as electrical contacts in β-Ga_2O_3 devices. A theoretical Landauer approach was used to model and elucidate the factors that impact the thermal transport at these interfaces. Experimental measurements using time-domain thermoreflectance (TDTR) provided data for the thermal boundary conductance (TBC) between β-Ga_2O_3 and a range of metals used to create both Schottky and ohmic contacts. From the modeling and experiments, the relation between metal cut-off frequency and the corresponding TBC is observed. Moreover, the effect of metal cut-off frequency on TBC is seen as the most significant factor followed by chemical reactions between the metal and the β-Ga_2O_3. Among all metal/Ga_2O_3 interfaces, for Schottky contacts, Ni/Ga_2O_3 interfaces show the highest TBC, while for ohmic contacts, Cr/Ga_2O_3 interfaces show the highest TBC. While there is a clear correlation between TBC and the phonon cutoff frequency of metal contacts, it is also important to control the chemical reactions at interfaces in order to maximize the TBC in this system.

5:10 PM EL04.08.05
Computational Fermi Level Engineering and Doping-Type Conversion of Ga_2O_3 via Three-Step Processing Anuj Goyal[1], Andriy Zakutayev[1], Vladan Stevanovic[2] and Stephan Lany[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Ga_2O_3 is being actively explored for power electronics, deep-ultraviolet optoelectronics, and other applications due to its ultra-wide bandgap and low projected fabrication cost of large-size and high-quality crystals. N-type doping of Ga_2O_3 can be achieved and tuned, but p-type doping faces fundamental obstacles due to deep character of acceptor levels and polaron transport of resulting holes. However, successful engineering of Ga_2O_3 based devices requires critical control of doping density, Fermi level position, and free carrier concentration, providing opportunities for predictive process simulation. We use first-principles defect theory and defect equilibrium calculations to simulate a 3-step growth-annealing-quench protocol for hydrogen assisted Mg doping in Ga_2O_3, taking into account the hydrogen-oxygen-water gas phase equilibrium. We predict type conversion to a net *p*-type regime following O-rich annealing after growth under reducing conditions in the presence of H_2. This process is similar to the Mg acceptor activation by H removal in GaN. We show that there is an optimal temperature that maximizes the net acceptor density during the equilibrium annealing step for a given Mg doping level. Quenching of non-equilibrium annealed samples then results in a Fermi level E_F below mid-gap down to about E_V +1.5 eV, creating a significant number of uncompensated neutral Mg_{Ga}^0 acceptors. The resulting free hole concentration in quenched samples is very low (10^9 – 10^{12} cm^{-3}) due to deep energy level of these Mg acceptors, but this type converted Ga_2O_3 material can create a significant built-in field in a *p-n* junction with an adjoining n-type material. Additionally, the electron concentration is greatly suppressed in such acceptor-doped Ga_2O_3, which could enable the use as a current blocking layer to fabricate normally-off (enhancement-mode) vertical Ga_2O_3 based metal-oxide-semiconductor field effect transistors (MOSFETs), and as a guard ring for edge termination in MOSFETs and Schottky barrier diodes (SBDs) with increased breakdown voltage.

Late News: Prospects for Donor-Doping AlGO Alloys Joel Varley[1], Darshana Wickramaratne[2] and John L. Lyons[2]; [1]Lawrence Livermore National Laboratory, United States; [2]U.S. Naval Research Laboratory, United States

Gallium oxide has emerged as a promising ultrawide-bandgap semiconductor partly due to its ability to be *n*-type doped. Alloying Ga_2O_3 with Al_2O_3 can further widen its band gap, potentially enabling novel device designs. But this alloying quickly leads to an increase in the position of the conduction-band minimum, and it is not clear whether $(Al_xGa_{1-x})_2O_3$ ("AlGO") alloys will also be *n*-type dopable. Here we systematically explore the properties of group-IV (C, Si, Ge, and Sn) and transition metal (Hf, Zr, and Ta) substitutional dopants in AlGO alloys using first-principles hybrid functional calculations. In Ga_2O_3, all of these dopants act as shallow donors, but in Al_2O_3 they are deep defects characterized by the formation of either *DX* centers or positive-U (+/0) levels. Combining our calculations of dopant charge-state transition levels with information of the AlGO alloy band structure, we estimate the critical Al composition at which each dopant transitions from being a shallow to a deep donor. We identify Si as being the most efficient dopant to achieve n-type conductivity in high Al-content AlGO alloys, acting as a shallow donor over the entire predicted stability range for AlGO solid solutions.

This work was partially performed under the auspices of the U.S. DOE by the Lawrence Livermore National Laboratory under Contract No. DE-AC52-07NA27344 and supported by the Critical Materials Institute, an Energy Innovation Hub funded by the U.S. DOE, Office of Energy Efficiency and Renewable Energy, Advanced Manufacturing Office. JLL and DW were supported by the Office of Naval Research through the Naval Research Laboratory's Basic Research Program.

8:15 PM EL04.09.02
Control of Surface Morphologies of M-Plane α-Al_2O_3 Homoepitaxial Films Using Plasma-Assisted Molecular Beam Epitaxy Riena Jinno and Hironori Okumura; University of Tsukuba, Japan

Rhombohedral α-Al_2O_3 (sapphire) (E_g=8.8 eV) and its alloys with α-Ga_2O_3 (E_g~5.3-5.6 eV) have attracted for high power electronic devices and optical devices with function in the deep ultra-violet region due to the large predicted critical electric field and wide bandgap energy [1]. Insulating α-Al_2O_3 substrates have been widely used for the thin film growth of different materials because of the large-area and low-cost α-Al_2O_3 bulks grown by melting methods. However, the reports on homoepitaxial growth of α-Al_2O_3 thin films are limited [2]. In this study, we investigated the surface morphologies of α-Al_2O_3 thin films, which were grown by plasma-assisted molecular beam epitaxy (PAMBE) under various growth conditions.
The aluminum-oxide thin films were grown on a m-plane α-Al_2O_3 substrate with a miscut angle of 2 ° toward [0001] by PAMBE. The radio frequent power and oxygen flow rate were fixed at 150 W and 1.0 sccm, respectively. The thermocouple substrate temperature (T_{sub}) and Al beam equivalent pressure (BEP) were changed in the ranges of 130-830 °C and 4.0×10^{-6}-1.8×10^{-5} Pa, respectively. The surface morphology was observed by atomic force microscopy.
The amorphous AlO_x films were grown for T_{sub}<330 °C, while the single-crystal α-Al_2O_3 films were homoepitaxially grown for T_{sub}>530 °C as revealed by reflection high energy electron diffraction and x-ray diffraction. The growth rate of the α-Al_2O_3 films increased with increasing the Al BEP, and showed a larger slope at the Al BEP higher than 1.3×10^{-5} Pa. The growth rate was independent on the substrate temperature between 130 and 830 °C. The α-Al_2O_3 surfaces exhibited root mean square (RMS) roughness smaller than 0.6 nm for the Al BEP lower than 1.3×10^{-5} Pa, while the α-Al_2O_3 surfaces suddenly increased the RMS roughness

larger than 10 nm for the Al BEPs higher than $1.3x10^{-5}$ Pa. The boundary between the smooth and rough surface morphologies corresponded with the singular point where the slope of growth rate versus the Al BEP changed. We consider that the Al BEP lower than $1.3x10^{-5}$ Pa agrees with the O-rich condition and that the Al-rich condition probably contributes to the rough surface morphologies and/or nonstoichiometry of the α-Al_2O_3 epitaxial films. From these results, the O-rich growth condition with higher growth temperature than 530 °C is suitable for the homoepitaxial growth of α-Al_2O_3.

This work was supported by NEDO Feasibility Study Program Uncharted Territory Challenge 2050.

Killer Defects in β-Ga_2O_3 Schottky Barrier Diodes Observed by Ultrahigh Sensitive Emission Microscopy and Synchrotron X-Ray Topography Makoto Kasu[1], Sayleap Sdoeung[1], Kohei Sasaki[2], Katsumi Kawasaki[3], Jun Hirabayashi[3] and Akito Kuramata[2]; [1]Saga University, Japan; [2]Novel Crystal Technology, Inc., Japan; [3]TDK Corporation, Japan

β-Ga_2O_3 with a bandgap of 4.5–4.8 eV is expected to serve as a high-power semiconductor surpassing the capabilities of SiC and GaN. Recently, we demonstrated the production of > 20 A-class β-Ga_2O_3 Schottky barrier diodes (SBDs) with a low on-state resistance of 6 mΩ.cm^2. However, the reliability of SBD plays a crucial role in the commercialization of SBDs in power system circuits. It is especially important to identify killer defects that can cause an increase of reverse leakage current and/or a decrease in the breakdown voltage. The sample was halide vapor phase epitaxy (HVPE)-grown ~10-μm-thick epitaxial layer on EFG-grown β-Ga_2O_3 (001) substrate. Pt/Ti/Au Schottky electrodes with diameters of 50–1000 μm were formed on the surface, and Ti/Au ohmic contacts were formed on the back surface. First, we observed light emission patterns from SBDs in operation using ultrahigh sensitive emission microscopy. The emission microscopy equipment consists of an ultrahigh sensitive electron-multiplying CCD camera and a probe station enabling the observation of light emission patterns of an SBD in real time.
In the reverse bias conditions, we detected emission patterns from SBDs with a high leakage current. The patterns were observed by AFM and synchrotron X-ray topography, and their cross-sections were observed by STEM. The killer defects were found to be stacking faults and polycrystalline defects in the HVPE epitaxial layer. Their properties will be reported.

8:45 PM EL04.09.05

Growth and Characterization of MOVPE-Grown Low Sheet Resistance β-$(Al_xGa_{1-x})_2O_3$/β-Ga_2O_3 Heterostructure Channels Praneeth Ranga[1], Arkka Bhattacharyya[1], Adrian Chmielewski[2], Rujun Sun[1], Saurav Roy[1], Mike Scarpulla[1], Nasim Alem[2] and Sriram Krishnamoorthy[1]; [1]The University of Utah, United States; [2]The Pennsylvania State University, United States

In this work, we study the growth and characterization of β-$(Al_xGa_{1-x})_2O_3$/ β-Ga_2O_3 heterostructure channels with record low sheet resistance. In the past few years, β-Ga_2O_3 has emerged as a promising material for next-generation power electronics applications. The high bandgap of β-Ga_2O_3 leads to a very high predicted breakdown field of 6 – 8 MV/cm, larger than that of GaN and SiC. However, room temperature mobility of low-doped β-Ga_2O_3 is still limited to 200 cm^2/V.s due to severe polar optical phonon scattering. Ab-initio calculations show that mobility of modulation-doped β-$(Al_xGa_{1-x})_2O_3$/ β-Ga_2O_3 channels could exceed that of uniformly-doped β-Ga_2O_3 layers at charge densities nearing 5 x 10^{12} cm^{-2} [1]. This is attributed to enhanced screening of LO phonons modes at high 2DEG sheet charge densities. Currently, the sheet charge density of single β-$(Al_xGa_{1-x})_2O_3$/ β-Ga_2O_3 heterostructure is limited to ~5 x 10^{12} cm^{-2} [2], which is in turn limited by the Al composition of the MBE-grown β-$(Al_xGa_{1-x})_2O_3$. To achieve such high sheet charge densities, a high Al content β-$(Al_xGa_{1-x})_2O_3$ barrier along with a sharp delta sheet is necessary. Recently, high-quality β-Ga_2O_3 films with mobilities close to 200 cm^2/V.s have been realized MOVPE. Growth of (100) β-$(Al_xGa_{1-x})_2O_3$ layers up to 52% has been realized using the MOVPE technique [3]. In addition, n-type doping and delta doping were also achieved [4,5]. However, the FWHM of the Si delta sheet was found to be larger than that of MBE-grown β-

Ga_2O_3. By optimizing the growth conditions MOVPE-grown β-$(Al_xGa_{1-x})_2O_3$/ β-Ga_2O_3 heterostructures with high charge and mobility can be potentially attained.

Growth of delta-doped (010) β-Ga_2O_3 films is performed by Agnitron Agilis MOVPE reactor with TEGa, O_2 and silane (SiH_4) as precursors and argon as a carrier gas. Delta doping of β-Ga_2O_3 is achieved by interrupting the growth of β-Ga_2O_3 and supplying silane to the reactor. Multiple samples are grown under varying growth temperatures to characterize the spread of silicon donors β-Ga_2O_3. CV measurements are used to characterize the sheet charge density and FWHM of the silicon delta sheet. SIMS characterization revealed that surface segregation is the key mechanism, which leads to large FWHM Si delta sheets. By reducing the growth temperature to 600 C, CV measured FWHM of 3.2 nm is achieved, which is close to the FWHM of an ideal delta sheet. Similar growth conditions are utilized to realize a sharp delta sheet in β-$(Al_xGa_{1-x})_2O_3$/ β-Ga_2O_3 heterostructure. Two delta-doped β-$(Al_xGa_{1-x})_2O_3$/ β-Ga_2O_3 heterostructure are grown with different β-$(Al_xGa_{1-x})_2O_3$ spacer thicknesses (2- 4 nm) under identical growth conditions. MOVPE based low-temperature n+ regrowth process is utilized to achieve ohmic contacts to the channel. Hall measurements showed a sheet charge density of 6.4 x 10^{12} to 1 x 10^{13} cm^{-2} and mobility of 125 – 111 cm^2/V.s. FET devices fabricated using heterostructure channels show a peak current of 22 mA/mm and transconductance of 7 mS/mm. Sheet resistance of 5.3 kΩ/square is realized at room temperature, which is the lowest value for a single heterostructure in current literature. CV and TLM characterization revealed similar charge density and sheet resistance values, confirming the properties of the heterostructure channel. These results show that high-quality β-$(Al_xGa_{1-x})_2O_3$/ β-Ga_2O_3 heterostructures with mobility exceeding 100 cm^2/Vs can be realized using MOVPE technique.

The evolution of defects in both He^+ and H^+ ion implanted β-Ga_2O_3 for exfoliation was assessed using triple-axis x-ray diffraction and transmission electron microscopy. First, (010) and (2̲01) substrates were He^+ ion implanted simultaneously at -20 °C with an ion energy of 160 keV and a dose of 5 × 10^{16} cm^{-2}. Strain profiles for both implanted orientations were obtained from modeling the symmetric X-ray diffraction curves with dynamical simulations and the differences are attributed to the structural anisotropy of β-Ga_2O_3. After annealing at 200 °C to initiate He blister nucleation followed by 500 °C for up to 96 hours to induce He blister growth, the crack formation at the ion projected range beneath the surfaces also differed between the (010) and (2̲01) implanted substrates. The annealed (010) substrates showed large continuous cracks at the projected range relatively parallel to the substrate surface. These cracks correspond to blistering directly above at the surface – a clear sign of exfoliation. In contrast, while the (2̲01) annealed substrate showed disjointed cracks at the projected range, which would also be compatible with exfoliation, did not exhibit surface blistering. Furthermore, the cracks in this substrate were tilted at a series of angles ranging from 0° to 54° from the surface towards the (2̲01̲) planes. Eighty percent of the cracks observed were tilted 54° – which is parallel to the (100) plane, a primary cleavage plane in β-Ga_2O_3. Note that the (100) is 90° from (010) and angled cracks were not observed in a previous effort[1] nor in this work. This directional dependence of the crack formation in the (2̲01) substrate is a consequence of the anisotropic properties of the monoclinic structure, suggesting the (100)

cleavage plane plays an important role in crack propagation for exfoliation. After annealing at 500 °C for 96 hours, the strain was removed from the (010) substrates while the ($\bar{2}$01) substrates still exhibited residual strain. In a second set of samples that used H^+ implantation at 35 keV, residual strain was also observed in annealed and exfoliated ($\bar{2}$01) β-Ga_2O_3 layers. These H^+ implanted ($\bar{2}$01) substrates were exfoliated and bonded to (0001) 4H-SiC substrates. Exfoliation due to blister growth of the implanted ions with annealing typically corresponds to the removal of the implant-induced strain. However, as was the case for the He^+ implant, diffraction measurements showed the presence of strain in the ($\bar{2}$01) β-Ga_2O_3 layers even after exfoliation that was only removed after further annealing. The analysis of the evolution of this strain is important because strain plays a significant role in important characteristics such as electrical and thermal transport. Subsequent annealing at 800 °C for 30 mins (with a ramp up rate of 5 °C/min), resulted in relieving this residual strain. Corresponding thermal measurements showed that the thermal conductivity of these β-Ga_2O_3 improved after annealing and removing the residual strain.

Mg Acceptor Level in Ga_2O_3 as Studied by Photo-Induced Electron Paramagnetic Resonance Suman Bhandari and Mary E. Zvanut; The University of Alabama at Birmingham, United States

Gallium oxide is a wide band-gap (4.6-4.9 eV) semiconductor that has potential for power electronics. Doping Ga_2O_3 with Mg makes it semi-insulating material, which can be an integral part of power devices. For such applications, knowledge of the Mg-related defect level is essential. Theory predicts a Mg acceptor level ($Mg^{-/0}$) ~1.2 eV above valence band maximum (VBM) whereas thermal measurements using electron paramagnetic resonance (EPR) place the level ~0.65 eV above VBM [1, 2]. To address the disagreement between the reported defect levels, we investigate optical absorption of neutral Mg acceptors (Mg^0) using photo-induced EPR. In this approach, we consider relaxation of the defect during optical excitation and determine the defect level and associated relaxation energy. Previously, using a similar technique, we have determined the $Fe^{2+/3+}$ level and associated relaxation energy in Ga_2O_3 [3]. In this work, by examining two different Mg-doped Ga_2O_3 samples, which were grown by the Czochralski method at two different institutions, we show that the presence of other defects could affect the experimental results and possibly lead to misinterpretation. The crystals are irradiated with energies between 0.6 and 4.7 eV after Mg^0 is generated with an LED (4.4±0.2 eV), and the effect on the amount of Mg^0 is investigated at 130 K. The steady state EPR results show that, for one set of samples, the amount of Mg^0 starts to decrease near 1.7 eV whereas for the other set of samples, the decrease begins at approximately 1 eV. The decrease in the amount of Mg^0 indicates that Mg^0 becomes Mg^- by either of the two processes: when electrons are excited 1) from valence band to Mg^0 or 2) from other defects to conduction band and subsequently captured by Mg^0. For samples with photo-threshold near 1.7 eV, no new defects appear nor do other existing defects change when the decrease of Mg^0 is initiated. Therefore, we disregard the second process for these samples. Furthermore, a preliminary analysis of the optical cross section spectrum obtained from photo-EPR yields values for the defect level and relaxation energy that agree reasonably well with the predicted defect level for $Mg^{-/0}$ when a relaxation energy of ~1 eV is considered. On the other hand, for the set of samples with the 1 eV photo-threshold, an unknown defect 'X' increases when Mg^0 starts decreasing, suggesting that the defect 'X' could be responsible for the decrease of Mg^0. We suggest that the 1 eV threshold could represent a defect level for 'X', which lies approximately 1 eV below conduction band minimum. In the talk, we will show the analysis of the optical cross section spectrum for both sets of samples and discuss ambiguities caused by the presence of other defects. In addition, we will present a detailed analysis of the optical cross section spectrum to supplement our preliminary results suggesting that the ~1.7 eV photo-threshold likely represents the $Mg^{-/0}$ level accompanied by a large relaxation energy.

9:45 PM DISCUSSION TIME

10:00 PM EL04.09.09
Recessed Gate Enhancement-Mode Ultrawide Bandgap $Al_xGa_{1-x}N$ Channel MOSHFET with Drain Current 0.48 A/mm and Threshold Voltage +3.6 V Shahab Mollah, Kamal Hussain, Abdullah Mamun, Mikhail Gaevski, Grigory Simin, MVS Chandrashekhar and Asif Khan; University of South Carolina, United States

For ultra-wide bandgap (UWBG) devices to truly exploit their potential for power electronics applications, it is essential to develop enhancement mode (normally-off) devices. In the past, normally off devices have been made using p-gate, fluorine treatment and recessed gate techniques. Recently, enhancement mode devices were reported by Douglas *et al* using p-AlGaN gate [1] and by Klein *et al* using fluorine treatment [2]. In the past, we have shown that the performance of normally-on UWBG AlGaN HFETs can be significantly improved using insulating gate MOSHFET design with Al_2O_3[3] and ZrO_2 gate dielectrics [4]. Here we use stack of these two dielectric materials to make high-current recessed gate enhancement mode UWBG $Al_{0.60}Ga_{0.40}N/Al_{0.40}Ga_{0.60}N$ MOSHFETs.

The epitaxial layers for the devices were grown by low pressure metal organic chemical vapor deposition on AlN (3 μm)/sapphire template on which a graded composition back-barrier $Al_xGa_{1-x}N$ layer (x from 1 to 0.4) was grown. The back-barrier design enables a reduction in leakage currents by screening the substrate-epilayer growth interface. It also leads to a tighter confinement of the 2-DEG which improves the ON-OFF ratios, drain-currents, and the sub-threshold swing factor. It was followed by the $Al_{0.40}Ga_{0.60}N$ channel layer of 185 nm thickness. On top of this a 170 Å thick n- $Al_{0.60}Ga_{0.40}N$ barrier layer was grown which was followed by a 200 Å highly doped composition graded $Al_xGa_{1-x}N$ layer with x-value changing from 0.60 to 0.3 towards the surface to facilitate the ohmic contact. The *n*-doping of this layer compensates the positive charges resulting from the reverse composition grading. The 2DEG sheet resistance was ~1900 Ω/square. Annealed source-drain ohmic contact metallization (Zr/Al/Mo/Au) yielded contact resistance of 1.7 Ω-mm. Gate recess etching through the top barrier, resulted in the positive shift of the threshold voltage by ≈ 12 V compared to devices without gate-recess (D-mode). Then a 25 nm thick ZrO_2-Al_2O_3 insulator stack was deposited in the recess region using Atomic Layer Deposition (ALD) to suppress leakage gate current and to enable positive gate bias operation. Gate electrode was made using Ni/Au metallization. The device exhibited a threshold-voltage (V_{TH}) of +3.6 V and drain source saturation current (I_{DS}) as high as 480 mA/mm at a gate voltage V_{GS} = +12 V. The peak extrinsic transconductance in the Al2O3-ZrO_2-MOSHFET is $G_M \approx$ 70 mS/mm.

To determine the factors leading to the high drain current we extracted the gate voltage dependencies of electron sheet density N_S and electron mobility μ. The extracted sheet carrier density is $N_S \approx 1.6 \times 10^{13}$ cm^{-2}. μ is as high as 1600 $cm^2/(V.s)$ at low gate voltage near threshold V_G=2V and decreases down to 200 $cm^2/(V.s)$ at V_G +12V. The on-state field effect mobility is comparable to our depletion mode devices [3]. The E-mode MOSHFET shows a hysteresis of 0.5 V between forward and reverse sweep of gate voltage, higher than that of D-mode MOSHFET (0.2 V) indicating higher trap charges at semiconductor/oxide interface or bulk. For our E-mode MOSHFET, we estimated a sub-threshold slope (SS) value of 128 mV/decade and an ON/OFF ratio of more than $1.5x10^8$, while the SS value for D-mode device is ~100 mV/decade. This slight increase of SS is

consistent with the increased hysteresis in the transfer curve. The gate leakage currents at V_G = -20V was 30 pA indicates the high quality of the oxide layer. Our studies suggest that UWBG AlGaN MOSHFETs are very promising candidates for next generation power electronic devices.

Growth of High-Purity Diamond Films and Doping for Quantum Device Applications Tokuyuki Teraji; National Institute for Materials Science, Japan

Formation and control of electron spin in diamond is attracting much attention for next-generation quantum information and quantum sensing devices. With this fact in mind, we provide a guideline for the growth of homoepitaxial diamond films that possess higher crystalline quality, higher chemical purity, and a higher carbon isotopic ratio and nitrogen doping. A custom-built microwave plasma-assisted chemical vapor deposition system was constructed to achieve these requirements. To improve both the purity and crystalline quality of homoepitaxial diamond films, an advanced growth condition was applied: higher oxygen concentration in the growth ambient. Under this growth condition for high-quality diamond, a thick diamond film of >30 μm was deposited reproducibly while maintaining high purity and a flat surface [1, 2]. Then, combining this advanced growth condition for non-doped diamond (100) and (111) film with a unique doping technique that provides parts-per-billion order doping, single-color centers of either nitrogen-vacancy or silicon-vacancy centers that show excellent properties were formed [3, 4]. These advanced growth techniques are expected to accelerate the research fields of quantum information and quantum sensing devices using diamond.

The author would like to thank Dr. K. Ichikawa, Dr. C. Shinei, Dr. T. Kageura, Dr. S. Koizumi, Dr. K. Watanabe, Dr. S. Onoda, for helpful discussion and supporting characterization.

Removal of Mechanical Polishing-Induced Nanoscale Damage in Diamond by Chemical Mechanical Polishing (CMP) Koji Koyama[1,2], Naoki Fujita[1], Seong-Woo Kim[1] and Mamoru Yoshimoto[2]; [1]Adamant Namiki Precision Jewel Co., Ltd., Japan; [2]Tokyo Institute of Technology, Japan

1. Introduction
Surface finishing is a fundamental process to obtain the maximum performance from a material. Chemical

Mechanical Polishing (CMP) following to mechanical polishing is widely used for semiconductor materials, such as Si, GaAs, SiC, and GaN. Diamond has traditionally been, however, mechanical-polished with diamond abrasive because it is the hardest material and ultimately inert. It is thought that nanoscale subsurface damage induced by mechanical polishing with diamond abrasive must be removed by CMP. Although there are many reports on diamond CMP, a detailed mechanism of diamond CMP has not been clarified yet. We proposed a new diamond CMP technology with chromium oxide abrasive. In this study, the time-dependent effect of the CMP treatment with chromium oxide slurry on the diamond substrate was investigated in the development of ideal diamond substrate with atomically flat and damage-less surfaces.

2. Experimental

We prepared four pieces of mechanically polished heteroepitaxial diamond substrates (KENZAN Diamond®) with diamond abrasive in order to obtain atomically flat surface prior to CMP. We applied CMP with chromium oxide slurry to three of them. The chromium oxide slurry was composed of 20 wt% of Cr_2O_3 abrasive, 70 wt% of water, and 10wt% of dispersant. The diamond substrate without CMP was also prepared as a reference sample. The surface morphology during/after CMP were observed with AFM and white-light interference microscopy.

We applied re-growth on the diamond substrates to evaluate the subsurface damage removal by CMP. The diamond thin film was grown on the polished substrates under the same growth condition. Surface morphology after re-growth was observed by SEM.

3. Results

We measured the surface roughness with white-light interference microscopy from a macroscopic viewpoint. The surface roughness drastically changed during CMP. In the initial stage from 0 to 5 hours, scratches appeared, and the surface roughness became extensive. Additional CMP up to 100 hours eliminated the scratches to attain a low surface roughness again. This phenomenon is known as a surface morphology change because of the subsurface damage removal among other hard-to-polish materials, such as sapphire, SiC, and GaN.

We observed the surface morphology with AFM from a microscopic viewpoint. An atomic step structure was observed on the 75-hours CMP substrate. The average step height was 0.09 nm, which is in good agreement with the atomic step height (a quarter of lattice constant) of the diamond (001). It is thought that the atomic step structure appears when CMP completely removes the subsurface damage induced by mechanical polishing.

We re-grown a diamond film on the polished diamond substrates in order to confirm the subsurface damage removal. The surface pits on the homoepitaxially grown film became less with increasing the CMP time. No pits were observed in the SEM image of the 100-hours CMP substrate. It is reasonable that the surface pits after homoepitaxial growth were reduced with increasing the CMP time because of the removal of the subsurface damage by CMP.

4. Summary

Surface morphology and surface roughness change after/during CMP with the chromium oxide slurry were observed to clarify the effect of CMP on the subsurface damage of the diamond substrate.

Drastic surface roughness change during CMP was observed with white-light interference microscopy.

Atomic steps were observed with AFM on the 75-hours CMP substrate.

We observed the pits reduction with increasing CMP time in the homoepitaxially grown film.

All these results indicate that the CMP removed the subsurface damage induced by the mechanical polishing. The diamond CMP with the chromium oxide slurry has the same effect on the subsurface damage removal as other reported diamond CMP technologies. Besides, this is the first time to report on the atomic step structure. We expect this result contributes to clarifying the mechanism of the diamond CMP.

8:55 AM EL04.10.04

618-V 2.63-mΩ cm^2 NO_2 P-Type Doped Diamond MOSFETs on a High-Quality Heteroepitaxial Diamond Layer

Makoto Kasu[1], Niloy Chandra Saha[1], Seong-Woo Kim[2], Yuki Kawamata[2], Koji Koyama[2] and Toshiyuki Oishi[1]; [1]Saga University, Japan; [2]Adamant Namiki Precision Jewel Co., Ltd., Japan

Diamond semiconductors, owing to a wide bandgap of 5.47 eV and superior properties compared to SiC and GaN, can be used to develop high-power devices. Previously, we had proposed and demonstrated an NO_2 adsorbed hydrogen-terminated diamond field-effect transistor. [1] In a subsequent study, we demonstrated a diamond metal–oxide–semiconductor field-effect transistor (MOSFET) exhibiting a high drain current of 1.3 A/mm. [2] Kitabayashi and Kawarada *et al.* reported a diamond MOSFET with a high off-state breakdown voltage of 2021 V. [3] Diamond MOSFETs exhibiting either high current or high voltage have been reported predominantly until now. However, for a high radio–frequency power operation, a device with a combination of both high current and high voltage is necessary.
In this study, we fabricated NO_2 p-type doped diamond MOSFETs showing high current, high voltage, and the highest output power on a (001) heteroepitaxial diamond layer called the Kenzan diamond®. The heteroepitaxial diamond layer was grown on an Ir buffer layer on a (11-20) sapphire substrate. For delamination of the diamond layer from the substrate, the microneedle technique was used.
The heteroepitaxial diamond showed the lowest threading dislocation density and full width at half maximum of the (004) X-ray diffraction rocking curve of 1.4×10^7 cm^{-2} and 113.4 arcsec, respectively. Further, the NO_2 p-type doping was performed to generate high-density hole carriers in the diamond layer. Additionally, an Al_2O_3 double layer, optimized to both the hole channel and gate breakdown, was deposited on the NO_2 adsorbed diamond layer. To minimize the source resistance, the gate contact was formed adjacent to the source contact. The diamond MOSFET with a gate length of 1.4 μm exhibited a high drain-current density of −776 mA/mm with a negligible gate leakage current (less than 0.1 μA/mm). MOSFETs with a gate-to-drain length of 4.8 μm showed a high off-state breakdown voltage of −618 V and a specific on-resistance of 2.63 mΩ cm^2. The experimental Baliga's figure-of-merit for the available output power density and maximum output power density were 145 MW/cm^2 and 12.3 W/mm, respectively. These values represent the highest values observed in diamond-based devices so far.

9:10 AM *EL04.10.05
Radiation Hard Diamond Electronics for Harsh Environmental Applications Hitoshi Umezawa; National Institute of Advanced Industrial Science and Technology (AIST), Japan

The huge earthquake and tsunami of 2011 in Japan caused the Fukushima Daiichi Nuclear Power Plant to lose all electricity and suffered a severe accident. The meltdown and subsequent hydrogen explosion caused harsh environmental conditions in the reactor containment vessels and the reactor buildings, with high radiation, high temperatures, and high humidity at the same time, which severely damaged the environmental monitoring equipment installed. Melted fuel, so called debris, are still in the damaged reactors and safe decommissioning operations are required under controlled conditions.
In order to increase the safety of next generation reactors and decommissioning operations, it is necessary to realize electronic circuits with semiconductor devices that can withstand the harsh environmental conditions. Diamond devices are known to realize long-term reliability at high temperatures [1] and are expected to be used as semiconductor devices for electronic circuits that can withstand severe accidents due to their high radiation hardness >10MGy [2]. The author and his colleague have developed active and passive devices based on diamond [2,3]. They have also succeeded in detecting pseudo-signals of radiations by a preamplifier circuit using diamond FETs under elevated temperatures. For the integration of diamond detector systems into nuclear reactors requires the development low noise circuits and mass production technology for the devices.
The author would like to thank Dr. J. H. Kaneko, Dr. A. Chayahara, Dr. S. Ohmagari and Dr. H. Kawashima for their great supports on experiments and discussion. The research is partially supported on the projects by Collaborative Laboratories for Advanced Decommissioning Science (CLADS) and MEXT, Japan.

A Highly Modular Implantation System for the Creation of High-Density NV Centres in Diamond

Lahcene Mehmel[1], Midrel Ngandeu[1], Alexandre Tallaire[1,2], Ovidiu Brinza[1], Audrey Valentin[1], Fabien Bénédic[1] and Jocelyn Achard[1]; [1]LSPM-CNRS, France; [2]IRCP- Chimie Paristech, France

The negatively charged nitrogen-vacancy centre (so-called NV^- centre) in diamond is one of the most promising systems for applications in quantum technologies because of the possibility to optically manipulate and read out the spin state of this defect, even at room temperature. These specific spin properties have paved the way to ultra-sensitive, high-performance and innovative quantum sensors (magnetometers, gyroscopes, spectrum analysers, etc.) which could open up perspectives in investigating properties that would remain inaccessible by conventional devices.
For the development of these applications, it is necessary to have diamond films of very high crystalline quality in which the density, environment, orientation and spatial localization of the introduced colour centres are perfectly controlled which is now possible thanks to microwave Plasma-Assisted Chemical Vapour Deposition (PACVD) [1]. Nevertheless, obtaining high densities of NV centres (> 500 ppb) remains particularly difficult due to the low conversion efficiency between substitutional nitrogen N_S and NV centres. In addition, the localization of these NV centres very close to the surface by in situ doping remains very challenging. For all of these reasons, the development of versatile implantation systems allowing both introducing nitrogen using N^+ or creating vacancies with He^+ ion bombardment is seen as a promising route towards this aim. In this paper, we present a single cavity ECR (electron cyclotron resonance) source module for producing relatively high energy ion (10-50 keV) beams using different gas sources. Using an electro-optic system, the beam size can be shaped and fitted to the surface to be implanted. We will show that the creation of high-density NV centres can be achieved near the surface using 2 approaches: (1) irradiating high purity CVD diamonds with N^+ and (2) irradiating highly nitrogen doped CVD diamond layers with He^+.

12:00 PM EL04.11.02

Late News: Germanium Color Centre Formation Studies in CVD Nanocrystalline Diamond

Rani Mary Joy[1,2], Paulius Pobedinskas[1,2], Celine Noel[3], Daen Jannis[4,4], Nicolas Gauquelin[4,4], Johan Verbeeck[4,4], Laurent Houssiau[3] and Ken Haenen[1,2]; [1]UHasselt, Belgium; [2]IMEC vzw, Belgium; [3]University of Namur, Belgium; [4]University of Antwerp, Belgium

Diamond-based structures with luminescent defects are prominent platforms for photonics, sensing, imaging, and various other applications[1]. Typically, high sensitivity systems with nitrogen vacancy (NV) centres in single crystal diamond (SCD) are demonstrated. However, challenges in scalable SCD processing and inferior optical properties of NV centres fuel the investigation for alternative emitters in micro- and nanocrystalline diamond (NCD) that offer wafer scale fabrication. A potential alternative is the Group IV defects that include silicon and germanium color centres[2].
In this study, we report *in-situ* fabrication of germanium vacancy (GeV) centres in polycrystalline diamond. NCD layers are grown on Ge substrates via the microwave plasma enhanced chemical vapour deposition technique under 1% CH_4 in H_2, 3000 W and 45 Torr process conditions. The deposition temperature is maintained at (700 ± 10)°C due to the proximity to Ge's melting point (937°C). The solid source Ge doping occurs via the gas phase by plasma etching of the substrate, followed by Ge-vacancy complex formation in the

deposited diamond layer[3,4]. We demonstrate that Ge substrate does not form carbide layer. It is evidenced from electron energy loss spectroscopy that carbide phases are absent, instead an amorphous carbon layer of 2 nm forms at the diamond/substrate interface. Therefore, we were able to fabricate ~ 9 µm thick self-separating freestanding GeV incorporated diamond films with dimensions up to 1 × 1 cm^2. Scanning electron microscope analysis reveal facetted morphology of the NCD films while diamond formation is verified by Raman measurements. Room temperature photoluminescence (PL) measurements reveal 602 nm peak associated with the GeV formation in diamond. We also present time-of-flight secondary ion mass spectroscopy (ToF-SIMS) results that confirm Ge incorporation in NCD and discuss the non-uniformities in Ge incorporation in the film with PL mapping supported by the high resolution ToF-SIMS elemental imaging technique.

Demonstration and Analysis of 100 kA/cm^2 Diamond Diodes Harshad Surdi, Franz Koeck, Mohammad Faizan Ahmad, Trevor Thornton, Robert J. Nemanich and Stephen Goodnick; Arizona State University, United States

Diamond as a semiconductor exhibits excellent thermal conductivity (20W/cmK)[1] and therefore is very suitable for high power electronics where self-heating is often the primary reason for failure. Owing to a high thermal conductivity, very high forward current densities can theoretically be rectified through diamond Schottky-pn or Schottky-pin diodes before self-heating limitations. Although a high forward current density at 60 kA/cm^2 was demonstrated by Makino et. Al [2], practical diodes start self-heating and fall short of the theoretical limits. It therefore becomes important to understand what the practical limitations in diamond diodes are, especially the effects of traps and recombination centers that limit the forward current density.
In this research we demonstrate a practical diamond Schottky-*pin* diode with a 114 kA/cm^2 forward current density at 17 V forward bias and fit theoretical drift-diffusion simulations to the measured data. The simulations were done with bulk trap densities of mainly three different energy levels uniformly distributed in the *i* and *n* regions of the diode. The trap energy and capture cross-sections for all trap levels were considered from Bruzzi *et. al*. [3] and Ščajev *et. al.* [4]. A hopping mobility is calculated for both electrons and holes to account for nearest neighbor and variable range hopping. We also observe velocity saturation in the *i* and *n* diode regions where the electric field gets large due to depletion from the Schottky metal contact as well as the *p-i-n* junction. Therefore, an electric field dependence in the mobility model is also considered. The simulations fit very well with the measured data and provide insight into different regions in the IV characteristics. Different regions in the IV characteristics are analyzed in detail by individually turning on the trap levels, field dependence on mobility and surface recombination effects. An ideal case for a theoretically possible current density before self-heating is also made.

Towards the Implementation of Diamond Power Devices in Power Converters and Measurements of Their Switching Losses Nicolas Rouger[1], Damien Risaletto[1], Pierre Lefranc[2], Pierre-Olivier Jeannin[2], Hugo Cagnol[1], Gaetan Perez[2], Sébastien Vinnac[1], Julien Pernot[3], David Eon[3] and Etienne Gheeraert[3]; [1]Université de Toulouse ; LAPLACE ; CNRS ; INPT ; UPS, France; [2]Univ. Grenoble Alpes, CNRS, Grenoble INP, G2Elab, France; [3]Univ. Grenoble Alpes, CNRS, Institut Néel, France

Ultra wide bandgap (UWBG) materials such as monocrystalline diamond exhibit the best figure of merits for power semiconductor devices: the ultra-wide bandgap of 5.5eV translates into the highest electric field above 10MV/cm, which offers a thinner drift region with an associated higher doping level than with other Wide Bandgap (WBG) materials for the same breakdown voltage. Consequently, power semiconductor devices based on UWBG and diamond in particular have theoretically the lowest specific on state resistance, which leads to smaller active area and lower conduction and switching losses. Many different diamond power device architectures have been previously introduced, but the implementation of those in actual power converters was only reported in a limited number of communications [1-3]. Although the measurement of on state resistance is straight forward, the measurement of switching losses is challenging with the existing and future High Voltage (>600V) diamond power devices. First, diamond devices need to be packaged in order to be integrated in, at least, one power commutation cell (one transistor and one diode, or two transistors, with the same breakdown voltage). This packaging should also be compatible with a high junction temperature operation (above 150°C) to fully demonstrate the performances of diamond devices based on bulk conduction. Second, the active area of diamond devices can be relatively small compared to other available power devices. Consequently, the maximum switching speed of diamond power devices can be extremely fast, and the intrinsic parasitic capacitors much smaller than 1pF. Third, the total current rating of diamond power devices can be rather small (µA to mA), which makes it difficult to probe the fast large signal variation of low drain currents, also with high voltage swings. Finally, the required gate to source driving voltages of diamond power transistors can be different from their Silicon and WBG alternatives, with large gate to source voltage swing [5]. For all these reasons, a specific experimental approach must be developed to adapt the implementation of diamond power devices in power converters, and to be able to accurately extract the large signal switching behavior of those devices.

In this work, we present the specific experimental characterization boards we designed and fabricated to achieve the fastest switching of diamond Schottky Barrier Diodes, and a flexible converter to extract switching losses of WBG and UWBG power transistors. The classical Double Pulse method is compared to the opposition method, where switching losses can be accurately measured without having to probe drain or source currents with fast dynamics. The converter is validated for high voltage inputs above 600V, load currents above 20A, switching frequencies above 100kHz, and flexible gate driver boards to adapt to specific gate voltages. Preliminary results on power switching with diamond MESFETs are also presented and discussed.

The research leading to these results has been performed within the GreenDiamond project (http://www.greendiamond-project.eu/), received funding from the European Community's Horizon 2020 Program (H2020/2014-2020) under grant agreement n° 640947 and is partially funded by French ANR Research Agency under grant ANR-16-CE05-0023 #Diamond-HVDC.

Normally-OFF Diamond Reverse Blocking MESFET Jesus Canas[1,2], Alexander Pakpour-Tabrizi[3], Etienne Gheeraert[1], Marina Gutierrez[2] and Richard Jackman[3]; [1]Univ. Grenoble Alpes, CNRS, Grenoble INP*, Institut Néel, France; [2]Universidad de Cádiz, Spain; [3]University College London, United Kingdom

Diamond transistors are promising for high temperature, high power and high frequency applications in harsh environments as a result of this material extraordinary properties, such as high electron and hole mobility (4500 $cm^2V^{-1}s^{-1}$ and 3800 $cm^2V^{-1}s^{-1}$), low dielectric constant (5.7), high breakdown field (10 MV/cm), high thermal conductivity (10 W/cm K) or high radiation hardness. However, no shallow dopants are found and p-type doping is acquired using boron (0.37 eV) and n-type using phosphorous (0.6 eV). Because of its specificities, it is often more convenient to find original ideas for diamond transistors rather than using the classical designs. A normally-off inversion Diamond MOSFET was demonstrated in 2016. Nonetheless, fabricating a power inversion MOSFET requires a control of diamond growth and etching that has not been yet reached. Instead, most of Diamond transistors are normally-on MOSFETs, based on the 2D hole gas emerging due to transfer doping in H-terminated surface. But also, new transistors concepts like the diamond deep depletion MOSFET have shown promising results based on bulk boron doped diamond conduction.
In this work, we demonstrate a normally-off high breakdown voltage p-diamond reverse blocking MESFET. The source is fabricated using selective p+ diamond growth and Ti/Pt/Au Ohmic contacts, while the gate and drain Schottky contacts are made of Molybdenum on O-terminated Diamond. The major challenge in the fabrication of a normally off-MESFET is to target the correct layer thickness and doping concentration, in order to have a closed channel that can be opened applying a BIAS to the Schottky gate. Despite, the progress made in diamond growth allow us for the first time to design and fabricate such a device. The Drain and Gate Schottky contacts have been characterized showing a high ideality factor of 2.1 at room temperature, tentatively explained by an interface oxidized layer. The density of states of the interface is estimated as ~$10^{13}cm^{-2}$ by the conductance method. The devices are normally off displaying undetectable gate leakage current. An on-state current level of 10^{-4} mA is reached in the ON-state at room temperature and 10^{-2} mA at 450 K. A breakdown voltage of <1kV was measured for the device.

1:00 PM EL04.11.06

Hybrid Power Module with Diamond and SiC Power Devices—Modeling, Performances and Challenges Nicolas Rouger[1], Anne Castelan[1,2], Idriss Nachete[1], Nazareno Donato[3], Florin Udrea[3] and Julien Pernot[4]; [1]Université de Toulouse ; LAPLACE ; CNRS ; INPT ; UPS, France; [2]ICAM, France; [3]University of Cambridge, United Kingdom; [4]Univ. Grenoble Alpes, CNRS, Institut Néel, France

Ultra wide bandgap (UWBG) materials such as monocrystalline Diamond are foreseen as the next-generation power semiconductor devices [1], whereas wide bandgap (WBG) materials such as SiC and GaN are already pushing towards more efficient and more integrated power converters [2,3]. Diamond has outstanding physical properties such as the highest thermal conductivity (20 $W.cm^{-1}K^{-1}$ at room temperature), a large critical electric field (10 $MV.cm^{-1}$), a wide doping range and a high carrier mobility in both P and N type doping types. Diamond devices are also maturing, with many improvements and breakthroughs in the recent years: Deep Depletion and inversion MOSFETs [4,5], 2DHG FETs with high current and high breakdown voltage capabilities [6], JFETs, high voltage and high temperature MESFETs, Schottky, PiN and Schottky PiN diodes [1]. Nonetheless, diamond devices based on bulk diamond conduction (e.g. MOSFETs, JFETs, MESFETs, Schottky diodes) suffer from the incomplete ionization of Boron dopants at typical operating junction temperatures (e.g. 300K-400K), which increases consequently the ON state resistance of such unipolar devices. Moreover, the active area of diamond can be limited by defect density and substrate size, which limits the high-current capability of diamond power devices in a short term.

How could one introduce as soon as possible diamond power devices in power modules to take benefits of their outstanding performances, while mitigating their weaknesses?

In this work, we propose to combine boron-doped diamond power transistors based on bulk conduction in a

hybrid association with WBG power devices such as SiC MOSFETs. Other hybrid associations between Si and SiC power devices have been previously proposed such as in [7], but UWBG such as diamond was never considered. A small area diamond power transistor is associated in parallel with a SiC MOSFET which is smaller than a SiC-only solution, and both SiC and diamond devices having the same breakdown voltage (1.7kV in this work). This hybrid association offer an attractive combination of the Positive and Negative Temperature Coefficients for the ON state resistance of SiC and Diamond power devices. This hybrid association is modeled, discussed and benchmarked with SiC-only (analytic and real datasheet) and Diamond-only solutions, considering representative specifications at the power converter level. Preliminary studies show a reduction of SiC active area by two. Particularly, the optimal sizing and the current sharing between the paralleled power devices are investigated as a function of operating conditions and junction temperatures. The thermal management solutions and electro-thermal coupling are also discussed based on analytical and numerical models.

Boron Incorporation in Monocrystalline CVD Diamond Films for Schottky Barrier Diodes Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]imec vzw, Belgium

Monocrystalline diamond is known as a material that possesss an extraordinarily combination of extreme properties. While this is an ideal starting point to become the next-gen electronic device material, several hurdles remain to be taken. The use of microwave plasma enhanced chemical vapour deposition (MW PE CVD) in combination with a a wide parameter space enables the production of films with a wide window of doping concentrations and thicknesses that range from a few hundreds of nanometers to over a millimeter thick. Nonetheless, many times the device performance of electronic applications based on such layers remains far below the theoretical predictions. This is partly due to a lack in fundamental understanding in the relation between (varying) substrate quality, process conditions, dopant incorporation, and final crystalline properties. The latter will not only influence the actual dopant mobility and lifetime, but also the level of leakage currents in device structures based on such films.

Here, a detailed study on the methane concentration dependence of the plasma gas phase on the surface

morphology and boron incorporation in monocrystalline CVD diamond layers is presented. Both heavily doped p^+ films, with boron concentrations above the Mott transition (~ 3 x 10^{20} / cm^3), as well as lightly doped p^- films with acceptor concentrations down to 1×10^{14} / cm^3 will be discussed. A combined use of several characterisation techniques to assess the electronic, optical, and structural properties, including Hall measurements, Raman and absorption spectroscopy, AFM, and TEM, will shed light on the beforementioned relation between process conditions and subsequent film quality. The combination of said p^+/p^- layers in pseudo-vertical Schottky barrier diodes leads to devices that show a very low leakage current, down to 10^{-12} A, with forward current levels up to ~ 10^3 A/cm^2.

Finally, the experimental findings on impurity incorporation are corroborated by first principles calculations that give insight in the relation between methane concentration and preferential boron incorporation sites, also providing a route to understanding impurity incorporation in diamond on a general level, potentially of great importance for color center formation [1].

Interface Properties of ZrO_2/p-type O-Terminated (001) Diamond MOSCAP Beatriz Soto[1], Jesus Canas[2,1], M. Pilar Villar[1], Daniel Araujo[1] and Julien Pernot[2]; [1]University of Cádiz, Spain; [2]Université Grenoble Alpes, France

Diamond has been exhaustively studied during the last few decades as semiconductor since it is theoretically the best candidate to meet the power electronics trade-off. However, the fabrication of devices based on diamond presents a set of challenges, for example the diamond available bulk size and surface termination quality and the fact of not having a native oxide among others, such problems prevent devices high performance and reliability. The present study is focused on the electrical and microstructural characterization of zirconium dioxide to be employed in diamond-based electronic devices for field effect transistor applications. Most of diamond Metal Oxide Semiconductor Capacitors (MOSCAPs) in literature were fabricated using Al_2O_3 or SiO_2 due to properties such as the wide band gap and their alignment with the diamond band setting. Based on those gate dielectrics, it has been recently demonstrated the first inversion channel normally-off Metal Oxide Semiconductor Field Effect Transistor (MOSFET) and a Deep Depletion MOSFET (D3MOSFET) showing great perspectives for the future of power electronics. However, in case of 2D hole gas channel, low channel mobility due to high density of interface states is still an issue so more effective passivation techniques are required to reduce losses of the performance. In this context, zirconia appears as a good candidate for the gate dielectric because of its high dielectric constant (with a minimum crystalline average value of about 19.7) , high band gap (around 6eV) and its chemical and thermal stability favouring the oxide-diamond interface quality. In this work, the devices under test are MOSCAPs and Metal Oxide Metal capacitors fabricated on a p-type oxygen-terminated (001) diamond layer using an insulating layer of ZrO_2 grown by Atomic layer deposition (ALD). I-V, C-V and C-f measurements with temperature ranging between room temperature to 125 °C have been performed in order to extract information such as the doping concentration of the p- diamond layer, the MOSCAP flat band voltage, the oxide charge density or the interface state density. On the other hand, microstructural characterization through different techniques have been performed to determine the crystallinity degree and oxide thickness through High resolution electron microscopy (HREM) and the relate Fast Fourier transform (FFT) or X-ray diffraction (XRD), the oxide band gap has been analysed by Electron energy loss spectroscopy (EELS) and the stoichiometry analysis of the oxide has been based on Energy-dispersive X-ray spectroscopy (EDX). Finally, helped by finite element calculation of MOSCAP band diagram, the correlation between the electrical response and the microstructural nature of the device will be established and discussed.

2:55 PM EL04.12.03
Science and Technology of Integrated Super-High Dielectric Constant AlO_x/TiO_y Nanolaminates /

Diamond for MOS Capacitors and MOSFETs Orlando Auciello[1,2], Jiangwei Liu[3], Elida I. de Obaldia[4,1], Bo Da[3] and Yasuo Koide[3]; [1]The University of Texas at Dallas, United States; [2]Original Biomedical Implants, LLC, United States; [3]National Institute for Materials Science, Japan; [4]Universidad Tecnológica de Panamá, Panama

A super-high dielectric constant AlO_x/TiO_y nanolaminate film is grown on hydrogenated crystalline diamond (H-diamond) to enable superior diamond-based metal-oxide-semiconductor (MOS) capacitors and metal-Oxide-Silicon-Field-Effect-Transistors (MOSFETs). In order to minimize or suppress leakage current, a nanometer thick AlO_x film is inserted at the AlO_x/TiO_y nanolaminate / H-diamond interface. The maximum values for the capacitance density and dielectric constant related to the summation of individual AlO_x and nanolaminate are 1.06 μF/cm^2 and 68.7, respectively. Capacitance density and dielectric constant for the AlO_x/TiO_y nanolaminate are as high as 5.22 μF/cm^2 and 308, respectively. Electrical properties of four H-diamond MOSFETs with gate lengths increasing from 2.4 μm to 10.1 μm were investigated. All of them showed p-type behavior and distinct pinch-off characteristics with drain current maxima of −47.4, −43.3, −26.6, and −24.6 mA/mm, respectively. On/off ratios and threshold voltages for the MOSFETs are higher than 10^4 and lower than 0.55 ±0.10 V, respectively. The low threshold voltages indicate that the AlO_x/TiO_y nanolaminate gate based MOSFETs can switch between ON and OFF stages at very low gate voltages. Effective mobilities of the H-diamond channel layers for all the MOSFETs raised firstly and dropped subsequently with increasing voltages, which can be explained by the effect of mobility limiting factors.

3:10 PM EL04.12.04
Time of Flight Measurement Using Electron Beam Induced Current on a Diamond Single Crystal
Alexandre Portier[1,2], Julien Pernot[2], Marie-Laure Gallin-Martel[1], Fabrice Donatini[2] and Denis Dauvergne[1]; [1]Laboratoire de Physique Subatomique et Cosmologie (LPSC), France; [2]Institut Néel, France

1. Introduction
Many techniques have already been used to characterize carriers' properties in diamond detectors by doing Time of Flight (ToF) measurements. The most common is to use alpha particles, which deposit their energy near the diamond surface [1, 2]. But some other techniques like using biphotonic absorptions [3] and neutrons [4] have already been carried out. Some experiments based on a pulsed laser [5] have found very high mobility at room temperature for electrons and holes. This high mobility is very interesting for fast timing and high rate detection applications. Time of flight using Electron Beam Induced Current (ToF-EBIC) is a new way to determine and study the carrier mobilities.

2. Time of Flight using Electron Beam Induced Current
The experiments were conducted through the following procedure: a CVD single crystal diamond is put in a scanning electron microscope chamber under vacuum, and biased by means of an external voltage source. A pulsed electron beam is focused on a small area of the diamond. The diamond works as a solid ionization chamber: electrons will lose their energy by creating electron-hole pairs in a small volume located close to the entrance surface. Because of the electric field, the carriers would drift to the negative electrode (holes) and to the positive electrode (electrons). The signal is extracted from the electrodes, amplified by a fast preamplifier (CIVIDEC C2-HV [6]) and the waveforms are digitized by an oscilloscope. Depending of the beam energy, the electrons are stopped in the first 1 to 5 μm from the diamond surface, which is quite small compared to the diamond bulk thickness (around 500 μm). Thus, one type of carrier is instantly collected (~10-100 ps) while the other one will drift a few nanoseconds to reach the opposite electrode. Then, it is possible to study separately the drift of electrons and holes so as to evaluate their mobilities for various bias voltages. In this work, thanks to this ToF-EBIC technique, diamond surface mapping for different depths (up to 5 μm) will be reported, charge carrier life time will be evaluated and carrier mobilities will be studied at different temperatures.

This work is supported by IDEX Université Grenoble Alpes and by DIAMTECH IN2P3.

EL04.13.01
Computational Prediction of P-Type Doping in Metastable $AlScO_3$ Perovskite with 8 eV Bandgap Cheng-Wei Lee[1,2], Prashun Gorai[1,2], Andriy Zakutayev[2] and Vladan Stevanovic[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

This work centers on $AlScO_3$, one of the 14 candidate oxides identified in our recent computational survey of semiconductors for power electronics [1]. The survey utilized intrinsic materials properties entering Baliga figure of merit (BFOM) to gauge performance. $AlScO_3$ is a distorted ABO_3 perovskite (metastable high-pressure phase) typically investigated for phase transformation under high-temperature and -pressure conditions. However, its electronic properties and doping tendencies are rarely explored. Our first-principle calculations predict an indirect electronic band gap around 8.0 eV (HSE06+G_0W_0), which is much larger than those of typical ultrawide bandgap semiconductors. Such wide bandgap makes it a promising candidate semiconductor for high-temperature or/and high-voltage applications. A functional device requires the underlying semiconductor to be dopable and we addressed this issue by performing first-principle defect calculations. Specifically, we adopted the well-established supercell approach to perform defect calculations and the total energies are calculated using the standard HSE06 hybrid functional with the bandgap corrected by the many-body perturbation theory (G_0W_0). Our calculations of native defects point to the cation and oxygen vacancies as the dominant point defects. The exothermic nature of the cation vacancies for Fermi energies close to the conduction band minimum at both cation- and oxygen-rich conditions suggest n-type insulating behavior. On the other hand, at the oxygen-rich conditions, the anion vacancies allow p-type doping. We further investigated the formation energies of potential extrinsic p-type dopants, like Mg and Zn, and found them to be deep acceptors implying moderate p-type doping. Lastly, we examined the hole self-localization and found stable small hole polarons with ionization energies of the order of 0.1 eV. Ionization energy of this magnitude implies activated transport that should be largely overcome at moderate to high-temperature. Our computational results also call for further investigations into the electronic properties and the search for shallower acceptor dopants of this promising p-type ultrawide bandgap oxide.

EL04.13.02
Design and Optimization of β-$(Al_xGa_{1-x})_2O_3/Ga_2O_3$ Delta-Doped High Electron Mobility Transistors
Dawei Wang and Houqiang Fu; Iowa State University of Science and Technology, United States

Beta-Gallium oxide (β-Ga_2O_3) has garnered tremendous research interests for high power, high voltage, and high frequency applications due to its ultra-wide bandgap (~4.8 eV), high critical breakdown field of 8 MV/cm, and large Baliga's figure of merit. $(Al_xGa_{1-x})_2O_3/Ga_2O_3$ delta-doped high electron mobility transistors (HEMTs) have been experimentally demonstrated with high quality electron channel and good electron mobility. Delta-doping regulates the electrical characteristics of $(Al_xGa_{1-x})_2O_3/Ga_2O_3$ HEMTs since it is responsible for the formation of two-dimensional electron gas (2DEG) in the channel. With epitaxial growth techniques such as

MOCVD and MBE, delta-doping position and concentration can be precisely controlled. However, the effects of delta doping on device performance of $(Al_xGa_{1-x})_2O_3/Ga_2O_3$ HEMTs are not comprehensively investigated.

In this work, we explore the design and optimization of $(Al_xGa_{1-x})_2O_3/Ga_2O_3$ delta-doped HEMTs via TCAD SILVACO simulation, which can serve as critical guidance for experimental realizations. To date, there are very few reports on the simulation of $(Al_xGa_{1-x})_2O_3/Ga_2O_3$ HEMTs, partly due to the immature status of Ga_2O_3 research and the lack of accurate material properties. In the simulations, we first calibrated our model with experimental electrical characteristics of $(Al_xGa_{1-x})_2O_3/Ga_2O_3$ HEMTs such as their transfer and transconductance curves. Then a comprehensive series of design and optimization of delta doping in the HEMTs was conducted, including delta-doping concentration, delta-doping position, delta-doping width, and multiple delta-doping channels.

The simulated HEMT structure consisted of Ga_2O_3 substrate, 130 nm unintentionally doped (UID) Ga_2O_3 layer, and 27 nm $(Al_xGa_{1-x})_2O_3$ layer, and two n^+-Ga_2O_3 contact regions for the source and drain. The delta-doping region was modeled by a thin n-Ga_2O_3 slab with a donor concentration of 1e18 cm^{-3}, which is positioned inside the $(Al_xGa_{1-x})_2O_3$ layer at 4 nm distance from the $Ga_2O_3/(Al_xGa_{1-x})_2O_3$ interface. With increasing delta-doping concentration, the device transconductance and drain current increased significantly. When the delta-doping concentration was over 1e19 cm^{-3}, the device exhibited large leakage from the delta-doping region because the conduction band at the delta doping position was lower than that of the channel. The position of delta doping also played a critical role. It was found that the closer the delta doping to the interface, the larger the device transconductance and drain current. The largest breakdown voltage was obtained when the delta doping was 2 nm from the channel. We also simulated the effect of delta doping diffusion across the interface, which is a great concern during growth. The current collapse was observed due to the diffused impurities into the Ga_2O_3 layer, which decreased the large built-in electric field generated by the interface barrier. In addition, multiple delta-doping channels can also significantly impact device threshold voltage and breakdown voltages.

In short summary, these results provide critical references for the future development of high performance Ga_2O_3 high power and high frequency electronics.

EL04.13.03

Stability and Electronic Properties of Ga_2O_3: Fe Alloys Studied Using Density Functional Theory Calculations

Luisa Scolfaro[1], Md Dalim Mia[1], Ahad Talukder[1], Brian Samuels[1], Pablo D. Borges[2], Wilhelmus J. Geerts[1] and Ravi Droopad[1]; [1]Texas State University, United States; [2]Universidade Federal de Vicosa, Brazil

Gallium oxide (Ga_2O_3) and its alloys are attracting great attention due to their potential in technological applications such as gas sensors, transparent conductive oxides for solar cells, UV detectors, magnetic sensors and devices, and high-power electronic devices. Doping Ga_2O_3 and/or alloying with foreign divalent elements, such as Mg^{2+}, Be^{2+}, Zn^{2+}, and Fe^{2+} are common ways to achieve high insulating materials needed in these applications. Although there have been few studies on the effects of iron in Ga_2O_3, no systematic investigation about the stability and electronic properties of $(Ga_{1-x}Fe_x)_2O_3$ have been reported so far.
In this work, we present the results of Fe doping in Ga_2O_3 using density functional theory-based calculations performed for different Fe concentrations (and). The role played by oxygen vacancies is also investigated. The effects of strain in the pristine oxide reveals that the band gap decreases with increasing lattice constant. This behavior is also observed in the Fe-doped systems with increasing . The theoretical results are compared with recent experimental measurements using XRD measurements and obtained in $(Ga_{1-x}Fe_x)_2O_3$ samples grown with various Fe contents and in different growth conditions, allowing to get insight into the stability of the structure.

This work was supported in part by NSF through an DMR-MRI Grant under Award 1726970 and in part by DOD through a HBCU/MI grant (W911NF2010298).

EL04.13.04

A Computational Search for UWBG Semiconductors for High-Power and High-Temperature Electronics

Emily McDonald[1,2], Prashun Gorai[1,2], Andriy Zakutayev[2,1] and Vladan Stevanovic[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

As we move toward a more renewable, variable, and distributed electricity grid, we will need to find power electronic (PE) semiconductors that can withstand high power and high voltage applications. Ultra-wide band gap (UWBG) materials are promising candidates as they tend to exhibit large breakdown fields which increases the operating voltage limit for a given device size. However, currently explored UWBG materials either lack the thermal properties needed to dissipate heat at high power (Ga_2O_3), are difficult to synthesize as quality single crystals at scale (diamond, c-BN), or are difficult to dope to desired carrier concentrations (AlGaN). Using density function theory (DFT) calculations, we conduct a high-throughput computational search to identify promising UWBG semiconductors beyond those currently used or studied for n-type power electronic devices. We consider >1,500 total oxides, nitrides, sulfides, carbides, silicides, and borides. First principles generalized gradient approximation (GGA) calculations and semi-empirical models are used to evaluate the carrier mobility and critical breakdown field which are inputs to the well-known Baliga figure of merit. We use this metric along with the lattice thermal conductivity identify top potential candidates with performance better than the current market materials for high power (SiC-4H and GaN). The electronic structures of a sub-set of the most-promising oxide candidates are further assessed using low-throughput, higher-accuracy HSE06 hybrid calculations. Our results find more than 28 promising candidates that have higher lattice thermal conductivity than Ga_2O_3 and higher n-type Baliga figure of merit than SiC-4H and GaN which are the current materials used in high-power PE applications today. Of these candidates, 65% are oxides and 35% are nitrides, with chemistries covering binaries to quaternaries. We also conduct a qualitative assessment of n-type dopability of the top candidates by evaluating the governing material properties, considering acceptor defects as the limiting factor. Given the large number of oxides in the top candidates, these UWBG materials are promising for use in high-temperature electronic devices as well as high-power PE applications. This work provides guidance for selecting candidates with confidence for further experimental investigation. Portions of this work have been published by Gorai *et al.* in: *Energy Environ. Sci.,* 2019, **12**, 3338.

EL04.13.05

A Study of Structural and Electronic Properties of Rippled 2D and 2D/Diamond Heterostructures Pegah S. Mirabedini[1], Alex Greaney[1] and Mahesh Neupane[1,2]; [1]University of California, Riverside, United States; [2]U.S. Army Research Laboratory, United States

An external lattice perturbation may lead to localized height variations (ripples) in two-dimensional (2D) materials during the growth process, and as a result, affect their functionality. Here, we conduct a systematic first principle study of the effect of rippling on the structural and electronic properties of 2D layers (hBN, graphene) and the resulting 2D/Diamond heterostructures. We find the most favorable alignment of the layer on the hydrogen-terminated diamond (H-diamond (100)) substrate using a combined sampling and a machine learning approach. Rippling of sheets can arise from templating on a variety of substrates. The rippled structures we studied on H-diamond were found to have a stronger vdW interaction between the constituent layer and the substrate. A higher degree of charge transfer was observed in the heterostructures composed of a rippled hBN (graphene) layer, as compared to their planner counterparts. The transferred charges are confined within the vdW-gap between the 2D layer and H-diamond (100) surface. The higher thermodynamic stability, improved charge transfer, and additional tunability of the electronic properties in the rippled 2D/Diamond heterostructures make them better choices for application in diamond-based field effect transistors.

EL04.13.06

The Facile Exfoliation of β-Ga_2O_3 Layers and Prediction of a New Phase Sajib K. Barman and Muhammad N. Huda; The University of Texas at Arlington, United States

The transparent wide bandgap semiconductor, β-Ga_2O_3 has gained considerable attention due to its suitability to a wide range of applications. For example, its wide bandgap and small electron effective mass are suitable for power electronic devices. Interestingly, even though this is not a van der Waals material, it can be peeled along

(100) surface by a scotch tape method like in graphene. The resulting ultra-thin layers are used for high power device fabrications. The theoretical calculation has shown that out of the two possible (100) surface terminations, (100)B surface is the most stable one, which is also experimentally observed from scanning tunneling microscope study (STM). One of the interesting properties of this material is that thin layers preserve the pristine bulk-like electronic properties, making it even more promising for applications in power devices. It is then of paramount importance to understand why the exfoliation occurs facilely even though the interlayer interaction in β-Ga_2O_3 is not van der Waals. This presentation will show the exfoliation phenomenon from the first principle thermodynamic total energy calculations and the mechanisms behind the easy exfoliation along (100)B surface. Lastly, we will show a theoretical prediction of a new phase of Ga_2O_3 obtained from the stacking of the exfoliated layers of β-Ga_2O_3. From the stability calculations, this phase is comparable to β-Ga_2O_3, as well as dynamically stable. From the hybrid density functional calculations, the new phase's bandgap is a little higher than the β-phase. The electronic and thermal properties of this new phase will be briefly presented and compared with β-Ga_2O_3. The methodology used and developed for this study can be utilized in general to understand bond breaking and forming in other wide bandgap materials as well. This understanding will give us better control to fabricate thin-film 2D devices, in general.

EL04.13.07

Anisotropic Thermal Boundary Conductance Across Metal/β-Ga_2O_3 Interfaces Jingjing Shi[1], Yee Rui Koh[2], Akhil Mauze[3], Chao Yuan[1], Shangkun Wang[1], Brian Foley[1,4], Takeki Itoh[3], Yuewei Zhang[3], James S. Speck[3], Patrick Hopkins[2,2,2] and Samuel Graham[1,1]; [1]Georgia Institute of Technology, United States; [2]University of Virginia, United States; [3]University of California, Santa Barbara, United States; [4]The Pennsylvania State University, United States

β-Ga_2O_3 is very promising to be applied in power electronic devices because of its superior properties, like the ultra-wide bandgap, high breakdown electric field, and the relatively low-cost growth of its single crystal. However, heat dissipation issue would limit the performance and reliability of β-Ga_2O_3 devices considering its extremely low thermal conductivity. A top-side cooling or double-side cooling strategy would be necessary to efficiently dissipate heat from the active region of β-Ga_2O_3 devices. As a result, thermal transport at the metal/β-Ga_2O_3 contacts is very important for device thermal management, and a thorough understanding of the thermal boundary conductance (TBC) at metal/β-Ga_2O_3 interfaces is needed. Anisotropy effects have been observed in the thermal conductivity of β-Ga_2O_3 but haven't been studied for TBC at β-Ga_2O_3 interfaces. In this work, we perform both experiments and theoretical simulations to study how the material orientation will affect the TBC at metal/β-Ga_2O_3 interfaces at different temperatures. The Al/β-Ga_2O_3 interface is studied as our model system because of the isotropic property of Al, which will not introduce other anisotropic mechanism into interfacial thermal transport. Both E-beam evaporated and molecular-beam epitaxy (MBE) grown Al/β-Ga_2O_3 interfaces are studied to minimize the influence of other factors (like growth method related defects at interfaces) on TBC. We apply the time-domain thermoreflectance (TDTR) method to measure the TBC at Al/β-Ga_2O_3 interfaces with different β-Ga_2O_3 substrate orientations (-201), (010), and (001), and the TBCs show strong anisotropy effect. In our theoretical calculation, to capture the anisotropy effect, a full first Brillouin zone k-space Landauer formula is applied. With the phonon information from ab initio calculations of the full first Brillouin in reciprocal lattice, there is no isotropic assumption and the influence of orientation can be captured and analyzed. Our modeling results are consistent with our experimental measurements that the TBC at (010) β-Ga_2O_3/Al interface is the highest, while the TBC at (-201) β-Ga_2O_3/Al interface is the lowest, and the difference is more than 50%. Our work shows that the anisotropy in β-Ga_2O_3 not only affects its thermal conductivity but its TBC as well. To capture the anisotropy effect, a modal approach with phonon information of the full first Brillouin zone is needed to accurately predict the TBC at β-Ga_2O_3 interfaces. The anisotropic TBC effect should be considered for the future thermal design of β-Ga_2O_3 devices.

EL04.13.08

The Structure and Properties of Amorphous Ga_2O_3 Julia E. Medvedeva; Missouri University of Science and Technology, United States

Gallium oxide has attracted a tremendous attention in recent years as a promising wide-bandgap semiconductor for power electronics and deep-UV optoelectronics. The optical properties of monoclinic β-Ga_2O_3 have been actively investigated both theoretically and experimentally, and a large range of the reported band gap values (from 4.3 eV to 5.1 eV) have been explained based on anisotropic onset of the optical absorption that originates from the crystallographic differences of the monoclinic gallium oxide phase.

Amorphous metal oxides have several advantages over their crystalline counterparts: the lack of lattice periodicity with defined crystal orientations, no grain boundaries, and an increased number of degrees of freedom for metal-Oxygen (MO) polyhedra packing in the disordered material lead to a uniform low-strain crack-resistant morphology, smooth surfaces over large areas, and in the case of ionic oxide semiconductors, a high carrier mobility. The effect of disorder on the optical properties of oxides is two-fold: on one hand, the fundamental band gap is determined by the nearest-neighbor interactions, i.e., the metal-oxygen bond strength, that is usually preserved upon amorphization; and on the other, disorder and structural defects may cause electron localization near the band edges, and these so-called tail states may contribute to the near-edge absorption.

In this work, computationally-intensive ab-initio molecular-dynamics liquid-quench simulations are combined with accurate electronic structure calculations using a hybrid functional in order to determine the structure and properties of amorphous Ga_2O_3 as a function of its density. Specifically, we calculate the coordination of individual Ga and O atoms in a large statistical ensemble of ten independent MD realizations at five different densities and predict changes in the coordination distribution as the density decreases to an optimal value for the amorphous oxide. In contrast to monoclinic β-Ga_2O_3 where half of the Ga atoms are octahedrally-coordinated with oxygen atoms and the other half is tetrahedrally coordinated, the number of the 6-fold GaO polyhedra is completely suppressed in amorphous oxide. These changes do not affect the electronic states in the conduction band which remains delocalized upon amorphization of stoichiometric Ga_2O_3. However, presence of 5-coordinated Ga and the resulting Ga coordination morphology determine the strong localization of the non-bonding O-*p*-states at the top of the valence band that contributes to the near-edge optical absorption. The calculated band gap of stoichiometric amorphous Ga_2O_3 is similar to the one in the crystalline phase, yet, the optical properties are isotropic in the disordered material. The effects of oxygen stoichiometry on the structure and properties of amorphous Ga_2O_{3-x} are also discussed.

EL04.13.09
Late News: Theoretical Investigation of Sn Deposition on Bare and Oxygenated Diamond (100) Surface Using Density Functional Theory (DFT) Sami Ullah and Neil Fox; University of Bristol, United Kingdom

Engineering a functionalised diamond surface that is stable and reproducible is of technological importance to future diamond electronic devices such as Schottky junctions and electron-emitting electrodes for field emission, thermionic energy converters, secondary electron multipliers.
One of the most interesting properties of diamond is the negative electron affinity (NEA) which means that the vacuum level lies below the conduction band, which makes diamond an efficient source of electrons. The NEA can appear when the surface carbon atoms are negatively charged which has been achieved by terminating the diamond surface suitably. Maier et al. [1] found EAs of 0.5 eV, -1.3 eV and 1.7 eV for the bare, H- and O-terminated (100) surfaces, respectively. A monolayer or sub-monolayer coverage of some of the electropositive group I and II metals and first-row transition metals (TMs) on the bare and oxygenated diamond surface have been found to be a suitable candidate for diamond surface termination. Transition metals like Cu, Ti, Ni and Co metals have been found theoretically to impart NEA to the diamond surface however their ability to do so depends upon their capacity to form a carbide on the diamond surface in which only Ti and V have been able to show higher NEA value than others. Most of these metals, however, do not form a stable monovalent bond with carbon which was solved by using an oxygen terminated diamond surface instead of a bare diamond surface. The key here is to induce stronger bonding between the metal layer and the underlying diamond surface and hence a large surface dipole. Recently Al was found to impart NEA of -1.47 eV at a layer thickness of 1 ML bare and -1.36 eV at 0.25 ML to the oxygenated surfaces of the diamond (100) [2].

Sn as termination on the bare and oxygenated surface of diamond has so far not been investigated although Sn is less electronegative than carbon and oxygen. Sn is also expected to form the carbide bonds and oxide on the surface of the diamond well. There has been a study on the same group elements (Si and Ge) termination of the diamond where they have been shown to bond well with the surface of diamond[3][4]. We wanted to study Sn as a potential NEA imparting termination on the bare and oxygenated surface of the diamond (100). DFT calculations were performed using CASTEP to model the system which contained 0.25 ML (Quarter Mono Layer), 0.5 ML (Half Monolayer) and 1 ML (Full Monolayer) Sn in different configurations on the bare and oxygenated surface of the diamond. It was found that Sn gives NEA on most of the absorption sites, largest being (-1.91 eV with an adsorption energy of -5.94 eV) in case of 0.5 ML (HML) Sn terminated oxygenated diamond surface. Sn on the bare surface gave NEA in all the configurations with lesser adsorption energies than the oxygenated diamond surface which again shows the important role of oxygen to improve the bonding between a metal atom and diamond surface and hence the properties.

Late News: Mesa Edge Terminated Wide Bandgap ß-Ga2O3/GaN Heterojunction Based Vertical p-n Diode Dinusha Herath Mudiyanselage and Houqiang Fu; Iowa State University, United States

ß-Ga_2O_3 is a wide bandgap (WBG) semiconductor material which has been extensively studied for power, optical and RF electronics due to its large bandgap of 4.7 - 4.9 eV and high breakdown field of ~ 8MV/cm. Most of the demonstrated ß-Ga_2O_3 devices are unipolar like high electron mobility transistors (HEMTs) and Schottky barrier diodes, due to the lack of p-type Ga_2O_3. To overcome this constraint, other p-type materials, such as GaN and NiO, have been studied to produce Ga_2O_3 based p-n heterojunctions. GaN is also a WBG semiconductor which attracted especial interest in power devices and has a clear crystallographic relationship to β-Ga_2O_3 for epitaxial growth. Metalorganic chemical vapor deposition (MOCVD) is an industrial standard tool which can produce both β-Ga_2O_3 and GaN. The growth of high-quality GaN on Ga_2O_3 by MOCVD has been recently reported. β-Ga_2O_3/GaN p-n heterojunction by mechanically exfoliation has also showed decent rectifying behaviors. However, due to the absence of effective edge termination the breakdown capability of the β-Ga_2O_3 based p-n heterojunctions is still in an early stage. Here we report the design and simulation of mesa edge terminated vertical β-Ga_2O_3/GaN heterojunction based p-n diode using SILVACO TCAD simulator. The heterojunction was first calibrated with conduction and valance band offsets and the device with electrical properties of the materials. The device structure consisted of n^+-Ga_2O_3 n-contact layer, 5 µm unintentionally doped (UID) β-Ga_2O_3 drift layer and 500 nm p-GaN layer. The ideal breakdown voltage (BV) of the heterojunction was 1.37 kV, while the BV of the reference device without any mesa edge termination fall drastically to 300 V due to the electric field crowding at the device edge. Therefore, it is crucial to design and optimize the mesa edge termination of the β-Ga_2O_3/GaN p-n heterojunction to improve the BV.

In this work, namely three mesa edge termination structures: beveled mesa, step mesa, and deeply-etched mesa were investigated. The key parameter in determining the device BV for beveled mesa is the mesa angle θ, which was varied from 15° to 90° and obtained the highest BV of 1224 V for θ =15°. For the edge termination with step mesa the width *(W)*, depth *(D)*, and the number of steps define the mesa structure. It was found that the device BV increased with increasing number of steps. The combination of *(W, D)* values of (0.5,0.5) and (0.5,1.0) and (1.0,1,0) was investigated, where all the values are in µm. The highest value of BV was obtained for W = 0.5 µm, D = 1.0 µm and the number of steps = 5. It was found that smaller W and larger D gave better

BV. To clearly understand the edge termination effect, electric field distribution of devices at -300 V with different edge termination mechanism were studied. Without any effective edge termination, the peak electric field at the junction edge was ~ 4.2 MV/cm. Introducing the mesa edge termination the electric field crowding was alleviated, and the peak electric fields at the edges were reduced to 1.8 MV/cm and 2.4 MV/cm for the beveled and step mesa edge terminations, respectively. Deeply-etched mesa structure was also investigated for mesa depths of 0.5, 1.0, 2.0, to 3.0 μm which showed a more relaxed uniform electric field at the junction edge. The peak electric fields were decreased from 2.1, 1.8 ,1.5 to 1.2 MV/cm, when the depth changes from 0.5 to 3.0 μm.
In brief, this work summarizes an extensive design and optimization of mesa edge terminations for the wide bandgap vertical β-Ga_2O_3/GaN p-n heterojunction diode structure. Beveled mesa, step mesa and deeply-etched mesa structures were exploited to gain knowledge on how the mesa edge terminations can mitigate the electric field crowding at the junction edge and increase the device BV. β-Ga_2O_3 based bipolar high voltage and high power devices can use this work as a guidance to improve their performance.

Late News: Nanoscale Investigation of Extended Defects in Wide Bandgap Semiconductors Joshua D. Caldwell[1], Benedikt Hauer[2], Claire E. Marvinney[3], Martin Lewin[2], Nadeemullah Mahadik[4], Jennifer Hite[4], Nabil Bassim[5], Alexander Giles[4], Robert Stahlbush[4] and Thomas Taubner[2]; [1]Vanderbilt University, United States; [2]RWTH Aachen University, Germany; [3]Oak Ridge National Laboratory, United States; [4]U.S. Naval Research Laboratory, United States; [5]McMaster University, Canada

The use of wide-bandgap semiconductor materials like SiC and GaN can dramatically improve the performance of electronic devices at high powers and temperatures. However, the propensity of extended defects in these materials does challenge their implementation in commercial electronic and optical applications. Spectroscopic and microscopic tools for identifying and characterizing these defects typically offer either spectroscopic or microscopic information exclusively and/or may be destructive. Here, we show how extended defects within 4H-SiC manifest in the nanoscale infrared phonon response probed by scattering-type scanning near-field optical microscopy (s-SNOM), a nondestructive method capable of simultaneously collecting topographic and spectroscopic information with frequency-independent nanoscale spatial resolution (≈20 nm).

We correlate the s-SNOM response of various defects in 4H-SiC with UV-photoluminescence, secondary electron and electron channeling contrast imaging, and transmission electron microscopy. We identify evidence of step-bunching, recombination-induced stacking faults, and threading screw dislocations, and also demonstrate the interaction of surface phonon polaritons with extended defects. Phonon-enhanced infrared nanospectroscopy and spatial mapping via s-SNOM thus offer significant insights into extended defects within emerging semiconductor materials and devices. It thus serves as an important diagnostic tool to help advance material growth efforts for electronic, photonic, phononic, and quantum optical applications.

Late News: Diamond Diode Detectors for (Nearly) Any Particle or Radiation Species—From Neutrons to X-Rays Jesse Brown[1,2], Anna M. Zaniewski[1,2], Manpuneet Benipal[2], Jason H. Holmes[1], Ricardo Alarcon[1] and Robert J. Nemanich[1]; [1]Arizona State University, United States; [2]Advent Diamond, United States

Radiation and particle detectors are a widely used technology for scientific, defense, environmental, industry, and other applications. However, many radiation detectors currently available on the market are bulky and many use fragile components. There is a great interest, therefore, in the development of solid state particle detectors. In this work, we will describe how we have designed, built, and tested breadboard versions of diamond diode-based particle detectors for a range of particle and radiation species, including: alpha particles, beta particles, neutrons, x-rays, and protons. This new class of radiation detectors are compact, rugged, low power, cost effective, easy to use, and reliable. Furthermore, for some species these detectors are capable of

energy measurements/spectroscopy for particle species/isotope identification, and real time dosimetry. We will describe our progress in bringing these detectors to the commercial market.

Metasurfaces—Then and Now Patrice Genevet; Université Côte d'Azur, CNRS, France

A class of planar and wavelength-thick optical components exhibiting exceptional optical properties have emerged in recent years. These artificial interfaces, known as metasurfaces, can manipulate the wavefront of light in almost any desired manner, leveraging on the scattering properties of the subwavelength nanostructures. To further develop this technology towards dynamic tuning, broadband applications and industrial production, new materials and new fabrication methods have been proposed.

In this tutorial, I will discuss basic design and fabrication methods of metasurfaces and summarize various applications for beam steering, polarization control and monolithic integration of metasurfaces in opto-electronic systems. As an alternative of conventional bulky, the development of this technology is expected to create a positive disruption in modern optical technologies, in particular in the fields of imaging, holography, 3D dynamic image rendering, AR/VR and LiDAR systems.

11:30 AM BREAK

11:45 AM *
Optimization and Machine Learning for Metasurface Design Jonathan A. Fan; Stanford University, United States

Inverse design, in which the design process is performed through iterative optimization, has the potential to push metasurface performance to the physical limits of composite materials engineering. In this tutorial, we will

discuss a range of state-of-the-art numerical optimization methods for metasurface design. We will introduce the objective-first and adjoint variables methods, which are gradient-based optimization concepts that can produce high performance freeform geometries. We will also provide an overview of machine learning techniques as applied to electromagnetics problems and show how generative neural networks can be harnessed as an effective global optimizer for photonic devices.

1:15 PM BREAK

1:30 PM *
Metastructures for Advanced Optical Applications Arka Majumdar; University of Washington, Seattle, United States

Dielectric metasurfaces are sub-wavelength diffractive optics, which can shape the phase, amplitude and polarization of the incident optical wavefront with high spatial resolution. While theoretically conceived decades ago, the availability of sophisticated nanofabrication techniques and computational techniques have recently rejuvenated this research field. In this tutorial, I will present the current state of the design and fabrication techniques of different metasurfaces. Going beyond single metasurface, I will present results with composite metasurfaces as well as tunable metasurfaces. Finally, I will show how computational post processing techniques coupled with metasurfaces can help create ultra-low-power and low-latency sensors.

EL05

8:00 AM *EL05.01.01
Metasurfaces for Orbital Angular Momentum Holography, Fibre Optical Trapping and Energy Harvesting Stefan A. Maier; Ludwig-Maximilians-Universität München, Germany

Metasurfaces allow the manipulation of the amplitude, phase, and polarization of light on an ultrathin platform, and have started to be explored also in the context of digitizing optical holograms. To increase the bandwidth of a metasurface hologram, essential for high-capacity holographic memory devices, different properties of light including polarisation, wavelength, and incident angles have been exploited for holographic multiplexing; however, the bandwidth of a metasurface hologram has remained too low for any practical use.

We present the design of a complex-amplitude metasurface hologram for ultrahigh-dimensional OAM-multiplexing holography in momentum space. To realise a complex-amplitude Fourier hologram, we have introduced an OAM diffuser array with a random phase function, capable of scaling down the amplitude variation in a typical Fourier image as well as eliminating the coherence of holographic image channels. We will demonstrate first realizations of holograms based on this concept.

8:40 AM EL05.01.02
Late News: Tunable Epsilon-Near-Zero Doped Zinc Oxide Thin Films Magdalena Nistor; National Institute for Laser, Plasma and Radiation Physics, Romania

Transparent conducting oxides (TCOs) continue to play an important role in optoelectronic applications due to the unique combination of optical transparency and electrical conductivity but recently TCOs have become an emerging class of nanophotonic materials with tailorable optical properties by synthesis, post-processing and optically generated free carriers [1].

Here we report on the Nd doped ZnO thin films with tunable epsilon-near-zero wavelength in the near-infrared region obtained by controlling the doping and the growth parameters. Epitaxial wurtzite Nd doped ZnO thin films with a wide range of optical and electrical properties were grown by pulsed electron beam deposition (PED) on c-cut single crystal substrates at relatively low substrate temperatures and gas pressures. PED is a well-established ablation method to grow thin films and has common features with the pulsed laser deposition [2, 3]. Rutherford backscattering spectrometry, X-ray diffraction and pole figure measurements were performed to determine the precise texture and in-plane epitaxial relationships between film and substrate in correlation with the electrical resistivity, mobility, carrier concentration and optical properties of the films. The physical basis of the metallic conductivity at room temperature of ZnO thin films leading to the observed optical tunability will be discussed, in particular the ability to precisely control the oxygen deficiency in these films together with the role of the Nd doping in both the carrier concentration and the structural disorder. This work demonstrates that degenerately ZnO thin films are promising epsilon-near-zero materials for nonlinear optical applications and nanophotonics. 8:55 AM EL05.01.03
Molecular Platform for Frequency Upconversion at the Single-Photon Level Philippe Roelli[1], Diego Martin-Cano[2], Tobias J. Kippenberg[1] and Christophe Galland[1]; [1]EPFL, Switzerland; [2]Max Planck Institute for the Science of Light, Germany

As applications in fields like security or medicine require sensitive schemes in order to detect IR photons, an interesting strategy consists in converting weak IR signals into the optical domain where detectors with single photon sensitivity are readily available. We introduce here a novel platform for ultra-sensitive conversion and detection of far and mid-infrared signals, which is inspired by our previous work where we describe the interaction between molecular vibrations and plasmonic antenna using the model of cavity optomechanics. Our study quantified the nonlinear coupling rateand revealed that it could be as high as tens of THz. We also predicted signatures of optomechanical amplification that should be observable in state-of-the-art systems. Novel plasmonic platforms could thus enable the realization of protocols inspired by cavity quantum optomechanics.

The protocol that we suggest here benefits from the intrinsic ability of specific molecular vibrations to interact both with optical and IR fields as routinely observed in Raman and resonant absorption spectroscopy. To insure an optimal overlap between the two beams and the molecular system, doubly resonant nano-antennas confine the fields into similar mode volumes and increase therefore the efficiency of the conversion process.

In this conversion scheme, an incoming IR field drives resonantly a vibrational mode and modifies its excited state population, which is mapped onto the scattered anti-Stokes Raman signal produced during the interaction between the same vibrational mode and an optical pump beam. When the optical beam is red-detuned from the plasmonic resonance the interaction Hamiltonian reduces to a state swapping Hamiltonian:, enabling an efficient optomechanical conversion process. Consequently, the modified vibrational population gives rise to an additional emission of coherent optical photons on the anti-Stokes sideband that can be detected with existing single photon counting techniques.

Our study demonstrates that the noise equivalent power (NEP) can be as low as few $pWxHz^{-1/2}$, improving on the state of the art for devices operating at room temperature. In addition to its low noise figure the sub-wavelength dimensions of the proposed converter promises the development of multi-spectral systems designed for IR source recognition and novel technological platforms harnessing the coherent nature of the conversion process.

Exciton-Resonance Tuning of an Atomically-Thin Lens Jorik Van de Groep[1,2], Jung-Hwan Song[2], Umberto Celano[3], Qitong Li[2], Pieter Kik[4] and Mark L. Brongersma[2]; [1]University of Amsterdam, Netherlands; [2]Stanford

University, United States; [3]imec, Belgium; [4]CREOL, United States

Since the development of diffractive optical elements in the 1970s research has focused on replacing bulky optical elements such as lenses and grating by thin counterparts. Over the last decade, nanophotonic metasurfaces rapidly advanced the development of flat optical elements based on the realization that resonant optical antenna elements enable local phase control. Present applications of metasurface flat optical elements include lenses, polarization control, and beam steering.

Next-generation applications of flat optics such as light detection and ranging (LIDAR), dynamic holography, and computational imaging require dynamic control over optical functionalities, e.g. the focal position or efficiency of optical elements. However, most nanophotonic structures are static after design and fabrication. Current approaches for dynamic control like electrical gating exhibit limited tunability due to the finite electrorefraction and electroabsorption effects in metals and semiconductors.

Here, we demonstrate actively-tunable and atomically-thin optical lenses by carving them directly out of monolayer transition-metal dichalcogenides (TMDs) like WS_2 with a strong excitonic resonance in the visible spectral range. This turns the 2D material into the antenna or metamaterial and incorporation of active materials into larger antenna structures will no longer be needed. Due to their sub-nm thickness, these materials are highly tunable through external control. We fabricate 1 mm diameter lenses with a 2 mm focal length by patterning large-area monolayer WS_2 on sapphire using nanolithography and reactive-ion etching. Using an electrochemical cell, we electrostatically control the carrier density in the monolayer WS_2 and thereby gain active control over the excitonic light scattering amplitude. Using confocal scanning microscopy, we characterize the focal shape and analyze the focal efficiency.

We demonstrate dynamic electrical tuning of the focusing efficiency with a 33% modulation depth through manipulating of the excitonic material resonance properties as opposed to tuning of antenna resonances. The highly tunable nature of these exciton resonances opens an entirely new approach for the design of dynamic flat optics and metasurfaces with applications in free-space beam tapping, wavefront manipulation, and augmented/virtual reality.

"Perfect" Gradient Metasurfaces are Not the Most Efficient Hsiang-Chu Wang, Karim Achouri and Olivier J. Martin; Ecole Polytechnique Fédérale de Lausanne, Switzerland

Metasurfaces rely on the resonances of nanostructures with dimensions in the nanometer range for devices working in the visible regime. The corresponding fabrication technology requires E-beam exposure and can be quite challenging. It is prone to defects associated with the many subtle process steps during fabrication, resulting in missing, distorted, or displaced nanostructures within the metasurface. In this work, we analyze the robustness of gradient metasurfaces to a variety of such defects using both simulations and experiments on purposely miss-fabricated samples. Surprisingly, we observe that a "perfect" structure, without any defect, is not that which exhibits the best performance in terms of efficiency and angular response. We demonstrate that specific, well-controlled, defects can actually significantly enhance the performance of such a metasurface and explain this behavior using the resonance and near-field properties of the corresponding nanostructures. This work sheds very new light on the design strategies for metasurfaces and significantly alleviates some constraints on their fabrication accuracy.

9:40 AM EL05.01.06
Late News: Material and Geometry Optimization of Nonlinear Coupler Based on Hybrid Plasmonic Waveguides Aleksandr Ramaniuk and Marek Trippenbach; University of Warsaw, Poland

Hybrid plasmonic waveguides are often considered as an alternative to traditional plasmonic systems in integrated photonics, as they exhibit significantly smaller losses while maintaining small structure size [1].

Nonlinear optics is another field of application for hybrid plasmonic waveguides [2]. Multiple groups have considered using both plasmonic and hybrid plasmonic waveguides to create nonlinear couplers [3,4,5]. Most of these configurations use silicon and silicon oxide in order to remain compatible with silicon-on-insulator technological framework [4]. Other proposals used highly nonlinear organic materials, such as DDMEBT or paratoluene sulphonate [5] to achieve stronger self-modulation response.
In this work we propose hybrid plasmonic waveguides based on high-index dielectrics, such as silicon, germanium, germanium telluride and germanium antimony telluride. High refractive index allows us to introduce materials with higher nonlinear response, although low refractive index contrast leads to increase of modal area. Additionally, high-index materials provide efficient coupling to dielectric waveguides with good mode confinement. We also propose fabrication method for "two-ridges-one-slab" nonlinear coupler, based on common deposition and litography technology. We use coupled mode theory based on Generalized Nonlinear Schrodinger Equation [6] to evaluate coupler performance. While nonlinear figure-of-merit remains relatively low ($F=\gamma*L_{prop} \sim 0.2\ W^{-1}$) due to two-photon absorption, we report significantly smaller coupling distances (down to several micrometers), which allows to minimize the coupler. Our simulations show that influence of both conductor nonlinear response and nonlinear coupling processes is negligible in hybrid plasmonic waveguides.

Structuring Light with 4D Metamaterials Nader Engheta; University of Pennsylvania, United States

In this talk, I will present some of our most recent results in one of our ongoing research projects in my group, namely, how to manipulate and tailor light using four-dimensional (4D) metamaterials, i.e., structures with judiciously chosen spatial and/or spatiotemporal inhomogeneities, in order to provide exciting functionalities. Several topics, including metamaterial computing machines, “time-vs-space scattering”, temporal anisotropy, spatiotemporal control of diffusion, and temporal cladding will be presented. Connection of these concepts with the photonic networks such as the Mach-Zehnder interferometers will also be given, and possible merging of these platforms will be mentioned. Potential applications of these results will also be discussed.

11:10 AM EL05.02.02
Optical Phonon Frequency Combs Dominik M. Juraschek[1], Adarsh V. Ganesan[2] and Prineha Narang[1]; [1]Harvard University, United States; [2]National Institute of Standards and Technology, United States

The generation of optical frequency combs has fundamentally advanced optical metrology and high precision measurements. Recently, frequency combs of acoustic phonons have been demonstrated in nonlinearly driven micromechanical resonators [1]. We take the theory underlying this comb generation to the atomic scale and investigate the possibility of optical phonon frequency combs [2]. Ultrashort laser pulses can be used to coherently excite infrared-active phonons, leading to atomic vibrations with large amplitudes. Nonlinear couplings between different phonons then arise from anharmonicities in the interatomic potential of the crystal lattice, which can be used for comb generation. A particularly challenging factor plays hereby the short lifetime of optical phonons, often on the order of several picoseconds. Using a combination of first-principles calculations and phenomenological modeling, we determine the atomistic parameters of materials that are required for a clear discrete spacing of frequency lines in the comb spectrum of the optical phonons. We propose a set of promising material candidates for displaying optical phonon frequency combs that would set a milestone in nonlinear phononic control of material properties.

11:25 AM EL05.02.04
Designer Tamm Plasmon Thermal Emitters Using Gradient Descent Regression Optimization Mingze He[1], Joshua R. Nolen[1], Josh Nordlander[2], Angela Cleri[2], Jon-Paul Maria[2] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]The Pennsylvania State University, United States

The mid-infrared (MIR) spectral range is often referred to as the molecular fingerprint region due to the multitude of molecular vibrational signatures it contains. As such, research focused on developing MIR optical sources of sufficiently narrow bandwidth, minimal power demands and small form factors are of great interest for potential spectroscopic and sensing applications such as bio- and chemical sensing, as well as the detection of harmful gases. One approach for such applications that has garnered significant attention recently has been frequency-selective thermal emitters. Here, by judiciously selecting and/or structuring semiconductor materials, the thermal photonic density of states can be tailored such that frequency-dependent far-field impedance matching, and therefore absorptivity, is achieved. Reciprocally, through Kirchhoff's law, this results in an emissivity of equivalent direction and magnitude. Here we report on a powerful approach towards realizing narrowband thermal emitters with a high degree of frequency selectivity, without sacrificing narrow emission linewidths that is typically an issue with plasmonic-based emitters, through the inverse design of aperiodic Tamm plasmon (TP) devices.

TPs are optical interface states that form between a distributed Bragg reflector (DBR) and a metal or between two dissimilar DBRs. These excitations exhibit a parabolic dispersion that falls within the photonic bandgap of the DBR and the air light cone and are therefore accessible from free space without the need for expensive and time-consuming lithographic and etching fabrication steps. Here, we employ a gradient descent regression (GDR) algorithm to design TP-supporting films in the metal-DBR geometry and grow films that reproduce the predicted spectral features of our designs with great success. We utilize n-CdO deposited through high-power impulse magnetron sputtering as our metal layer. This highly-promising transparent conducting oxide (TCO) has been demonstrated to exhibit broad spectral tunability of the plasma frequency, while maintaining exceptionally low optical losses. This is due to CdO possessing both a low effective mass (ranging from 0.12 – 0.26 in epitaxially-grown films with carrier densities ranging from 10^{19}-10^{20} cm^{-3}) as well as electron mobilities extending upwards to 500 cm^2/V-s. As TP modes correspond with the impedance-matched condition of the

DBR and the metal film, having such control over the impedance of both the DBR (through changes to individual layer thicknesses and dielectric index), and the CdO layer (through changes to the carrier density and layer thickness), grants significant flexibility to our design.

Inverse design has been used to design TP-supporting films in the past, however, these efforts have relied on computationally-expensive techniques, such as genetic algorithms, Bayesian optimization or deep learning, often requiring several hours or days to reach a final solution for a single-peak emission spectrum. In contrast, our GDR approach is capable of arriving at a solution on the timescale of seconds or minutes, all while running on a consumer-grade CPU. As we demonstrate, this opens the door to realizing thermal emitters with varying levels of spectral complexity. For example, realizing arbitrarily positioned single- and multi-peak thermal emission spectra, which can accurately match to the IR absorption spectra of greenhouse gases such as CO_2 and N_2O. We are also able to achieve quality-factors that far-exceed conventional plasmonic devices ($Q > 300$ for designed films), and control the full TP-dispersion and therefore spatial coherence of the thermal emission, all while maintaining a simple, planar structure. Therefore, the design principles used here outline a highly-tunable and potentially scalable platform for realizing applications such as filter-less non-dispersive infrared gas sensing and free-space communications.

11:40 AM *EL05.02.05
Engineering Light Emission for Frequency-Conversion Imaging and Quantum Technologies Mikhail Kats; University of Wisconsin-Madison, United States

This talk will discuss two recent developments related to engineering light emission. First, I will demonstrate a passive down-conversion imaging system that converts broadband ultraviolet light to narrow-band green light using perovskide nanocrystals, while preserving the directionality of rays, and thus enabling direct down-conversion imaging. The system preserves high transparency in the visible, enabling superimposed visible and ultraviolet imaging.

Then, I will discuss our design of a nanoscale light extractor (NLE) that enables efficient outcoupling and beaming of broadband light emitted by nitrogen-vacancy centers in diamond. The NLE consists of a patterned silicon layer on diamond and requires no etching of the diamond surface. Our design process is based on adjoint optimization using broadband time-domain simulations and yields structures that are inherently robust to positioning and fabrication errors.

Artificial-Intelligence Assisted Photonics Zhaxylyk Kudyshev, Alexander Kildishev, Vladimir Shalaev and Alexandra Boltasseva; Purdue University, United States

Discovering novel, unconventional optical designs in combination with advanced machine-learning assisted data analysis techniques can uniquely enable new phenomena and breakthrough advances in many areas including on-chip circuitry, imaging, sensing, energy, and quantum information technology. *Topology optimization,* which has previously revolutionized aerospace and mechanical engineering by providing non-intuitive solutions to highly constrained material distribution problems, has recently emerged as a powerful architect for *advanced photonic design*[1]. Compared to other *inverse-design* approaches that require extreme computation power to undertake a *comprehensive search* within a large *parameter space*, topology optimization

can expand the design space while improving the computational efficiency. This talk will highlight our most recent findings on 1) merging topology optimization with *artificial-intelligence-assisted algorithms* and 2) integrating *machine-learning based analysis* with *photonic design* and *quantum optical measurements*. Particularly, we will discuss our studies on implementing deep-learning assisted topology optimization for advanced metasurface design development[2-4]. Specifically, we will cover different generative network-based optimization strategies, covering local and global optimization frameworks. We will summarize our research on merging topology optimization technique with quantum device design for achieving ultrafast single-photon source that offers efficient on-chip integration. Finally, we will also describe our recent works on implementing a novel convolutional neural network-based technique for real-time material defect metrology at the quantum level that outperforms all existing approaches in terms of speed and fidelity. This new method rapidly extracts the values of the single-photon autocorrelation function at zero delays from sparse data and ensures one order speed up on solving "bad"/"good" emitter classification problems in comparison with conventional techniques[5]. Along with emitter classification, we will cover the ML-based regression schemes, which open up a way for the realization of rapid antibunching-induced super-resolution imaging applications.

High Refractive Index Nanopillar Metasurface for Control of Coherent Light States Vahid Karimi and Viktoriia Babicheva; The University of New Mexico, United States

Metasurfaces of high-refractive-index materials, such as silicon, III-V compounds, and similar material groups, enable manipulation of light on a subwavelength scale and support well-defined Mie resonances. These ultra-thin optical nanostructures of high-refractive-index materials can be used at the subwavelength scale for amplitude and phase modulation. Hence, the metasurface supporting Mie resonances has a high potential in effective control of coherent light states. The integration of light-emitting devices, such as VCSELs and VeCSELs, and high-refractive-index metasurfaces is proven to be an efficient method for addressing light-emitting beam-shaping problems.

The monolithic integration approach is a new direction and offers many opportunities in designing beam-shaping VCSELs. The III-V compound nanopillar meta-atoms can be used in polarization-insensitive metasurface at the back-side surface of a bare VCSEL [1]. In this design, each nanopillar functions as an independent resonator with a low-quality factor. The large refractive index of the metasurface elements enables the large transmitted amplitude. Instead of modifying the laser cavity, the integrated III-V compound metasurface acts as a passive element that forms the laser beam profile on the emission surface.

We aim at designing metasurface with the desired phase modulation, and we study properties of III-V compound nanopillars of various dimensions. We study periodic nanopillar arrays on either high-index or low-index substrate with an intermediate layer in the visible and near-infrared frequencies [2]. Arrays of various

periodicity, with different heights and radii of nanopillars, as well as thicknesses of the intermediate layer are analyzed. Numerical simulations of III-V compound metasurfaces are carried out for arrays of different arrangements for reflection, transmission, and absorption spectral profiles.

The metasurface supports Mie type and other nanostructure resonances, and with an increase of intermediate layer thickness, the spectral positions of the nanostructure resonances move towards longer wavelengths. We report on the metasurface scattering characteristics to modulate the arbitrary beam shapes employing a phase-matching technique in the least-squares sense. We show the possibility of engineering the VCSEL's output beam shape by introducing nanopillars of specific arrangement and adding the intermediate high-index layer.

Engineering New Solid State Quantum Defects for Quantum Networks Nathalie P. de Leon; Princeton University, United States

Engineering coherent systems is a central goal of quantum science and quantum information processing. Point defects in diamond known as color centers are a promising physical platform. As atom-like systems, they can exhibit excellent spin coherence and can be manipulated with light. As solid-state defects, they can be produced at high densities and incorporated into scalable devices. Diamond is a uniquely excellent host: it has a large band gap, can be synthesized with sub-ppb impurity concentrations, and can be isotopically purified to eliminate magnetic noise from nuclear spins. Currently-known color centers either exhibit long spin coherence times or efficient, coherent optical transitions, but not both. We have developed new methods to control the diamond Fermi level in order to stabilize a new color center, the neutral charge state of the silicon vacancy (SiV) center. This center exhibits both the excellent optical properties of the negatively charged SiV center and the long spin coherence times of the NV center, making it a promising candidate for applications as a single atom quantum memory for long distance quantum communication. We have recently discovered bound exciton transitions associated with SiV^0, which enable efficient optical spin polarization and optically detected magnetic resonance. Finally, I will describe our efforts to integrate SiV^0 centers in nanophotonic devices, specifically in heterogeneously integrated III-V/diamond nanophotonic platforms designed to enhance the atom-photon interaction and achieve quantum frequency conversion to the telecom band.

Late News: Tunable Cavity-Controlled Field Enhancement in Self-Assembled Plasmonic Metasurfaces
Timothy J. Palinski[1], Amogha Tadimety[2], Gary W. Hunter[1] and John X. Zhang[2]; [1]NASA Glenn Research Center, United States; [2]Dartmouth College, United States

Locally enhanced electric fields in nanoplasmonic systems play an important role in a range of sensing and detection applications, including surface enhanced spectroscopies, fluorescence measurements, and refractive index-based biosensing. As these technologies move increasingly towards point-of-care applications, it is critical that sensor substrates maintain high-performance while being low profile, inexpensive, and easily fabricated. Here, we demonstrate tunable field enhancement in a self-assembled plasmonic metasurface via coupling to a stimuli-responsive photonic cavity. Our structure consists of a near-percolation plasmonic gold film on a polymer spacer above a gold mirror, creating a Fabry–Perot nanocavity. Simulations of the as-fabricated nanostructures reveal that the strongest field enhancement occurs when the cavity mode overlaps with the plasmonic top film, resulting in nearly perfect light absorption/trapping by the system. Compared to the nanoislands alone, the cavity-coupled system yields a ~4x increase in field enhancement. The random size and distribution of the plasmonic nanoislands contribute to its strong, broadband absorption >95% and corresponding field enhancement over 400-nm bandwidths. By varying the cavity thickness, the cavity mode overlap and resulting absorption-based field enhancement can be tuned to a spectral range of interest. Using a vapor-responsive polymer spacer, we demonstrate real-time, reversible tuning of these absorption bands across >100-nm ranges in wavelength in the presence of organic solvents. This structure was readily fabricated using standard wafer-scale thin-film deposition processes. The plasmonic top film can also be formed using other bottom-up techniques, including dispersion or printing of colloidal nanoparticles and seed-mediated particle growth, extending the range of potential applications and further simplifying the fabrication process. This platform forms the basis for a simple, dynamically tunable substrate which may be applied in a variety of sensing contexts, with potential application to other absorption-based processes such as energy harvesting and photodetection.

4:55 PM EL05.04.03
Late News: High Quality Factor Metasurfaces for Dynamic, Electro-Optically Controlled Wavefront Shaping
Sahil Dagli[1], Elissa Klopfer[1], David Barton[2], Mark Lawrence[3] and Jennifer Dionne[1]; [1]Stanford University, United States; [2]Harvard University, United States; [3]Washington University in St. Louis, United States

Wavefront shaping and control is essential for advancements in optical technologies including LiDAR, AR/VR, and LiFi systems. Metasurfaces offer a promising route for these technologies, as they allow for precise control of the amplitude, phase, and polarization of light in a sub-wavelength-thick footprint. However, most current metasurface designs are static, relying on fixed geometric patterning and lacking tunability once fabricated. Here, we design high quality factor (high-Q) metasurfaces that enable electro-optically tunable beam-steering through dynamic phase and amplitude control of the constituent nanoantennas. Our metasurface consists of a uniform array of subwavelength nanobars of Silicon, each 500 nm wide and 220 nm tall, atop 100 nm thick lithium niobate. By introducing subtle geometric perturbations into each constituent nanobar, we excite guided mode resonances with normally-incident light. Using full-field simulations, we show how these guided mode resonances excite strongly enhanced fields localized in the lithium niobate, with mode quality factors exceeding 20,000. Applying a voltage across individual nanoantennas shifts the spectral position of the high-Q resonance, modifying the antenna phase and amplitude. In reflection, we achieve a full 2 pi phase variation with applied bias, with a reflectance efficiency above 93%. Using these results, we computationally design a fully-reconfigurable, solid-state beam steerer: without bias light is directly reflected from the metasurface, whereas an applied biases of +9.2 V, 0 V, and -9.2 V across three constituent antennas diffracts the light to 30 degrees with 65% efficiency. Biases of 13 V, 2 V, -2 V, and -13 V across four constituent antennas diffracts the reflected light to 22 degrees. Near-continuous beam-steering can be achieved by modifying the bias across each antenna.

We also show how this platform can enable dynamic modulation of other optical transfer functions, including beam-splitting and lensing. Our high-Q electro-optic metasurfaces provide a foundation for light-weight, fully reconfigurable, solid-state classical and quantum information processing spanning LiDAR, LiFi, AR/VR, and quantum communications.

5:10 PM EL05.04.04
Beamforming Tradeoffs in Quasi-Static and Time-Modulated Optical Phased Arrays Raana Sabri, Mohammad Mahdi Salary and Hossein Mosallaei; Northeastern University, United States

Realization of dynamic beam steering for free-space data communication and light detection and ranging (LiDAR) technology, demands a class of high-performance devices with capability of generating fast-scanning and low-divergence beams. Optical phased arrays (OPAs), consisting of several typically identical optical nanoantennas, hold a great promise for achieving real-time beam steering, by imparting local, space-variant phase gradients on the incident light. Integration of dynamically tunable electro-optical materials into the constituent building blocks of OPAs facilitates active control over the intrinsic properties of subwavelength antenna elements with high speed and offers post-fabrication modifications to their optical response. The phase tuning mechanism of the active OPAs has thus far relied on the modulation of the resonant modes between the over-coupled and under-coupled regimes by applying external DC bias voltages to nanoantennas. This leads to high variations of amplitude during phase modulation and restricts the maximum achievable phase span into a narrowband critical coupling regime. Moreover, the phase modulations in such so-called quasi-static OPAs is typically less than 2π. Introducing time into OPAs, as an additional dimensionality, offers a way out to surmount these obstacles through generation of sideband signals and translating the spatial diversity of scattering into the spectral diversity. In this work, a comparative study on active beam steering performance of quasi-static and time-modulated reflective OPAs operating at near-infrared (NIR) spectral regime is presented. Plasmonic strip nanoantenna in a metal-insulator-metal (MIM) configuration integrated with indium-tin-oxide (ITO) is considered as the building block of the active OPA. First, the beamforming performance of the quasi-static OPA is analytically studied to highlight its main shortcomings including narrow bandwidth, limited angle-of-view, and large sidelobe level (SLL) as results of strong resonant dispersion of phase, limited dynamic phase span, and dramatic variations in amplitude. Moreover, a multiobjective evolutionary optimization is adopted to identify the non-intuitive beamforming tradeoffs between SLL and gain in the quasi-static OPA due to covarying amplitude and phase responses. Then, beam steering performance of a time-modulated OPA under the application of radio frequency biasing signals is investigated. Modulation waveform is optimized to achieve beam steering with uniform amplitude via non-resonant and dispersionless phase shift induced by modulation phase delay at the first order sideband. This dispersionless phase elevates time-modulated OPAs beyond their quasi-static counterparts in that it increases the functionality bandwidth, expands the angle-of-view, and minimizes the power coupled into undesired sidelobes by providing access to the full phase span (2π) with uniform amplitude. In addition, Taylor one-parameter distribution is employed to implement amplitude tapering for engineering of the beamforming tradeoffs between SLL and gain.

On-Demand Beam Shaping Using a Reconfigurable Metasurface Hanwei Wang, Hsuan-Kai Huang, Yun-Sheng Chen and Yang Zhao; University of Illinois at Urbana-Champaign, United States

In magnetic resonance imaging (MRI), the signal-to-noise ratio (SNR) is the main figure of merit that assesses the imaging quality. Existing studies mainly focus on improving the magnetic field intensities of the constant homogenous field from the main coil or the oscillating field from the radio frequency (RF) coil. In addition to these options, SNR also depends on the coupling between the imaging subject and the RF coil during the signal reception, which has been largely ignored. Here we provide a different route towards enhancing the SNR of MRI by improving this coupling during the signal reception. We elucidate a theoretical design of an ultrathin metasurface with micrometer thickness and high flexibility. This metasurface is reconfigurable; it can selectively boost the SNR at a desired imaging region with any arbitrary shapes. Our design has shown that this metasurface can enhance SNR by up to 28 times in the

region of interest. At the same time, the metasurface is designed to minimally disturb the excitation fields by less than 1.6%, thus maintaining the uniformity of the excitation, which is important to achieve a high-quality MR image without artifacts.

Extreme Color Tuning of Dynamic Metasurface via Electrochemical Intercalation of Lithium in TiO_2
Janna Eaves-Rathert[1], Elena Kovalik[1,1], Chibuzor Ugwu[1], Cary Pint[2,1] and Jason Valentine[1]; [1]Vanderbilt University, United States; [2]Iowa State University of Science and Technology, United States

Faced with the ability to arbitrarily engineer the interaction of electromagnetic energy with a medium, the optics community is enchanted by the innumerable, though fixed, configurations of passive metamaterials. Looking forward, infusing such structures with dynamic tunability may help realize both practical applications and novel functionality. While many phase change materials are capable of wild property modulations induced by heat, electrochemical intercalation presents opportunities for complete rearrangement of atomic structure and composition in a reversible manner, resulting in potentially dramatic permittivity changes. In the age of the lithium ion battery, rapid materials innovation and research has uncovered numerous compounds which accommodate lithium, though the resulting changes in optical properties lack clarity. We explore the properties of titanium dioxide (TiO_2), which is both a high-index dielectric material with negligible absorption in the visible spectrum, making it popular for all-dielectric metasurfaces, as well as an established lithium anode material known for minimal volume expansion (<1%) and good cyclability. Upon lithiation to $Li_{0.5}TiO_2$, DFT calculations predict significant changes in dielectric constants in the visible and near-IR regions of the electromagnetic spectrum. These calculations are verified by air-free ellipsometry measurements on TiO_2 thin films deposited via atomic layer deposition and electrochemically lithiated, thereby reducing the refractive index by $\Delta n = 0.5$ at ~650 nm. When incorporated into metal-insulator-metal type metasurfaces, the resulting devices demonstrate sweeping spectral shifts across the visible regime with applied voltages < 2 V. Through unraveling the optical properties of this abundant, non-toxic battery material, our findings open the door to low-power, multistable, active metasurfaces for color modulation and tunable filters.

Strain-Tunable Resonators Based on an Integration of Bragg Reflectors and Metasurfaces Sravya

Nuguri[1], Benjamin Cerjan[2], Vince Einck[1], Mark Griep[3], Naomi Halas[2] and James Watkins[1]; [1]University of Massachusetts Amherst, United States; [2]Rice University, United States; [3]U.S. Army Research Office, United States

Bragg reflectors from layer by layer (LBL) assembly of Slide Ring elastomer and Zirconia Nanoparticles have been shown to offer desirable elasticity and strain tun-able optical properties. With a high loading of zirconia nanoparticles of nearly 80 wt% in the photonic crystal results in a refractive index contrast of 0.18 between the filled and unfilled layers of 6 periods. Further, we study an integration of Au meta-surfaces by utilising soft-imprinting lithography of 400 nm spaced rectangular pillars and other modulated nanofeatures on the Bragg Reflectors and harness the enhanced tuning ability. The nanoimprinting ink is composed of a bi-layer polymer resist, among which only the top layer renders lower viscosity that fills the stamp via capillary pressure. The resulting patterns are metallised with 50 nm of Au using e-beam evaporating technique and followed by transferring the metal features on the Bragg reflectors. By stretching the resulting photonic crystal over 40% strain we demonstrate the mechano-chromic sensing abilities in a span of wavelengths.

Self-Assembled $BaTiO_3$-Au_xAg_{1-x} Low-Loss Hybrid Plasmonic Metamaterials with Ordered "nano-Domino-Like" Microstructure Di Zhang[1], Shikhar Misra[1], Jie Jian[1], Ping Lu[2], Leigang Li[1], Ashley Wissel[1], Xinghang Zhang[1] and Haiyan Wang[1]; [1]Purdue University, United States; [2]Sandia National Laboratories, United States

Metallic plasmonic hybrid nanostructures have attracted enormous research interests due to the combined physical properties coming from different material components and the broad range of applications in nanophotonic and electronic devices. However, the high loss and narrow range of property tunability of the metallic hybrid materials has limited their practical applications. Here, a metallic alloy-based self-assembled plasmonic hybrid nanostructure, $BaTiO_3$-Au_xAg_{1-x} vertically aligned nanocomposite, has been integrated by a templated growth method for low-loss plasmonic systems. Comprehensive microstructural characterizations including (HR)STEM, EDS and 3D electron tomography demonstrate the formation of an ordered "nano-domino-like" morphology with the $Au_{0.4}Ag_{0.6}$ nanopillars as the round cores, and the BTO as the squared shells. By comparing with the BTO-Au hybrid thin film, the BTO-$Au_{0.4}Ag_{0.6}$ alloyed film exhibits much broader plasmon resonance, hyperbolic dispersion, low-loss, and thermally robust features in UV-Vis-NIR wavelength region. This study provides a feasible platform for complex alloyed plasmonic hybrid material design with low-loss and highly tunable optical properties towards all optical integrated devices.

Multifunctional Metasurface and Its Applications Byoungho Lee, Chusoo Choi, Jangwoon Sung and Gun-Yeal Lee; Seoul National University, Korea (the Republic of)

Metasurfaces are planar optics composed of artificially fabricated subwavelength meta-atoms with unique optical scattering characteristics. Thanks to their outstanding abilities to modulate electromagnetic waves, metasurfaces have been enthusiastically researched. The research on metasurfaces especially focuses on wavefront modulation and many approaches have been proposed to implement novel optical devices with versatile functionality. It has been demonstrated that metasurfaces can implement high-quality holographic light reconstruction with both amplitude and phase information at sub-wavelength scale spatial resolution, which is

expected to be applied to next-generation imaging technologies such as three-dimensional holographic imaging and optical data storage. In addition, metasurface lenses, called meta-lenses, have powerful features such as flatness, high numerical aperture, and versatility that cannot be found in conventional optical lenses. Based on these meta-optics, recent advances in metasurfaces have led to the development of various optical systems, and several studies have begun to be reported in recent years. In this talk, we will introduce our representative works that achieve significant progress of optical systems through utilizing elaborately designed multifunctional metasurfaces. The first part will introduce the passive and active type metasurfaces exhibiting enlarged light modulation capabilities with their practical applications. The passive type metasurface is designed to exhibit different scattering characteristics for two orthogonal polarizations of incidence light with their full-space controllability. Through exploiting multifunctionlaity, the polarizing beam-splitter and full-space holographic image generation are demonstrated. And, the active type metasurface is engineered to exhibit enlarged switching levels through exploiting optical-thermal analysis. To utilize the expanded switching level at best, the metasurface is designed to generate high-contrast holographic images according to the state change of metasurface. Thanks to the thermo-optical complexity of our active metasurface, the visual cryptosystem is demonstrated, providing an extremely high-security level. In the second part, we will introduce the novel concept of metalens, called see-through metalens for augmented reality (AR) device application. The see-through meta-lens effectively combines the real and virtual images in a compact manner thanks to the flatness and high-numerical-aperture of the proposed metalens. The proposed geometric-phase metalens can distinguish the two lights – light from outside object and one from an image projector based on polarization orthogonality. Especially, our study is highlighted for dramatically improving the field-of-view compared to previous AR imaging devices. Lastly, our perspective on the possibilities and challenges of metasurface hologram, metasurface multifunctional diffraction devices and metalens will be discussed.

Dynamic Meta-Holograms with Designer Liquid Crystals for Interactive Displays and Unconventional Photonic Sensors Inki Kim, Won-Sik Kim, Young-Ki Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Computer-generated holography (CHG) involves iterative numerical algorithms to obtain the phase and/or amplitude profiles needed to physically realize holograms. Metasurfaces consist of arrays of subwavelength nanoresonators that can control the wavefront of light in a desired way. They recently proved themselves to be an effective platform for CGH by surpassing the quality of traditional holograms in terms of image resolution and field-of-view. Those metasurface holograms showed prospects not only in imaging and display but also in security applications [1]. In particular, applying metaholograms to anticounterfeiting applications requires not only the technology of encoding multiple pieces of information, but also the manufacturability of highly efficient devices. To meet these complex needs, we have implemented high-efficiency metaholograms based on hydrogenated amorphous silicon (a-Si:H), which realize pragmatic images holograms working under unpolarized light (*e.g.* sunlight or flashlight of cellphone) and spin/direction-multiplexed metaholograms [2-4]. However, ‘real-time’ active operations of those flat optical devices have remained unresolved yet.
In this abstract, I will discuss our efforts in realizing dynamic metaholograms by leveraging specifically-designed (‘designer’) liquid crystals that can respond to target external stimuli. First, I will present high-efficiency interactive holographic displays, which can switch holographic images according to external stimuli like voltage, heat and touch sensing [5]. For examples, the voltage-responsive metahologram is able to switch the holographic images within few milliseconds promising for real-time video holographic displays demanding 60 ~ 120 frames/s. Also, the heat or touch-responsive metaholograms can monitor external temperature and impact by visualizing different hologram images according to the pre-programmed external stimuli standart. Such demonstrated systems may permit a diverse range of smart sensing and display applications such as smart hologram labels monitoring temperature/pressure/touch changes and interactive holographic displays recognizing haptic motions. Secondly, I will propose a compact gas sensor platform to autonomously sense the existence of a toxic volatile gas and provide an immediate visual holographic alarm [6]. By combining the

advantage of the rapid responses to gases realized by liquid crystals with the compactness of holographic metasurfaces, we develop ultra-compact gas sensors without the requirement of additional complex instruments or machinery to report the visual information of gas detection. It is expected that such a holographic metasurface gas sensor platform will provide a path to ubiquitous, compact, and smart unconventional photonic sensing applications that quickly alert users about harmful gases or biochemical leaks.

Collective Excitations and Optical Response of Ultrathin Carbon Nanotube Arrays Igor Bondarev and Chandra Adhikari; North Carolina Central University, United States

We develop a theory for collective near-field interactions and associated ElectroMagnetic (EM) response of planar, closely packed, periodically aligned Single-Wall Carbon Nanotube (SWCN) arrays embedded in finite-thickness ultrathin dielectric layers. The features that make this system interesting are the periodic CN alignment and the spatially periodic anisotropy associated with it. Additionally, the vertical confinement in dense ultrathin planar systems of finite thickness leads to the effective dimensionality reduction from 3D to 2D while still retaining the thickness as a parameter to represent the vertical size. This is the transdimensional regime [1] — neither 3D nor 2D but something in-between — turning into 2D as the thickness tends to zero, challenging to study what the 3D-to-2D continuous transition has to offer for new material functionalities [2-4]. The spatial anisotropy, periodic in-plane transverse inhomogeneity and vertical quantum confinement make the ultrathin array near-fields strong and anisotropically nonlocal, adding both extra challenges in developing the problem theoretically [3] and extra flexibility in designing CN films with desired EM properties experimentally [5]. Here, we derive the SWCN array EM response tensor in terms of the individual SWCN conductivity, plasma frequency and the volume fraction of CNs in the dielectric film. In the CN alignment direction the real part of the EM response has a sufficiently wide negative refraction band, indicating that the CN film behaves as a hyperbolic metamaterial [4]. Inhomogeneous and thermal broadening of the exciton and plasmon resonances lead to their overlap, making the exciton-plasmon hybridization possible. Being very stable and highly sensitive to the vertical size/CN-density/diameter/chirality variations, the ultrathin periodically aligned SWCN arrays and films show great potential to serve as a new flexible multifunctional nanomaterial platform for single-molecule detection and manipulation, including the near-field control of photoluminescence rate/directionality, chemical reactivity, and Casimir-Polder interactions [6,7].

Linear and Nonlinear Plasmonic Properties of Metallic Particle-on-Film Nanocavities Dangyuan Lei; City University of Hong Kong, Hong Kong

Plasmonic nanocavities, consisting of metallic nanoparticles closely separated from a thin metal film by nanometric dielectric gaps, support hybridized plasmon modes with extremely small mode volumes and strongly enhanced local fields. They constitute a versatile nanophotonic platform for exploring many exotic light-matter interaction phenomena at the nanoscale, such as plasmon-enhanced nonlinear optics and quantum plasmonics.

This talk will review our recent studies on the linear and nonlinear plasmonic properties of metallic particle-on-film nanocavities (PoFNs), including plasmon resonance hybridization and decomposition [1-3], plasmon-enhanced polarized photoluminescence [4], and light-induced symmetry breaking for enhancing second-harmonic generation (SHG) [5]. I will present a new polarization-resolved spectral decomposition and color decoding approach for understanding the rich scattering radiation properties of two types of gold PoFNs. Our results reveal an unusual plasmon resonance in a gold nanosphere dimer-on-film nanocavity (absent in a nanosphere monomer counterpart), having strong radiation yet a large quality factor, which turns out to arise from the metal substrate-mediated dipole-quadrupole hybridization. Following this, I will show this strong yet narrow hybrid resonance gives rise to highly polarized photoluminescence emission from gold, with a 200-fold intensity enhancement and 5-fold linewidth reduction compared to a dimer of similar size on silica.

Finally, I will discuss a new mechanism for SHG enhancement in such plasmonic PoFNs, that is, the light-induced electromagnetic asymmetry. Our results show that such symmetry breaking efficiently suppresses the cancelling of locally generated SH fields and is further amplified in the SHG-induced plasmonic excitation through preferential coupling to the bright, bonding dipolar resonance mode of the nanocavity, leading to a record high far-field SHG efficiency of up to 3.56×10^{-7} W^{-1} in plasmonic nanostructures.

Vectorial Holography and Polarization-Maintaining Metasurfaces Qinghua Song[1], Arthur Baroni[2], Samira Khadir[1], Stéphane Vézian[1], Benjamin Damilano[1], Philippe de Mierry[1], Sébastien Chenot[1], Virginie Brandli[1], Patrick Ferrand[2] and Patrice Genevet[2]; [1]Université Cote d'Azur, CNRS, CRHEA, France; [2]Aix Marseille Univ, CNRS, Centrale Marseille, Institut Fresnel, France

In this presentation, we will review our recent results on the realization of vectorial holograms. We will also introduce a specific computational imaging technique, dubbed Ptychography, to reconstruct the Jones matrix map of the metasurfaces at microscopic resolution, including all amplitude, phase and polarization effects. We also report on the realization of broadband polarization maintaining metasurfaces.

In this contribution, we will present **a general method that enables wavefront shaping with arbitrary output polarization** by encoding both phase and polarization information into pixelated metasurfaces[1]. We apply this concept to convert an input plane wave with linear polarization to a holographic image with arbitrary spatial output polarization. Our approach relies on pixelated metasurfaces, in which each pixel acts as a deflector able to encode both the polarization and the holographic phase information, resulting in a holographic image in a specific angle with arbitrary polarization.

Vectorial ptychography technique is introduced for mapping the Jones matrix to monitor the reconstructed metasurface output field and to compute the full polarization properties of the vectorial far field patterns, confirming that pixelated interfaces can deflect vectorial images to desired directions for accurate targeting and wavefront shaping.

Exploring further this concept of polarization addressing metasurface, we propose a general method for polarization-maintaining and angular nondispersive wavefront shaping with, essentially, unlimited bandwidth[2]. Our results show that we can eliminate the chromatic dispersion of material by properly designing the geometry of the meta-structures, resulting in perfect nondispersive optical properties. As a proof of concept we realize white-light broadband image projection, in which we control both the polarization and the projection angle over an unlimited spectral range.

Our work solves the problem of polarization mode dispersion and demonstrates that classical Pantcharatnam broadband metasurfaces, such as those published recently by several groups and that address broadband angular dispersion relying exclusively on the nanostructure dispersive properties, are unable to control the polarization over broadband frequency range. To really prove the performance of our approach, we have adopted a metasurface doublet configuration to address both angular and polarization dispersion, thus demonstrating the first broadband polarization-maintaining and dispersive-less metasurface.

Our experimental results prove that metasurfaces, designed and realized using precise nanofabrication methods could efficiently tailor the wavefront and control the polarization in the entire visible range, promising various applications in polarization imaging, augmented/virtual reality displays, full color display and broadband-polarimetry.

The Plasmonic Phase-Change Material In_3SbTe_2 as a Programmable Nanophotonics Material Platform for the Infrared Andreas F. Hessler[1], Sophia Wahl[1], Till Leuteritz[2], Antonios Anotonopoulos[1], Christina Stergianou[1], Carl-Friedrich Schön[1], Lukas Naumann[2], Niklas Eicker[1], Martin Lewin[1], Tobias Maß[1], Matthias Wuttig[1], Stefan Linden[2] and Thomas Taubner[1]; [1]RWTH Aachen University, Germany; [2]University of Bonn, Germany

The high dielectric optical contrast between the amorphous and crystalline structural phases of non-volatile phase-change materials (PCMs) provides a promising route towards tuneable nanophotonic devices [1-3]. Here [4], we employ the next-generation PCM In_3SbTe_2 (IST) whose optical properties change from dielectric to metallic upon crystallization in the whole infrared spectral range. This distinguishes IST as a switchable infrared plasmonic PCM and enables a new programmable nanophotonics material platform. We show how resonant metallic nanostructures can be directly written, modified and erased on and below the meta-atom level in an IST thin film by a pulsed switching laser, facilitating direct laser writing lithography without need for cumbersome multi-step nanofabrication. With this new technology, we demonstrate large resonance shifts of nanoantennas of more than 4 μm, a tuneable mid-infrared absorber with nearly 90% absorptance as well as screening and nanoscale "soldering" of metallic nanoantennas. Our novel concepts will empower new and improved designs of programmable nanophotonic devices for telecommunications, (bio)sensing and infrared optics, e.g. programmable infrared detectors, emitters and reconfigurable holograms.

Exciton-Enhanced Light Scattering in Atomically-Thin Metasurfaces Ludovica Guarneri[1], Qitong Li[2], Jung-Hwan Song[2], Mark L. Brongersma[2] and Jorik Van de Groep[1]; [1]University of Amsterdam, Netherlands; [2]Stanford University, United States

Nanophotonic metasurfaces employ dense arrays of optically-resonant nanostructures to manipulate the properties of light in nm-thick optical coatings. By harnessing plasmonic or Mie resonances in metallic or dielectric nanoparticles, the phase and amplitude of the scattered light can be controlled at the nanoscale. Based on rapid advances in metasurface design, metasurfaces are now widely applied in flat optical elements for beam steering, lensing, and holography. However, novel applications in dynamic holography and augmented reality require metasurfaces and metadevices with actively-tunable functionality. So far, the use of plasmonic and Mie-resonances in dynamic metasurfaces is limited as their optical resonances are difficult to tune dynamically.

Monolayer transition metal dichalcogenides like WS_2 exhibit strong exciton resonances in the visible spectral range that dominate their optical response. The excitonic light-matter interaction in these 2D quantum materials is inherently very strong and highly tunable, which can be leveraged to realize mutable flat optical elements. To unleash the full potential exciton-enhanced light scattering in atomically-thin metasurface elements, it is essential to first achieve detailed understanding of the role of the exciton's quantum mechanical properties in passive nanophotonic wavefront shaping.

Here, we employ atomically-thin metasurface lenses carved out of a monolayer of WS_2 to directly study the influence of exciton decay and dephasing on the metasurface functionality and spectral line shape. We fabricate 500 μm diameter zone plate lenses using electron-beam lithography and reactive-ion etching. At resonance, excitonic light scattering strongly enhances the focal intensity. We systematically characterize the focal shape and focusing efficiency as a function of wavelength using confocal microscopy. To study the influence of exciton-phonon scattering and dephasing on the optical functionality of the lens, we then characterize the efficiency spectrum as a function of temperature.

At ambient conditions, the spectrum shows a strong asymmetric line shape revealing that the scattered light fields are directly governed by the monolayer susceptibility. This enables an almost background-free measurement of the optical properties of the monolayer, and thereby the excitonic light-matter interaction.

Careful analysis of the line shape shows that the relative contribution from resonant excitonic light scattering is comparable to the non-resonant monolayer scattering. For decreasing temperatures on the other hand, the exciton's non-radiative decay and dephasing are suppressed and the exciton becomes fully radiative. As a result, the asymmetric line shape not only narrows and increases in amplitude, but also transitions into a symmetric line shape. This directly shows the increasing prevalence of the exciton resonance in the focusing efficiency. By comparing the results to numerical simulations and an analytical model, we show that the efficiency of the metasurface lens directly scales with the excitonic oscillator strength.

The results give direct insight in the role of exciton dynamics in optical wavefront shaping using atomically-thin metasurfaces. A full understanding of the role of exciton resonances in metasurfaces paves the way for dynamic components, combining tunable effects in quantum materials with classical metasurface optics.

Photovoltage Management with Surface Arrays of Subwavelength Silicon Formations Ashish Prajapati, Ankit Chauhan and Gil Shalev; Ben Gurion University of the Negev, Israel

Surface arrangements of subwavelength formations are extensively discussed in the context of photocurrent enhancement for photovoltaic (PV) applications. Recently, the potential contribution of such arrangements toward photovoltage augmentation is suggested. This study numerically demonstrates the potential for photovoltage management based on arrays composed of inverted silicon cones, referred to as light funnel (LF) arrays. The transition from an optimized nanopillar (NP) array into an LF array is examined. It is shown that a decrease in NP bottom diameter (Db) is accompanied by an increase in open-circuit voltage (Voc). The highest photovoltage enhancement is recorded for the smallest considered Db ¼ 50 nm with a Voc increase of 75 mV and reflects a 22% Voc enhancement compared with the NP Voc. It is shown that this Voc increase is due to 250% increase in the excitation level, and that the spatially resolved excitation level of the array-nested LFs is more than two orders of magnitude higher than the highest spatially resolved excitation level in the array-nested NPs. Finally, it is shown that the suggested photovoltage management entails almost a factor of 2 increase in the nominal power conversion efficiency upon the transition from an NP PV cell into LF PV cell.

9:25 AM EL05.07.05
A Re-Configurable Infrared Metasurface Utilizing Acoustoelectric-Induced Charge Aggregation in Graphene Amun Jarzembski[1], Michael Goldflam[1], Thomas Beechem[1,2] and Aleem Siddiqui[1]; [1]Sandia National Laboratories, United States; [2]Center for Integrated Nanotechnologies, United States

Acoustoelectric charge patterning of graphene is leveraged to create dynamically tunable infrared filters having expanded capability by not only modulating the properties of the plasmonic medium but the metasurface itself. While active spectral tuning within a graphene-based platform is well established, plasmon excitement has overwhelmingly been facilitated through a patterned metasurface whose properties derive from the physical shape of the material(s) involved thereby fixing its response at fabrication. The metasurface does not provide any tunability in itself but only excites the tunable plasmon. Here, in contrast, acoustoelectric induced charge aggregation of graphene permits a means to arbitrarily pattern charge distributions that can be modified in real time thus changing both the plasmonic dispersion and where on this dispersion the plasmon is excited.

To show the viability of a reconfigurable graphene metasurface controlled by a surface acoustic wave (SAW), a combined numerical and experimental methodology was employed. The interaction between the acoustic wave and graphene is obtained by solving for the coupling between the displacement field of the SAW and mobile charges at the graphene interface. In doing so, the periodic profile of the SAW-driven fields creates charge stripes in the graphene via the acoustoelectric effect, which in turn spatially modulates the two-dimensional material's optical properties. Numerically solving for the full-field spectral optical response under normal mid-infrared illumination at various acoustoelectric powers reveals a dynamic resonance behavior that tunes in both energy and depth. In particular, the plasmonic response can be switched on or off by simply enabling/disabling the SAW. Through careful consideration of both the optical and acoustoelectric design spaces, a single system

with compelling spectroscopic performance is obtained. Experimentally, charge stripes in graphene resting on top of a periodically poled substrate are observed via Raman imaging that confirms the achievable aggregation as well as the ability to spatially pattern graphene's optical properties. Subsequently, the effect is extended to acoustoelectric devices leveraging the SAW to induce charge aggregation in graphene. Future directions are highlighted, where the interdisciplinary acoustoelectric-optoelectronic interaction can further customize the graphene plasmon coupling mechanism and hence the device's optical response.

Strainoptronics—A New Degree of Freedom for 2D Material Device Engineering Volker Sorger; George Washington University, United States

2D materials have a number of intriguing value propositions that could be harnessed for compact, tunable, high-performance optoelectronic devices when heterogeneously integrated in photonic circuits. Here I review our latest work including; (1) tunable TMD-based microring resonator with engineered critical-coupling condition, (2) a broadband graphene plasmon-slot detector (R=0.7A/W), (3) a bandgap-shifted strain-engineered absorption-enhanced MoTe2 photodetector at 1.55um (R=0.5A/W, low-dark-current <10nA@-1V), (4) a record-high responsivity (R=1.4A/W) slot-plasmon exciton-modulated MoTe2 detector, all enabled by our recently developed method of cross-contamination-free yet deterministic dry transfer 2D material 'printer' mimicking a 3D printer for enabling rapid prototyping. These devices are based on heterogeneous integration of 2D materials into Silicon and SiN photonics, with the latter used for on-exciton modulation or exciton absorption.

Late News: Configurable Phonon Polaritons in Twisted α-MoO3 Mingyuan Chen; Auburn University, United States

Van der Waals materials stacked with a relative twist angle are attracting tremendous interest in physics and have been intensively investigated to tune the electronic, magnetic, and optical properties of materials (known as"twistronics"). However, previous discoveries are based on the formation of peculiar moiré superlattices at small and specific twist angles. Here we report configurable nanoscale light–matter waves—phonon polaritons—by twisting stacked α-phase molybdenum trioxide (α-MoO_3) slabs over a broad range of twist angles from 0° to 90°. Our combined experimental and theoretical results reveal a variety of polariton wavefront geometries and topological transitions as a function of the twist angle, extending twistronics and moiré physics to nanophotonics and polaritonics. The origin of the polariton twisting configuration is attributed to the electromagnetic interaction of highly anisotropic hyperbolic polaritons in stacked α-MoO_3 slabs.

Late News: Hyperbolic Phonon Polaritons in Suspended α-MoO3 Jialiang Shen[1], Zhiren Zheng[2], Thao Dinh[2], Shuai Shao[1], Mingyuan Chen[1], Xiaojie Jiang[1], Nima Shamsaei[1], Qiong Ma[3], Pablo Jarillo-Herrero[2] and

Siyuan Dai[1]; [1]Auburn University, United States; [2]Massachusetts Institute of Technology, United States; [3]Boston College, United States

Polaritons are half-light-half-matter electromagnetic waves confined in materials. These nanoscale light-matter waves offer the access to optical properties and energy at the subwavelength scale. In this work, we studied the effect of environmental permittivity on polaritons in a prototype van der Waals materials of α-MoO_3. Different than majority polariton waves that spread towards all directions, polaritons in α-MoO_3 are highly anisotropic in the basal plane. Our nano-infrared imaging augmented with electromagnetics simulations reveal distinct effects of the sample suspension on the polariton parameters including wavelength, damping and dispersion, at various infrared frequencies. Our results are expected to offer guidance on engineering nano-polaritons propagation properties for desired nanophotonic functionalities.

Silicon waveguides are the most indispensable building block in on-chip photonics. With demand for continuous increases in operational bandwidth, there is a desire to expand the operating frequency regime, as multiplexing of near- and mid-infrared (mid-IR) signals could provide unique applications for both signal processing and chemical sensing. However, this is challenging with integrated silicon photonics, since accommodating longer wavelength modes requires expanding the size of the silicon waveguide, which in turn would cause severe modal dispersion in the near-IR. Thus, an architecture that maintains the silicon waveguide's performance in the near-IR, while still providing confinement and propagation of mid-IR light would be highly beneficial.
Hyperbolic phonon polaritons (HPhPs) can compress long-wavelength free-space light to deeply sub-diffractional volumes and overcome the length-scale mismatch with structures designed for operation in the near-IR. Such HPhPs are supported within highly anisotropic media where the permittivity along orthogonal axes are opposite in sign, with hyperbolicity being demonstrated in an expanding list of natural materials, such as hexagonal boron nitride (hBN). Guiding of HPhPs in hBN has been studied previously using patterned strips and by introducing in-plane polaritonic refraction of HPhPs. However, previous research suffers from either unavoidable material damage of hBN or detrimental substrate absorption in the near-IR, which precludes the waveguide application at dual frequency domains. Thus, an architecture for frequency multiplexing of mid-IR and near-IR is yet to be demonstrated.
Here we address this challenge by realizing guided mid-IR and near-IR light within a hybrid hyperbolic-material/silicon waveguide heterostructure. By exploiting substrate-induced changes in polariton wavelength and thus in-plane polaritonic refraction, we demonstrate that the HPhPs supported by hBN can be confined laterally and guided by the underlying silicon waveguide structure, without the need for fabrication of the hyperbolic medium. Furthermore, we experimentally demonstrate that the hBN slab results in a negligible influence on waveguiding of near-IR light in the underlying Si waveguide. Thus, the prototype hybrid waveguide can operate in both the near- and mid-IR simultaneously. Such integration offers a generalizable approach for multiplexing dramatically different free-space wavelength light within a compact and on-chip footprint, offering a new toolset for nanophotonic design that maintains the low-loss properties of naturally

hyperbolic materials.

Leveraging Optical Non-Locality and Block Co-Polymer Lithography to Create High Frequency Plasmonic Resonances in Graphene Victor Brar; University of Wisconsin--Madison, United States

I will discuss recent experiments aimed at creating plasmonic resonances in graphene in the short-wavelength infrared (SWIR). The plasmonic dispersion of graphene dictates that reaching such short wavelengths requires fabricating increasingly smaller nanostructures in the graphene surface, with lengthscales < 10nm. While conventional electron beam lithography has been shown to be effective at creating structures as small as 15nm, measurements of those systems revealed only mid-IR resonances, with wavelengths as short as 3.5um. We push to smaller lengthscales by introducing a new, bottom-up block co-polymer lithography method, which can easily pattern cm-scale sheets of graphene into 12nm nanoribbon arrays. Subsequent infrared absorption measurements from these samples reveals that they exhibit resonant behavior at frequencies much higher than predicted, reaching free-space wavelengths as short as 2.2um, well into the SWIR. We show that this behavior is due to strong non-local effects in the graphene, which effectitvely blue shifts the graphene plasmons at short wavelengths. This allows optoelectronic devices based on graphene plasmons to operate over a larger range than commonly assumed, possibly reaching the near infrared or visible. Another significant implication of this finding is that light-matter interactions driven by graphene plasmons are smaller than what is expected from first order calculations; for some spontaneous emission processes, these weaker interactions will create Purcell enhancements that are orders of magnitude smaller than expected. Finally, I will discuss recent attampts at integrating graphene nanoribbons derived using block co-polymer lithography with metal and diectric metasurfaces, with an aim of creating an enhanced optoelectronic response.

1:00 PM *EL05.09.01
Topology Optimization of Artificial Photonic Materials with Deep Generative Networks Jonathan A. Fan; Stanford University, United States

Inverse design algorithms enable metasurfaces and other nanophotonic devices to achieve new functionalities and high efficiencies. Inverse algorithms based on global topology optimization networks (GLOnets), in which global optimization is framed as the training of a generative neural network, are a promising approach towards globally searching a non-convex design landscape. However, the relationship between the GLOnets algorithm and network architecture is not clear and the selection of a proper architecture is required to ensure GLOnets stability. We will discuss the role of network architecture in the GLOnets algorithm and show that, counterintuitively, relatively shallow networks are sufficient to performing stable global optimization. With select problems based on benchmark mathematical functions and diffractive nanophotonic systems, we discuss GLOnets in the context of problem-dependent architectures. We will also discuss viable and effective pathways towards conditional GLOnets, in which ensembles of related devices are co-designed.

1:40 PM EL05.09.02
Experimental Demonstration of Inverse-Designed Active Metasurface Arrays Prachi Thureja[1], Ghazaleh Kafaie Shirmanesh[1], Meir Grajower[1], Ruzan Sokhoyan[1], Katherine Fountaine[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]Northrop Grumman Corporation, United States

We experimentally demonstrate an array-level inverse design approach that accounts for the nonideal optical response to optimize the spatial array phase and amplitude profile of active metasurfaces for desired target functions [1]. Optical phase control in planar metasurfaces has recently been the subject of intensive worldwide research. While significant prior effort has addressed phase control in passive metasurfaces, active metasurfaces comprising of arrays of programmable nanoantennas have garnered widespread interest owing to their power for versatile wavefront shaping in real-time [2,3]. Notably, modulation of active metasurfaces generally relies on permittivity tuning near optical resonances in nanostructured antennas. This gives rise to an inherently nonideal optical response that creates strong interdependence between the scattered light phase and amplitude, and limits the accessible phase modulation range. As a consequence, conventional forward design of active metasurface phase profiles for beam steering results in significant losses of power coupling into undesired sidelobes, motivating our inverse design method, which enhances the performance of active metasurfaces with nonideal antenna components.

In contrast to passive metasurface design via shape optimization of individual antennas, active metasurfaces can be 'designed' by reconfiguration of independently gated, geometrically identical nanoantennas. This enables an array-level optimization of phase and amplitude for arbitrary user-defined metasurface functions, such as high-directivity dynamic beam steering. By performing optimization, we investigated the impact of phase and amplitude modulation on the beam steering performance of an active metasurface array of 100 non-interacting subwavelength antennas. We then examined the optical response of a nonideal plasmonic, electro-optically tunable metasurface using indium tin oxide as an active layer. The reflected light measurements indicate a limited phase modulation range of ~220° as well as covarying, non-unity amplitude at an operating wavelength of $\lambda = 1548$ nm. We find that nonintuitive array phase and amplitude profiles generate high performance despite a nonideal antenna optical response. Using inverse design, we demonstrate a reduction in the sidelobe radiation, thus increasing beam directivity compared to forward designs. We further used the array-level inverse design algorithm to experimentally validate high-directivity continuous beam scanning with a broad field-of-view of nearly 50° as well as simultaneous steering of beams in multiple different directions. Finally, we consider the impact of metasurface inter-antenna coupling on the beam steering performance. These findings highlight the power of array-level inverse design as a general approach for active metasurfaces, including all-dielectric metasurfaces. Inverse design thus has the potential to ultimately usher in a modern era of hierarchical co-design of nanophotonic materials, devices, and systems to realize highly efficient optical elements for complete space-time control of the scattered light wavefront.

Single-Crystal Noble Metal Films and Nanostructures from Solution—A Low-Loss, High-Yield, Green Strategy for Plasmonic Metasurfaces Gary W. Leach, Sasan V-Grayli, Finlay MacNab, Xin Zhang, Saeid Kamal and Dmitry Star; Simon Fraser University, Canada

The confinement of electromagnetic waves to nanometer-scale metal structures amplifies local fields that can be harnessed for application in information processing, energy harvesting, sensing and catalysis. Metal nanostructures offer the opportunity to manipulate the phases and amplitudes of electromagnetic waves to enable flat optics, subwavelength resolution imaging and patterning. However, the controlled fabrication of high-definition single-crystal subwavelength metal nanostructures has remained a significant hurdle due to the tendency for polycrystalline metal growth using conventional physical vapor deposition methods, and the challenges associated with placing solution-grown nanocrystals in desired orientations and locations on a surface to manufacture functional devices. Here, we introduce a scalable and green, wet chemical approach to monocrystalline noble metal thin films and nanostructures. The method enables the fabrication of ultrasmooth, epitaxial, single-crystal films of controllable thickness that are ideal for the subtractive manufacture of

nanostructure through ion beam milling, and additive crystalline nanostructure *via* lithographic patterning for large area, single-crystal metamaterials and high aspect ratio nanowires. Our single-crystal nanostructures demonstrate improved feature quality, pattern transfer yield, reduced optical and resistive losses, and tailored local fields to yield greater optical response and improved stability compared to polycrystalline structures, supporting greater local field enhancements and enabling practical advances at the nanoscale.

2:10 PM EL05.09.04
Topological Space-Time Photonic Transition Enabled by Time-Modulated Metasurfaces Hooman Barati Sedeh and Hossein Mosallaei; Northeastern University, United States

Light-matter interaction has been the heart of electromagnetic and optics for many years and thus an immense effort has been put into introducing different platforms and materials that can effectively control the flow of light in the desired fashion. Spatiotemporally modulated systems have gained the attention of the scientific community in recent years due to their extended dimensionality and enabling several exotic space-time phenomena. In particular, it has been established that the temporal frequency conversion of an optical mode in such systems is accompanied by a correlated change in its spatial frequency [1]. This phenomenon, which is known as space-time photonic transition, not only enables numerous exotic functionalities such as generating an effective magnetic field to control the flow of photons but also is the underlying mechanism for constructing optical isolators in space-time varying platforms [2]. Recently, it has been demonstrated that time-modulated metasurfaces (TMMs), which are planar structures whose subwavelength unit cells are tuned periodically in time via an external stimulus, can also enable nonreciprocal wavefront engineering and extend the degree of light manipulation through space-time photonic transitions. In addition to the nonreciprocal responses, TMMs have been shown to enable a wide range of other novel physical phenomena including wavefront engineering and signal camouflaging [3,4].
In this work, we introduce a new type of space-time photonic transition of light, dubbed as topological space-time photonic transition, which occurs upon the scattering of light from an angular-momentum-biased metasurface and gives rise to the generation of a twisted light beam that carries an orbital angular momentum (OAM) with proportional topological charge and shift in the temporal frequency. An angular-momentum-biased metasurface renders a virtually rotating TMM which yields a superposition of OAM-carrying beams at distinct frequencies, whose topological charges can be controlled via varying the applied phase delay modulation. The competency of topological space-time photonic transitions in the active tuning of OAM states with high mode-purity is analyzed, which yields minimal cross-talk between OAM channels in a mode-multiplexed communication system. Moreover, the role of the spatiotemporal modulation profile of the metasurface on the spatial and spectral diversity of OAM states is explored in detail. It is also demonstrated that the established concept can pave the way for hybridized mode-division and wavelength-division multiple access through the generation of distinct OAM states at different frequency harmonics. The nonreciprocity and broken time-reversal symmetry in topological space-time photonic transitions across the temporal frequency domain and Hilbert space of OAM states is also investigated giving rise to distinct twisted light channels in up- and down-links. To realize a time-modulated metasurface with angular-momentum biasing, a reflective dielectric metasurface is considered consisting of silicon nanodisk heterostructures integrated with indium-tin-oxide and gate dielectrics placed on a back mirror forming a dual-gated field-effect modulator. The metasurface is azimuthally divided into several sections where the nanodisk heterostructures are interconnected via biasing lines. This configuration enables addressing each section independently via a radio-frequency biasing signal and with a different modulation phase delay, thus enabling the flexible implementation of different spatiotemporal modulation profiles.

Bio-inspired Disordered Metaphotonic Devices for Medical Applications Radwanul H. Siddique[1], Daniel Assumpcao[1,2] and Hyuck Choo[2]; [1]Samsung Semiconductor, Inc., United States; [2]Samsung Advanced Institute of Technology, Korea (the Democratic People's Republic of)

Over the last decades, photonic metamaterials with tailored -i.e. with deliberately introduced- structural disorder have attracted considerable interest in various optical applications due to their extended spectral and angular range of effectiveness[1]. However, millions of years of evolution in the biological world has developed a plethora of micro- and nanoscopic photonic structures with the deliberately introduced disorder in their respective geometries and compositions[2]. In this talk, I will discuss how the development of metaphotonic devices harnessing bioinspired attributes can provide novel yet highly practical solutions for the global health sector. I will present our studies on biophotonic nanostructures found in butterfly wings that show unique optical properties with the tailored structural disorder, and their successful replication in laboratories using self-assembly based scalable nanofabrication techniques[3,4,5]. We utilize this approach to pattern Si_3N_4-based metasurfaces onto a Fabry-Perot-resonator-based intraocular pressure (IOP) sensor for glaucoma management[4]. The metasurface integration onto the IOP sensor led to a 2.5-fold improvement in readout angle allowing easy handheld monitoring and in a one-month in vivo study conducted in rabbits, showed a 3-fold reduction in IOP error and a 12-fold reduction in tissue encapsulation and inflammation, compared to an IOP sensor without nanostructures. We will further discuss our second-generation metaphotonic IOP sensor that is made of only flexible nanostructured foil with a 3D hybrid periodic and amorphous photonic crystal using a newly developed colloidal lithography[5]. I will conclude the talk showing our recent progress in developing an ultra-compact optical spectrometer for smartphones using bioinspired tricks with high angular tolerance, resolution, and throughput, suitable for the realization of high-performance point-of-care biosensing[6].

Recent Advances and Applications of Epsilon-Near-Zero Materials—From Photodetectors and Hydrogen Sensors to Casimir Forces Jeremy N. Munday; University of California, Davis, United States

Materials whose dielectric functions approach zero have many unique properties ranging from enhanced non-linear behavior to suppression of quantum electromagnetic fluctuations. Beyond these interesting physical phenomena, epsilon-near-zero (ENZ) concepts can be applied to devices to exploit these effects. In this talk, I will discuss our recent work on the development of devices that take advantage of these effects to create super-absorbing optical films for novel photodetectors and hydrogen sensors, as well as quantum effects that can be

exploited using ENZ materials. Two examples of the later are the suppression of spontaneous emission and modifications to the Casimir force, a force that it purely quantum in nature and is related to the electromagnetic boundary conditions placed on vacuum fluctuations. We will conclude with an outlook for this emerging area of research.

4:40 PM EL05.10.02
Engineering the Spectral and Spatial Dispersion of Thermal Emission via Polariton-Phonon Strong Coupling Guanyu Lu[1], Christopher R. Gubbin[2], Joshua R. Nolen[1], Thomas G. Folland[1,3], Marko J. Tadjer[4], Simone D. Liberato[2] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]University of Southampton, United Kingdom; [3]The University of Iowa, United States; [4]U.S. Naval Research Laboratory, United States

Phonon polaritons are quasiparticles comprising a photon and a coherently oscillating charge on a polar lattice, which are supported in the form of propagating (SPhP) and localized surface phonon polaritons (LSPhP). The promising properties of LSPhP modes are exceptionally high predicted Purcell enhancements and narrow resonance linewidths, with the potential for near-unity absorption (emissivity). However, one drawback is that as a highly localized mode, they offer no significant degree of spatial coherence (directionality) for thermal emission applications. Alternatively, high spatial coherence can be achieved using propagating SPhPs launched by grating elements. However, the non-localized nature of such propagating modes yields thermal emission into frequency-specific angles across the entire Reststrahlen band where such modes can be supported. The introduction of strong coupling between different polaritonic modes, therefore, provides us an opportunity to combine the virtues of the narrowband LSPhP resonances with the high spatial coherence associated with propagating SPhPs into a novel, mixed character polariton. Further, it has been proposed that strong coupling between LSPhPs with zone-folded longitudinal optic phonons (ZFLO) could provide a mechanism to use the longitudinal fields of an electrical bias to stimulate the transverse fields of SPhPs through Ohmic loss. Thus, we propose that through inducing strong coupling between LSPhPs, propagating SPhPs, and ZFLO phonons, that realization of a narrow-band, spatially coherent emitter amenable to electrically driven emission could be possible. Additionally, through coupling to such a ZFLO mode, the extremely narrow linewidths could be employed via strong coupling to further reduce the linewidths of the SPhP modes.
In this work, we report on three-oscillator strong coupling within a SPhP platform using nanopillar arrays fabricated into a 4H-SiC substrate. Here, we experimentally manipulate the dispersion relation of coupled SPhP modes by strongly coupling LSPhPs, propagating SPhPs, with the ZFLO. In the strong coupling regime, the formation of such hybrid modes with mixed character is expected. Furthermore, the strength of the interactions between such optical modes can be precisely controlled through the hybridization of three oscillators. We further report on the influence of such strong coupling upon thermal emission within the long-wave-IR (LWIR), demonstrating significant narrowing of the spectral and spatial dispersion of the individual modes within this strongly coupled regime. In our three-oscillator strong coupling platform, we simultaneously demonstrate a five-fold reduction in the angular spread of the thermally emitted light and a three-fold enhancement of the quality factor over that of the uncoupled LSPhP mode at the anti-crossing point where the splitting occurs. Furthermore, the high Q-factors (over 200) achieved are realized using traditional photolithography, enabling such devices to be produced at large-scale and reasonable costs. Our results demonstrate that by leveraging three-oscillator strong coupling that the spectral and spatial dispersion of thermal emission can be engineered for a variety of LWIR applications extending from spectroscopy, sensing, to free-space communications.

4:55 PM EL05.10.03
Experimental Observation of the Violation of Kirchhoff's Thermal Radiation Law Using a Guided Mode Resonator Coupled to Magneto-Optical InAs Komron J. Shayegan[1], Bo Zhao[2], Yonghwi Kim[1], Shanhui Fan[2] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]Stanford University, United States

For all thermal absorbers and emitters in equilibrium, the amount of radiation absorbed from a blackbody at a specific wavelength and incident angle is re-emitted reciprocally from the absorber back to the blackbody. This phenomenon has been formalized as Kirchhoff's law of thermal radiation (KLTR) and relies on the

absorber/emitter obeying time-reversal symmetry.
In our experiments, we showWe report the first experimental observation of a reciprocity breaking of this reciprocal , behavior in theat mid-infrared wavelengths, using in a magneto-optical deviceheterostructure. The device consists of a low-loss, Si guided mode resonant (GMR) grating waveguide structure made of Si on a top of degenerately-dopeddegenerately doped InAs wafer, which in an applied magnetic field, acts serving as our magneto-optical material. The degenerately-dopeddegenerately doped InAs, behaves responds optically as a Drude metal conductor with non-zero off-diagonal permittivity values when ain an applied magnetic field is applied. We design the Si GMR grating to critically couple to light at wavelengths (~17 microns) in the epsilon-near-zero regime of for the InAs wafer, where the magneto-optical effect response is largest. Using this structure, we are able to break time-reversal symmetry by changing the direction of an in-plane magnetic field (~ 0.5 T) applied along the length of the grating. We are able toBy measuring te the polarization- and angle-dependent reflectivityce of the structure'sand absorption, we obtained dispersion relations for the non-reciprocal, time-asymmetric InAs reflectivity and compared the our results to theoretical predictions.[1] We do not observe a breaking of reciprocity for *s*-polarized infrared light but do see reciprocity a breaking of reciprocity for *p*-polarized light. This is, in agreement with the direction in which we apply ourpredicted field polarization required to break time-reversal symmetry. This work shows theconstitutes the first experimental observation of reciprocity ability to break ring, and was performed using thermal radiationeciprocity in under room ambient conditions, and using modest magnetic fields attainable with permanent magnets.

5:10 PM EL05.10.04
Noble-Transition Alloy Excels at Hot-Carrier Generation in the Near Infrared Kevin M. McPeak and Sara Stofela; Louisiana State University, United States

Above-equilibrium "hot" carrier generation in metals is a promising route to convert photons into electrical charge for efficient near-infrared optoelectronics. However, metals that offer both hot-carrier generation in the near-infrared and sufficient carrier lifetimes remain elusive. Alloys can offer emergent properties and new design strategies compared to pure metals. We will show that a noble-transition alloy, Au_xPd_{1-x}, outperforms its constituent metals concerning generation and lifetime of hot carriers when excited in the near-infrared. At optical fiber wavelengths (e.g., 1550 nm), $Au_{50}Pd_{50}$ provides a 20-fold increase in the number of ~0.8 eV hot holes, compared to Au, and a 3-fold increase in the carrier lifetime, compared to Pd. The discovery that noble-transition alloys can excel at hot-carrier generation reveals a new material platform for near-infrared optoelectronic devices.

5:25 PM EL05.10.05
Photonic Crystal Waveguides as Thermal Concentrators for Catalytic Carbon Monoxide Reduction Haley Bauser, Xueqian Li, Magel Su and Harry A. Atwater; California Institute of Technology, United States

While photonic crystal waveguides have an extensive history in nanophotonics, we introduce a photonic crystal concept - as an infrared photon (thermal) concentrator, designed for solar-driven thermal heterogeneous catalysis for carbon monoxide reduction. A key goal in reducing global CO_2 emissions is the development of a net-zero carbon synthesis route for renewable generation of chemical fuels to replace conventional fossil fuels. Solar driven processes under mild conditions present a sustainable alternative to large-scale industrial processes that typically operate under high temperatures (>200 ºC) and elevated pressures (>10 atm). However, thermal radiation losses typically prevent a catalyst photothermally heated by unconcentrated sunlight from reaching the minimum operating temperatures for heterogeneous catalysis of carbon monoxide which is generated by photoelectrochemical CO_2 reduction, to fuel and chemical products by the Fischer-Tropsch reaction pathway under direct 1 sun (1000 W m^{-2}) illumination. While higher temperatures can be reached through the use of geometry solar concentrators, these systems are difficult to scale up due to their complexity and reliance on solar tracking systems to optimize concentration.
Instead, building upon the concept of photonic crystals as medium for light trapping in photovoltaics, the emission of a catalyst coupled to an infrared photonic crystal can be trapped to infrared photons generate by

solar heating of a visible photoabsorber, thereby concentrating the solar-generated heat. A 3.5 micron thick lightly doped germanium is chosen as the photonic crystal waveguide material due to its high index, solar absorption absorption coefficient stability in the visible range, and nearly lossless infrared characteristic. While two-dimensional photonic crystal designs can involve rod or hole arrays, the benefits of a hole array in this application are twofold: (1) stable trapping across a wide range of wavelengths, and (2) the ability to flow a reactive gaseous easily through the structure. We have designed a holey germanium photonic crystal with thermal infrared photon trapping efficiency above 90% for wavelengths from 8-15 microns. This prototype indicates promise for a first photonic crystal thermal concentrator to address scaling challenges and temperature requirements for solar thermochemical reactions under ambient sunlight.

SESSION EL05.11: Metasurfaces and Plasmonics/2D Material-Based Tunable Metasurface

Diatomic Metasurface for Multifarious Polarization Optics Zilan Deng and Xiangping Li; Jinan University, China

Metasurface based flat optics, an ultrathin layer of structured nano-antennas imparting local and space-variant abrupt phase changes, promises great potentials in shaping light's wavefronts in desirable manners. However, most of the reported metasurfaces are restrained by their design strategies and can only allow one or two physical parameters such as phase, polarization or amplitude to be controlled at the same time. Geometric metasurface provides dispersionless phases depending on the in-plane orientation angles of the meta-atoms. However, the polarization state of the incident light is restricted to circular polarization only. The combination of geometric phase with propagation phase was proposed to relieve the constraint and realize full control of the phase and polarization. However, this is achieved at the cost of increased thickness of the antennas to wavelength scale and concomitant massive computations for complicated meta-atom designs with intricate geometries at variant locations, meanwhile, the propagation phase is intrinsically dispersive, which restricts its ability to working at a specific wavelength. Here, we demonstrate a new dimerized metasurface design that can allow simultaneous control of the four basic parameters in one go as well as underpin variety of multi-functional optical elements. The proposed dimerized metasurface is consisting of two identical meta-atoms with exquisitely controlled in-cell displacements and orientations. Consequently, multi-functional holography that the amplitude, phase, polarization and color components of the diffracted beam can be completely controlled has been demonstrated. The proposed diatomic metasurfaces may extensively promote applications based on flat optics

Meta-Lens for Imaging, Sensing and Quantum Technology Mu Ku Chen[1], Lin Li[1,2,3], Zexuan Liu[2,2,4], Xifeng Ren[5,5], Shuming Wang[2,2,4], Vin-Cent Su[6], Cheng Hung Chu[7,8], Hsin Yu Kuo[8,7], Ren Jie Lin[7,8], Biheng Liu[5,5], Wenbo Zang[2,4], Pin Chieh Wu[9], Guangcan Guo[5,5], Lijian Zhang[2,2,4], Zhenlin Wang[2,4], Shining Zhu[2,2,4] and Din-Ping Tsai[1,8,7]; [1]The Hong Kong Polytechnic University, Hong Kong; [2]Nanjing University, China; [3]East China Normal University, China; [4]Collaborative Innovation Center of Advanced Microstructures, China; [5]University of Science and Technology of China, China; [6]National United University, Taiwan; [7]Academia Sinica, Taiwan; [8]National Taiwan University, Taiwan; [9]National Cheng Kung University, Taiwan

Meta-lens can achieve diffraction-limited focusing with nanoantenna array in a compact size. Many flat optical

devices have been demonstrated using meta-lens lately. For applications of full-color imaging and detections, the correction of chromatic aberration is a key issue. We introduced the integrated-resonant unit to incorporate with the geometric phase method to realize achromatic meta-lens. Broadband meta-lenses working over the near-infrared in reflection and entire visible spectrum in transmission are achieved. The full-color imaging is demonstrated by using GaN-based achromatic meta-lens. The high-dimensional light field imaging system was implemented by the nature-inspired 60 × 60 achromatic meta-lens array. The depth and velocity sensing of the imaging objects are achieved. A high-dimensional quantum entanglement light source is demonstrated by using a meta-lens array which composed of 10 by 10 meta-lenses. The meta-lens array can make multi-focusing spots into the nonlinear crystal simultaneously, and generate the multi entangled photon pairs. The entangled photon pairs are generated due to the spontaneous parametric down-conversion (SPDC) effect in the nonlinear crystal. We demonstrated the high-dimensional entanglement and 2-, 3- and 4-dimensional two-photon path-entanglement with different phases coded by the metalenses. It is a great progress for the quantum light source and quantum applications such as quantum computing, quantum cryptography, and quantum communication. We have developed optical meta-devices for beam deflection and reflection, polarization control and analysis, holography, second-harmonic generation, laser, tunability, imaging, absorption, color display, focusing of light, multiplex color routing, light-field sensing, and high-dimensional optical quantum source. The great advantages of meta-lens and meta-devices are their new properties, lighter weight, small size, high efficiency, better performance, broadband operation, lower energy consumption, and CMOS compatibility for mass production.

Spin Hall Effect of Light Using Structured Optical Materials Minkyung Kim, Dasol Lee and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Spin Hall effect of light (SHEL) refers to a spin-dependent and transverse splitting of light at an optical interface. This phenomenon can be readily found in various interfaces, but has been often left out of consideration because the splitting is much smaller than the wavelength. Thus, increasing the amount of the shift by using artificially structured materials has attracted scientific interests recently. We demonstrate that vertical hyperbolic metamaterial, or nanotrench structure consisting of metal and dielectrics, can be served as a platform to enhance the SHEL [1]. Under the same conditions of material combinations and total thickness, the enhancement, which is incident angle-dependent, can be higher than 800-fold when the incident angle is 5°, and 5000-fold when the incident angle is 1°. The gigantic SHEL in a vertical hyperbolic metamaterial will enable helicity-dependent control of optical devices including filters, sensors, switches, and beam splitters.
This tendency of diverging shift as the incident angle decreases is not a unique characteristic of the vertical hyperbolic metamaterial, but is a universal feature that appears in many systems to increase SHEL. In other words, previous proposals to enhance the SHEL is limited to a small incident angle, on the order of milli-radians. Diffraction can be used to improve SHEL at a large incident angle [2]. We present the enhancement of SHEL in a dielectric grating on a metal film by maximizing the difference between the transmission coefficients of two linear polarizations. The metal film impedes light transmission except the p-polarized first-order diffracted mode that is coupled to surface plasmon polaritons. These polarization-dependent transmission coefficients lead to a large SHEL at a large incident angle.
Lastly, an approach to achieve a large SHEL with near-unity efficiency is proposed. Despite the remarkable enhancement of SHEL, the efficiency of the effect has been rarely discussed. The enhancement of SHEL in most of the previous proposals and demonstrations has been underpinned by small Fresnel coefficients, which in turn yield extremely low efficiency. In this last part, we present an approach using anisotropic impedance mismatching to attain a large SHEL with near-unity efficiency in the microwave spectrum [3]. A wire medium that has a near-unity transmission for one polarization and low transmission for the other is used to achieve high efficiency. The spin-dependent splitting is experimentally confirmed by measuring transmission coefficients and the spatial profile of Stokes parameters. The large SHEL with near-unity efficiency will enable highly efficient devices with spin-selective functionalities.

Deep UV Surface-Enhanced Resonance Raman Spectroscopy for Ultrasensitive Label-Free DNA Detection and 2D Materials Using an Aluminum Film Abhishek Dubey[1], Ragini Mishra[1], Chang-wei Cheng[1], Wei-Lin Du[1], Ta-Jen Yen[1] and Shangjr Gwo[1,2]; [1]National Tsing Hua University, Taiwan; [2]Academia Sinica, Taiwan

Surface-enhanced Raman spectroscopy has been well investigated in the visible to the IR regime. In the visible to IR spectrum, several plasmonic materials have been given promised results like gold (Au) and silver (Ag). To explore the plasmonic properties in the Ultraviolet (UV) regime, aluminum (Al) has enormous potential to operate in the deep UV to the visible spectrum, so we present deep UV surface-enhanced resonance Raman Spectroscopy (SERRS) driven ultraviolet (UV) plasmonics through aluminum nanoholes. Therefore, the generation of deep UV range localized surface Plasmon resonance (LSPR) for electric field enhancement, the epitaxial aluminum film is grown by PA-MBE (plasma-assisted Molecular beam epitaxy) on sapphire substrate and CMOS compatible techniques are used to fabricate Al nanoholes. To assess, the deep UV SERRS nature of epitaxial Al film, we used the basis of nucleic acid and 2D materials as a benchmarked analyte. An ultra-thin layer (~1 nm) of Adenine, Thymine, Cytosine, and Guanine is sublimated on Al nanoholes and recorded the highest Raman intensity enhancement (~10^6) with comparison to the non-plasmonic substrate. Here, we report the ultrasensitive detection limit of adenine and enhanced visualization of second-order Raman mode of MoS_2 using 266 nm wavelength Raman. This work thus enables, the sensitive detection of DNA and 2D materials.

Electron Dynamics in Plasmons Hue T. Do[1,1], Wen Jun Ding[2], Zackaria Mahfoud[2], Lin Wu[2] and Michel Bosman[1,2]; [1]National University of Singapore, Singapore; [2]Agency for Science, Technology and Research, Singapore

The Particle-in-Cell (PIC) simulation is a widely used numerical method in plasma physics. We show that it can also be used to robustly describe plasmon resonances, similar to the conventional FDTD method, but with a unique emphasis on the motion of the electrons by tracking the individual conduction electrons in the time domain [1]. Our statistical studies of electron motions provide insight into the femtosecond time-scale dynamics of electrons in plasmons, including the plasmon dephasing, the contributions from different plasmon damping channels, and the electron kinetics during damping. An analysis of the time-resolved velocity distribution of the conduction electrons shows that only a small offset in this distribution constitutes the plasmon oscillation in each cycle. We describe the non-radiative damping through both electron-electron and electron-surface scatterings, where the latter is automatically and inherently included in the electron motions. Electron-surface scattering in PIC can be interpreted as a self-consistent interaction between the electrons and the enhanced local field at the surface. The presented framework will be particularly useful in future studies of plasmons in bimetallic nanostructures.

Refractory Plasmonic Perfect Absorbers and Color Filters Using Transition Metal Nitride Metasurface
Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Broadband perfect absorbers in the visible have attracted a great deal of attention in many fields, especially for solar thermophotovoltaic (STPV) and energy harvesting systems. However, realizing light absorbers with high absorptivity, thermal stability and broad bandwidth remain a great challenge. In this work, we theoretically and experimentally demonstrate that a single-layer titanium nitride (TiN) metasurface absorber with a total thickness of 160 nm that exhibits broadband perfect absorption with an average absorption of more than 92% for a broad wavelength range from 400 nm to 750 nm in the visible. Unlike reported metamaterial absorbers based on the metal-insulator-metal (MIM) structure, we use a single-layer TiN metasurface, which simplifies the nanofabrication process and also maintains high absorption. The broadband perfect absorption of a single-layer TiN metasurface absorber is contributed by the combination of the intrinsic absorption of TiN and the broadband localized surface plasmon resonance (LSPR) of the lossy TiN nanodisk arrays. These results enable a new approach to realizing hot-carrier devices and solar-thermal energy conversion devices. In addition, we use the same concept of metasurface structure to design and fabricate the refractory color filters. We will also discuss the outlook for refractory metasurface in applications of the hot-carrier photodetection, photocatalysis, radiative cooling, and solar thermophotovoltaics.

Determination of the Absolute Chirality of Single Plasmonic Nanostructures in Solution Johannes Sachs[1,2], Jan-Philipp Günther[1,2] and Peer Fischer[1,2]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]University of Stuttgart, Germany

Chiral plasmonic structures, which exist in two distinct non-superimposable mirror-image forms, are interesting for (bio)chemical sensing. Almost all biomolecules are chiral, and are of only one handedness. Typically their handedness is detected via differential interactions with circularly polarized light. These interactions are weak, because the molecular dimensions are much smaller than the wavelength of light. Larger plasmonic nanostructures can boost the chiral signal and hence possibly yield high sensitivity and selectivity as well as permit detection in ultra-low volumes. Chiral metasurfaces exploit this and their interaction with chiral molecules, including proteins, has been studied. However, a difficulty in all experiments on metasurfaces to date is that – depending on their orientation – even achiral structures were reported to give chiral signals. This is because the experimental geometry (light in, object, light out) may become handed. It is then not trivial to distinguish the true (inherent real chirality) of a nanostructure from effects that arise due to the geometry of the setup.
We have succeeded in devising a new scheme to measure the true chirality of a single nanostructure that is free from artefacts and that reports a new observable [1]. The polarization-sensitive light scattered off a single nanoparticle can be measured while it is freely suspended in solution. For this, we have engineered a complex-shaped metal nanoparticle with defined handedness [2]. A novel spectrometer is introduced that can measure for the first time an artefact-free circular dichroism spectrum of a (reorienting) single nanoparticle. We thereby show that only the average spectrum taken over isotropic orientations of a single particle gives the same information as the corresponding ensemble spectra measured with the traditional instruments. This is in accordance with the ergodic principle, which is demonstrated for the first time in the context of chiroptical spectroscopy. Finally, we show that by growing hybrid nanostructures that contain a magnetic moment, we can re-orient single chiral metamaterials by means of an external field and obtain their spectral response as a function of their orientation.

8:45 AM EL05.12.03
Late News: Inflluence of Plasmonic Surface Lattice Resonances Energy Transfer Between Two BODIPY Dyes Robert Collison[1], Vinod Menon[2], Joel Yuen Zhou[3], Juan Perez-Sanchez[3], Matthew Du[3], Jacob Trevino[4] and Stephen O'Brien[2]; [1]The Graduate Center of the City University of New York, United States; [2]The City College of New York, United States; [3]University of California, San Diego, United States; [4]New York University, United States

To study the effect of surface lattice resonances (SLRs) on energy transfer, SLR-supporting square lattices of vertically layered Al-Al_2O_3-Al nanocylinders were fabricated onto a glass substrate. The substrate and lattices were coated with a film containing 800 mM (20 wt %) of the donor dye (P580) and 8 mM (0.16 wt %) of the acceptor (P650) dispersed in poly(methyl methacrylate) and the film's fluorescence spectra on the bare substrate and on the lattices were studied. In the absence of any SLR-supporting lattice, the fluorescence of the donor dye was less than that of the acceptor, with a donor-to-acceptor peak fluorescence ratio of 0.45, indicating that energy was readily transferred from donor to acceptor. In contrast, on a lattice that supports an SLR at 551 nm at $k\| = 0$, coinciding with the donor dye emission peak at 550 nm, the fluorescence of the donor dye exceeded that of the acceptor, giving a donor-to-acceptor peak fluorescence ratio of 5.4. Additionally, the film exhibited a greater absolute donor fluorescence and a lesser absolute acceptor fluorescence on this lattice than on those that supported SLRs at other wavelengths. These results suggest that the SLR that coincides at $k\| = 0$ with the donor dye's emission peak enhances the radiative decay of the donor at the expense of energy transfer to the acceptor. Notably, the SLRs that coincided with the donor emission peak at larger values of $k\|$ (at angles of emission of *ca*. 20° or 50°) did not have this effect.

9:00 AM EL05.12.04
Full-Field Imaging of Electromagnetic Fields via the Polarization Dependence of Photoemission Microscopy (DUV-PEEM) Thomas Beechem[1], Sean Smith[1], R. Guild Copeland[1], Fangze Liu[2] and Taisuke Ohta[1]; [1]Sandia National Laboratories, United States; [2]Los Alamos National Laboratory, United States

Through development of an electron-based imaging technique, the electromagnetic field profiles emanating from the edges of an atomically thin MoS_2 flake buried between Al_2O_3 and SiO2 were characterized using photoemission electron microscopy excited by deep-ultraviolet light (DUV-PEEM). The photoemission yield is proportional to the square of the electric field for the single-photon process excited by the UV-light, thereby providing a pathway to the imaging of nanophotonic phenomena using emitted electrons. Because electrons are the sensing entity, the resulting images exhibit resolutions below the photon wavelength. To validate this concept, the dependence of photoemission yield on the wavelength and polarization of the exciting light was first measured and then compared to simulations of the optical response and the electric field quantified with classical optical theory. Close correlation between experiment and theory indicates that photoemission probes the optical interaction of the UV-light with the material stack directly. Utility is then demonstrated by employing the polarization dependence of photoemission to observe fringes indicative of the electromagnetic field profiles resulting from the interaction of the exciting UV-light with the MoS_2. Taken together, this “electron-based ellipsometric imaging” offers an analytical approach through which to visualize the electromagnetic field distributions central to many nanophotonic phenomena while simultaneously mapping optical property variation at sub-wavelength scales.

Vectorial Holographic Color Prints for Double-Encrypted Optical Security Platform Inki Kim, Jaehyuck Jang, Gyeongtae Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

We propose bi-functional metasurface which contains structurally colored print and vectorial holograms with eight polarization channels towards advanced encryption applications. The encoded structural color prints can be observed under white light and the fully polarized holograms can be reconstructed using coherent laser source with combination of output polarizer/retarder. To encode multiple hologram images having different polarization states, a pixelated metasurface is adopted thereby digitalizing sets of phase distribution retrieved from the images into single metasurface. Such superpixel consists of four phase-gradient metaatom groups: meta-atom group rotated either clockwise or counterclockwise. Depending on the combination of clockwise and counterclockwise rotating meta-atom group, the polarization states of the reconstructed images are determined. The metaatom contains specifically designed geometric and propagation phase, and reflection spectrum at each spatial location. As a proof-of-concept, we devise electrically tunable optical security platform using our multifunction metasurface incorporated with liquid crystal. The optical security platform is double encrypted: Color printing image that can be decrypted by camera scanning provides first key and corresponding information will be used to fully unlock the double-encrypted information via projected vectorial hologram images. Such an electrically tunable optical security platform will provide a new route towards internet-of-things sensors for security and anticounterfeiting applications.

9:20 AM EL05.12.06
Gap-Plasmon-Mediated Luminescence Enhancement of Upconversion Nanoparticle-Sensitized Perovskite Quantum Dots in Metal-Insulator-Metal Configuration Minju Kim, Youngji Kim, Kiheung Kim, Jerome K. Hyun and Dong Ha Kim; Ewha Womans University, Korea (the Republic of)

All inorganic $CsPbX_3$ perovskite quantum dots (PeQDs) have received much attention due to their excellent properties such as large absorption coefficients, tunable bandgap, and narrow band emission. However, due to their low upconversion efficiency under near-infrared light excitation, potential applications have been limited. Recently, upconversion nanoparticle (UCNP) sensitized PeQD has been reported as a solution, but the low quantum yield of UCNPs and low photoluminescence (PL) intensity of PeQDs film have still remained challenges. In this study, enormous luminescence enhancement of PeQDs was achieved under near-infrared (NIR) excitation through sensitization by UCNPs and plasmonic coupling. To overcome the low luminescent quantum yield of UCNPs, gap plasmonic mode was integrated into the UCNP-perovskite film via metal-insulator-metal (MIM) configuration consisting of gold nanorods (AuNRs) and Ag thin film. The AuNRs-UCNPs/PeQDs-Ag film (MUPM) configuration is reported, for the first time, using UCNPs and PeQDs as an insulator layer, which provides high interfacial stability of perovskites-metallic nanostructures. Despite a thin active layer, a dominant green emission of PeQDs is observed under NIR excitation with high energy transfer efficiency by using similarly sized UCNPs and PeQDs. Furthermore, by capping AuNRs with the amphiphilic diblock copolymer, PL quenching and morphology deformation were suppressed. Therefore, an overall 29-fold upconversion enhancement was achieved for the green emission in the MUPM configuration owing to the strong localized electric field and the coupling of longitudinal localized surface plasmon resonance band of AuNRs with excitation of UCNPs. The present study provides a novel route to prepare highly efficient and effective emissive devices based on MIM configurations using an insulator layer composed of UCNPs and PeQDs, which can be expanded to serve a generalized platform in a broad range of applications.

Instrument-on-a-Chip for *In Situ* Planetary Research Mahmooda Sultana; NASA Goddard Space Flight Center, United States

In situ measurements of trace gases in planetary environments are crucial for the understanding of atmospheric, geological, and possible biological processes. Currently, most planetary missions rely on large, heavy, high power instrumentation such as mass spectrometers for *in situ* chemical analysis. The size, weight and power (SWAP) of these payloads make the overall missions costly and challenging. In addition, some of the key species required for the origin of life as we know it, such as methane, ammonia, and water, are difficult to distinguish using mass spectrometry alone due to mass interference issues. To enable lower cost science missions, we have developed a highly miniaturized and compact multifunctional environmental sensor platform based on additive manufacturing techniques of low dimensional materials. The unique electrical and physical properties of nanomaterials coupled with the high surface area-to-volume ratio make them outstanding candidates as extremely sensitive gas detecting elements. In addition, our functionalized sensors are able to distinguish between key species of interest to astrobiology. The ability to print the sensor systems, heaters, interconnects and wireless antenna directly on the same substrate eliminates the need to integrate individually fabricated components. This makes the packaging significantly more robust and reduces the footprint of the overall instrument. In this talk, I will present the development and status of a unique instrument-on-a-chip for *in situ* planetary research, and potential upcoming mission opportunities.

12:45 PM EL05.13.03
Chiral Kirigami Metamaterials Wonjin Choi, Gong Cheng, Sang Hyun Lee, Theodore B. Norris and Nicholas A. Kotov; University of Michigan–Ann Arbor, United States

Kirigami, the art of paper cutting, presents a powerful tool to create complex and reconfigurable three-dimensional (3D) geometries from simple 2D cut patterns, which can be scaled across many orders of magnitude to yield macro- to nanoscale structures. The ability to achieve out-of-plane buckling, designed 3D shape, the robustness of the patterns under cyclic reconfiguration and the compatibility to conventional fabrication processes of kirigami structures together promise untapped possibilities for the efficient modulation of optical beams. Here we show that kirigami optics affords real-time modulation of THz beams with polarization rotation and ellipticity angles as large as 80° and 40° over thousands of cycles, respectively. The unusually large amplitudes of polarization rotation and ellipticity angles exceeding all known THz modulators were enabled by double-scale patterns composed of microscale metallic stripes together with submillimeter-scale kirigami cuts. We measured terahertz circular dichorism (TCD) spectra of several representative biological samples using chiral kirigami metamaterials and found distinctive TCD peaks. Kirigami metamaterials will also play an indispensible role for other applications, such as biomedical imaging, biosensors, line-of-sight telecommunication, information encryption and space exploration.

12:50 PM EL05.13.04
Computational Design of Buckypaper/Epoxy Shape Memory Polymer Nanocomposites Yelena Sliozberg[1], Martin Kröger[2], Todd Henry[1], Siddhant Datta[3], Bradley Lawrence[1], Asha Hall[1] and Aditi Chattopadhyay[3]; [1]U.S. Army Research Laboratory, United States; [2]ETH Zürich, Switzerland; [3]Arizona State University, United States

The objective of this work is to understand the underlying molecular mechanisms of structural and mechanical properties of shape memory polymer (SMP) nanocomposites used for reconfigurable structures. In this work, we have performed coarse-grained molecular dynamics simulations and entanglement analysis of buckypaper (BP)/epoxy nanocomposites with a focus on their mechanical and shape memory performances, specifically on prediction of the Young's modulus of the material as a function of carbon nanotube (CNT) loading. We found

that the Young's modulus linearly increases with CNT volume fraction below 0.16 (40 wt%) followed by a sharp growth of the modulus at higher loading where the onset of entanglements of nanotubes was determined. Additionally, we found a significantly greater increase of the modulus at $T > T_g$ compared with the values below the glass transition temperature for all considered systems. The simulation suggests that incorporation of BP restricts relaxation of network strands of the polymer matrix and leads to resistance in the recovery process of composites. Computational results are compared with our experimental data on temperature controlled mechanical testing in tension of BP/epoxy nanocomposites.

12:55 PM EL05.13.05
A Quantum Leap in Nanophotonic Sensing: Ultrasensitive Fano Sensors Enabling SARS-CoV-2 Viral Load Detection Beyond the RT-PCR Techniques Xiangchao Zhu, Mustafa Mutlu, Reefat Inum, Ray Jara, Ahsan A. Habib and Ahmet A. Yanik; University of California, United States

A number of recent viral outbreaks, including the recent COVID-19 pandemic, have caused significant public health and economic concerns. Rapid and reliable point of care (POC) diagnostic technologies would provide a necessary first step for the proper treatment and management of these diseases [1]. State-of-the-art in vitro diagnostics (IVD) technologies including enzyme-linked immunosorbent assays (ELISA), and quantitative polymerase chain reaction (qPCR) are labor intensive, require cumbersome sample preparation, sophisticated equipment, and skilled operators. Here, using a novel nanophotonic approach, we present an ultrasensitive optofluidic diagnostic platform allowing detection of viral antigens with simple instrumentation at a concentration level five orders of magnitude lower than the most sensitive ELISA tests, and orders of magnitude more sensitive than the most advanced IVD technologies. In our tests with human serum samples, we experimentally demonstrated quantitative detection of viral antigens at attomolar sensitivities corresponding to 5-10 virus particles per 100 microliters. At this sensitivity level, our novel nanophotonic platform provided a compelling alternative to RNA-based quantitative-PCR tests for viral load detection.

Rapid Ge Diffusion Along Si/SiO_2 Interfaces During High Temperature Oxidation Chappel Sharrock[1], Benjamin Hicks[1], Emily Turner[1], Mark Law[1], George Wang[2] and Kevin S. Jones[1]; [1]University of Florida, United States; [2]Sandia National Laboratories, United States

In order to continue improving the performance of transistors beyond the 5nm node, there is interest in optimizing the use of Si and Ge in unique geometries [1]. A novel diffusion mechanism of Ge along an oxidizing Si/SiO_2 interface was reported, which resulted in the formation of strained Si nanowires [2]. Taking advantage of this diffusion mechanism has the potential of forming nanowires, nano-dots, and arbitrary shapes based on lithographic patterning; however, there is no understanding of the diffusion mechanism that results in the formation of these structures. To investigate this mechanism, alternating 20nm thick layers of Si and $Si_{0.7}Ge_{0.3}$ were grown in a superlattice and patterned into fins via electron beam lithography. The final pattern contained multi-layered Si/SiGe fins with widths varying from 70 to 280nm with a single 100nm layer of Si at the base in which to observe the diffusion of Ge down the fin's sidewall during high temperature oxidation.

This lateral diffusion was observed over a range of times and temperatures between 800 and 950°C. Cross-sectional TEM samples were prepared after each anneal and the rate of diffusion was measured through analysis of HAADF-STEM images. The diffusion constant for Ge's lateral movement down the Si sidewall was measured to be approximately $1x10^{-14}cm^2/s$ during 900°C oxidation. This is several orders of magnitude larger than Ge's interdiffusion with Si, which helps to explain why the nanowires and quantum dots are formed within these materials [3], [4]. The correlation between the thickness of the thermally grown oxide, the width of the SiGe layer forming on the side of the fin, and the length of the Ge diffusing down the side of Si sidewall has also been studied, providing additional insight into the diffusion mechanism. This analysis has been carried out

at multiple temperatures between 800 and 950°C, and the activation energy for Ge's lateral diffusion will be presented. These experimental results will be accompanied by a model using the Florida object-oriented process and device simulator (FLOOXS), which has been using to assist in the extraction of diffusivities. Preliminary results using the process simulator's model will be compared to the experimentally observed evolution of the nanostructures.

Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

1:05 PM EL05.13.07
Late News: A Numerical Study of Near-Field Thermophotonic Devices Including Local Emission and Absorption Distributions Julien Legendre and Pierre-Olivier Chapuis; Univ Lyon, CNRS, INSA Lyon, Université Claude-Bernard Lyon 1, CETHIL UMR5008, France

Thermophotonics (TPX) is a technology close to thermophotovoltaics (TPV), where a heated light- emitted diode (LED) is used as the active emitter of the system [1]. With the development of LEDs and the increase of their achievable quantum efficiency, TPX has come out as an attractive concept for both energy harvesting and refrigeration [2]. The many studies on near-field (NF) thermal radiation and their application into efficient NF TPV devices [3] highlight the possibility to extend the concept to near-field thermophotonics [4], where enhanced energy conversion is due to both the electric control and wave tunneling.
This contribution explores the theoretical capabilities of NF-TPX systems. Ideal cases are compared with more realistic structures, involving materials such as Si, GaAs and GaN. Based on the local absorption and emission distributions [5], the results include detailed IV characteristics of the LED and PV cell sides around the maximum power point, and highlight in particular the advantages in comparison to far-field TPX and NF TPV. A particular attention is drawn to the search of optimal surface properties for the LED and the PV cell, which could potentially be approached by using metasurfaces. The impact of the temperature difference between these two elements, their quantum efficiency and the thickness of the different components are amongst the studied parameters.

Meta-Optical Computational Imaging Systems for Large Aperture, Aberration-Free Imaging Arka Majumdar; University of Washington, United States

By exploiting computational backend, coupled with a designer meta-optics we demonstrate high-quality aberration free imaging using a single meta-optic in the visible wavelength range. The aperture is currently 0.5-1mm, but can be extended further. Several inverse design tools and end-to-end optimization are used to achieve such performance.

1:40 PM EL05.03.04
Tunable and Enhanced Absorption of Extended Short-Wave Infrared GeSn Nanopillar Arrays Anis Attiaoui, Etienne Bouthillier, Gerard Daligou, Aashish Kumar, Simone Assali and Oussama Moutanabbir; Polytechnique Montréal, Canada

Engineering light absorption in GeSn structures is crucial to enhance their basic device performance for a variety of applications such as MIR photodetectors and solar cells. Surface texturing to reduce the reflectivity is a key strategy to tune the optical properties. Since Group IV semiconductors typically have large refractive indices compared to air (between 3.4 and 4.2), planar opto-electronic devices are plagued by this refractive index mismatch. A promising method to circumvent this limitation is the use of semiconductor nanowires arranged in arrays covering an area of macroscopic dimensions. Top-down etched GeSn nanowire (NW) arrays were microfabricated with varying geometrical configuration. Visible and near IR spectroscopic ellipsometry measurement was undertaken in the spectral range from 900 nm to 2500 nm to evaluate the complex optical constant (n and k) for a 10% GeSn material. Detailed finite difference time domain (FDTD) simulations were combined with experimental analyses to systematically investigate light-GeSn nanowire interactions to tailor and optimize the NW array geometrical parameters and the corresponding optical response. The diameter-dependent leaky mode resonance peaks are theoretically predicted and experimentally confirmed with a tunable wavelength from 1.5 to 2.2 μm. A three-fold enhancement in the absorption with respect to GeSn thin film at 2.1 μm was achieved using nanowires with a diameter of 325 nm. The coupling between the HE_{11} and HE_{12} resonant modes manifests at NW diameters above 325 nm, while at smaller NW diameters and longer wavelengths the HE_{11} mode is guided into the underlying Ge layer. Additionally, the presence of tapering in NWs further extends the absorption range while minimizing reflection. The ability to manipulate light-matter interactions at the nanometer scale with GeSn is opening up new opportunities for spectral tunability in the extended short-wave infrared range.

Flat Optics for Dynamic Wavefront Manipulation Mark L. Brongersma; Stanford University, United States

Since the development of diffractive optical elements in the 1970s, major research efforts have focused on replacing bulky optical components by thinner, planar counterparts. The more recent advent of metasurfaces, i.e. nanostructured optical coatings, has further accelerated the development of flat optics through the realization that resonant optical antenna elements can be utilized to facilitate local control over the light scattering amplitude and phase. At the same time, researchers have aimed to identify ways to dynamically tune the properties of resonant optical antennas. The two developments are now leading to the development of dynamic flat optics.
In this presentation, I will highlight recent efforts in our group to realize electrically-tunable metasurfaces employing nanomechanics, electrochemistry, microfluidics, phase change materials, and atomically-thin semiconductors. Such elements can find application in systems for optical beam steering and wavefront manipulation as well as dynamic holography. I will illustrate how the proposed optical elements can be fabricated by scalable fabrication technologies, opening the door to many commercial applications.

Late News: Spectroelectrochemical Measurement and Modulation of Exction-Polaritons Wonmi Ahn[1] and

Blake S. Simpkins[2]; [1]Excet, Inc., United States; [2]U.S. Naval Research Laboratory, United States

Quantum emitters strongly coupled to optical cavity modes create new hybrid states called polaritons, resulting in a vacuum Rabi splitting (Ω). Strikingly, the magnitude of this splitting correlates with modified emission properties and chemical reaction rates. However, active control of this coupling strength is difficult due to the fixed properties of the coupled oscillators (both, the quantum emitter and optical resonator). Here, we demonstrate active tuning of excitonic strong coupling in a system where organic dyes strongly couple to propagating surface plasmon polaritons (SPPs). After electropolymerization of a methylene blue (MB) film on a SPP-supporting Au surface, we demonstrated active control of coupling strength through reversible redox cycling of the MB film. Excitonic strong coupling was effectively cycled on and off with electrode potential either continuously tuned (*transient*) or held at a fixed value (*static*) and were quantitatively correlated with simultaneously measured electrochemical charge. Switching between reduced and oxidized forms of the dye resulted in Ω values tuned from ~0 to ~280 meV, *i.e.*, ~14% of the transition energy. The ability to control coupling strengths in a given emitter-cavity coupled system is a key capability for utilizing polaritonic states for cavity-mediated chemical reactions or optical devices.

Observation of Exciton-Polariton Emission in 2D Hybrid Perovskites with Intrinsic Cavity Induced Coupling Surendra B. Anantharaman[1], Jason Lynch[1], Baokun Song[1], Jin Hou[2,2], Huiqin Zhang[1], Kiyoung Jo[1], Pawan Kumar[1], Jean-Christophe Blancon[2], Aditya Mohite[2,2] and Deep M. Jariwala[1]; [1]University of Pennsylvania, United States; [2]Rice University, United States

Hybrid states such as polaritons emerging from light-matter interaction are mostly observed in excitonic materials integrated in an external optical cavity. Two-dimensional (2D) hybrid organic/inorganic perovskites namely Ruddlesden-Popper (RP) perovskite have shown strong exciton confinement and oscillator strengths (12 (n=1) and 6 (n=2)).[1] Further, their optical constants suggest that the loss tangents in RP phase perovskites are among the highest for known excitonic semiconductor materials. These extraordinary optical properties can be exploited to create both the gain and cavity media in the semiconductor for strong light-matter interaction. Here, we show that intrinsic cavity mode formation in 2D perovskite flakes of intermediate thickness (~200 nm) on Au substrate leads to polariton state formation with Rabi splitting ~135 meV. In contrast, the thin flakes (15 nm) remain purely excitonic in nature. We confirm exciton-polariton formation from reflectance spectroscopy and associated emission spectroscopy at room temperature. Using transfer-matrix calculations, the experimentally observed exciton-polariton states can be modelled with two-coupled oscillators that corroborate well with the reflectance spectra. Further, temperature dependent photoluminescence and reflectance spectra shows the Rabi splitting and hybrid emission from exciton-polariton states present at room temperature, remains unperturbed down to 80 K. Tunable polariton formation from 520 nm to 610 nm by varying the perovskite composition will be presented. Rabi splitting increases with increase in oscillator strength of the perovskite as n is varied from 4 to 1. We believe that our work will open new avenues for exploring polariton in optoelectronic devices and photochemistry.

Keywords: Ruddlesden-Popper perovskites, Hybrid states, Polaritons, Rabi splitting, Intrinsic cavity mode

Ultrabroadband Nanophotonic 2D Material-Based Architecture for Reflection and Thermal Emission Control in Laser-Driven Lightsails John B. Brewer[1], Pawan Kumar[2], Matthew F. Campbell[2], Mohsen Azadi[2], George A. Popov[2], Igor Bargatin[2], Deep M. Jariwala[2] and Aaswath Raman[1]; [1]University of California, Los Angeles, United States; [2]University of Pennsylvania, United States

We present a holistic nanophotonic 2D material-based design strategy for ultrathin laser-driven lightsails that provides both high weight-constrained reflectance over a defined bandwidth and enhanced thermal emittance. Our investigation explores the use of hexagonal boron nitride (h-BN) and molybdenum disulfide (MoS_2) arranged in an inverse-designed layered photonic crystal architecture. Both the optical and thermal properties of the design are shown to be viable, emphasizing the holistic merit of its functionality. Relative to other designs, our concept exhibits impressive spectral emissivity values and accelerations for its mass, as well as the potential for excellent mechanical compliance. We compare its performance against other designs and show reasonable benchmarks of emissivity necessary to produce given steady state temperatures.

The Breakthrough Starshot Initiative aims to send a nanocraft to Earth's nearest habitable exoplanet, Proxima Centauri B, within 20 years of launch. To do so, the craft will use a reflective light sail accelerated by a ~100 GW phased array of lasers to speeds of 0.2c[1]. This requires a sail that is highly reflective over a Doppler-broadened wavelength range starting from the laser wavelength, is highly emissive in the mid-wave and long-wave infrared to effectively dissipate heat during acceleration, is mechanically robust enough to not degrade under the large forces acting on it, is correctly shaped to provide beam riding stability, and has a mass totaling ~1 g with a similarly-sized payload. Previous work has demonstrated designs using conventional dielectric materials such as Si_3N_4[2], Si, and SiO_2[3,4]. Given the stringent weight and mechanical requirements of the sail, 2D materials may be ideally suited to serve as key lightsail components; however, to date they have not been extensively explored for this application. In addition, while several studies have considered optical factors in order to minimize acceleration distances, few have co-optimized thermal properties in order to present a holistic assessment of the overall suitability of a sail design.

Here we present an optimized 2D material-based nanophotonic sail design that is optically suitable and able to effectively dissipate heat as thermal radiation to maintain reasonable in-flight temperatures. This sail consists of a 1.264-gram multi-layer photonic crystal slab composed of h-BN and MoS_2 layers and is shown, through full-field electromagnetic simulations, of being capable of accelerating an equivalent mass payload to 0.2c within 14 gigameters. The materials utilized have refractive indices ranging from ~2.13 for h-BN to 3.98-3.87 for MoS_2 over the doppler broadened range. We show the sail's fabricability using currently available patterning and etching techniques, provide benchmark material emissivity values necessary to maintain a given steady-state sail temperature, and demonstrate how payload weight influences the optimal sail design. Additionally, we discuss thermal considerations such as vacuum evaporation of features and how maximum temperature limits of materials should be set to ensure sail viability. Finally, we discuss the need for high resolution measurements of 2 dimensional optical, thermal, mechanical, and coupled material constants to continue to improve simulation accuracy and true viability of future sail designs.

Tunable Light-Matter Interactions in Excitonic Semiconductors Deep M. Jariwala; University of Pennsylvania, United States

The isolation of stable atomically thin two-dimensional (2D) materials on arbitrary substrates has led to a revolution in solid state physics and semiconductor device research over the past decade. A variety of other 2D materials (including semiconductors) with varying properties have been isolated raising the prospects for devices assembled by van der Waals forces.[1] Particularly, these van der Waals bonded semiconductors exhibit strong excitonic resonances and large optical dielectric constants as compared to bulk 3D semiconductors. . First, I will focus on the subject of strong light-matter coupling in excitonic 2D semiconductors, namely chalcogenides of Mo and W. Visible spectrum band-gaps with strong excitonic absorption makes transition metal dichalcogenides (TMDCs) of molybdenum and tungsten as attractive candidates for investigating light matter interaction and applications as absorbing media in opto-electronics.[2, 3] We will present our recent work

on the fundamental physics of light trapping in multi-layer TMDCs when coupled to plasmonic substrates. We systematically demonstrate via calculations and matching experiments that the presence of strong excitonic resonances in multilayers (< 20 nm thickness) combined with surface plasmon excitations of the nearby metals can achieve strongly coupled modes with apparent voided crossings in reflectance spectra.[4]
Next, we will show the extension of these results to multilayers and superlattices of excitonic chalcogenides with alternating layers of boron nitride and aluminum oxide. These hybrid multilayers offer a unique opportunity to confine light in < 3 nm thick direct band gap absorbers over cm^2 scale areas. We will discuss the physics of strong light-matter coupling and applications of these multilayers. Finally, we will also present our recent and on-going works on tunable light-matter interactions in hybrid organic-inorganic perovskites[5] where we observe exciton-polariton hybrid state emission at room temperatures in an external cavity-less geometry. Finally, I will also present our recent work on giant gate-tunability of optical constants in the telecom band in thin-films of high purity, semiconducting, carbon nanotubes.[6] Our results highlight the vast opportunities available to tailor light-matter interactions in quantum confined materials in simple and practical designs enabling study of novel photonic phenomena and presenting avenues for practical technologies.

High-Q Phase Gradient Metasurfaces for Compact Sensors and Modulators Jennifer Dionne, Jack Hu, Fareeha Safir, Mark Lawrence, David Barton and Jefferson Dixon; Stanford University, United States

High quality factor (“high Q”) cavities have revolutionized information processing, communications, sensing, and nonlinear optics by increasing photon storage times and significantly enhancing light-matter interactions. However, when the size of dielectric cavities is reduced to the nanoscale, resonant modes start to resemble point sources, scattering an incident wave in many different directions. While this scattering has been leveraged to create remarkable metasurfaces that precisely control the phase, amplitude, and polarization of light in an ultrathin footprint, metasurfaces generally exhibit high radiative loss rates and thus low Q-factors. Here, we present a general strategy for crafting high quality factor resonances in a phase gradient metasurface, and apply these results to achieve 1) multiplexed nucleic acid detection and 2) efficient electro-optic modulation. To creat a high-Q metasurface, we introduce subtle structural perturbations to individual resonators to weakly couple free-space light into otherwise bound modes. We experimentally demonstrate control over the quality factor and resonant wavelengths in this scheme, achieving record phase-gradient metasurface Q’s greater than 2500. We highlight this scheme’s general applicability by designing and fabricating high-Q metasurfaces that act as beamsteerers to different angles, beam splitters, and lenses. Next, we show how high-Q metasurfaces can enable multiplexed nucleic acid detection. Our high-Q metasurfaces are functionalized with single-stranded DNA to target specific RNA gene sequences, then illuminated with a laser diode; the scattered intensity provides a

quantitative measure of the bound nucleic acid concentration. As a proof-of-concept, we focus on SARS-CoV-2 genetic sequences, including recent viral variants; through "multi-color" printing of the probe nucleic acid, we show multiplexed detection of viral variants within 15 minutes. Finally, we show how high-Q metasurfaces can be integrated with electro-optic materials for low-power metasurface modulation. Here, an array of uniform lithium niobate-on-Si antennas is individually addressed with an electrical bias, leading to a full 2 pi phase variation. We show how near-continuous beam-steering can be achieved by modifying the bias across each antenna, en-route to fully reconfigurable, solid-state information processing spanning LiDAR, LiFi, AR/VR, and quantum communications.

5:55 PM EL05.15.02

Self-Assembled Multi-Phase Metamaterials for Enhanced Magneto-Optical Anisotropy Xuejing Wang[1,2], Jie Jian[1], Haohan Wang[3], Yash Pachaury[1], Ping Lu[4], Xiaoshan Xu[3], Anter A. El-Azab[1], Xinghang Zhang[1] and Haiyan Wang[1,1]; [1]Purdue University, United States; [2]Los Alamos National Laboratory, United States; [3]University of Nebraska-Lincoln, United States; [4]Sandia National Laboratories, United States

Magneto-optical coupling incorporates photon-induced change of magnetic polarization that can be adopted in ultrafast switching, optical isolators, mode convertors, and optical data storage components for advanced optical integrated circuits. However, integrating plasmonic, magnetic and dielectric properties in one single material system is challenging since one natural material can hardly possess multiple functionalities. We use a bottom-up self-assembling synthesis method to integrate multifunctional phases as a nanopillar-in-matrix thin film nanostructure that realizes epitaxial quality, sharp atomic interface and large throughput. Using titanium nitride (TiN) as a durable plasmonic matrix, a metal-free metamaterial platform with embedded nickel oxide (NiO) vertical nanorods that function as tunable ferromagnetic nanodomains has been demonstrated. Such a dissimilar ceramic-ceramic combination enables a strong hyperbolic dispersion in the visible and near infrared frequencies. More interestingly, when Au is introduced in TiN-NiO, a hybrid core-shell nanopillar array is formed where the two-monolayer Au shell serves to release the strain energy at the TiN/NiO interface. We demonstrate that a significantly enhanced long-range ordering of core-shell nanopillars can be achieved by using a template bottom-up growth process, which enables stronger Kerr anisotropy that is promising for building tunable and modulated all-optical nanodevices.

6:10 PM EL05.15.03

Semiconductor and Metal Metalattice Nanostructures—3D, Ordered and Extended Plasmonic Platforms for the NIR-VIS-UV Regime Parivash Moradifar[1], Lei Kang[1], Pratibha Mahale[2], Yunzhi Liu[1], Nabila Nova[1], Andrew Glaid[1], John Badding[1], Tom Mallouk[2], Douglas Werner[1] and Nasim Alem[1]; [1]The Pennsylvania State University, United States; [2]University of Pennsylvania, United States

Plasmonics is an emerging field in the intersection between nanotechnology, photonics and electronics. Surface plasmons are coupled collective excitations of conduction electrons and an applied electromagnetic field. Plasmons hereby enable enhancement, confinement and manipulation of light at the nanoscale level. Noble metal-based nanostructures are the most widely studied plasmonic materials since they exhibit strong electromagnetic field enhancement in the visible spectral range. However, strong dissipation originating from interband electronic transitions and losses in noble metals, makes it imperative to investigate alternative building blocks with lower losses and more diverse properties. Metamaterials are new emerging building blocks in electronics and photonics. They are proposed as versatile and tunable platforms supporting various surface plasmon modes exhibiting exotic plasmonic phenomena.

This study will focus on the plasmonic behavior of novel 3D hybrid metamaterials using monochromated electron energy loss spectroscopy (Mono-EELS) in conjunction with scanning/transmission electron microscopy (S/TEM) and X-ray energy dispersive spectroscopy (XEDS) to identify and spatially resolve various surface plasmon resonances (SPRs) over a wide spectral range of NIR-Vis-UV. Metalattices as a subgroup of metamaterials, are nanostructured 3D ordered hybrid materials on the range of sub 100 nm (sub wave-length scale). The metalattice nanostructures are high pressure confined CVD (HPcCVD) synthesized

nanostructures, compromised of a SiO_2 close-packed template infiltrated by either Ag or Si-Ge, forming periodic and long-range interconnected structures. A void-free infiltration of these 3D ordered frameworks can provide a versatile and tunable platform as integrated plasmonic interconnects for large optical confinement and long propagation distance applications. By spatially and spectrally resolving the plasmonic response, localized and delocalized effects are studied, and the implications of confinement, interconnectivity, substrate effect, presence of cavity arrays as potential tools for modulating and tuning SPRs are explored. This work also utilizes theoretical calculations to further support the experimental measurements.

Plasmonic metalattice as a periodic and long-range interconnected structure is a novel route to make highly tunable and cost-efficient plasmonic materials with enhanced photonic properties providing a significant control over ultra-local modification of surface plasmon resonances. This understanding is a crucial key for a more efficient electromagnetic energy storage, enhanced biological, chemical sensing and next generation of transparent and flexible optoelectronic/plasmonic devices.

6:25 PM EL05.15.04
Porous Ceramics as a Near-Ideal Radiative Cooling Design Jyotirmoy Mandal; University of California, Los Angeles, United States

Passive radiative cooling (PRC) of terrestrial objects is achieved by radiative heat loss into space through the long wavelength infrared (LWIR) atmospheric transmission window. Due to its passive nature and net cooling effect, it is a sustainable way to cool human environments. A major goal of radiative cooling research is to create designs with near-ideal spectral properties – i.e. selective emittance in the LWIR (λ~8-13 μm), and perfect reflectance elsewhere in the solar-thermal wavelengths (λ~0.2-40 μm). However, most PRC designs are non-ideal with regard to selectivity [1-2], or else need multiple materials and complex architectures [3].
This presentation proposes a bilayer porous ceramics as selectively LWIR emissive radiative coolers with near-ideal optical performance. The selective emittance arises from the Christiansen effect, while the high reflectance elsewhere arises from the porous structure (for $\lambda < 8$ μm) and Restrahlen reflection (for $\lambda > 13$ μm). It theoretically shows how this can lead to near-ideal spectral properties, and demonstrate real examples that can achieve this behaviour. Along with their robustness and resistance to weathering, this makes porous ceramics near-ideal materials for radiative cooling.

Advancing Functional Materials for Robust and Dynamic Nanophotonics Nathaniel Kinsey, Dhruv Fomra, Kai Ding, Md. Ariful Hoque Sojib, Samprity Saha, Ray Secondo, Adam Ball, Vitaliy Avrutin and Umit Ozgur; Virginia Commonwealth University, United States

Materials drive innovation across science and technology, and photonic applications are no exception. In the last decade, a wide range of new and emerging materials have been realized to improve nonlinear interactions, support single-photon emission, and explore new realms of light-matter interaction. Among them, two classes of materials have had a particular impact in the area of nanophotonics, transition metal nitrides and transparent conducting oxides. The former has provided a robust and CMOS-compatible metallic alternative to traditional elemental metals while the latter has unlocked a new field of dynamic tunability and enhanced nonlinearities through epsilon-near-zero properties. In this talk, we will highlight our work to extend the development of two key materials, TiN and Al:ZnO, using new realms of scalable, low-temperature, CMOS-compatible plasma-enhanced atomic layer deposition. In addition, we will discuss some recent applications of these materials to realize robust plasmonic security devices, and enhanced dynamic applications for nonlinear optics and

integrated photonics.

EL05

9:00 PM *EL05.16.01
Dielectric Metasurfaces for Flat Optics—Wavefront Engineering and Future Applications Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Miniaturization is a main stream in modern technology, but reduction of conventional optical components accompanies performance degradation that limits the minimum feature size of optical devices. Metasurfaces that consist of ultrathin subwavelength antenna arrays can be a promising solution because metasurfaces provide an effective way of wavefront engineering without constraints on the device size. Electromagnetic responses of individual building blocks are determined by its geometric configurations, and many kinds of antennas have been explored to clarify the capability of metasurfaces; thereby, it has been verified that dielectric antennas can control amplitude, phase, and even both of them simultaneously.

The capability of wavefront engineering allows to realize versatile future applications such as holograms, lenses and color filters. Fundamental limitations of conventional holograms such as twin image and narrow viewing angle can be removed by metaholograms due to their sub-wavelength pixel size. Propagation phase of isotropic building blocks enables polarization-insensitive operation while geometric phase of anisotropic building blocks allows broadband operation of multifunctional metaholograms (*i.e.* image hologram, multiplexed metaholograms). Furthermore, both propagation phase and geometric phase can be considered in design of meta-atom, which enables a multicolor metahologram and complex-amplitude hologram. The recent advanced understanding of building blocks brings about an increase of the number of hologram encoded in the metasurface based on dispersion engineering and orbital-angular-momentum multiplexing. The metaholograms can also be extended to random point-cloud generation for application toward 3D object detection. The same design method described above can be applied to polarization independent broadband beam splitting and ultrathin light-focusing devices, *i.e.* metalenses.

Metasurfaces can engineer transmission/reflection spectrum in visible regime, i.e. sub-wavelength color printing. The building block to modulate scattering response is high-index dielectric Mie-scatterer which resonantly radiate light with fundamental modes when its size become comparable to wavelength of incident light. The metasurface, composed of arrays of Mie-scatters, transmit/reflect lights with the resonance modes, thus rendering structural colors which are changed according to the geometry of the scatterers. The metasurface which consists of asymmetric unit structure switch its colors depending on the polarization state of incident light, thus enabling application for optical cryptograpy. Adoption of phase change materials and stimuli-responsive materials enables active color filters.

Comprehensive metasurfaces that control both phase and amplitude have been realized by adjusting unit structures. The hologram resolution can be drastically improved by controlling complex amplitude using X-shaped antennas, and both functions of holography and color printing can be integrated in a single metasurface.

Recently, much metasurface research has aimed to embed nanoparticle-based hierarchy in building blocks to enhance the chirality[21] and refractive index[16,22,23]. Furthermore, actively tunable meta-holographic displays with designer liquid crystal modulators will enable interactive holographic displays and unconventional photonic sensor applications[24,25]. In the future, metasurface research will be further expanded to a practical region by

exploiting diverse light properties (*e.g.* orbital angular momentum) to realize real-time 3D holographic video displays or advanced optical security labels[6].

9:30 PM EL05.16.02
Complex Refractive Index Modulation of Hydrogenated Amorphous Silicon for Efficient Metasurfaces at the Visible Frequencies Younghwan Yang, Gwanho Yoon and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Hydrogenated amorphous silicon has emerged as materials for dielectric metasurfaces, which are promising optical platforms since it has compatibility with mature complementary metal-oxide-semiconductor processes. However, the bandgap of hydrogenated amorphous silicon filters electromagnetic waves at the visible frequencies, preventing it from being optical devices at the visible. Here, we investigate structural disorders of silicon and hydrogenation in order to suppress the bandgap of it to produce visibly transparent hydrogenated amorphous silicon. The structural configuration of silicon-hydrogen bindings is varied by the chemical deposition equilibrium of plasma-enhanced chemical vapor deposition chambers. The chamber atmospheres are changed by manipulating substrate temperatures, chamber pressures, radio frequency power, and input gas ratio. Chemical deposition equilibrium affects the bonding configurations and we reveal that substrate temperature and chamber pressure affect bonding configuration, providing wide coverages of complex refractive index at the visible frequencies. The refractive index of hydrogenated amorphous silicon can be changed from 3.0 to 4.1; the extinction coefficient can be as low as 0.09 at the wavelength of 450 nm. We also reveal the bonding configuration to interpret the relationship between bandgap and composition of hydrogenated amorphous silicon. The X-ray diffraction and Raman were conducted to uncover the crystallinity and stretching vibration, respectively. Micro-crystallinity induces a low extinction coefficient at the visible, and the polyhydride bonding contributes to high transparency. This low-loss hydrogenated amorphous silicon achieves the lowest values of the extinction coefficient are 0.082, 0.017, and 0.009 at the wavelengths of 450, 532, and 635 nm, respectively. Low-loss hydrogenated amorphous silicon is confirmed with beam steering metasurfaces, which deviate the incident light with precisely designed angles. Demonstrated low-loss metasurfaces achieve modulation efficiencies of 64.7% at 450 nm, 90.9% at 532 nm, and 96.6% at 635 nm, which are compatible with conventional low-loss dielectrics such as titanium dioxide and gallium nitride. The metasurfaces steer incident light with 9.9, 12.7, and 11.3 degrees operating at 450, 532, and 635 nm, respectively, which highly coincide with 10.8, 12.8, and 11.4 degrees at each wavelength. Considering its low optical losses and a large coverage of the complex refractive index, our low-loss hydrogenated amorphous silicon will be the dominant platform material at the visible frequencies.

9:45 PM EL05.16.03
Sub-Ambient Daytime Radiative Cooling by Silica-Coated Porous Anodic Aluminum Oxide Dasol Lee, Minkyung Kim and Junsuk Rho; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Passive radiative cooling is a concept where an object on the Earth can radiate heat into outer space through the atmospheric window (AW) in the mid-infrared spectrum (8-13 μm). As the objects radiate, they cool down. For effective energy-free radiative cooling, the object must have low absorption of energy from the atmosphere, high emission through the AW, and minimal heat exchange with its surroundings. Passive cooling of an object under direct sunlight in the daytime can be achieved by radiating more energy away than what is absorbed. For this process, absorption of the strong solar radiation is undesirable, so it must be minimized by achieving high reflectivity in the ultraviolet (UV) and near-infrared (NIR) regime (0.3-2.5 μm), while simultaneously maximizing the emission of energy through the AW.
In this work, we propose an approach for passive radiative cooling that uses silica-coated porous anodic aluminum oxide (AAO), which shows near perfect spectral emissivity in the AW. Nanoporous structures have the benefits of simple and low-cost fabrication, and compatibility with engineering to achieve selective emissivity in the AW. However, conventional AAO has a large extinction coefficient over 10 μm and by itself, does not produce the required near perfect spectral emissivity band over the entire AW. To compensate for this,

thin layers of silicon dioxide (SiO_2) are coated on the porous AAO to achieve near perfect emissivity over the AW. The experimentally fabricated SiO_2-coated AAO membrane shows an average cooling flux of 65.6 W/m^2 during the daytime, and a maximum cooling of 6.1 °C below ambient temperature under direct sunlight.

Enhanced Photochemical Reactions Under Modal Strong Coupling Conditions Hiroaki Misawa[1,2];
[1]Hokkaido University, Japan; [2]National Chiao Tung University, Taiwan

Metallic nanoparticles such as gold (Au) and silver (Ag) shows light absorption and scattering at the arbitrary wavelength of visible and near-infrared regions based on localized surface plasmon resonances (LSPRs). LSPRs which are collective oscillations of conductive electrons give rise to the enhancement of near-field and are expected as a light harvesting optical antenna for light energy conversion devices due to their spectrum tunability. We have successfully developed the plasmon-induced artificial photosynthesis systems such as water splitting and ammonia synthesis systems as well as solid-state plasmonic solar cells based on the principle of plasmon-induced charge separation between gold nanoparticles (Au-NPs) and the semiconductor photoelectrode.[1]-[7] Previously, the plasmon-induced charge separation has received considerable attention as a novel strategy for solar energy conversion.[8],[9] However, for the monolayer of Au-NPs on the semiconductor the insufficient absorption limited its solar energy conversion efficiency.
Recently, we reported Au-NPs/TiO_2/Au-film photoanode with a modal strong coupling between Fabry–Pérot nanocavity (FPnanocavity) mode and LSPR of Au-NPscan enhance water splitting reaction.[10] In particular, it should be noted that in addition to the absorption increment, the internal quantum efficiency (IQE) is enhanced under strong coupling conditions.
Additionally, we investigated the efficiency of hot-electron transfer under modal strong coupling conditions by monitoring the photocurrent generated at a plasmonic photoanode. We explored the effect of the modal strong coupling on the incident photon-to-current conversion efficiency (IPCE) and IQE in the presence of triethanolamine (TEOA) as a sacrificial electron donor to accelerate the surface reaction enough.[11] The absorption spectrum showed distinct dual bands,which corresponded to the strong-coupling-induced splitting ofenergy levels into upper and lower branches. The IPCE was dramatically enhanced as the TEOA concentration increased, and finally, the IPCE reached a maximum of ca. 4%. Additionally, both hybrid modes formed by the modal strong coupling contributed to the hot-electron transfers and photocurrent generation in the presence of TEOA because the IPCE action spectracan be separated into two peaks. Furthermore, the integrated IQE, which was obtained for wavelengths from 500 to 800 nm, was enhanced by approximately 5 times upon the addition of 1 vol% of TEOA and reached 3%.

Metasurfaces for Vortex Generation, Multiplexing and Laser Cheng-Wei Qiu; National University of Singapore, Singapore

Interfacial engineering via the artificially constructed structures of ultrathin thickness compared to the wavelength has enabled a plethora of advanced manipulations of light-matter interactions. I will report some of the most recent developments in my group as well as in the field of the interfacial engineering of manipulation of light-matter interactions, via the artificially nanostructured metasurfaces. Amongst various applications of metasurfaces, I will focus on how to design vortex metasurfaces[1] to generate and multiplex orbital angular momentums (OAMs), with other degrees of freedom of light such as polarization and frequency. Furthermore, we will show some more recent and exciting results about high-purity orbital angular momentum lasing by synergize the metasurfaces and cavities. It may provide an alternative paradigm toward an extremely compact and multifunctional nanodevices resorting to the OAM states of the light. The multiplexing and hybridization of OAM states with other properties of light open up new opportunities for the advanced flat-profile optics.

Late News: Plasmonic LASiS Metal Nanoparticles for Food Packaging Applications Margherita Izzi[1,2], Maria C. Sportelli[1], Antonio Ancona[1], Annalisa Volpe[1], Caterina Gaudiuso[1], Amalia Conte[3], Valentina Lacivita[3], Matteo A. Del Nobile[3], Rosaria Anna Picca[1,2] and Nicola Cioffi[1,2]; [1]University of Bari Aldo Moro, Italy; [2]CSGI (Center for Colloid and Surface Science), Italy; [3]University of Foggia, Italy

The application of metal and metal oxides in the form of nanostructures, to enhance physicochemical properties of materials has increasingly attracted the interest of materials scientists in different fields. Among other features, these nanomaterials show a broad antimicrobial activity and can be advantageous to design bioactive coatings and/or surfaces, with controlled metal ion release, exerting significant biological action and associated low toxicity for humans. In recent years, we have developed and deeply characterized many different nanoantimicrobial systems [1-3] as a powerful alternative route to fight bacterial resistance towards conventional antibiotics and disinfecting agents. In this study, bioactive Cu- and Ag- nanoparticles were

produced as ultra-stable [4] nanocolloids by means of laser ablation synthesis in solution (LASiS) for hypothetical food packaging application. We exploited the key features of LASiS, which is a green and versatile route to obtain nanoparticles without any toxic reductant or stabilizer. The resulting nanocolloids were used as additives for the controlled modification of different biodegradable polymeric matrices. Antibacterial ion release kinetics from modified surfaces was monitored, showing a tuneable and long-term release of bioactive species over time. The risk of entire nanoparticle release was ruled out by electron microscopy investigations of the contact solutions. Finally, the coatings' surface chemical composition (assessed by photoelectron and vibrational spectroscopies) was correlated with the ion release and bioactivity properties. They were examined in different cases of study, in order to evaluate their employment in active food packaging and bacteriostatic coatings for the car industry.

Exploring the Chemical Reactivity of Gallium Liquid Metal Nanoparticles in Galvanic Replacement Laia Castilla i Amorós, Dragos Stoian, James R. Pankhurst, Seyedeh Behnaz Varandili and Raffaella Buonsanti; École Polytechnique Fédérale de Lausanne, Switzerland

Liquid metals are an interesting class of materials with fascinating properties deriving from their simultaneous metallic and liquid nature.[1] Besides their use as self-healing contacts in stretchable electronics, shrinking the size of the particles down to the nanoscale adds an extra dimension of complexity which generates new physicochemical properties and opens up new applications. Liquid metal micron- and nano-sized particles are being explored for biomedical applications, chemical sensors, imaging, and batteries. Nevertheless, the knowledge of their chemistry is still very limited compared to other classes of materials. Ga-based nanoparticles (NPs) are the most studied systems so far. Interestingly, Ga NPs have been demonstrated to possess plasmonic properties that are influenced by their size-dependent solid-liquid transition.[2,3] Along with Ga, Cu is another non-noble metal presenting attracting catalytic and plasmonic behavior.[4] Yet, the combination of these two metals at the nanoscale has not previously been reported.
In this work, we explore the reactivity of colloidal liquid Ga nanoparticles (NPs) toward a copper molecular precursor to synthesize bimetallic Cu-Ga NPs.[5] Anisotropic mushroom-shaped Cu-Ga nanodimers, where the two segregated domains of the constituent metals share an interface, form as the reaction product. We combine transmission electron microscopy techniques, ICP elemental analysis, cyclic voltammetry and X-Ray absorption spectroscopy to investigate the formation mechanism of these anisotropic bimetallic nanostructures. We demonstrate that a galvanic replacement reaction (GRR) between the Ga seeds and a copper-amine complex takes place. GRRs are spontaneous electrochemical processes wherein one metallic domain (the sacrificial template) is oxidized by the cations of another metal that possesses a more positive reduction potential, usually resulting in alloyed hollowed structures in crystalline noble-metal systems. We, therefore, attribute the unusual final morphology of the bimetallic NPs to both the presence of the native oxide shell around the Ga NPs and their liquid nature, and we explain the reaction mechanism involving these phenomena. The same reaction scheme was then extended to the synthesis of Ag-Ga and Cu-In NPs, and their final morphologies further supported the above-stated hypothesis.
Based on this understanding, we also demonstrate that sequential GRRs to include more metal domains are possible and trimers including Ag-Cu-Ga were also obtained.
Overall, this first study on colloidal liquid metal NPs as sacrificial templates in GRRs showcases the very intriguing and peculiar reactivity of this class of materials at the nanoscale which has certainly been

underexplored to date. Furthermore, it opens the way toward achieving much more sophisticated and complex structures of Ga-based nanomaterials, which possess promising properties for top-scientific challenges including CO_2 electroreduction, sensing, plasmonics, and self-healing electronics.

Metal Chalcohalide Nanocrystals and Their Heterostructures with Halide Perovskite Nanocrystals
Liberato Manna; Istituto Italiano di Tecnologia, Italy

Halide perovskite semiconductors can merge the highly efficient operational principles of conventional inorganic semiconductors with the low temperature solution processability of emerging organic and hybrid materials, offering a promising route towards cheaply generating electricity as well as light. Following a surge of interest in this class of materials, research on the corresponding halide perovskite nanocrystals (NCs) as well has gathered momentum in the last years.1 Another class of materials that has been recently investigate by us is that of metal chalcohalides. These materials offer a broad solid-state chemistry and they been investigated for applications in solar energy conversion, thermoelectrics, hard radiation detection, and superconductivity. Among them, lead chalcohalides have been rarely studied in the past. We have recently reported the synthesis of a series of lead chalcohalides, by means of colloidal approaches, delivering phases and compositions that had not been previously identified in the bulk.2 These materials present indirect band gaps, they emit in the NIR region of the spectrum at cryogenic temperatures and have unique crystal structures. We will also show our recent results on the synthesis and advanced characterization of heterostructured nanocrystals in which one domain is a lead chalcohalide and the other domain is a cesium lead halide perovskite.3 The two domains are separated by a flat, atomically defined, epitaxial interface. In these materials, the photogenerated carries are separated at their interface, and as such they might be promising in applications ranging from catalysis to photovoltaics.

8:55 AM EL06.01.04
Late News: Study of the Surface Plasmon Resonances in Silicon Nanowires with Diameters Less Than 100 nm Giovanni Borgh[1,2], Corrado Bongiorno[2], Antonino La Magna[2], Giovanni Mannino[2], Salvatore Patanè[1], Jost Adam[3] and Rosaria A. Puglisi[2]; [1]Università degli Studi di Messina, Italy; [2]Consiglio Nazionale delle Ricerche, Italy; [3]University of Southern Denmark, Denmark

Silicon nanowires (Si-NWs) represent useful building blocks for nanoelectronic devices in many fields such as photovoltaics, photocatalysis, sensing or photodetectors. This is because they show interesting optical properties, including plasmon resonance (PR), the collective oscillation of free electrons, induced by an electromagnetic field at the proper frequency. PR is a versatile phenomenon because it is tunable depending on the intended application by modulating the nanosystem geometry, the medium covering or surrounding it and its shape. It allows, for example, to use Si-NWs to collect and amplify, by several orders of magnitude, radiant energy by generating a locally amplified electric field, a beneficial mechanism in many applications. Till now, however, there are no direct observations neither deep understanding in the literature on PR in Si-NWs. In this talk, the surface plasmon resonances triggered in isolated Si-NWs with diameters below than 100 nm are

visualized at high spatial resolution. We characterize the systems through transmission electron microscopy (TEM) coupled to electron energy loss spectroscopy (EELS) with a subnanometer electron probe. The plasmon behavior of the SiNWs is then modeled through theoretical calculations, and the results are in good agreement with the experimental data. The electrical field spatial distribution generated by the PR is mapped and rationalized. As an extension of our study, we show experimental and modeling data on SiNWs coated with different materials and structures, and we compare the plasmonic behavior to the one of pristine SiNWs.

9:10 AM EL06.01.05

Late News: Regular Self-Assembled Plasmonic Nanoparticle Superlattices—Characterization, Modelling and Applications Mathias Charconnet[1,2], Matiyas T. Korsa[3], Søren Petersen[3], Luis M. Liz-Marzán[2,4,5], Jost Adam[3] and Andreas Seifert[1,4]; [1]CIC nanoGUNE BRTA, Spain; [2]CIC biomaGUNE, Basque Research and Technology Alliance (BRTA), Spain; [3]University of Southern Denmark, Denmark; [4]IKERBASQUE, Basque Foundation for Science, Spain; [5]Centro de Investigación en Red de Bioingeniería, Biomateriales y Nanomedicina(CIBER-BBN), Spain

Noble metal nanoparticles (NPs) are known for their ability to confine visible and near-infrared light at the nanoscale through plasmonic resonances. The plasmonic resonance frequency can be tuned by changing the nanostructure shape, material, or adjacent environment. To extend the features of plasmonic resonances, NPs can be arranged into periodic structures, also called superlattices. Such lattice structures potentially foster inter-particle and inter-cluster interactions through photonic coupling, giving rise to so-called lattice plasmons, which have interesting properties, the potential for high Q factors, strong near-field enhancement, and the potential to be tuned by period, incident angle and polarization. Moreover, the inner structure of a unit cell (cluster) of such periodic arrangement and its homogeneity has a strong influence on the plasmonic response.
Here, we present a self-assembly process that allows us to assemble a controlled number of nanospheres, nanorods or nano triangles into superlattices on large-scale. Capillary forces drive the NP self-assembly, via a nanostructured mold that confines the NPs in periodically arranged wells, yielding NP clusters in a superlattice. The chemical composition of the NP dispersion controls the formation of homogeneous NP superlattices. We studied the impact of homogeneity concerning extinction properties, near-field enhancement and irregularities of superlattices. Further, we demonstrate the generalization of our process regarding different shapes of NPs. The fabrication of superlattices with a defined number of NPs in each cluster allows us to compare their extinction properties, moreover, to study the formation of hybrid plasmonic modes originating from the individual clusters and the lattice.
We support our experimental studies by numerical modelling, thereby calculating the superlattice-induced extinction. To minimize the gap between electromagnetic simulations and experimental characterization, we combine statistical image analysis (based on SEM images of self-assembled clusters), finite-element modelling, and material and structure optimization. To identify the superlattice plasmonic shift for a varying lattice parameter, we analyze the cluster's near-field electromagnetic response, for weighed superpositions of statistically relevant particle arrangements identified by image analysis. Based on statistical analysis, we introduce and superimpose various geometric irregularities in our model, for matching the fabricated superlattice extinction curve, alongside optimization of particle radius, potential shell thickness and refractive index, and particle materials. By Mie theory and colloidal particle measurements, we calibrate our material model and incorporate the results regarding the gap between self-assembled NPs. We demonstrate polarization effects and extinction spectra with respect to variations of aforementioned parameters. As a special case, we additionally show how sensitive the system responds when irregularities are introduced.
Our results, corroborated by electromagnetic simulations and complemented by surface-enhanced Raman scattering (SERS) measurements, provide insight into the near-field enhancement of nanospheres, nanorods and nanotriangles, arranged in sub-wavelength superlattices of macroscopic dimensions, and give rise to new ideas for plasmon-coupled sensing.

9:25 AM *EL06.01.06

Designing Au Nanocrystal Assemblies for Optical Metamaterials Cherie R. Kagan; University of Pennsylvania, United States

We report the use of colloidal Au NCs as building blocks in the design of optical metamaterials. Chemical exchange of the long ligands used in NC synthesis with more compact ligand chemistries brings neighboring NCs into proximity and increases interparticle coupling.[1,2] This ligand-controlled coupling allows us to tune through a dielectric-to-metal phase transition seen by a 10^{10} range in DC conductivity and a dielectric permittivity ranging from everywhere positive to everywhere negative across the whole range of optical frequencies.[1] For example, by partially exchanging the NC assemblies, we create strong, ultrathin film optical absorbers with a 6x increase in extinction in the infrared compared to that of bulk Au thin films.[2] For more complete ligand exchange and with thermal annealing, we realize strong optical scatterers useful in the design of optical metamaterials.[3] Ligand exchange and annealing of NC films also triggers a large volume shrinkage. By juxtaposing plasmonic NCs and bulk materials, we exploit their different chemical and mechanical properties to transform lithographically-defined two-dimensional structures, upon ligand exchange, into three-dimensional structures.[4] We use the three-dimensional structures to demonstrate large-area metamaterials with chiroptical responses of ~40% transmission difference between left-hand and right-hand circularly polarized light and that are suitable broadband circular polarizers.[5]

10:30 AM *EL06.02.01
Plasmonic Gold Nanorods: Tuning Absolute Dimensions and Properties Catherine J. Murphy; University of Illinois at Urbana-Champaign, United States

Gold nanorods, first made in the mid-late 1990's by several groups, are the quintessential examples of shape-controlled properties at the nanoscale: the aspect ratio of the rods governs the positions of their transverse and longitudinal plasmon bands. The "standard" synthesis, a seed-mediated growth approach in aqueous solution, yields gold nanorods with diameters of 10-15 nm and tunable lengths from 20-80 nm. These standard gold nanorods exhibit corresponding extinction spectra that show a transverse plasmon band at ~520 nm and

longitudinal plasmon bands at ~600-850 nm. Recently our laboratory has expanded its capability to create "mini," "maxi" and "mega" rods, where the range of aspect ratios are similar, and in some cases beyond, the standard rods. The fundamental absorption and scattering of light by this library of nanomaterials have been measured; and while the general expectation that larger particles scatter more light, and smaller particles absorb more light, is generally held, the details offer some surprises. The smallest nanorods enable surface chemical characterization by NMR; and recent STEM/EELS experiments show that the density of ligands at the ends and sides of the nanorods depends on ligand type and absolute rod dimension.

10:55 AM *EL06.02.02
It's Getting Hot in Here—Design of Thermally Stable Plasmonic Nanocrystals Sara E. Skrabalak; Indiana University Bloomington, United States

Gold and silver nanostructures are common for applications in plasmonics. However, additional metals can be added to bring new function and enhanced properties. Here, the synthesis of branched gold-palladium nanostructures by seed-mediated co-reduction will be discussed. These nanocrystals have localized surface plasmon resonances (LSPRs) that can be tuned throughout the visible and near-infrared through control of particle size, composition, and finer features such as tip sharpness. Significantly, the LSPRs of the branched gold-palladium nanostructures display higher sensitivity to changes in refractive index compared to all-gold analogues. This feature opens up the potential of such materials in LSPR sensor applications. The branched gold-palladium nanostructures also display high structural stability in photothermal applications. Electromagnetic simulations reveal that the Pd content, and specifically its distribution, has a significant impact on optical properties and is an essential criterion for efficient heating. This insight provides new synthetic targets and highlights the importance of developing synthetic methods where the distribution of different metals in multimetallic structures can be precisely controlled.

11:20 AM EL06.02.03
Late News: Plasmonic Nanostructures for Photothermal Conversion Yadong Yin; University of California, Riverside, United States

The plasmonic photothermal effect involves nonradiative conversion of light to heat by plasmonic nanostructures. It has attracted significant attention due to the widespread potential applications in developing energy conversion devices, therapeutic agents, and sensors and actuators. Here we report our recent progress on the design and preparation of plasmonic nanostructures for photothermal conversion. We first introduce the general principle of plasmonic photothermal conversion and then discuss the strategies for improving efficiency, which has been the focus of this field. We then discuss a number of typical application types, such as solar energy harvesting, steam generation, photothermal actuation, and color printing, to elucidate how to tailor the nanomaterials to meet the requirements of these specific applications. In addition to the photothermal effect, other unique physical and chemical properties can be coupled to further explore the application scenarios of plasmonic photothermal materials.

11:35 AM *EL06.02.04
***In Situ* Tracking Chemical Species at the Catalytically Active Surfaces of Silver Nanocrystals by Spectroscopy Fingerprinting** Dong Qin; Georgia Institute of Technology, United States

We report a mechanistic study of the Ag-catalyzed redox reaction between surface-bound nitroaromatic and isocyanide molecules for the production of an aromatic azo compound and isocyanate. We elucidate the mechanistic details by tracking the vibrational bands of all chemical species involved in the reaction through *in situ* surface-enhanced Raman spectroscopy (SERS). In a typical study, we functionalized the surface of Ag nanocubes with 1,4-phenylene diisocyanide (1,4-PDI) and demonstrated their adsorption by analyzing the Ag-bound N-C stretching band ($\nu_{NC(Ag)}$). When 4-nitrothiophenol (4-NTP) molecules were introduced onto the Ag surface covered with 1,4-PDI, we observed the decrease of the $n_{NC(Ag)}$ band and the appearance of the –NCO stretching band (ν_{NCO}) of isocyanate. Concurrently, we detected the formation of *trans*-4,4'-

dimercaptoazobezene (*trans*-DMAB) at the expense of 4-NTP by characterizing the vibrational bands of these two species. Because the binding of isocyanide to Ag contributed to the formation of an electron-rich surface through s donation, the redox reaction could occur when the oxygen atoms of the electron deficient nitro-groups of 4-NTP were extracted by the electron-rich Ag surface and subsequently used to oxidize the isocyanide to isocyanate. The coverage densities of both 1,4-PDI and 4-NTP on the Ag surface had a strong impact on the production of *trans*-DMAB. The redox reaction still took place when 1,4-PDI was replaced with 4,4'-biphenyldiisocyanide, confirming the pivotal role played by the isocyanide group.

1:00 PM *EL06.03.01
A New Twist on Nanoparticle Assembly—Chiral Plasominc Nanoparticle Superstructures from Molecular Peptide Precursors Nathaniel Rosi; University of Pittsburgh, United States

Replacing one atom or linkage in an organic molecule or polymer can dramatically affect its structure and properties. Chemists have long leveraged the power of synthesis to adjust and fine tune the properties of molecules and materials. Nanoparticles are a class of fundamental structural and functional building blocks for the construction of new materials. The properties of these materials depend on the size, shape, and composition of the constituent nanoparticles as well as their precise organization within the material. In order to fine tune the properties of the material, we must be able to carefully adjust the organization of its component nanoparticles. We are interested in using the power of synthetic chemistry to program and carefully adjust the structure and properties of hierarchical nanoparticle-based materials. This talk deals with peptide-based methods for controlling the synthesis and assembly of nanoparticles into well-defined chiral helical architectures. It will be demonstrated that the atomic make-up of the peptide constructs can be carefully adjusted and that these subtle yet purposeful modifications lead to significant structural changes to the chiral nanoparticle superstructure assembly and properties.

1:25 PM *EL06.03.02
Plasmon-Mediated Synthesis of Bimetallic Plasmonic-Catalytic Hybrid Nanomaterials Michelle L. Personick; Wesleyan University, United States

Bimetallic nanomaterials composed of a less reactive core metal with a dilute surface coverage of a second, catalytically active metal can exhibit improved catalytic performance resulting from a fine balance of activity and selectivity. Similarly, hybrid nanoparticles with a plasmonic core can be excited by visible light to influence the reactivity or selectivity at atoms or satellites of a more catalytically active metal localized at their surface. In both cases, the differing catalytic reactivity of the two component materials in the solid state is also reflected in differences in the reactivity of their metal salt precursors during nanomaterials synthesis. Our research group has developed a set of versatile synthetic tools for differentially controlling the rates of reduction of metal precursors to facilitate the growth of nanostructures with desired morphologies and surface compositions. Recently, we demonstrated that visible light excitation of a silver core nanostructure can be used to drive the plasmon-assisted reduction of platinum ions—a material that is not plasmonic in the visible region. This plasmon-mediated synthesis relies on the oxidation of a weak reducing agent, sodium citrate, by plasmonic hot holes to generate thermalized electrons that reduce platinum ions at the surface of the silver nanoparticle core. The approach overcomes key challenges in bimetallic nanomaterials synthesis, including accelerating the kinetically slow reduction of one metal precursor while also preventing competing galvanic exchange processes. Tuning of reduction kinetics controls the localization and amount of platinum deposited on the silver cores and

enables the selective generation of silver-platinum core-shell and core-satellite architectures, the latter of which are not accessible using standard thermal synthesis approaches.

1:50 PM *EL06.03.03
Solid State and Materials Chemistry (SSMC) in the Context of NSF's Division of Materials Research Birgit Schwenzer; National Science Foundation, United States

An overview of the Solid State and Materials Chemistry (SSMC) program will be discussed in the context of the 2019 workshop "Frontiers in hybrid and interfacial materials chemistry research" (workshop report by B. S. Guiton et al., MRS Bulletin, 45(11), 951-964. doi:10.1557/mrs.2020.271). The workshop participants identified interdisciplinary challenges and opportunities as well as current areas of progress in subdisciplines including hybrid synthesis, functional surfaces, and functional interfaces. The scope of the workshop included several research topics beyond the scope of the SSMC program. To address this, the presentation will also briefly describe the other Topical Materials Research Programs (TMRPs) in DMR in addition to showcasing highlight outcomes of some recent research projects supported by SSMC.

2:15 PM *EL06.03.04
Light-Mediated, Directed Placement of DNA Ligands on Gold Nanoparticles Teri W. Odom; Northwestern University, United States

Nanoparticle assemblies show interesting optical properties and show distinct advances in sensing and therapeutics. Short, thiolated DNA strands are common linkers in gold nanoparticle (NP) assemblies; however, the precise placement of different DNA sequences on single NPs is challenging, which limits possible architectures. Moreover, because of the similar physical and chemical proprieties of different DNA sequences, the uniform gold NP core material makes regiospecific functionalization challenging. This talk will describe a gold NP platform and functionalization process that allows for the spatially-controlled placement of multiple DNA sequences on single NPs. We will discuss how gold nanostars fully conjugated with one DNA sequence can selectively release the DNA from the tips under excitation of fs-pulses at the plasmon wavelength of the branch. Then, we will show how these now bare Au regions can be functionalized with a different thiolated DNA sequence to result in constructs with different DNA strands at specific structural NP features. This selective functionalization can be further exploited to create unique nanoparticle assemblies by hybridization to other DNA-functionalized gold colloids.

2:40 PM EL06.03.05
The Essential Role of Reduction Potential in the Seed-Mediated Synthesis of Gold Bipyramids Dong He[1,2], Xing Zhang[1], Bhanu Sharma[1], Thomas Egan[1] and Gang Chen[1]; [1]University of Central Florida, United States; [2]Jilin University, China

Colloidal synthesis of nanoparticles is a complex process, which is subject to both thermodynamic and kinetic restrictions. Understanding and controlling these thermodynamic and kinetic factors are critical for the reproducible and reliable synthesis of nanoparticles. A common thermodynamic factor is the reduction potential of the reactants, whose role in nano-synthesis is not yet well understood. Here we took the gold bipyramids (GBPs) synthesis as an example to explore the quantitative relationship between reduction potential and synthetic products. For the convenience of comparison, phenol derivatives with similar structure (4-R-phenol) but different standard reduction potential were chosen as reductants, where R is chlorine, hydrogen, methyl, and methyl oxide, respectively. When they were used to reduce gold precursor, their actual reduction potential can be regulated easily through the pH value of the growth solution to study the effect of reduction potential on the products. For each phenol derivative we tested, it was found that there is an appropriate pH range, in which GBPs of high quality were synthesized and their longitudinal LSPR peak red-shifted with the increase of the initial pH value. This pH range is related to the substituent on phenol, those with electron-withdrawing groups are higher while those with electron-donating groups are lower. Although these phenol derivatives work in different pH ranges, the plots of the longitudinal LSPR peak of their resultant products versus the pH are quite

similar. When pH was substituted by the corresponding reduction potential calculated from the Nernst equation, these plots coincide together, meaning that the influence of reduction potential on the formation of GBPs is independent of the specific phenol derivatives (reductants), so the reduction potential is a fundamental factor in the synthesis of GBPs. This role of reduction potential is expected to be general in the synthesis of other types of nanoparticles, which is important not only for understanding the mechanism of nano-synthesis but for improving the reproducibility and reliability of nano-synthesis.

Highly Efficient Plasmonic Membrane Activation of Peroxide for Alcohol Oxidation Hao Tang, Guozheng Shao and Bruce Hinds; University of Washington, United States

Many industrial oxidation processes based on peroxide, have a difficulty of over oxidation in homogeneous solution principally due to faster oxidation rates of already oxidized species and high statistical probability of secondary oxidation near the completion of reaction. Ideal for stepwise oxidation is to limit the residence time of target molecule in a reaction zone to allow for single (or quantized) reaction events. This can be achieved in a membrane geometry where catalyst along a pore length and set flow velocity can precisely control residence time for oxidation. It is also known that Au nanoparticles can catalytically activate peroxide under light irradiation due to the formation of concentrated surface plasmon electromagnetic fields and thus hypothesized to be present in nanoporous planes. A plasmonic membrane was synthesized by evaporation of 25nm thick Au films onto pore entrances of anodized aluminum oxide membranes (AAO) with pore diameters of 20-200nm. This allowed solutions of peroxide and sec-phenethyl alcohol to flow through membrane and interact with Au surface plasmon upon exit of the membrane. Under light illumination of 10-100 mW/cm2, quantum efficiencies (photon/peroxide radical) above 100% were seen (as high as around 250%), indicating a combination of both field induced activation of peroxide as well as a hot electron injection mechanism. By flowing sec-phenethyl alcohol and peroxide through the optimized Au@AAO system, the controlled single oxidation product of acetophenone was observed demonstrating the promise of the plasmonic flow membrane reactor design.

Plasmonics for Hot-Electrons and Energy Applications Alexandra Boltasseva; Purdue University, United States

Hot carriers refer to energetic electrons/holes with energy distributions deviated from equilibrium Fermi-Dirac distributions. In metallic nanostructures, hot carriers can be generated from the decay of surface plasmons (SPs), which holds great promise for plasmon-enhanced photocatalysis, solar-energy harvesting devices, etc. One key knowledge needed for developing these applications is the hot-carrier energy distributions (HCEDs). Recently, an effective way to determine HCED experimentally utilizing a scanning tunneling microscope (STM)1 was reported. With carefully chosen molecules that possess appropriate transmission characteristics between the plasmonic gold film and the gold tip of a STM, single-molecule junctions are created for current-voltage measurements at various voltage bias. The difference in the measured currents for the cases with and without plasmonic excitation reflects the so-called hot-carrier current which enables the direct quantification of HCED.
The knowledge of HCED is of fundamental and practical importance. Hot electrons/holes generated in metallic nanostructures can be transferred/injected to adjacent semiconductors with appropriate band structures for plasmon-enhanced photocatalytic or photovoltaic processes. Gold- and silver-semiconductor heterostructures

are most commonly studied for such applications based on hot electron transfer. In the last few years, titanium nitride (TiN) has been studied as an alternative plasmonic material with optical properties comparable to gold. Its chemical inertness plasmon resonance in the bio-transparent window (750 nm- 900 nm) makes it promising for biophotonic applications. We synthesized TiN@TiO2 core-shell nanoparticles (NPs) and demonstrate that with the illumination of a 700 nm laser, such NPs efficiently convert free oxygen into singlet oxygen molecules (1O2) which are key molecules used to kill cancer cells in photodynamic therapy (PDT).2 We also show that hot electrons injected from TiN to TiO2 play a major role in this photocatalytic process and provide an analytical model for evaluating the hot electron injection efficiency. Our study confirms the promise of TiN in hot electron-mediated applications especially in areas of biomedical and therapeutic interest.
Yet another direction that will be covered is a machine learning assisted topology optimization of thermal emitters for far-field thermophotovoltaic (TPV) applications. We have developed a unique optimization framework that allows to significantly speed-up meta-structure design optimization, and allows to significantly increase thermal emission reshaping efficiency of TiN based thermal emitters.3 Specifically, we have demonstrated that ML assisted optimization framework ensures more than 4900-time speed up of thermal emitters design development in comparison with conventionally used topology optimization. The developed thermal emitter design ensures more than 97% thermal emission efficiency.

Plasmon-Induced Resonance Energy Transfer for Photoconversion, Sensing and Therapy Nianqiang Wu; University of Massachusetts Amherst, United States

This talk will discuss the plasmon-induced resonance energy transfer process as the mechanism of energy transfer from plasmonic metals to semiconductors. It will show the effort to develop solar energy conversion devices, biosensors, and therapeutic agents based on this mechanism. This talk will demonstrate some application examples across several relevant fields.

4:50 PM *EL06.04.03
Optical Interaction in Metal and Hybrid Metal-Semiconductor Nanoparticle Assemblies Jing Zhao; University of Connecticut, United States

Metal nanoparticles exhibit unique size and composition dependent optical properties, known as localized surface plasmon resonance (LSPR). When they assemble into small clusters, the optical coupling between the nanoparticles lead to new plasmonic properties. Specifically, when Ag or Au nanoparticles assemble into dimers and trimers, they exhibit polarization dependent optical spectra due to short range coupling. When they formed randomly arrays, the long-range coupling could result in changes in the LSPR band width and peak position. In addition, when semiconductor quantum dots (QDs) were placed closed to the metal nanoparticle assemblies, the plasmonic feature is altered due to the coupling between the exciton in the QDs and the plasmons. The fluorescence of the QDs changes as well due to this interaction. Under specific conditions, we observed peak splitting in both the dark-field scattering and fluorescence spectra of Au-QD-Au hybrid nanostructures.

5:15 PM *EL06.04.04
Prospect of Silicon Nanoparticles and Au-ZnO Nanowires in Energy and Health Sectors Ateet Dutt; Universidad Nacional Autónoma de México, Mexico

A significant investigation has been done on understanding and implementing the well-known effect of surface plasmon resonance (SPR) in nanomaterials, and it has opened extensive research possibilities. Our lab has grown different nanomaterials such as Si nanoparticles and hybrid Au-ZnO nanowires to explore their

opportunity in solar cells, water splitting, and chemical/biosensing applications. The aim is to control these nanostructures' size and shape and study their influence on different properties. I will present the embedding of Si nanoparticles in various matrices such as SiOx, SiNx, SiOxCy, and their unique properties for downshifting applications in the third generation of solar cells. Further, I will report the growth of hybrid Au-ZnO nanowires and the associated opportunities in hydrogen production and chemical/biosensing applications.

5:40 PM EL06.04.05
Ultra Efficient Hot Electron Generation with Aluminum Plasmonics: A Radiative Engineering Approach Enabling Photoinactivation of Multi-Drug Resistant Bacteria with Ambient Light Xiangchao Zhu[1], Mingran Liu[1], Michael Trebino[2], Jin H. Park[2], Fitnat A. Yildiz[2] and Ahmet A. Yanik[1]; [1]University of Calfornia, United States; [2]University of California, United States

Widespread misuse and overuse of antimicrobial drugs had led to emergence of multidrug-resistant (MDR) bacteria, placing tremendous pressure and even posing threat on health care worldwide. According to the recently released data by Infectious Diseases Society of America (IDSA), MDR infections are becoming the third leading cause of deaths (~160,000 deaths annually) in the United States. If left unchecked, MDR bacteria caused diseases could kill more people than cancer. Therefore, it is of crucial importance to develop effective antimicrobial approaches to combat bacterial infections, rather than merely relying on identification and development of new classes of antibiotics or antimicrobial agents. Recently, light-activated disinfection (LAD) has emerged as an efficient and efficacious way to eradicate biofilm-mediated microbial infections, advancing conventional concepts and bolstering current prevention efforts of bacterial disinfection. LAD approaches have shown excellent ability to instantaneously photo-inactivate a wide range of microbes and can work synergistically with medical antimicrobial agents. Ultraviolet (UV) germicidal irradiation is among one of most reliable and well-studied LAD-based antimicrobial technologies. It provides rapid and effective inactivation of drug-resistant microorganisms by destroying their nucleic acids and disrupting their DNA, rendering them incapable of reproducing and infecting. However, prolonged UV exposure can pose significant health risks to humans, causing skin cancer and eye damage, thus can only be applied at discrete moments in time (i.e. episodically). Especially for implementing the tool for continuous environmental cleaning activities within the clinical environment, this disinfection method is not suitable for prevention and control of healthcare-associated infections (HAI), which are a significant burden globally with millions of patients affected annually.

Violet-blue 405-nm light is emerging as a safe and cost-effective alternative to UV-based LAD technologies for continuous environmental decontamination since it can be used automatically without any downtime or side effects. Using sophisticated configured light emitting diode (LED) ballistic photons that are non-harmful to humans, this bactericidal visible light possesses outstanding antimicrobial properties against a wide range of bacterial and fungal pathogens. Nevertheless, its photo-inactivation efficiency is still several orders of magnitude lower than that of UV light. Here, we introduce a plasmonic approach enabling rapid (minutes) and extremely efficient (> 99.995%) inactivation of MDR *Vibrio Cholerae* biofilms with 405-nm light. We demonstrate nearly three orders of magnitude improvement in photo-inactivation efficiencies using 405-nm light activated radiatively coupled aluminum plasmonic nanoantenna arrays. We achieve highly effective light-induced local hyperthermia and toxic reactive oxidative species to irreversibly disrupt MDR biofilms. Our technique opens the door to light-activated smart antimicrobial coatings for continuous decontamination in occupied areas, thereby can help infection control practices by preventing mature biofilm development using low-intensity incoherent light.

8:15 PM *EL06.05.01
Peptide Induced Chirality in Single Gold Nanoparticle Ki Tae Nam; Seoul National University, Korea (the Republic of)

Chiral structure controlled at nanoscale provides a new route to achieve intriguing optical properties such as polarization control and negative refractive index. However, asymmetric structure control with nanometer precision is difficult to accomplish due to limited resolution and complex processes of conventional methods. In this regards, utilizing chirality transfer occurring at organic-inorganic materials offers viable route to overcome these limitations. Previously we developed a unique synthesis strategy that characteristic of molecule is transferred to gold nanoparticle morphology. Based on the system, here, we demonstrated novel chiral gold nanostructures exploiting chirality transfer between peptide and high-Miller-index gold surfaces. Enantioselective adsorption of peptides results in unequal development of nanoparticle surface and this asymmetric evolution leads to highly twisted chiral element in single nanoparticle making unprecedented 432 helicoid morphology. The synthesized helicoid nanoparticle showed strong optical activity (dissymmetry factor of 0.2 at 622 nm) which was substantiated by distinct transmittance color change of helicoid solution under polarized light. Modulation of peptide recognition and crystal growth enabled diverse morphological evolution and the structural alterations provided tailored optical response, such as optical activity, handedness, and resonance wavelength. We believe that our peptide directed synthesis strategy offers a truly new paradigm in chiral metamaterial fabrication and will be beneficial in the rational design of chiral nanostructures for use in novel applications.

Plasmonic Nano-Molecules and Nano-Polymers Zhihong Nie; Fudan University, China

Plasmonic nanoparticles (e.g., gold, silver particles) show unique optical properties, such as localized surface plasmon resonance. Organization of plasmonic nanoparticles into discrete nanostructures with precise control allows for fine-tuning their interparticle plasmon coupling and collective properties. The assemblies of plasmonic nanoparticles have shown diverse applications in photonics, sensing, catalysis, and energy harvesting. In this talk, I will present our efforts to the fabrication of discrete plasmonic nanostructures with molecular-like and polymer-like configurations through directional bonding of nanoparticles and the exploitation of the plasmonic properties of the hierarchically assembled nanoparticles.

9:05 PM EL06.05.03
Hygroscopy-Induced Nanoparticle Reshuffling in the Ionic-Gold-Residue-Stabilized Gold Suprananoparticles Sungmoon Choi and Junhua Yu; Seoul National University, Korea (the Republic of)

Stabilization of nanoparticles is usually achieved by either charging the nanoparticle surface (electrostatic stabilization) or capping the nanoparticle surface with ligands (steric stabilization). Because organic capping ligands can also be used to tune the size, morphology, and chemical reactivity of nanoparticles during the nanoparticle formation process, attention has largely focused on how organic molecules influence the growth of nanoparticles.[1-2] However, the roles of ionic precursors and the influence of their presence in the reaction mixture on their properties have been mostly overlooked. Gold nanoparticles are excellent species for investigating the impact of the ion residue in the reaction solution on the synthesis and properties of gold nanoparticles owing to their good stability and characteristic photophysical properties.[3] We used polyethyleneimine (PEI) as the reducing and stabilizing agent for gold nanoparticles and tuned the ratio between PEI and Au(III) to adjust the abundance of gold ions in the nanoparticles. We found that a low level of the elemental gold and the stabilization of gold nanoparticle by an excess of gold ions contributed to the production of ultra-small nearly neutral gold nanoparticles.[4] The cross-linking between gold

ions/PEI/nanoparticles further led to the assembly of these small gold nanoparticles into supranananoparticles that were stable in water. The hygroscopic Au(III) residues in the supranananoparticles absorbed moisture to form a micro-water pool and subsequently the nanoparticles in the new aqueous solution reshuffled to form larger nanoparticles, resulting in significant changes in their optical properties. This phenomenon was used to formulate a material for a fast, sensitive and straightforward detection of water content in organic solvents. Our results indicate that ionic precursors may play an important role in the formation and stabilization of nanoparticles. Moreover, the ionic residues, regardless of whether they are a part of the nanostructure or impurities, may introduce further characteristics and significantly change the properties of the nanostructure.

Designing Janus Microspheres with Photonic and Plasmonic Faces for Active Color Pixels Jong Bin Kim[1], Su Yeon Lee[2], Nam Gi Min[1], Seung Yeol Lee[1] and Shin-Hyun Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

Nature and humans are inextricably linked to colors, and they adopt nanostructures—not a dye or chemical pigment—to generate nonfading colors that have unique optical properties. The nanostructures are dominantly embodied in two optical phenomena: photonic crystals and plasmonics. Photonic crystals give rise to the selective reflection of certain wavelengths as the periodic nanostructures create photonic bandgap inside the structures. Plasmonic colors happen at the metal surface of which morphology is defined in nanoscale; surface plasmon polariton (SPP) and localized surface plasmon resonance (LSPR) are largely known for the origins of plasmonic resonance. The two colors that have structural origins have great potentials when they are realized in a granular format. The structurally-colored granules serve as aesthetic pigments, microsensors that monitors microenvironment, optical barcodes, and nanoscale blocks constructing macroscopic structures. The granular combination of photonic and plasmonic colors are expected to couple two unique advantages into a single template.

Here, we utilize emulsion drops to create a plasmonically resonant surface on a microsphere with a photonic bandgap inside. The dual-mode Janus microspheres that exhibit plasmonic and photonic colors on the opposite side as a consequence of directional metal deposition. We microfluidically fabricate single emulsions with highly saturated colloids inside and on the interface at the same time, where the 3D crystallized colloids inside the emulsions develop a photonic bandgap, and the 2D crystallized colloids at the surface lead to the plasmonic color. We found the optimal range of suitable nanoparticle diameter for plasmonic colors from aluminum, from gold, and photonic colors to be 300-400, 200-300, and 180-250 nm in this system, respectively. It indicates that there is a limit to independently control the two colors so we adopt double emulsions of which the core and shell have crystallized nanoparticles with different diameters.

For the fabrication of Janus photonic/plasmonic microspheres, we disperse silica nanoparticles in an acrylate polymer, where silica nanoparticles are spontaneously crystallized by repulsive interactions from disjoining pressure. Silica nanoparticles are anchored at the emulsion interface and slowly exposed to the water phase as the emulsions are incubated in water. Also, the distance between nanoparticles becomes shortened with time because the polymer is slowly dissolved into water. The colloidal aging determines the surface nanostructure of the microparticles afterward, which determines plasmonic colors whereas the crystallization inside determines the photonic colors. Silica particles are removed and metal is deposited unidirectionally, which results in a continuous film with periodic pores on the top and metal bowls inside the pores. SPP occurs at the former and LSPR occurs at the latter, two of which are coupled to make plasmonic resonance by the incoming light. When the resonance occurs in the visible range, the surface generates plasmonic colors and longer incubation time blue-shifts the resonant wavelength so that the colors change from blue to purple to red. An incubation time of

emulsions thus changes the nanostructure and it is first to sophisticatedly control plasmonic colors in a granular format including all the rainbow colors. The colors are also adjusted by the metal type, metal thickness, and the relative location on the microspheres with respect to the metal-deposited apex. Finally, the anisotropic location of metal renders the microspheres react to an electric field so that the group of them makes a reflective display. The Janus microspheres are great candidates for microsensors with photonic barcodes, aesthetic colorants for secondary macrostructures, and active pixels for a reflective display.

SERS-active Microgels Produced by Simultaneous Photocross-Linking and Photoreduction for Direct Raman Analysis of Pristine Samples Jiwon Yoon[1], Dong Jae Kim[1], Dong-Ho Kim[2], Sung-Gyu Park[2] and Shin-Hyun Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Materials Science, Korea (the Republic of)

Raman spectroscopy is one of the riveting methods for molecular sensing as it provides noninvasive and label-free molecular identification. However, the intensity of Raman scattering is remarkably low, which makes it challenging to detect the infinitesimal amount of molecules. Metal nanostructures or nanoparticles can localize electromagnetic field on their surface for specific wavelengths of incident light through surface plasmon resonance, which can enhance Raman signal extraordinarily for the molecules near the surface; the phenomenon is referred to as surface-enhanced Raman scattering (SERS). SERS is a key to overcoming the weakness of Raman spectroscopy for molecular detection. However, metals are prone to contamination by adhesives such as protein, resulting in a reduction in Raman signal. Therefore, the pretreatment of samples is unavoidable for Raman analysis because many analytes are complex mixtures of small molecules, proteins, and/or cells.
To prevent contamination, hydrogel networks have been employed as a protection layer. The hydrogels allow the infusion of smaller molecules than the mesh size while excluding larger molecules. Therefore, the hydrogel layer with a proper mesh size obviates the need for a time consuming and costly pretreatment, allowing the on-site analysis. One of the simple and practical structures as pretreatment-free SERS-based molecular sensors is metal nanoparticles encapsulated in hydrogel microparticles or microgels. For high Raman intensity and signal reproducibility, metal nanoparticles are required to be homogeneously embedded in the hydrogel matrix at a high concentration without local aggregates. However, it is very challenging to produce such a structure through post-encapsulation of metal nanoparticles due to the low dispersion stability of metal nanoparticles at a high concentration.
Here, we design SERS-active microgels containing a high density of gold nanoparticles through simultaneous photoreduction of gold precursor and photocross-linking of hydrogel precursor. To produce the microgels, the mixture of gold precursor, polyethylene glycol diacrylate (PEGDA), photoinitiator, sodium citrate, and distilled water is emulsified into monodisperse water-in-oil (W/O) emulsion droplets using a microfluidic device. The droplets are irradiated by ultraviolet (UV) for 2 min and incubated at 50°C for 2 days. During the UV irradiation, the photoinitiator is decomposed to form radicals, which cause photoreduction of gold precursors to form gold nanoparticles and photocross-linking of PEGDA to form a hydrogel network. During the thermal treatment, the unreacted gold precursor is reduced in the presence of sodium citrate, forming new gold nanoparticles or promoting the growth of preformed gold nanoparticles. The size and number density of gold nanoparticles formed in the hydrogel matrix strongly depend on the concentration of sodium citrate. The concentration of sodium citrate is optimized according to the intensity of Raman signals of the rhodamine 6G molecule. The microgels made using optimized sodium citrate concentration exhibit high Raman intensity as well as high signal uniformity, indicating high dispersion stability of gold nanoparticles at a high concentration. With the SERS-active microgels, we can detect pyocyanin dissolved in saliva without any sample pretreatment; the pyocyanin is one of the biomarkers for sepsis which is caused by infection of Pseudomonas aeruginosa. The limit of detection (LOD) is found to be 100 nM, which is two orders of magnitude lower than the typical concentration in clinical saliva samples of sepsis patients. It is noteworthy that the SERS-active microgels can detect the small molecules in the presence of large adhesives and cells in saliva. We believe that our microgels can be used as a general sensing platform for the on-site detection of small toxic molecules and biomarkers in various samples, including foods, drugs, biological fluids, and many others.

EL06

8:00 AM *EL06.06.01
Two-Dimensional Infrared Spectroscopy of Molecules on Metal Nanostructures Lev Chuntonov; Technion–Israel Institute of Technology, Israel

Conformation and dynamics of small molecules, peptides, and proteins on the surface of metal nanostructures strongly affect the properties and applicability of these materials. However, despite the urgent need in understanding of molecule-surface and surface-induced intermolecular interactions, because of a great complexity of the associated phenomena and limitations of the available analytical methods, in many cases these details still remain elusive. Infrared spectroscopy, and especially its nonlinear two-dimensional variant conducted with sequences of femtosecond laser pulses, 2DIR, is a powerful method to elucidate molecular structure. Recently, the application of 2DIR spectroscopy was extended to studies of molecules on nanostructures. I will present results of our 2DIR experiments with molecules on two different classes of nanostructures: sub-wavelength colloidal silver nanoparticles with sizes of few to few tens of nanometers and half-wavelength gold infrared antennas of micrometer size.
Frequently, molecular organization within the nanoparticle capping layer has highly disordered character. Surprisingly, our 2DIR studies of a small tripeptide glutathione on silver nanoparticles revealed that under favorable conditions the interaction with silver surface leads to formation of highly-ordered intermolecular aggregates, with structure that apparently resembles tightly-stacked β-sheet-like layers wrapping the nanoparticle. This finding may have important implications in situations where ordered structure of the capping layer can impart unique chemical properties to the nanoparticles or can serve as a basis for design of multilayer macromolecular architectures.
In order to boost the sensitivity in 2DIR studies of surface molecules, we use resonant plasmonic infrared nano-antennas. The optical properties of these antennas can be controlled by the design of their size and shape to optimally suit the needs of the advanced nonlinear experiments. Signal enhancements factors of up to 10^5 have been observed, whereas molecular quantum dynamics probed by 2DIR spectroscopy have not been affected by the interaction with plasmonic antennas. Among the direct consequences of signal amplification are dispersive line shapes of the vibrational transitions, competition between the near-field coupling and the radiation damping enhancement mechanisms, and lack of the selectivity of molecular excitation to the laser light polarization, imposed by the surface boundary conditions. Interestingly, we observed that molecules subjected to the enhanced near-field of the plasmonic antennas are excited within the highly non-perturbative excitation regime, even though weak laser pulses are used for the excitation. This result can pave a way towards magnetic resonance-style spectroscopic experiments in the infrared.

8:25 AM *EL06.06.02
Novel Plasmonic Materials, Structures and Applications—A Computational Perspective Jost Adam; University of Southern Denmark, Denmark

Working with plasmonic materials involves many scientific steps, including, aside from the laboratory-level experiments, the numerical creation, their comparison, and the device fabrication. Besides these challenging steps, the design of new plasmonic materials with unique physical and chemical characteristics, and outstanding optical properties, which are traditional realms of gold and silver, merits an important place. Optimizing the material properties to improve their functionality and performance in plasmonic applications is a subsequent challenge to be tackled, also through iterative feedback from the experiments.

This presentation will demonstrate an overview of recent advances in the computational design of potential future plasmonic materials, such as translational metals, transparent conducting oxides, or plasmonically active semiconductor allotropes, and their application in plasmonic structures, concepts, and devices. The extraction of complex dispersion characteristics from density functional theory (DFT) calculations allows the integration into subsequent electromagnetic modeling steps. This talk will illustrate the panorama of applying the so-developed materials into plasmonic particle investigations, ranging from isolated particles of various shapes and materials to self-assembled regular structures, exhibiting collective plasmonic crystal responses. The applications range from plasmonic sensing, metamaterials, and self-assembled particle clusters for surface-enhanced Raman scattering and catalysis.

The Computational Materials Group at SDU investigates computational pathways, from the first-principles calculation-based molecular design to the three-dimensional multi-physical modeling of plasmonic nanostructures and plasmonically enabled devices for sensing, lighting, and catalysis applications. Our group recently developed the "Photonic Materials Cloud," a cloud-based platform to support streamline the experimental, numerical, research, and education-based work on plasmonic materials. It allows for creating and comparing various material data via various methods and applying them to standard photonic applications, such as nanoparticle scattering and layered thin-film responses. The export of publication-ready graphics and column-based data facilitates its easy integration into a photonic materials science research line.

8:50 AM *EL06.06.03
Strong and Weak Vibrational Coupling in Metal Nanostructures Studied by Ultrafast Microscopy Greg Hartland[1] and Kuai Yu[2]; [1]University of Notre Dame, United States; [2]Shenzhen University, China

The rapid heating induced by ultrafast excitation of metal nanostructures coherently excites the breathing vibrational modes of the structure. Detailed information about these modes can be obtained by studying single nanoparticles with transient absorption microscopy. However, in single particle experiments the breathing modes are usually heavily damped by radiation losses into the substrate. Recently we discovered that using low density substrates drastically reduces radiation losses and creates very high vibrational quality factors for gold nanoplates. This allows several new phenomena to be explored, including strong vibrational coupling between stacked nanoplates, and new vibrational modes that correspond to motion of the nanoplates relative to the substrate and, for the stacked nanoplates, relative to each other. The results from these experiments will be described in this talk, along with studies of mass loading effects for the nanoplates. In the mass loading experiments a localized change in vibrational frequency is observed when a particle is adsorbed onto the surface of a nanoplate. This is an unusual result, as the breathing modes of the nanoplates are normal modes that are spread out over the entire plate. This implies that the adsorbed mass hybridizes the normal modes. Insight into this effect is obtained from finite element simulations that model the vibrational modes of the coupled system.

9:15 AM EL06.06.04
Late News: Versatile Nanomasks for Fabrication of Plasmonic Resonators Aleksandra Szymanska, Mihai Suster and Piotr Wrobel; Faculty od Physics, Uniwersity of Warsaw, Poland

Over the years, tremendous advances have been made in the design and fabrication of nano-size objects in a variety of geometries. Nanosphere Lithography is a large-area nanostructurization technique introduced in the early 80s which utilizes dielectric nanospheres for the preparation of nanoapertures or nanoparticles formed in the gaps between the nanospheres. The process is cost-effective and easily scalable, therefore it is often chosen in favor of expensive and time-consuming electron lithography or low-resolution photolithography.

In this report, we describe a simple method of preparing versatile plasmonic nanomasks based on electrostatic-driven assembly of silica nanoparticles (SNPs) of diameters ranging from 60 to 300 nm. This technique makes it possible to produce homogenous masks of uniform apertures on bare or PMMA-coated glass substrates covering an area of a few cm^2. Fabricating different nanomasks starting from single holes, through dimers or

trimers, up to long, nanowire-like apertures is possible due to a high degree of control of the sizes and concentrations of the SNPs, as well as of the temperature during the process. In combination with physical vapor deposition of metals, such as silver or gold, the masks can be used further as platforms for obtaining many different plasmonic nanostructures like discs, cones, dimers, or even more sophisticated shapes by simply changing the evaporation angle. Such plasmonic resonators are very suitable for SERS, photovoltaic and biosensing applications because of their high tunability stemming from a number of degrees of freedom within the described method of fabrication.

9:30 AM EL06.06.05
Coupling and Rabi Splitting of Plasmonic Modes in Nanopillar Array Dominic Bosomtwi, Marek Osinski and Viktoriia Babicheva; The University of New Mexico, United States

High light field enhancement and its nanoscale confinement in plasmonic nanostructures facilitate stronger light-matter interaction, including spontaneous emission rate, nonlinear response, light absorption, and so on. Plasmonic metasurfaces are two-dimensional nanoantennas arrays enabling subwavelength field localization. Because of the nanoscale light confinement, the metasurfaces provide an exceptional ability to manipulate light accompanied by unique spectral features, including high quality factor resonances.

We design the plasmonic metasurface that consists of multi-segment silver-silicon nanopillars, and we analyze the multiple mode excitations in this nanopillar array. The effect is similar to the excitations of multiple plasmonic modes at the complex interfaces of multilayer metal and dielectric structure. We numerically study the spectral response of a single and paired nanopillars in the unit cell of the periodic array [1]. Because of the hybrid silver-silicon multilayer design, we can realize Fano resonances and Rabi splitting in the metasurface's spectral response.

The study's emphasis has been placed on the analysis of bright and dark modes excited in the nanopillar array. Mode interplay and coupling give rise to asymmetric spectral profiles in often referred to as Fano resonances. Strong coupling between plasmonic states causes the energy levels to repel by splitting, and because of the mode coupling facilitated by the lattice, we observe their Rabi splitting.
The effects of multiple mode excitations and their Rabi splitting facilitated by the lattice can also be observed in another spectral range providing all parameters of the structure are scaled proportionally. However, it also imposes requirements on material properties in the spectral range of interest. In this case, a common condition for the observation of plasmonic resonances needs to be satisfied, and in particular, the real part of permittivity of the metal-like material should be comparable in magnitude to the semiconductor permittivity.

Support from the Navy HBCU-MI program under the grant N00014-18-1-2739 and the Office of Naval Research under the grant N00014-19-1-2117 is gratefully acknowledged.

9:45 AM EL06.06.06
Deep Learning Analysis of Vibrational Spectra of Bacterial Lysate for Rapid Antimicrobial Susceptibility Testing Regina Ragan; University of California, Irvine, United States

Even in the 21st century, bacterial infections are still treated empirically. Antibiotics are prescribed preemptively, because a proper diagnosis relies on culture growth which takes a day or more and can delay patient treatment, increasing morbidity. Yet the unnecessary administration of powerful, broad-spectrum antibiotics leads to the proliferation of antibiotic resistance. A bioinspired sensing platform, composed of 2-dimensional physically activated chemically (2PAC) assembled surface enhanced Raman scattering (SERS) sensors coupled with machine learning (ML) algorithms, has been developed for rapid phenotypic antibiotic

susceptibility tests (AST). This platform provides new diagnostic tools for antibiotic stewardship, complementing existing genomic tests that only provide feedback on known antimicrobial resistance mechanisms. Just as one can smell the difference between coffee and chocolate amongst multiple odors, SERS+ML rapidly measures and classifies spectral features of bacterial metabolite signatures in response to antibiotics, which are correlated with antibiotic lethality mechanisms. As individual odor receptors are incapable of identifying odorant molecules, so are individual SERS spectra unable to differentiate in a complex background.

SERS + ML is an exciting nascent area where some recent work using vector machines and artificial neural networks has greatly improved concentration predictions from SERS data. However, this is a longstanding challenge to produce large, high quality and reproducible data sets are needed for any ML analysis with SERS. Since the nanogap distance between gold nanospheres determines performance in SERS devices, small variations on the order of angstroms lead to large signal variations. 2PAC is low-cost, scalable, and reproducible chemical assembly method able to control of sub-nm nanogaps and is capable of reproducibly probing individual molecules over mm^2 areas. An implemented CNN regression model trained on SERS data of Rhodamine 800 resulted in limits of detection (LOD) and quantification (LOQ) of 10 fM (~10^{-5} ng/mL) with prediction accuracy (r^2 value) of 0.96 over a dynamic range of 6 orders of magnitude.

In order to reduce the time required for phenotypic AST, we present a metabolomics approach rather than direct measurement of cell growth or viability to detect phenotypic susceptibility or resistance to antibiotics Yet there is an important price to pay to reduce AST time in this way: metabolomics approaches introduce an enormous parameter space. Consider that the *E. coli* metabolome contains over 2600 different metabolites. Nevertheless, SERS + ML allows for a fingerprinting approach to handle the complex data. Analysis of SERS data using a generative model, the variational autoencoder (VAE), is able to identify spectral features associated with molecular fingerprints the in the cell lysate data associated with antibiotic efficacy. The high interpretability of the VAE generated SERS spectra allows us to identify useful vibrational information which guides additional targeted data collection to improve classification accuracy. Culture-free and easily acquired datasets of bacterial metabolites in aqueous solution can be leveraged to improve predictive models of complex metabolite response of bacterial communities and is one of the most significant advantages of using a generative model. Greater than 99% accuracy is achieved with unsupervised Bayesian Gaussian Mixture analysis when using data informed transfer learning with only a few training examples. Our results show differentiation of bacterial populations of ESKAPE pathogens based on antibiotic susceptibility in 10 min when using SERS + ML. This enormously reduces the amount of time needed to validate phenotypic AST with conventional growth assays and outlines a promising approach towards practical SERS AST.

SESSION EL06.07: Plasmonic Applications

Colloidal Nanoparticle Clusters for Efficient Conversion of Light to Chemical Energy Seunghoon Lee; Ludwig-Maximilians-Universität München, Germany

The assembly of plasmonic metal nanostructures can efficiently merge the reactivity and energy harvesting abilities with enhanced plasmonic performance for visible light photocatalysis. Here we explore the influence of the presence of electromagnetic hotspots in the ability of plasmonic colloidal structures to induce efficient energy transfer for plasmonic catalysis. We report a novel synthetic strategy for the fabrication of colloidally assembled nanoparticles (NPs) in aqueous solution through fine controlled galvanic replacement between Ag nanoprisms and Au precursors.[1-5] Colloidally assembled nanostructures, e.g. Au particle-in-a frame and bimetallic assembled Au@M (M=Pd, Pt) nanostructures with catalytically active metals, exhibited superior

performance over their constituent nanostructure counterparts in plasmonic sensing, surface-enhanced Raman scattering (SERS), and plasmonic catalysis.[1-4] Recently, we successfully synthesize colloidal Au and Au@M (M=Pd, Pt) NP trimers with remarkable structural stability in various solutions.[1] These model systems allow us to study the synergy effect of hot spots and bimetallic composition in plasmonic catalysis. Our computational and experimental results highlight the synergy effect of geometry and composition of plasmonic catalysts in plasmon-driven chemical reactions. The plasmonic properties of NP trimers show that core-shell bimetallic NPs with hot spots can induce efficient light-to-chemical energy conversion as an increment of non-radiative plasmon decay to the catalyst surface. We monitored the plasmon-mediated reduction of 4-nitrobenzenethiol (4-NBT) using SERS for studying hot electron-induced chemical conversion. Core-shell bimetallic NP trimers show distinguishable photo-induced reduction of 4-NBT compared to their monomer or monometallic counterparts due to their efficient energy transfer. We expect that the present study can provide a new direction for the development of efficient photocatalysts.

Macroscopically-Expanded 3D Nanostructures for High Brightness Illumination Applications Fabian Schuett[1], Maximilian Zapf[2], Lena M. Saure[1], Jürgen Carstensen[1], Carsten Ronning[2] and Rainer Adelung[1]; [1]Kiel University, Germany; [2]Institute for Solid State Physics, Germany

Laser diodes (LDs) are regarded as the next generation of ultra-efficient light sources, being able to produce more photons at high power densities than conventional light-emitting diodes.[1] Even though most state-of-the-art technologies are based on a blue LD pumping a white-light-emitting phosphor, an all-laser wavelength mixing approach, e.g. a combination of three (RGB) or even four (RGBY) laser wavelengths would outperform the efficiency of any other known white-light source.[2] However, in illumination applications, laser-based lighting systems still suffer from their monochromatic, low-divergent, and coherent nature, which demands a new generation of extremely efficient and versatile optical diffusers based on disordered nanostructured materials.[2] In the here presented study, we demonstrate a macroscopically expanded, three-dimensional (3D) laser light diffuser based on a highly porous (>99.99%) nanoarchitecture, composed of interconnected hollow hexagonal boron nitride (h-BN) microtubes, with a wall thickness below 25 nm. The 3D hollow h-BN microtubular framework structure is synthesized by a novel template approach, which is based on a highly porous ceramic network consisting of tetrapodal-shaped microparticles.[3] The synthesis results in a disordered and non-absorbing photonic network with thinly spread Rayleigh-type scattering centers, based on a combination of feature sizes greater than, equal to, and well below the magnitude of the impinging wavelength.[4] With densities close to that of air, these aero-materials basically resemble an artificial solid fog, but with a defined hierarchical internal structure. This enables an isotropic 3D light distribution from energetic, highly directional, as well as coherent laser light, with speckle contrasts well below the human sensitivity limit. In combination with the excellent heat management of the 3D h-BN exceptionally high laser damage thresholds can be reached, enabling the usage of these aero-materials for high brightness illumination applications. Functionalization of these structures with photoactive materials will additionally open new fundamental

research prospects in the field of disordered photonics, including 3D plasmonic systems, random lasing, up/down conversion, and other non-linear optical effects.

Plasmonic Nanoparticles with Unique Structures for Biosensing Xiaohu Xia; University of Central Florida, United States

Nanoparticles of gold and silver have been widely used in biosensing due to their fascinating plasmonic properties. Most of previously reported gold and silver nanoparticles are solid particles. Our recent studies showed that gold-silver alloyed nanoparticles with hollow interiors possess unique plasmonic properties that make them particularly suitable for biosensing applications. In the first part of this talk, I will introduce our new strategy to craft hollow gold-silver nanoparticles with unique physical and chemical parameters. Rational design and chemical synthesis of the nanostructures will be specified. In the second part, I will discuss the application of these hollow plasmonic nanostructures in biosensing. Examples of in vitro diagnostics of disease biomarkers will be highlighted.

12:50 PM *EL06.07.04
Photochemistry on Quantum-Sized Metal Nanoparticles Yugang Sun; Temple University, United States

The incompatibility of solar energy and the light absorption band of a chemical bond prevents the use of light to activate the chemical bond for interesting chemical reactions directly. This presentation will focus on a strategy that enables the efficient coupling of photon energy into chemical bonds to selectively promote the desired chemical reactions. The strategy relies on the excitation of hot electrons in quantum-sized metal nanoparticles (QSMNPs, with size in the range of 2 ~10 nm) upon photo-illumination and the following efficient injection of the hot electrons into specific chemical bonds. The redistribution of hot electrons in the chemical bonds dissipates the kinetic energy of hot electrons to the chemical bonds, activating the chemical bonds to promote the target chemical reactions. These sequential processes occur in a confined space, representing a series of quantum transitions, i) optical-to-electronic transition in quantum-sized metal nanoparticles (i.e., hot electron generation), ii) electronic-to-electrical transition at the nanoparticle/adsorbate interface (i.e., hot electron injection), and iii) electrical-to-electronic transition in adsorbate molecules (i.e., chemical bond activation). Selective oxidation of alcohols to aldehydes rather than ketones/acids, a class of important chemical reactions for many industrial processes (e.g., esterification), will be used as an example to highlight the use of QSMNPs for photo-driven selective chemical transformation on platinum group metal (PMG) nanoparticle catalysts, which do not exhibit strong optical absorption.

All-Gas Phase Plasma Synthesis of Plasmonic Zirconium Nitride for Advanced Photochemistry Applications Chris Rudnicki, Alejandro Alvarez, Stephen Exarhos, Carla Berroscope Rodriguez and Lorenzo Mangolini; University of California, Riverside, United States

Plasmonic nanomaterials interact strongly with light, and as a consequence there are of great interest in a broad variety of fields, such as photocatalysis, photochemistry, biophotonics, sensing, and wave-guiding. We present a novel technique for the synthesis of plasmonic zirconium nitride (ZrN) nanoparticles using a scalable non-thermal plasma process.[1] Cost, production concerns and most importantly thermal and chemical stability

motivate the search for alternative plasmonic materials to gold and silver[2], like Group IV transition metal-nitrides[3] such as TiN[4] and the relatively unexplored ZrN. Our ZrN nanoparticles display a plasmonic peak around 620 nm and from XRD and TEM we infer the crystallinity of the particles to be a cubic rock salt structure and a tunable size distribution below 10 nm. An attractive application of these plasmonic particles is the reduction of metals like platinum and chromium (VI) species in water which are extremely toxic.[5] Here we have provided evidence of plasmon-driven photocatalytic activity within visible wavelengths to reduce platinum ions in solution.[6] An aqueous solution of ZrN, methanol, and chloroplatinic acid (H_2PtCl_6) was illuminated using a monochromator to spectrally select wavelengths in the visible regime. Energy dispersive X-ray spectroscopy (EDS) was then used to determine the ratio of reduced platinum to zirconium at a given wavelength. A similar method was used to reduce Chromium (VI), a carcinogen commonly found in water, except we use the diphenyl carbazide method to determine the amount of Chromium (VI) in solution before and after exposing it to light. We then spectrally select visible wavelengths to compare the quantum yields of Chromium (VI) reduction between our synthesized ZrN and commonly used TiO_2 nanoparticles. We are able to achieve a quantum yield of up to 1.50% reducing Chromium (VI) to Chromium (III) using visible wavelengths, providing convincing evidence of photocatalytic response in this class of alternative plasmonic materials.

A Look at Nonlinear Optic Polymers in Bioelectronics and Beyond Kaitlyn E. Crawford; University of Central Florida, United States

Bioelectronics, the integration of biology with electronics, encompasses sub-topics such as bioimaging, and transduction or actuation of biochemical or physiochemical signals using wearable or implantable devices. One component that these sub-topics have in common is the generation of large amounts of data, which feeds into Big Data. With Big Data comes emerging areas of AI-ML, data mining, deep learning, and neural networks. While bioelectronic topics and complementary disciplines are receiving significant attention, there is at least one other topic to consider: How to handle the transmission and storage of such large volumes of data? Copper wire is the traditional material to transmit information, but the theoretical speed and volume limits, at which electrons can travel through copper wire, are near capacity and cannot accommodate the projected global data demands. Compelling solutions using fiber optic cables are on the horizon as, compared to copper, they can handle 6000x the bandwidth, are of lower cost, lighter weight, and maintain lower temperatures. A bottleneck, however, for replacing copper with fiber optics cables, on the scale necessary to sustain our data transmission and storage needs, is the limited availability of nonlinear optic (NLO) materials that are necessary for optical modulation – which operate similar to the "on-off" modulation in electronics for coding information using 0s and 1s. Beyond optical modulators, NLOs also find broad application in areas such as: imaging, (bio)sensors, and terahertz spectroscopy. NLO materials are either inorganic such as lithium niobate, or organic such as electro optic polymers, wherein an asymmetric chromophore is combined with a glassy, amorphous polymer. *This talk will cover the development and characterization of a new family of easy to synthesize, stable, asymmetric chromophores, and their subsequent use in electro optic polymers for in demand, NLO modulator and sensing applications.*

8:25 AM EL07.01.02
Multi-Dimensional Fuzzy Graphene Bioelectronic Actuators Raghav Garg, Daniel San Roman, Yingqiao Wang and Tzahi Cohen-Karni; Carnegie Mellon University, United States

The ability to manipulate the electrophysiology of electrically active cells and tissues has enabled a deeper understanding of healthy and diseased states. This has primarily been achieved via bioelectronic actuators that interface engineered materials with biological entities. Graphene has gained recent interest as a building-block for bioelectronic actuators due to its advantageous electrochemical properties and biocompatibility. However, functional graphene bioelectronics exhibit a two-dimensional (2D) topology. This leads to inherent performance limitations due to the limited exposed surface-area and poor interactions with interfaced cells and tissues. Ideal geometry of graphene-based actuators needs to leverage the material's high surface-area-to-volume ratio to facilitate maximum interaction with the electrode.

Here we report a breakthrough three-dimensional (3D) topology of graphene: 3D fuzzy graphene (3DFG), for actuation of electrically active cells and tissues. Using a bottom-up approach, we synthesize an interconnected network of free-standing graphene flakes. The 3D topology leads to enhanced surface-area compared to planar surfaces allowing 3DFG microelectrodes to exhibit lower electrode impedance than planar microelectrodes. 3DFG also exhibits greater cathodic charge storage capacity (CSC_C) and charge injection capacity (CIC). We further combine one-dimensional (1D) Si nanowires (NWs) with 3DFG to fabricate a truly 3D topology of graphene: NW-template 3D fuzzy graphene (NT-3DFG). The increased surface-area of NT-3DFG enhances the exhibited CSC_C and CIC. This enables miniaturization of graphene-based microelectrodes to ultra-microelectrodes for functional bioelectronics. Our results demonstrate the importance of extending the topology

of nanomaterials to 3D to push the physical and functional limits of conventional bioelectronics.

8:40 AM *EL07.01.03
Implantable Bioelectronics George Malliaras; University of Cambridge, United Kingdom

One of the most important scientific and technological frontiers of our time is the interfacing of electronics with the human brain. This endeavour promises to help understand how the brain works and deliver new tools for diagnosis and treatment of pathologies including epilepsy, Parkinson's disease, and brain cancer. Current solutions, however, are limited by the materials that are brought in contact with the tissue and transduce signals across the biotic/abiotic interface. Using novel organic materials coupled with thin substrates we make implants that are biocompatible and show exceptional performance in multimodal recordings and stimulation of the brain. I will outline examples of devices that simultaneously monitor the electrical and metabolic activity of the brain, and devices that locally deliver drugs with excellent spatiotemporal control. I will further discuss how the interface with soft robotics can enable devices that change shape and thereby decrease the invasiveness of neurosurgery.

9:05 AM EL07.01.04
Biological Modulation from Micro-Supercapacitor-Like Mesoporous Carbon Membranes Aleksander Prominski[1,1,2] and Bozhi Tian[1,1,2]; [1]The University of Chicago, United States; [2]University of Chicago, United States

Electrical stimulation devices find numerous therapeutic applications, such as in the treatment of heart defects, epilepsy, and Parkinson's diseases. It is critical to search for new materials and methods to make these treatments safe and affordable to everyone in need. Design of bioelectronic devices requires materials with mechanical and electrochemical compliance to the cells and tissues to minimize their invasiveness. Recently, carbon nanostructures have been studied as bioelectronics components due to their excellent electrical and mechanical properties and the past success in energy research. Nevertheless, there is still a strong need to advance synthetic methods for the fabrication of cost-effective and safe carbon-based bioelectronics.

In this presentation, I will first discuss the synthesis of hierarchical meso- and macroporous carbon membranes using micelle-assisted self-assembly, as well as the fabrication of binder-free carbon-based microelectrode arrays using SU-8 as flexible support. The material design allows us to optimize its mechanical compliance and to leverage its biocompatible electrochemical properties for efficient biological stimulations. Inspired by micro-supercapacitors used in energy research, we explored the application of a comb-like interdigitated electrode design for *in vitro* stimulation and training of cells. For example, we applied the confined electric field to cardiomyocyte monolayer and achieved efficient overdrive pacing and subthreshold levels of training *in vitro*. We also explored the stimulation of retina and heart *ex vivo* and stimulation of a sciatic nerve *in vivo*, demonstrating efficient coupling between the carbon nanostructures and excitable tissues. Our results illustrate a promise of applying porous carbon materials for biological modulation and how traditional energy research tools can be adapted to design bioelectronic systems.

9:20 AM *EL07.01.05
Multiscale Bioelectronics from Liquid-Phase Processing of Nanoscale Carbides Flavia Vitale; University of Pennsylvania, United States

Bioelectronic technologies are enabling paradigm-shifting approaches to diagnosing and treating a number of disorders of the central and peripheral nervous systems. While tremendous progress has been made in the last decade, current bioelectronic interfaces are still dramatically inadequate to address the mechanical, chemical, and electrical properties of nervous structures. Nanostructured carbon materials are uniquely positioned to address these challenges, as they combine remarkable electronic and electrochemical properties, with intrinsically high mass-specific surface area and mechanical flexibility. Furthermore, they can be easily integrated within scalable solution-based processing, thus allowing easy modulation of their electronic,

mechanical, and optical properties.
In this talk, I will discuss how nanoscale soft conductors can be engineered into high-resolution, minimally invasive bioelectronic interfaces designed to seamlessly map and control the activity of excitable circuits at multiple scales. Specifically, I will introduce novel bioelectronic interfaces based on 2D transition metal carbides (a.k.a. MXenes) for recording and stimulation. I will discuss the fundamental electronic and electrochemical behavior of MXenes as well as present scalableliquid-phase processes to translate the remarkable molecular properties into high-resolution interfaces with customizable scale and coverage. Finally, I will present examples of applications in multiscale mapping and microstimulation of bioelectrical circuits *in vivo* in different models.

Late News: Graphene Based Nanopore Sequencing—An Assessment on the Current State of Next Gen Sequencing Samuel Escobar, Kiara Gonzalez-Gonzalez, Marcel Grau, Solimar Collazo Hernandez, Ernesto Espada, Brad Weiner and Gerardo Morell; University of Puerto Rico at Río Piedras, Puerto Rico

Using solid-state nanopores to sequence DNA is a promising third generation sequencing method. Graphene is used because it can provide a suitable membrane for sequencing applications. Sequencing DNA with graphene nanopores is a topic of interest for many researches, but how does it work? As the DNA molecule passes through the nanopore, the nanopore will eventually be blocked by the negatively charged DNA molecule. Each nucleotide has presented a distinct current blockage signal as it interacts with the nanopore via the formation of temporary Van der Waals interactions. Therefore, the differentiation of each base is possible since we can observe different sources reporting distinct ionic currents for each nucleotide. It is by this principle that the DNA is sequenced. Here, we present how Graphene Nanopores could be ideal for DNA Sequencing by taking into consideration many factors that may help overcome the challenges that have been found within this method. These factors include: the functionalization - whether it is hydrogen functionalization, hydroxyl functionalization, or nitrogen functionalization - of the graphene, the number of graphene layers needed, the type of nanopore used, type of DNA, among others. All these variables have to be taken into consideration in order to obtain single-base resolution with all the advantages that graphene-nanopore sequencing has to offer.

EL07.02.02
Bioresorbable Primary Battery Built on Core-Double-Shell Zinc Microparticle Networks Yutao Dong, Jun Li and Xudong Wang; University of Wisconsin–Madison, United States

Bioresorbable electronics, which decomposed in the physiological environment after a designed period of stable function and corresponding byproducts are resorbed and vanish, have gained increasing interests in state-of-the-art biomedical implants for pre-diagnosis, monitoring and treatment of diseases, drug delivery which only requires the function for a certain period of time. [1,2] Compared to other transient power supplies, such as piezoelectric nanogenerators, supercapacitors, bioresorbable batteries are promising power source with higher energy density and continuous output which typically are composed of bioresorbable material that degrade into non-toxic contents in physiological environment during and/or after discharge. State-of-the-art bioresorbable batteries are built upon Mg or Zn metal-based galvanic cells due to their good biosafety and electrochemical activity. Due to extreme high chemical activity of Mg, current Mg-based bioresorbable batteries all exhibited fluctuating voltage output and rapid output drops without a controllable lifetime, which cannot meet the

requirements of an implantable power supply. Additionally, the fast degradation rate could induce localized releasing of concentrated hydroxyl ions, leading to inflammation or other harmful effects. [3] Compared to Mg, Zn metal has moderate degradation rate which can circumvent undesirable local pH increase and minimize gaseous hydrogen evolution. [4] Furthermore, in all bioresorbable metal-based galvanic cell systems, although both anode and cathode are needed, it is the metal anode that dictates overarching electrochemical reaction and most battery characteristics. Nevertheless, almost all current models were built on bulky foils or plates, where their degradation occurred naturally on the metal surface. Therefore, there was no control over the degradation rate, direction and sequence, and thus all showed a poor controllability on the battery output and lifetime, which further limits their practical applications.
In this work, we report a bioresorbable zinc primary battery anode filament built on Zn micro-particles (MPs) coated with chitosan and Al_2O_3 nano-films. This battery filament exhibited a well-controlled dissolution direction and rate due to the mesoscale MP assembly, and the protective coatings. When discharged in 0.9% NaCl saline, single Zn MP filament with a 0.17 x 2 mm^2 cross-section exhibited a stable voltage output of 0.55 V at a current of 0.01 mA, where the current and voltage output could be simply designed by integration of the battery filaments in parallel or in series, respectively. The operational time could be directly adjusted by the length of filament. A stable 200-hour discharging time was achieved by a 15 mm Zn MP filament. By increasing the filament cross-sectional area, higher current output can be achieved at the same discharging voltage, raising the output power. The final discharging byproducts, mostly $ZnO/Zn(OH)_2$, could slowly dissolve in biofluids, making this composite filament completely degradable. This complete bioresorbable primary battery showed a full level of control of output and lifetime, providing a promising solution to *in vivo* powering transient bioelectronics.

EL07.02.03
Single-molecule Electrical Detection and Characterization of Biomolecules for New Bioelectronics Applications in Biophysics and Biomedicine Juan M. Artes Vivancos, Keshani G. Pattiya Arachchillage and Subrata Chandra; University of Massachusetts Lowell, United States

The fundamental understanding of diverse processes in biology requires bridging the gaps between studies at different levels; organisms, tissues, cells, biomolecular complexes, and, ultimately, individual biomolecules. Biophysical characterization studies require new integrated experimental and computational approaches leading to a complete quantitative picture. Single-molecule biophysics has experienced a boom in the last decades. Not only the developments in optical microscopy[1] have allowed researchers to study biological details of fundamental processes with a high resolution, but nanoscience tools such as Scanning Probe Microscopies,[2] have led to biophysical studies at the single-molecule level. Notably, Scanning Tunneling Microscopy(STM)[2] has enabled researchers to perform single-molecule bioelectronic studies, including nucleic acids[3-6].

Herein, we introduce examples of the new biomaterials science projects in our lab, where we are integrating these methods for the study of different biological systems. In particular, we recently demonstrated the first single-molecule electrical detection of a biologically-relevant nucleic acid[6,7]. We are now applying these methods to:
 # The study of the biomolecular interactions in the RNA Induced Silencing Complex at the individual complex level and,
 # The single-molecule electrical detection of circulating tumor nucleic acids for the study of cancer biomarkers and the early diagnostics through liquid biopsy.

These methods and results could be applied to numerous biological problems, paving the way to a new body of knowledge in biophysics and materials science. On the applied research front, enabling single-molecule electrical detection in biomedical research and diagnostics constitutes a step forward in biosensors; this novel method is potentially simpler, faster, and cheaper than the established methods such as optical detection or PCR-based methods. These measurements are the first single-molecule electrical investigation of sequences from human origin.

EL07.02.04

Understanding Different Biomolecular Interactions by Single-Molecule Electrical Methods Subrata Chandra, Keshani G. Pattiya Arachchillage and Juan M. Artes Vivancos; University of Massachusetts Lowell, United States

Biomolecular interactions are fundamental for any cellular function in organisms.[1] Understanding the interface between electronic materials and biological interactions with single molecule resolution can create a bridge between the knowledge gaps at different levels in organisms, tissues, cells, and, ultimately in individual molecules. This knowledge could also have a broader impact in elucidating the molecular basis of many diseases. [2] There is an urgent need for new concepts that appropriately describe the behaviour of biological interactions at the single-molecule level using bioelectronics. Determining the biophysical aspects of these interactions is also essential to understand the fundamental biology at interfaces which can tune the functionality and biocompatibility of next-generation bioelectronic devices.

Biomolecular electronics methods based on scanning probe microscopies can act as a promising alternative tool for measuring these interactions electrically.[3] We use single-molecule electrical methods to study electrical signals at these bioelectronic interfaces using the Scanning tunneling microscope-assisted break junction method (STM-BJ).[4] This technique has enabled the measurement of charge transport properties of biomolecules by reproducible conductance histograms related to the biomolecular structure and conformations.[5] STM-BJ measurements have recently shown the detection of RNA:DNA hybrids from E-coli by measuring their electrical conductance properties at the single-molecule level. [6] We aim at having a complete understanding of the interactions between different components of the RNA Induced Silencing Complex (RISC) applying these methods. RISC is a multiprotein complex that uses the siRNA or miRNA as a template to recognize complementary mRNA and plays a pivotal role in regulatory mechanisms. [7] This electrical approach also gives us a good opportunity to understand the signal transduction in RNA induced gene regulatory process.

The first step in our investigation is demonstrating the single molecule electrical detection of dsRNA. Next, we will measure the conductance of a protein (Argonaute) – dsRNA complex. This can give us a better understanding of the formation of the multiprotein complex and allowing the study of the thermodynamics and kinetics of regulation of gene expression at the individual complex level. The future work for this research will be exploring the specificity of these interactions, kinetics of those adducts and measure the thermodynamic quantities of those physical interactions. Lastly, we could use these fundamental results for designing next-generation smart biomaterials and biosensors that may address improved biological performances and advanced health monitoring in the future.

Inkjet-Printed Stretchable PEDOT:PSS-Based Electrodes and Interconnects for Wearable Health Monitoring Devices Li-Wei Lo, Haochuan Wan, Junyi Zhao and Chuan Wang; Washington University in St. Louis, United States

Stretchable conductor is one of the key components in soft electronics that allows seamless integration of electronic devices and sensors on elastic substrates. Its unique advantages of mechanical flexibility and stretchability has enabled a variety of wearable or bioelectronic devices that can comfortably adapt to curved skin surface for long-term health monitoring applications. Here, we report a PEDOT:PSS-based stretchable material that can be patterned using a simple inkjet printing process while exhibiting low sheet resistance and accommodating mechanical deformations. We have systematically studied the effect various types of polar solvent additives on the electrical performance of the ink. The polar solvent induces the phase separation of the PEDOT and PSS grains and changes the conformation of PEDOT chain which leads to a more conductive film due to the charge hopping along the percolated PEDOT network. The optimal ink formulation is achieved by adding 5wt% of ethylene glycol into pristine PEDOT:PSS aqueous solution which results in a sheet resistance of as low as 58 Ω/sq. Elasticity can also be achieved by blending the above solution with soft polymer poly(ethylene oxide) (PEO). Thin-films of PEDOT:PSS-PEO polymer blends patterned by inkjet printing exhibits low sheet resistance of 84 Ω /sq and can resist up to 50% of tensile strain with minimal changes in electrical performance. With its low sheet resistance and high mechanical stability under deformations, we have further demonstrated the use of the polymer blend as stretchable interconnects on thin PDMS substrate for photoplethysmography (PPG) sensor for heart rate and cardiac output monitoring and stretchable dry electrodes for electrocardiography (ECG) recording applications.

Late News: Characterization by Electric Impedance Sensing of Normal Cell and Cancer Cell Attachment and the Effects of Ginseng Alejandra Martinez[1], Steffi Kong[2] and Maddy Behravan[3]; [1]University of Glasgow, United Kingdom; [2]St George's University, Grenada; [3]Converse College, United States

This research introduces an application of an electric impedance sensing technique to investigate cell attachment of normal epithelial cells (HaCAT) and cancerous cells (A431) before and after addition of Ginseng. In this study, an impedance sensing system is used to measure and characterize real-time changes in electric impedance (resistance and capacitance) with respect to an alternating current (AC) applied to HaCAT and A431 cell colonies. The impedance data is related to the properties of cell spreading, attachment, and delamination. The effect of Ginseng at various dosages on these cellular properties was inferred from impedance data. The

initial impedance data show that resistance is greater for A431 cells than HaCAT cells and that capacitance for A431 cells is less than the capacitance for HaCAT cells. Further, the data shows the resistance for HaCAT cells and for A431 cells increases with time, and the capacitance for both decreases with time. The impedance data analysis shows that Ginseng does not alter the impedance of HaCAT cellular matrix significantly over a long period. Ginseng results in partial detachment and reattachment of A431 cell-to-cell bonds, thus reordering the cellular matrix. This effect is not seen in HaCAT cell colonies.

EL07.02.07
Late News: Flexible Intra-Cardiovascular Monitoring Sensor and Electrode Device Ulises G. Vidaurri Romero; University of Texas Rio Grande Valley, United States

In recent years, triboelectric nanogenerators (TENGs) have been the center of attention for research due to its wide range of applications as microsystem components, energy harvesting devices, and heath monitoring sensors. The flexibility and ability to produce energy of the TENGs are perfect attributes for a health monitoring sensor as well as an alternative to the conventional medical devices. This research focuses on an Intra-Cardiovascular Monitoring Sensor and Electrode Device (ICMSED) that is biocompatible, cost-effecive, and has high response to size ratio than other devices in its category. The framework can be implemented to achieve sensory applications as well as an electrical impulse supplier to the heart like a defibrillator in case of any cardiovascular failure. The fabrication of the device shows the combination of flexible Nitinol, with Poly-Dimethyl Siloaxane (PDMS) and Poly-Vinylidene Flouride (PVDF) polymers. Flexible nitinol wires are dip coated with these functional polymers and intertwined to achieve the framework. Nitinol wires are bi-laterally connected with the polymer coated nitinol sheets, which upon constant contact and separation within the cardiovascular system is capable to yield electrical output. Thus, as synthesized device can provide real-time data of vascular vibrations, vascular pressure, heartbeats per minute, Cardiac arrest, and defibrillation of the heart and vascular system. With its high output-to-size ratio, this Nitinol triboelectric nanogenerator is a promising step to a new chapter in medical advancements and devices.

A Microfluidic Ion Sensor Array Harika Dechiraju, Chunxiao Wu, John A. Selberg, Brian Nguyen, Pattawong Pansodtee, Manping Jia, Mircea Teodorescu and Marco Rolandi; University of California, Santa Cruz, United States

A balanced concentration of ions is essential for biological processes to occur. For example, [H+] gradients power adenosine triphosphate synthesis, dynamic changes in [K+] and [Na+] create action potentials in neuronal communication, and [Cl−] contributes to maintaining appropriate cell membrane voltage. Sensing ionic concentration is thus important for monitoring and regulating many biological processes. This work demonstrates an ion-selective micro-electrode array that simultaneously and independently senses [K+], [Na+], and[Cl−] in electrolyte solutions. To obtain ion specif icity, the required ion-selective membranes are patterned using microf luidics. As a proof of concept, the change in ionic concentration is monitored during cell proliferation in a cell culture medium. This microelectrode array can easily be integrated in lab-on-a chip approaches to physiology and biological research and applications.

EL07.02.09
Late News: Biodegradable Piezoelectric Ultrasonic Transducer for Brain Drug Delivery Thinh T. Le and Thanh Nguyen; University of Connecticut, United States

The blood-brain barrier (BBB), comprised of monolayers of endothelial cells, which prevents most therapeutics from accessing the brain tissue, is the major hurdle for treating brain diseases. The ultrasound has been shown

to be the most effective tool to disrupt the BBB. However, an external focused ultrasound system is complicated and tedious since it required MRI monitoring and a bulky transducer system, while the current implanted ultrasound transducers rely on non-degradable, toxic materials. Poly-L-lactic acid (PLLA), a biocompatible and biodegradable polymer, has been reported to exhibit piezoelectricity when appropriately processed. This research presents an air-backed unfocused biodegradable piezoelectric ultrasonic transducer made from piezoelectric electrospun nanofibers PLLA that can be implanted on the skulls to temporarily and locally disrupt the BBB for delivering drugs into the brain. The device will safely self-degrade, causing no harm to the body and avoiding invasive brain surgery for removal. We have also shown that the dextran model (3 kDa) can be delivered to the parenchyma of the mice brain by utilizing the ultrasound generated by this device. The improvements of this device can impact various medical fields such as sonodynamic therapy, sonothrombolysis, or ultrasound imaging.

EL07.02.12

Programmable Soft Liquid-Metal Electronics by Micromechanical Valving Xiangchao Zhu[1], Daniel Freitas[2], Yixiang Li[1], Sierra J. Catelani[1], Ismail Araci[2] and Ahmet A. Yanik[1]; [1]University of California, United States; [2]Santa Clara University, United States

The Internet of Things (IoT) is envisioned as a global infrastructure interlinking the physical and cyber worlds through “smart” objects continuously interacting with each other. It is predicted that IoT will connect more than 50 billions of “things” to each other by 2020, and have an economic impact surpassing 36 trillion of dollars by the year 2025. This will require tremendously large numbers of next-generation radio-frequency (RF) devices that can adapt to specific tasks, collect a wide variety of physical information, and exchange data wirelessly through communication networks. Reconfigurability in RF electronics is conventionally achieved by implementation of dynamically controllable components including semiconductor diodes and micro-electromechanical systems. However, these systems have certain limitations: nonlinearities and losses in p-i-n diodes and varactors cause degradation of the RF spectrum and yield low quality-factor responses, while MEMS switches demanding high strength fields suffer from self-actuation. Use of liquid-metals, offering high Q-factor response of a conductor in a versatile reconfigurable form, is an attractive alternative to these conventional approaches that use solid metals. Liquid-metal based reconfigurable methods, however, require large length scale (mm – cm) repositioning of liquid-metals in order to reshape them into a new electrical configuration, rendering long switching times.

Here, we introduce a scalable and electrically reconfigurable electro-microfluidic platform merging injection-based liquid-metal electrodes and micromechanical pneumatic microvalves. Without loss of generality, we demonstrate a PRogrammable INterdigitated Transducer (PRINT), an electro-acoustic RF transducer consisting of a sophisticated arrangement of two interlocking flexible comb-like electrodes conjugated with large arrays of individually addressable micromechanical valves. PRINT possesses precise and dynamically reconfigurable resonance tuning capability and high Q-factor (~ 334) resonance characteristics, both of which are challenging to achieve simultaneously. By directly compressing and modulating the electrical contacts between different liquid-metal microfluidic channel regions via microvalve actuation, we create electrically isolated regions with ultrasmall volumes (75 – 300 picolitres) and realize fast tuning of on-demand electrode configurations in a dynamic, reversible, and reliable way. Our electro-fluidic approach is distinctively different from the conventional methods that rely on emptying and refilling by pressure-driven flow or reshaping of the bulk material through electrowetting, electrocapillarity or electrochemical reactions. Our device architecture and reconfiguration scheme, employing microfluidic large-scale integration (mLSI) techniques, is generic and scalable to thousands of microvalves and hundreds of addressable chambers that are integrated in a single microfluidic chip. Complex reconfigurable device architectures for a number of different applications in the fields of RF electronics and electromagnetics could be created using on-chip multiplexers.

EL07.02.13

Late News: A Novel Green Bilayer Dielectric for High Performance Organic Thin-Film Transistors Mathieu Tousignant, Nicole Rice, Jukka Niskanen, Chloé Richard and Benoit Lessard; University of Ottawa,

Canada

Smart packaging is an emerging multi billion-dollar industry that relies on integrated flexible and inexpensive sensors to provide critical information such as temperature, pH, and time to aid with quality assurance. However, for these sensors to be incorporated into a wide variety of packaging they need to be flexible, biodegradable, and low cost.[1]
These issues can be addressed using organic electronics, where carbon-based materials are used as the active layer within electronic devices. For example, organic thin film transistors (OTFTs) are commonly used in sensing applications. One of the active layers within an OTFT is the dielectric. The dielectric facilitates charge accumulation at the interface between the dielectric and the organic semiconductor when a source-gate voltage is applied. Ideally, we want a dielectric material with a high dielectric constant (high-k) and low leakage current. Unfortunately, most polymer dielectrics that meet these requirements are not environmentally friendly. However, poly(vinyl alcohol) (PVA) meets these requirements. It is a biodegradable, water soluble, high-k dielectric polymer. While, it does have some drawbacks such as poor film forming, sensitivity to moisture and large leakage currents; we found that the addition of low weight percentages of cellulose nanocrystals improved the film forming capabilities by increasing the viscosity of the solutions.[2] Building upon these findings, a thin layer of polycaprolactone (PCL) was deposited on top of our PVA dielectric to reduce the moisture sensitivity and leakage currents of PVA. PCL is a hydrophobic, low-K, biodegradable polymer with good insulating properties. The PCL layer was functionalized with toluene diisocyanate (TDI), which can be thermally cross-linked to the hydroxyl groups of PVA at the TDI-PCL/PVA interface. Bilayer crosslinking increased the thin film stability and facilitated orthogonal processing of the semiconducting layer. The fabricated PVA/PCL metal-insulator-metal capacitors were found to be highly stable, even after being exposed to 95% relative humidity, unlike pure PVA based devices. Finally, the TDI-PCL dielectric was used in the fabrication of single walled carbon nanotube top gate bottom contact OTFTs. When compared against native PVA, the TDI-PCL/PVA dielectric showed similar mobilities of ~1 cm^2/Vs, a reduced average hysteresis of 0.2 V compared to 2.85 V for PVA, a negative threshold voltage shift and greater on/off ratios with a lower device variation. When compared against silicon dioxide the TDI-PCL/PVA dielectric had a six-fold decrease in operating voltage for both the output and transfer curves. These results demonstrate a novel method for using green dielectrics in high performing OTFTs while mitigating challenges associated with thin film processing and moisture sensitivity.

EL07.02.14
Late News: On Processing Sputtered Iridum Oxide Films (SIROF) for Neural Interfaces Tiffany W. Huang[1], Jens Duru[2], Zhijie C. Chen[1], Ludwig Galambos[1], Theodore I. Kamins[1] and Daniel Palanker[1]; [1]Stanford University, United States; [2]ETH Zürich, Switzerland

Porous sputtered iridium oxide films (SIROF) are relied upon for a variety of applications, including pH sensors and neural stimulation and recording electrodes. For neural applications, their ability to store and inject a high amount of charge is particularly important. This capability depends on the state of the material itself and access to its porous microstructure, which can be affected by a number of processes during fabrication. Of notable interest is the effect of heat treatment. Several processing steps require the use of heat, such as high temperature lithography (i.e., the SU-8 prebake typically performed at 150-250°C) or annealing of etch-related defects (i.e., a forming-gas anneal performed at 425°C). The currently available studies in this area are limited and relegated to effects of short anneals done by differential thermal analysis or temperature during deposition of SIROF. Additionally, the usage of aluminum as a sacrificial layer for electrical contacts would necessitate aluminum etchants used on SIROF, and the effect of such etchants has not been evaluated in the literature. Finally, ensuring that photoresist deposition on top of SIROF has no adverse effect and can be easily removed would give full confidence to depositing resist on SIROF for its protection during the device fabrication and release.

Here, we report on SIROF charge storage capacity (CSC) as a function of temperature and demonstrate only minimal effect of heating up to 300°C. We also show that two common etchants for aluminum, MF-26A (2.3%

tetramethylammonium hydroxide (TMAH)) and Aluminum Etch 80:3:15 NP (60-80% phosphoric acid, 5-15% acetic acid, and 1-5% nitric acid), significantly decreased SIROF capacitance and should thus be avoided in its processing. Additionally, we show that resist (20 μm spray-coated of a mixture of 7.5% SPR 220-7, 68% MEK, and 24.5% PGMEA) significantly decreases the SIROF capacitance, likely due to contamination of its pores, and thus affects performance in neural stimulation applications. We demonstrate that its capacitance can be restored by cleaning with N-methyl-pyrrolidine based solution Remover 1165 (5 min soak at 80°C followed by a 2 hr soak in NaClO). These results provide information about proper processing of SIROF for preservation of its charge injection capabilities for neural interfacing devices.

EL07.02.15
Bioelectronic Control of Chloride Ions and Concentration with Ag/AgCl Contacts Manping Jia, Harika Dechiraju, John A. Selberg and Marco Rolandi; University of California, Santa Cruz, United States

Translation between ionic currents and measurable electronic signals is essential for the integration of natural systems and artificial bioelectronic devices. Chloride ions (Cl^-) play a pivotal role in bioelectricity, and they are involved in several brain pathologies, including epilepsy and disorders of the autistic spectra, as well as cancer and birth defects. As such, controlling [Cl^-] in solution can actively influence biochemical processes and can be used in bioelectronic therapies. Here, we demonstrate a bioelectronic device that uses Ag/AgCl contacts to control [Cl^-] in solution by electronic means. We do so by exploiting the potential dependence of the reversible reaction, $Ag + Cl^- \leftrightarrow AgCl + e^-$, at the contact/solution interface, which is at the basis of the well-known Ag/AgCl reference electrode. In short, a negative potential on the Ag/AgCl contact transfers Cl^- from the contact to the solution with increasing [Cl^-] and vice versa. With this strategy, we demonstrate precise spatiotemporal control of [Cl^-] in solution that can be used to affect physiological processes that are dependent on [Cl^-]. As proof-of-concept, we use [Cl^-] control to influence the membrane voltage on human pluripotent stem cells.

2:15 PM *EL07.03.01
Ultraflexible Electrodes for Brain Disorders Lan Luan; Rice University, United States

Brain functions and dysfunctions involve complex interactions between neural, vascular and other cellular activities in a dynamic and spatially resolved manner. This vast complexity demands the ability to simultaneously detect multifaceted brain activities at sufficient spatiotemporal resolutions and to longitudinally track their evolution over a long period of time. In this talk, I will discuss our efforts to meet these needs. These efforts include: 1) the development of ultra-flexible intracortical electrodes (the NanoElectronic Threads -- NETs) to prolong the recording longevity of spiking activities; 2) massively scaling up the recording channel number, density and coverage over brain regions; 3) integrating functional optical imaging techniques with long-lasting electrical recordings to resolve and track hemodynamic and neural activities longitudinally in ischemic brains, and 4) further extension of the spatiotemporal coverage by the co-implantation of NETs into deeper brain structures and a near-cortex-wide cranial window. These neurotechnology advances enables new opportunities for detecting, understanding, and potentially treating a broad spectrum of neurological and neurodegenerative disorders.

2:40 PM EL07.03.02
Late News: New Frontiers for Wireless, Battery-Free and Fully Implantable Neuromodulation Tools—

Transcranial Optogenetic Stimulation and Multimodal Operation in Freely Flying Animals Philipp Gutruf; University of Arizona, United States

Wireless, battery-free and fully implantable tools for the interrogation of the central and peripheral nervous system have quantitatively expanded the capabilities to study mechanistic and circuit level behavior in freely moving subjects. The light weight and small footprint of such devices enables full subdermal implantation that results in the capability to perform studies with minimal impact on subject behavior and yields broad application in a range of experimental paradigms.
Yet, current limitations in wireless power delivery require invasive modes of stimulus delivery that penetrate the skull and disrupt the blood brain barrier, causing tissue displacement, neuronal damage, and scarring. Power delivery constraints also sharply curtail arena volume, limiting operation to mostly rodent subjects in well controlled arena sizes. Here, we implement digitally managed, highly miniaturized, capacitive power storage to wireless and subdermal implants. This approach enables power delivery to optoelectronic components to enable two classes of new applications: transcranial optogenetic activation up to 5 mm deep into the brain without the need to penetrate the blood brain barrier and substantially increased arena volumes for rodents with a quadrupling of experimental arenas for wireless optogenetics to over 1 m^2 in size. By combining this technique with deep neural net enabled behavior guided primary antenna design we report multimodal optogenetic stimulation and physiological recording in freely flying songbirds for the first time and demonstrate optogenetic manipulation of song renditions, highlighting the capability to expand neuromodulation to a variety of animal model species.

2:55 PM *EL07.01.01
Wireless, Closed-Loop Photostimulation of the Nervous System Enabled by Miniaturized and Compliant Optoelectronic Implants Frederic Michoud[1], Claudia Kathe[1], Corey Seehus[2], Philipp Schoenle[3], Qiuting Huang[3], Clifford Woolf[2], Gregoire Courtine[1] and Stephanie P. Lacour[1]; [1]EPFL, Switzerland; [2]Harvard Medical School, United States; [3]ETHZ, Switzerland

In the past decade, multiple approaches for optical stimulation of neurons have been proposed, mainly focused on the brain. Optogenetic activation of axons in the spinal cord or the peripheral nerves has specific challenges related to their anatomy, softness, opacity and demanding mechanics. We propose a wireless and implantable neurotechnology that offers safe and long-term photostimulation of any targeted neurons and pathways in untethered and unrestricted mice. The implantable system consists of (1) a conformable array of high efficiency micro-scale light emitting diodes, (2) elastic thin-film interconnects that dampen effects of local motion and join the LEDs via (3) a subcutaneous cable and (4) an ultraminiaturized, battery powered, head-mounted, wireless recording and stimulation platform. The platform is operated via a handheld tablet that displays a real-time preview of the acquired physiological signals, the timing of the photostimulation, and a feedback on the accurate delivery of the configured current.
The talk will review the design and manufacturing of the implantable system, highlighting critical steps to engineer compliant optoelectronic interfaces, safe and spatially-selective photostimulation in freely behaving animals. The versatility and robustness of the system will be demonstrated in the context of pain fibers modulation in the peripheral nerves and closed-loop control of spinal cord wherein the onset of a burst of muscle activity instantly triggers photostimulation.

3:20 PM *EL07.03.03
Magnetic Materials for Miniature Wireless Bioelectronics Jacob Robinson; Rice University, United States

Electrical stimulation of neural circuits is a key tool for studying brain function and developing new therapies for neurological disorders. Traditionally, these electrical stimulators include an implanted pattern generator (IPG) that includes a battery and a tether connecting the device to the stimulating leads. These components are one of the most common failure points of the system and comprise the vast majority of the implant volume. To create miniature neural implants without lead wires or large IPGs recent work as turned to wireless data and power delivery to miniaturize neural stimulators. The challenge for these devices, however, is the fact that the

body absorbs electromagnetic radiation often used to power miniature devices making it difficult to deliver sufficient power within operational safety limits. Here, we describe how magnetoelectric (ME) materials offer an efficient method to power millimeter-sized neural implants, achieving power levels of several mW well within the safety limits for human operation.

3:45 PM *EL07.03.04
Modulating Neurophysiology with Multifunctional Fibers Polina Anikeeva; Massachusetts Institute of Technology, United States

Integration of multiple disparate materials within flexible fibers has permitted simultaneous probing and modulation of multiple neurophysiological processes in behaving subjects. In this talk, I will highlight the recent materials and fabrication advances that extend applications of multimaterial fibers to long-term studies of brain dynamics, delivery and probing of neurochemicals, and modulation of neural circuits connecting the brain and the peripheral nervous system. For instance, I will show applications of hydrogels as a means of tuning the modulus of the fibers as well as a tool for drug delivery. Convergence drawing will be introduced as a means to expand the array of materials compatible with fiber fabrication. Finally, I will discuss the introduction of solid-state devices into fibers, and demonstrate their applications for wireless control of behavior and physiology.

5:15 PM *EL07.04.01
Bioelectronic Modulation with Soft-Hard Composites Aleksander Prominski and Bozhi Tian; The University of Chicago, United States

Biointerface devices can probe fundamental biological dynamics and improve the lives of human beings. However, the direct application of traditional rigid electronics onto soft tissues or cells can cause signal transduction and biocompatibility issues, due to mechanical mismatch at the biointerfaces. One common mitigation strategy is the use of nanostructures or soft-hard composites to form more biocompatible interfaces with target cells or tissues. My group integrates nanoscience and soft matter physics with biophysics to study several semiconductor- or conductor-based biointerfaces. In this talk, I will first pinpoint domains where semiconductor properties can be leveraged for biointerface studies. Next, I will present a few recent studies from our lab and highlight key bioelectrical mechanisms underlying the non-genetic optical or electrochemical modulation interfaces. The non-genetic and soft-hard composite-based methods have the potential to overcome the limitations of current metal electrode-based devices such as bulk and cell membrane disruption, and are not dependent on genetic modifications. Finally, I will discuss new tissue-like materials and other biological targets that could catalyze future advances.

5:40 PM EL07.04.02
Exceptionally Tough and Self-Healing Polymer Blend for Electronic Skin Sung Hwa Hong; University of Toronto, Canada

Electronic skin is an emerging platform with multifunctionalities such as pressure, strain, temperature and humidity sensors while being soft, self-healable, flexible and stretchable. Such multifunctional materials are suitable for soft robotics, wearable devices and prosthetics. However, low toughness and manufacturability hinders the translation of the technology into practical applications.
Toughness is influenced by chemical structure of polymers and crosslinker. For instance, thermoplastic

polyurethane (TPU) is a commercially available polymer that has suitable mechanical properties for smart skin applications. However, most of TPUs have high elastic modulus and does not exhibit self-healability. There have been some attempts to endow self-healability, but the rate of healing typically took more than weeks for recovery. Recently, a TPU was labelled with covalently crosslinkable disulfide group and tuned with varying hard segments. This TPU with loosely packed hard segment facilitated the healing by thiol-disulfide exchange reaction. However, its Young's modulus above 5 MPa limits the application for smart skin.
Herein, we report TPU blended with a synthesized self-healing polymer for highly tough and self-healable material. The self-healing polymer with a low Young's modulus is synthesized by using industrially friendly free radical polymerization involving methacrylic acid that enables crosslinking through metal-ligand interaction. This type of bond can be broken and re-formed easily, thus promotes self-healing. Subsequently, this polymer was blended with PU and electrospinning process was used to induce the film formation. Dynamic mechanical analyzer results revelated that the resulting film exhibits a toughness of 70 MJ/m^3 and heals from macro-damages within 5 hrs. The film was further coated with polypyrrole endowing electrical conductivity. The material has been examined as a piezoresistive sensor and supercapacitor as to show its versatility for electronic skin application.

5:55 PM *EL07.04.03
Green Bioelectronic Interfaces Made from Protein Nanowires Jun Yao; University of Massachusetts Amherst, United States

Biosystems are made from biomaterials (*e.g.*, protein), whereas conventional electronic systems or interfaces are made from non-biological materials. This leads to some inherent gap in terms of material compatibility in interfacing electronics with biosystems. We explore the possibility of making active electronic devices from protein nanowires harvested from microbe *Geobacter sulfurreducens* for 'green' bioelectronic systems/interfaces. We show how we can utilize the unique properties in the protein nanowires to realize energy devices, sensors, and computing devices, the three key basic elements for integrated electronic interfaces/systems. Specifically, we show 1) energy devices made from the protein nanowires can continuously harvest electric energy from ambient humidity to provide sustainable energy solution to microsystems; 2) neuromorphic devices (e.g., memristors) made from protein nanowires can achieve biological-amplitude functions for ultralow-power computation; and 3) protein nanowires can serve as the active sensing element in constructing electronic biosensors. The perspective of integrated systems/interfaces based on these elements will also be discussed.

6:20 PM EL07.04.04
Late News: Energetic Control of Redox-Active Polymers Towards Safe Organic Bioelectronic Materials Alexander Giovannitti; Stanford University, United States

In my presentation, I will explain the common electrochemical side reactions between redox-active conjugated polymers and aqueous electrolytes in ambient conditions. We find that electron-rich polymers such as PEDOT:PSS or pg2T-TT[1] can undergo electron transfer reactions with molecular oxygen (oxygen reduction reaction), forming hydrogen peroxide (H_2O_2) as a side product. H_2O_2 itself is an oxidant that can cause harm to biological environments and devices and can also impact the device performance such as increasing the OFF currents of organic electrochemical transistors (OECTs). The origin for the side reaction is an electron transfer from the electron-rich conjugated polymers to molecular oxygen dissolved in the electrolyte where the ionization potential (IP) of the redox-active polymer determines if the reaction occurs spontaneously. By designing and synthesizing redox-active polymers with large ionization potentials (IP > 4.9 eV)[2], we show that the side reaction can be avoided during the operation of electrochemical devices in ambient conditions. When tested in the OECT, the materials achieve low OFF currents (nAs), high ON/OFF ratios of $>10^{5,}$ and excellent redox-stability during continuous operation. This study elucidates the interaction of redox-active conjugated polymers and molecular oxygen which has previously been overlooked with potentially critical issues for operating electrochemical devices in oxygen-containing aqueous electrolytes (biological environments).

6:35 PM *EL07.04.05
Controlling the Properties of Organic Mixed Ionic-Electronic Conductors Using Living Radical Polymerization Laure V. Kayser; University of Delaware, United States

Organic mixed ionic-electronic conductors (OMIECs) are materials capable of bridging the gap between biological entities ('soft' and ionically conductive) and electronic devices ('hard' and electronically conductive). They have therefore been used extensively in biosensors, organic electrochemical devices (OECTs), and wearable and implantable electronics. Among these OMIECs, the polyelectrolyte complex poly(3,4-ethylene dioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) is the most commonly used for bioelectronic interfaces owing to its high conductivity, water and air stability, biocompatibility, and commercial availability. While the latter makes it easy to adopt and incorporate in devices, it limits our ability to modify the structure of PEDOT:PSS to achieve specific properties and performance. A possible solution to tune the properties of PEDOT:PSS is to use additives (plasticizers, polymers, crosslinkers, surfactant…). While effective at achieving the desired performance, additives often lead to other, sometimes undesirable, effects; making it difficult to predict and/or rationalize structure-property relationships. To address this issue, the Kayser laboratory specializes in modifying the PSS component to understand and *intrinsically* tailor the mixed ionic-electronic conduction, degradability, mechanical properties, and dynamic behavior of PEDOT:PSS derivatives. We use living radical polymerization techniques (e.g., reversible addition-fragmentation chain transfer polymerization, RAFT) to synthesize PSS with a control over the molecular weight and dispersity. For example, we found that we can precisely increase the conductivity of PEDOT:PSS, compared to its commercial form, without using external additives by synthesizing PSS with low molecular weight and dispersity (M_n = 48 kDa, *PDI* = 1.2). We are currently studying how these changes in the structure of PSS affect the transconductance of PEDOT:PSS in OECT devices. Another important factor for the integration of PEDOT:PSS in bioelectronics, besides conductivity, is its mechanical properties and compliance. In its commercial form, PEDOT:PSS is relatively 'hard' (Young's modulus ~ MPa) and poorly stretchable (< 5%) which limits its use in wearable and implantable devices.[1] We have developed a method to obtain intrinsically stretchable samples by preparing block copolymers of PSS with poly(ethylene glycol methyl ether acrylate) (PEGMEA).[2] We are now exploring a similar copolymer strategy to obtain conductive materials with dynamic mechanical properties (i.e., stimuli-responsive PEDOT:PSS). A combination of published data and preliminary results will be presented that highlight our ability to control the intrinsic properties of PEDOT:PSS for applications in bioelectronics and human-machine interfaces.

EMIm-OTf Ionogel Coated Fibres—Characterisation and Development, Aiming at Ionic Smart Textiles

Claude Huniade[1], Shayan Mehraeen[2], Edwin Jager[2], Tariq Bashir[1] and Nils-Krister Persson[1]; [1]The Swedish School of Textiles - University of Borås, Sweden; [2]Linköping University, Sweden

Ions are prevalent within bioelectronics, as they are the main charge carriers in living systems. In contrast to electronic systems, ionic ones are closer to what can be found in our body; in muscles, neurons and nerves.

Textiles are a much used biomedical material, both in vivo and in vitro due to its membrane character, high efficient area, softness, biocompatibility and biodegradability. Modifying the physicochemical properties of the core or the surface of textile has been reported a countless amount of times, but still, its use in a bioelectrical context is limited.

Fibres are the building blocks of textiles and what make textiles an architected class of material. Then ionically conductive fibres are of great interest.

Here, we show the preparation of iono-conductive textile fibres through the (semi-)continuous dip-coating of ionogel on the cellulose-based viscose.

Ionogels are composed of salts in liquid state and a 3-dimensional solid network, in our case an ionic liquid (IL), 1-Ethyl-3-methylimidazolium trifluoromethanesulfonate, commonly named EMIm OTf or EMIm Triflate, and a thiol acrylate network, allowing the mobility of the ions within or in/out of the gel. This specific combination is a first effort towards the development of ionic textile fibres and ionic smart textiles, as a variety of ILs with different cations and anions exists, potentially allowing a large amount of different combinations.

We investigate how the coating of this ionogel affects the mechanical properties as well as the conductivity in AC or DC arrangement and their relation to temperature and humidity. Also, the thermal stability and sensitivity of degradation of the fibre system is studied.

Moreover, we introduce different textile structures, and potential applications directed to bioelectronics.

Proton-Activated Synaptic Plasticity of Synaptic Transistors Based on Peptide Min-Kyu Song[1], Seok Daniel Namgung[2], Daehwan Choi[1], Hyeohn Kim[2], Hongmin Seo[2], Misong Ju[2], Yoon Ho Lee[2], Taehoon Sung[1], Yoon-Sik Lee[2], Ki Tae Nam[2] and Jang-Yeon Kwon[1]; [1]Yonsei University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

With the recent advances on artificial intelligence, the need for advanced computing processors has been enormously growing to eliminate von Neumann bottleneck in conventional computing processors. To overcome this barrier, novel devices inspired by human brain have been newly proposed. Human brain processes neural signals with 10^{11} neurons and 10^{14} synapses which are connected in parallel while it consumes only 20 W which is extremely low compared to the super computers including IBM's Pohoiki Springs which consumes up to 500 W to emulate elementary brain tasks. To mimic the energy efficiency of biology, researchers in the area of nanoelectronics have proposed various neuromorphic devices. Among them, synaptic transistors have been regarded as the essential component for spiking neural network that emulates synaptic plasticity that pre-synaptic spikes induce timing-dependent post-synaptic responses.
In this work, we demonstrate the novel synaptic transistors that can be turned on and off by controlling humidity. Tyrosine-rich peptide was utilized for proton control layer (PCL) that proton conducting property is exponentially regulated by controlling humidity. IGZO and Au were used as a semiconducting layer and electrode, respectively. Electrical characteristics were measured as a function of relative humidity (RH). Long range gating effect was observed only in highly humid condition while no gating effect was observed in ambient condition. Capacitance-voltage (C-V) characteristics and impedance analysis indicate that the threshold effect of the electrostatic coupling is due to electric double layer (EDL) of protons in the peptide film. On the basis of this phenomenon, we demonstrate the synaptic functions of the device at high humidity including

paired pulse facilitation (PPF), spike-number dependent plasticity (SNDP) and transition from short-term plasticity (STP) to long-term plasticity (LTP). This result demonstrates not only the expansion of the controllability of synaptic function that proton is another control, but also the emulation of proton activation in acid sensing ion channel in biological synapse.

EL07.05.04

Late News: Current-Driven Organic Electrochemical Transistor for the Assessment of Biological Barriers Katharina Lieberth[1], Maximilian Brückner[1], Fabrizio Torricelli[2], Volker Mailänder[1,3], Paschalis Gkoupidenis[1] and Paul Blom[1]; [1]Max-Planck-Institute, Germany; [2]University of Brescia, Italy; [3]University Hospital JGU Mainz, Germany

To use the organic electrochemical transistor (OECT) as a biosensor is of great importance, as it is a state-of-the-art technique in the field of drug delivery.[1] Allowing ion-to-electron conversion and having a high amplification of gating due to volumetric capacitance, enables the OECT to operate with aqueous electrolytes at low voltages.[2] When using the OECT as an inverter in a current-driven configuration, a constant current is applied at the channel by an external power supply. It was found that the OECT offers an enhanced sensitivity compared to standard transfer characteristics of an OECT.[3] The impact of measurement scan rate on the inverter characteristics was also studied. Even small changes in the ionic current can be detected, which is required to study tight junction modulation.[4] Tight junction barriers of epithelial cell layers impede the transcellular pathway of nutrients and drugs from organs into the blood.[5,6] Hence, monitoring the effect of external stimuli such as poly-L-lysine (PLL) on tight junction modulations is crucial for drug delivery.[7] As a well-established model for oral drug delivery, the epithelial colon carcinoma (Caco-2) cell line,[8] found in the small intestine, was used to evaluate reversible modulation of tight junctions over time, under the effect PLL. Investigating PLL-concentration and TJ-modulation time dependence resumed that the exposure to a medium concentration of PLL initiates reversible modulation, whereas a too high concentration induces an irreversible barrier disruption. To support electrical measurements occluding-staining has been performed using immunofluorescence imaging. The results demonstrate the suitability of OECTs to *in-situ* monitor temporal barrier modulation and recovery, which can offer valuable information for drug delivery applications.[9]

EL07.05.07

Late News: Study of Bio-Modified Gold Electrode for Forefront Point-of-Care Sensors Lucia Sarcina[1], Eleonora Macchia[2] and Luisa Torsi[1,2,1]; [1]Università degli Studi di Bari Aldo Moro, Italy; [2]Åbo Akademi University, Finland

In the last decade, there has been a growing demand for rapid, cost-effective point-of-care (POC) platforms for

early detection of clinically relevant biomarkers.[1] This need gave rise to the implementation of novel bioelectronic systems, capable of interfacing biological samples with smart electronic devices. Thus, the robustness of transistor technology has been applied to the functional sensing of clinically relevant species, through the Electrolyte-gated Organic Field Effect Transistors (EGOFET) technology.[2] Here a huge transducing surface is settled on the gate electrode by conjugating specific bio-elements, for the recognition of relevant analytes, such as protein, DNA strands or enzyme substrates.[3] The subsequent interaction between the sensing pairs cause a variation on the electrode work-function, which is traduced in a sensor output modification, even at low analyte concentrations. This technology has been already employed for the label-free detection at the physical limit of different antigens such as the HIV-p24 protein.[4] The sensor selectivity could be guaranteed by the proper functionalization of the sensing electrode. Thus, gold surfaces bio-modification has been deeply studied to investigate best configurations for the anchoring of specific antibodies, for the recognition of the target proteins, by means of a real-time Surface Plasmon Reference (SPR) assay. Through the well-known method of self-assembly of alkylthiols on gold, densely packed layer of 10^{11}-10^{12} antibodies/cm^2 are covalently bound to the electrode and subsequently exposed to HIV-1 p24. Moreover, for testing the selectivity of the functionalized surface, the SPR response to a non-binding analyte, namely human C-reactive protein, was further investigated. In this perspective, the same method has been applied to the study of more complex systems as the detection of relevant bacteria. Both the SPR platform and EGOFET apparatus have been characterized, to assess functionalization procedures and electronic sensing evidences, competitive with current POC assays.

EL07.05.08

Late News: Floating Gate Organic Electrochemical Transistors Erica Zeglio[1], Shirin Khaliliazar[1], Mahiar Hamedi[1] and Anna Herland[1,2]; [1]KTH Royal Institute of Technology, Sweden; [2]Karolinska Institutet, Sweden

Organic electrochemical transistors (OECTs) are electronic devices having conjugated polymers in conducting or semiconducting form as core components. In a typical OECT configuration, the channel is made by a drain and source metal contacts connected by a conjugated polymer film, which is then separated from a gate electrode by an electrolyte.[1] The mixed electronic/ionic conductivity of conjugated polymers allows for low operating voltages, high amplification, and adaptability to various form factors, making OECTs appealing devices for bioelectronics, including biosensors and electrophysiological sensors.[2]
For such sensing applications, it would be beneficial to explore configurations where the channel is physically separated from the target fluid containing the analyte or biological system of interest. Floating gates were introduced in electrolyte-gated transistors to provide such physical separation between the amplification and sensing compartments (though maintaining electronic connection).[3] This configuration offers two main advantages: 1) the conjugated polymer and electrolyte can be chosen only based on device performance to maximize amplification, and 2) the sensing area can be built to optimize sensing in contact with biological fluids, such as electrolyte composition and electrode functionalization strategy (e.g. using simple thiol functionalization chemistry).[4]
Here, we present an OECT with a floating gate configuration. We explore the effect of floating gate parameters (e.g. geometry and composition) on OECT operating and sensing performance. Our data suggest that the floating gate geometry is a promising strategy to maximize amplification while minimizing the volume of electrolyte required at the sensing area – something important for biological applications where the volume of the analyte is limited (e.g. DNA sensing).

In-Operando Kinetic of PEDOT:PSS Electrochemical Doping Gonzague Rebetez, Olivier Bardagot, Julien Réhault and Natalie Banerji; University of Bern, Switzerland

Organic Electrochemical Transistors (OECTs) are sensitive sensors used in increasingly challenging biologic applications such as wearable textiles with integrated biosensors and *in vivo* recording of brain activity.[1,2] They can be described as an ionic circuit embedded with an electronic circuit. The former arises from ions penetrating the organic channel upon gate bias, while the latter arises form source-drain electron flow across the organic channel.[3] Even if our knowledge on OECT behavior and their performance has increased drastically during the last years, a complete picture of these two circuits and how they interact is still missing. Here, we innovatively combine two spectroscopic techniques to study the ionic and electronic transport processes in OECTs:

1) Time-resolved *in-operando* UV-vis-NIR absorption spectroscopy unravels the kinetics of the ionic circuit. This measurement monitors the ion penetration into the organic channel and the subsequent electrochemical doping processes with millisecond temporal resolution. Thanks to our multivariance curve resolution analysis,[4] we extracted the neutral, polaron and bipolaron dynamics, providing insights to the limiting steps of the dedoping/redoping processes.

2) *In-operando* THz steady-state absorption spectroscopy investigates the electronic circuit. This measurement probes the nature and the nanoscale conductivity of the charges inside the organic channel.[5] Connected to the doping level, the nanoscale conductivity grants further understanding about the nature of the interaction between the ionic and electronic circuit.

Results on PEDOT:PSS, the current state-of-the-art material in OECT applications, will be presented.

Late News: Biocompatible and Biodegradable Solid-State Electrolyte for Organic Transistors Young Jin Jo and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

Organic electronics are essential components of bio-integrated due to their flexibility and stretchability. There are various issues related to mechanical properties similar to those of skin, tissues and organs, reliability of electrical characteristics under deformations, biocompatibility, biodegradability and low-voltage operation. electrolyte-gated transistors (EGTs) are candidates for decrease of operating voltage using electrolyte as dielectrics in organic transistors. Electrolytes reduce the voltage of organic transistors by high capacitance from the electrical double layers. However most of electrolytes are liquid state that requires harsh passivation layer for stable working in the biological environment. Also, synthetic ion gel based on ionic liquid and polymers has

not been proved as being biocompatible and biodegradable. Here, we suggest a novel concept of solid-state electrolytes based on biocompatible levan polysaccharide for organic transistor. We also used choline based biocompatible and biodegradable ionic liquid by coupling acidic components found in nature. The electrolyte is flexible and highly transparent, also can be served as both dielectric and substrate for organic transistors. Therefore, we fabricated organic transistor on free-standing electrolyte films directly and we also utilized the electrolyte based organic transistors for measuring bio-signals on the skin or heart due to their flexibility, biocompatibility and biodegradability.

EL07.05.11
Late News: Catalytic Properties of Electropolymerized Poly(3,4–ethylenedioxythiophene) Films in Biological Media Prem D. Nayak, David Ohayon, Shofarul Wustoni and Sahika Inal; KAUST, Saudi Arabia

Various electrocatalytic and photocatalytic devices, promising for use as power supplies of bioelectronic devices, rely on oxygen reduction reaction (ORR). Poly(3,4–ethylenedioxythiophene), PEDOT, is an efficient ORR catalyst with hydrogen peroxide (H_2O_2) being the major product. Although H_2O_2 is an excellent green fuel for batteries and fuel cells, and an industrial oxidant, it is toxic for living systems when PEDOT films are used in bioelectronic devices. In this work, we investigated the ORR behavior and H_2O_2 production of a series of electropolymerized PEDOT films. By varying the counterion (monomeric vs. polymeric), including a hydroxyl terminated EDOT monomer in the polymer architecture, or adding a conductivity enhancer in the reaction mixture, we aimed to understand the synthetic parameters that govern the ORR properties. We found that the pristine doping level of the polymer – influenced by counterion type and the presence of the conductivity enhancer – controls the ORR pathway in PEDOT films. High levels of intrinsic doping leads to films with H_2O_2 as the ORR product. Using this information, we synthesized a new PEDOT derivative for which H_2O is the major ORR product. This systematic work will aid designing conducting polymers and choosing operational parameters that (i) maximize film performance in catalytic applications, and (ii) minimize the production of harmful chemicals in bioelectronic devices.

EL07.05.12
Late News: A Microfluidic and Nanoporous Membrane Integrated Organic Electrochemical Transistor for amyloid-β detection Anil Koklu[1], Shofarul Wustoni[1], Valentina Musteata[1], David Ohayon[1], Maximilian Moser[2], Iain McCulloch[2,1], Suzana Nunes[1] and Sahika Inal[1]; [1]King Abdullah University Science and Technology, Saudi Arabia; [2]University of Oxford, United Kingdom

Alzheimer's disease (AD) is a neurodegenerative disorder associated with a severe loss in thinking, learning, and memory functions of the brain. A common pathological indicator found in AD-affected brains is the aggregates of a protein named amyloid-β (Aβ). In this work, we developed an organic electrochemical transistor (OECT) integrated with a microfluidic platform and a nanoporous membrane for the label-free detection of Aβ aggregates in human serum. The nanoporous membrane is functionalized with Congo red (CR) showing a strong affinity for Aβ aggregates. The detection relies on the modulation of the electric field between the gate and the channel as the aggregates are captured by the membrane. Integration of the OECT with the microfluidics enables minute amounts of fluids to be processed and reduces the sample incubation time. Novel *p-type* and *n-type* semiconductors used at the OECT channel improve the sensitivity, decrease the detection limit, and lower the power requirements, ranking these sensors' performance beyond the state-of-the-art Aβ sensors. The high transconductance of the OECT, the precise porosity of the membrane, and the compactness endowed by the microfluidic enables protein detection as low as fM concentrations and over eight orders of magnitude wide concentration range in only 1 μL of human serum.

10:30 AM *EL07.06.01
***In Vitro* Biomimetic Electronic Platforms** Francesca Santoro; Istituto Italiano di Tecnologia, Italy

The interface between biological cells and non-biological materials has profound influences on cellular activities, chronic tissue responses, and ultimately the success of medical implants and bioelectronic devices. The optimal coupling between cells, i.e. neurons, and materials is mainly based on surface interaction, electrical communication and sensing.
In the last years, many efforts have been devoted to the engineering of materials to recapitulate both the environment (i.e. dimensionality, curvature, dynamicity) and the functionalities (i.e. long and short term plasticity) of the neuronal tissue to ensure a better integration of the bioelectronic platform and cells.
On the one hand, here we explore how the transition from planar to pseudo-3D nanopatterned inorganic and organic materials have introduced a new strategy of integrating bioelectronic platforms with biological cells under static and dynamic conditions. Although a spontaneous penetration does not occur, adhesion processes are such that a very intimate contact can be achieved. On the other hand, we investigate how organic semiconductors can be exploited for recapitulating electrical neuronal functions such as long term and short term potentiation. In this way, both the topology and the material functionalities can be exploited for achieving in vitro biohybrid platforms for neuronal network interfacing.

10:55 AM EL07.06.02
About the Amplification Factors in Organic Bioelectronic Sensors Luisa Torsi and Eleonora Macchia; Università degli Studi di Bari Aldo Moro, Italy

Several three-terminal organic bioelectronic structures have been proposed so far to address the needs for a variety of biosensing applications. The most popular ones utilized organic field-effect transistors operated in an electrolyte, to detect both proteins and genomic analytes. They are endowed with selectivity by immobilizing a layer of bio-recognition elements. These features along with the foreseen low-cost for their production, make them very appealing for point-of-care biomedical applications. However, organic bioelectronic transistors do not always exhibit a performance level beyond state-of-the-art electrochemical sensors, which have been dominating the field for decades. This review offers a perspective view based on a systematic comparison between the potentiometric and amperometric electrochemical sensors and their organic bioelectronic transistor counterparts. The key-relevant aspects of the sensing mechanisms are reviewed for both, and when the mathematical analytical expression is actually available, the amplification factors are reported as the ratio between the response of a rationally designed transistor (or amplifying circuit) and that of a homologous electrochemical sensor. The functional dependence of the bioelectronic sensor responses on the concentration of the species to be detected enabling their correct analytical quantification, is also addressed.

11:10 AM EL07.06.03
Unraveling Enzyme/Conjugated Polymer Interactions for High Performance Metabolite Sensors David Ohayon and Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

The tight regulation of metabolite metabolism in the body is crucial for balanced physiological function and any irregularities in metabolite uptake or consumption underlie various diseases. In our previous work, we demonstrated the development of a third-generation metabolite sensor, i.e., a microscale electrochemical device comprising an n-type conjugated polymer at the channel and as the gate electrode coating, which detects lactate or glucose without the need of an electron mediator.[1-2] Here, we adopt a more fundamental approach to understand how the molecular structure of the n-type polymer enables the adsorption of the enzyme glucose oxidase on its surface. We investigate the interactions of the enzyme with six different n-type polymers which have the same backbone but different side chains. We find that depending on the polymer surface properties,

governed by the nature of the side-chains, the enzyme changes its conformation and footprint, which in turn determines the sensor sensitivity. Our work provides new guidelines for the structure-performance relationships of electronic materials with enzymes, crucial for the development of enzymatic metabolite biosensors and biofuel cells.

11:25 AM EL07.06.04
Conjugated Molecularly Imprinted Polymers for Biological Sensing Christina J. Kousseff[1], Shofarul Wustoni[2], Fani E. Taifakou[1], Sahika Inal[2] and Christian Nielsen[1]; [1]Queen Mary University of London, United Kingdom; [2]King Abdullah University of Science and Technology, Saudi Arabia

The structure-based tuneability of the electronic and optical properties of conjugated polymers have enabled their application across a range of fields, including energy harvesting, photovoltaics, and medical imaging. However, in the context of biological sensing, the use of conjugated polymers has thus far incorporated little specificity in terms of covalent modification.

Developing robust, highly selective, biologically compatible sensing platforms is of critical importance because the measurement of analyte concentrations in biological samples is crucial for the management or detection of many diseases. For example, fluctuations above or below the optimal range of sodium ion concentration in many bodily fluids can impact blood pressure, nerve and muscle function, while glucose concentration in the blood must be monitored constantly in diabetes. Currently, commercial glucose sensors and many proposed alternatives rely on enzymes, which are expensive and subject to temperature and pH sensitivity, instability, and leaching over time. Meanwhile, other devices are based on complex composite designs featuring separate components to impart conductivity, analyte binding, or selective response. Synthetic strategy with conjugated polymers, especially using the technique of molecular imprinting, enables the efficient combination of analyte specificity, biological interfacing and electroactive or optical functionality into a single multipurpose material. In addition, these entirely organic systems offer affordability, stability, biocompatibility, and simple design and fabrication.

However, due to the well-known difficulties associated with the covalent modification of one of the most effective polymers for this application, poly(3,4-ethylenedioxythiophene) (PEDOT), one of the main challenges in this area thus far has been the attainment of specificity at a molecular level. I will present my work on the concept, design and synthesis of novel molecularly imprinted, electroactive polymers for biological sensing. This includes the creation of a sodium-chelating electrochromic polymer, and a cross-linked glucose-binding electroactive material, both based on covalently modified PEDOT. I will discuss the selectivity and sensing behaviour of these materials in response to the respective analytes, their properties when incorporated into transistor devices, and how this highly adaptable approach can be applied to create a range of materials for many applications across the field of biological sensing.

11:40 AM EL07.06.05
Ultra High Density Optical Nanoelectrode Arrays: Multi Million-Plex Electrophysiological Measurements with Subcellular Resolution Ahsan A. Habib[1], Xiangchao Zhu[1], Uryan Can[2], Maverick McLanahan[1], Pinar Zorlutuna[2] and Ahmet A. Yanik[1]; [1]University of California, United States; [2]University of Notre Dame, United States

Since the first measurement of the nerve impulse by Hermann von Helmholtz in 1849, understanding how a

network of neurons works has been one of the biggest scientific, engineering, and medical challenges [1]. The challenge remains unsolved in the realm of electrical technology, which has limited spatial resolution mainly due to the need for on-chip signal conditioning elements and tighter upper limits for the low noise transfer of spiking cell information by a multiplexed wire [2]. Here, we turn optics since light offers unprecedented spatiotemporal resolution and information-carrying capabilities [3]. Achieving electrophysiological recordings through optical means, on the other hand, largely depends on our ability to recruit reliable electro-optic translators converting electrophysiological signals into photons. After decades of research, state-of-the-art translators cannot provide the high signal-to-noise ratio requirements because of the low photon counts (e.g., voltage sensitive dyes) or low electric-field sensitivities (e.g., quantum dots). We recently invented a novel electro-optic probe by merging nanoionics, plasmonics, and electrochromism that we term "electro-plasmonic field probe" for the transduction of electrophysiological signals into high photon count optical signals [4]. Using the electro-plasmonic nanoprobe, we demonstrated a large scattering intensity change of ~7 % for low field values of 8×10^{-2} mV/nm consistent with the extracellular electric field. Our field probe compares favorably with the quantum dots that provide a ~11% change in photoluminescence signals for an applied field of 10 mV/nm. This field sensitivity is nearly two orders of magnitude lower than that of the electro-plasmonic nanoprobe. Moreover, our electrochromically loaded plasmonic nanoelectrodes have 10-100 million times larger cross sections than those of the widely-adopted genetically incorporated fluorescence molecules and therefore provide an extremely large signal-to-shot-noise ratio (~60-200) with a single loaded nanoelectrode compared to a low signal-to-shot-noise ratio (< 10) that millions of genetically incorporated fluorescence molecules could achieve. In our experiments, we realize extracellular label-free optical detection of electrophysiological activity with high signal-to-noise ratios at three orders of magnitude low light intensity conditions compared to genetically incorporated fluorescence molecules and demonstrate sub-millisecond temporal response time measurements (< 0.2 ms). Our novel approach presents a quantum technological leap for label-free optical imaging of electric-field dynamics with high spatiotemporal resolution.

Micro-Invasive Interfaces for Interstitial Fluid Sampling in the Brain and Beyond Ritu Raman; Massachusetts Institute of Technology, United States

Introduction: Biochemical dysregulation underlies many pathologies. Diagnosis and treatment of biochemical dysregulation involves monitoring biomarkers in bodily fluids. While methods for sampling bodily fluids such as blood are well-established, there is a need for robust micro-invasive methods for sampling the interstitial fluid (ISF) between cells, especially in delicate tissues such as the brain. The current state-of-the-art in neural ISF sampling, microdialysis, enables the collection of small, highly concentrated neurochemicals from ISF via diffusion across a semipermeable membrane. Large probe sizes (> 150 μm) limit spatial resolution, which leads to tissue scarring and limits chronic recording. Membranes also limit measuring neuropeptides and proteins, which are prone to nonspecific absorption and are present at very low concentrations in ISF, and preclude measuring dense core extracellular vesicles (EVs), which play critical roles in cell-cell signaling. There is thus a critical need for a micro-invasive interface that is membrane-free and enables sampling small ISF volumes from the brain. Such a platform can be readily adapted to other tissues *in vivo*, and also enables precise spatial and longitudinal tracking of biomarkers in tissue engineered constructs. We anticipate this tool will enable a deeper understanding of the onset, mechanism, and progression of diverse pathologies.
Methods: We have designed and built a micro-invasive membrane-free platform that enables direct sampling of

ISF from tissues *in vivo* and engineered tissues *in vitro*. The platform is composed of flexible hollow borosilicate probes (80 µm outer diameter, 50 µm inner diameter) coupled to a custom-made nanofluidic peristaltic pump (nanopump). Peristaltic flow within the nanopump is driven by the sequential contraction of nickel titanium alloy wires around flexible tubing (1 mm outer diameter, 100 µm inner diameter). The contraction of the wires is controlled via electrical currents that heat the material and trigger a phase transition. This simple two-component design enables bidirectional flow within a single lumen with nanoliter precision (3 nL stroke volume) and negligent dead volume (< 30 nL), capabilities not demonstrated by other low-flow pumps. Sampled fluid is analyzed via liquid chromatography-tandem mass spectrometry (LC-MS/MS) with processing protocols optimized for proteomics.
Results & Discussion: We have shown that our micro-invasive probes can be inserted into tissues *in vivo* and engineered tissues *in vitro* with minimal scarring. In fact, when the probes are chronically implanted in rodent brains, they demonstrate negligible gliosis and retain fluidic functionality for a year post-implantation. Performing nanopump-driven *in vivo* ISF sampling from the substantia nigra in three rats revealed this method was robust and repeatable. Of the 136 peptides identified, 77 overlapped with another biological replicate, while 28 were detected in all replicates. These included several biomarkers of interest such as brain acid soluble protein-1, myelin basic protein, gamma enolase, transthyretin, and kinesin-like protein 15. Ongoing studies will enable chronic tracking of covariant neuropeptides and EVs in physiological and pathological states. We have also shown that deploying this ISF sampling platform *in vitro* in engineered tissues of the central and peripheral nervous system enables spatially focused tracking of biomarkers in a high-throughput manner.
Conclusions: We have developed a novel tool for investigating the biochemical basis of diverse pathologies, with proof-of-concept demonstrations in one of the most challenging *in vivo* environments, the brain, as well as in diverse engineered tissues *in vitro*. Our ISF sampling platform has the potential to generate new fundamental knowledge and enable more accurate diagnosis and treatment of disorders caused by biochemical dysregulation.

Evaluation of Partially Cracked Organic/Inorganic Multilayer Barrier Coatings for Compliant Bioelectronic Interfaces Kyungjin Kim[1], Matthias Van Gompel[2], Kangling Wu[1], Florian Bourgeois[2], Yves Leterrier[1] and Stephanie P. Lacour[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Comelec SA, Switzerland

A critical challenge to overcome to deploy miniaturized and compliant implantable bioelectronic interfaces in vivo is the design, synthesis, and validation of barrier coatings that combine hermeticity, biocompatibility, and microfabrication in agreement with physiological and therapeutic timescales.
Thin-film barriers prepared with vacuum deposition methods, e.g. atomic layer and chemical vapor deposition (ALD and CVD), are a promising strategy for conformal and hermetic coatings. Although ALD offers ultrathin metal oxides at low deposition temperature and low WVTR ($< 10^{-4}$ $g.m^{-2}.d^{-1}$), the presence of pinholes and defects hinder further improvement. Thus, to be suitable for in vivo conditions, organic-inorganic multilayers are investigated to offer a low water vapor transmission rate (WVTR $< 10^{-6}$ $g.m^{-2}.d^{-1}$) by separating such defects in the inorganic layers with the organic layer. Parylene C is an excellent candidate among engineered polymer films because of its low permeability and useful combination of dielectric properties and conformability. Besides, a wide range of medical implants already uses Parylene coatings. We, therefore, focused on a process enabling growth of the alternating stack of Parylene C and ALD Al_2O_3 / TiO_2 multilayers within a single

deposition chamber. Then, we assessed the chemical transport properties of these barrier films in parallel with their mechanical reliability and structural durability during flexural deformation.
The multilayer stack was deposited in a novel hybrid deposition equipment from Comelec SA, allowing for alternating deposition of Parylene then Al_2O_3 / TiO_2 films within a single batch process chamber and at low process temperature. Pristine samples were first characterized by a thin-film corrosion test, leakage current monitoring across interdigitated electrodes, and lifetime tests of coated optoelectronic devices under accelerated aging conditions. Then, we studied and observed channel cracks formed within the organic/inorganic multilayer structure using an in-situ optical microscopy tensile test and scanning electron microscopy with combined modeling. We calculated the fracture energies of the multilayers and applied these parameters to predict their failure mode. A cross-sectional area of a multilayer film strained to crack onset strain was ion-polished, and imaging confirmed the proposed channel crack configuration. Finally, we assessed the lifetime of structures coated with cracked multilayers, which surprisingly displayed an extended lifetime equivalent to 3 years.
In summary, we have developed a multimodal characterization protocol to assess thin-film hermetic coating. Organic-inorganic multilayers are proposed as a potential solution for thin-film hermetic coating for in-vivo applications.

1:15 PM *EL07.07.02
Interfacing Skin-Inspired Electronics with Biological Systems Zhenan Bao; Stanford University, United States

Skin is the body's largest organ, and is responsible for the transduction of a vast amount of information. This conformable, stretchable, self-healable and biodegradable material simultaneously collects signals from external stimuli that translate into information such as pressure, pain, and temperature. The development of electronic materials, inspired by the complexity of this organ is a tremendous, unrealized materials challenge. However, the advent of organic-based electronic materials may offer a potential solution to this longstanding problem. Over the past decade, we have developed materials design concepts to add skin-like functions to organic electronic materials without compromising their electronic properties. These new materials and new devices enabled arrange of new applications in medical devices, robotics and wearable electronics. In this talk, I will discuss several projects related to engineering conductive materials and developing fabrication methods to allow electronics with effective electrical interfaces with biological systems, through tuning their electrical as well as mechanical properties. The end result is a soft electrical interface that has both low interfacial impedance as well as match mechanical properties with biological tissue. Several new concepts, such as "morphing electronics" and "genetically targeted chemical assembly - GTCA" will be presented.

1:40 PM EL07.07.03
Multifunctional Artificial Artery from Direct 3D Printing with Built-in Ferroelectricity and Tissue-Matching Modulus for Real-Time Sensing and Occlusion Monitoring Jun Li and Xudong Wang; University of Wisconsin-Madison, United States

Treating vascular grafts failure often requires complex surgery procedures and associates with a high mortality rate. Real-time monitoring vascular system could enable quick and reliable identification of complications and initiate safer treatments in the early stage. In this work, electric field-assisted 3D printing technology was developed to fabricate *in situ*-poled ferroelectric artificial arteries that offered battery-free real-time blood pressure sensing and occlusion monitoring capability. The complex functional artery architecture was made possible by the development of a printable ferroelectric bio-composite which could be quickly polarized during printing and reshaped into devised objects. Synergistic effect from the ferroelectric potassium sodium niobate (KNN) particles and the ferroelectric polyvinylidene fluoride (PVDF) polymer matrix yielded a superb piezoelectric performance (bulk-scale $d_{33} > 12$ pC N^{-1}, confirmed by piezometer) on a par with that of commercial ferroelectric polymers. The sinusoidal architecture brought the mechanical modulus down to the same level of human blood vessels. The desired piezoelectric and mechanical properties of the 3D-printed artificial artery provided an excellent sensitivity to pressure change (0.306 mV/mmHg, $R^2 > 0.99$) within the range of human blood pressure (11.25 to 225.00 mmHg). The high pressure sensitivity and the ability to detect

subtle vessel motion pattern change enabled early detection of partial occlusion (e.g., thrombosis), allowing for preventing grafts failure. This work demonstrated a promising strategy of incorporating multi-functionality to artificial biological systems for smart healthcare systems.

2:10 PM *EL07.07.05
Laser-Engraved Graphene-Based Wearable and mHealth Biosensors Wei Gao; California Institute of Technology, United States

Wearable sensors have the potential to provide rapid, non-invasive, and in-home health monitoring by real-time analyzing biomarkers in human sweat and saliva. However, most current biosensors suffer from low sensing accuracy for low-level analyte detection in biofluids and are difficult to fabricate on a large scale. In this talk, I will review our latest advances in developing fully-integrated laser-engraved graphene-based biosensors which can selectively and accurately measure a wide spectrum of sweat and saliva biomarkers including metabolites, nutrients, hormones, and proteins. The clinical value of these telemedicine platforms is evaluated through multiple human studies involving both healthy and patient populations toward metabolic monitoring and stress assessment. I will also introduce our recent work on a multiplexed wireless platform for the rapid COVID-19 test which could provide information on infection status, severity, and immunity. We envision that these telemedicine devices could open the door to a wide range of personalized healthcare applications.

2:35 PM *EL07.07.06
High-Sensitivity and Wide-Range Capacitive Pressure Sensors Enabled by the Hybrid Responses of a Porous Nanocomposite Nanshu Lu; The University of Texas at Austin, United States

Soft pressure sensors with high sensitivity over a wide pressure range are required for various applications such as electronic skins for human-mimetic robotics and electronic tattoos for pulse pressure measurement. In the last decade, most research aiming at increasing the sensitivity of capacitive pressure sensors focused on developing dielectric materials with added air gaps and/or higher dielectric constants. After extensive research, sensitivity has been significantly improved at low pressure range, e.g. 1 kPa, but drops drastically as the pressure increases. To overcome this challenge, we present a novel soft capacitive pressure sensor employing an electrically conductive porous nanocomposite with both piezoresistive and piezocapacitive responses. The porous nanocomposite is made out of functionalized carbon nanotubes and Ecoflex and can be inexpensively fabricated without MEMS technology. The nanocomposite is 600-μm thick, 85% porous, and open cell with tubular ligaments. An ultrathin dielectric layer was added between the conductive foam and the electrode to ensure the whole device is still capacitive. The sensor has a modulus of 2 kPa and an initial impedance of 47 MΩ with a phase angle of -86°. This capacitive sensor exhibits a sensitivity of 1.95 kPa^{-1} within 0-1 kPa, 1.06 kPa^{-1} within 1-5 kPa, 0.88 kPa^{-1} within 5-10 kPa, 0.52 kPa^{-1} within 10-30 kPa, and 0.35 kPa^{-1} within 30-50 kPa of pressure ranges. The hybrid response is fully understood through a simplified circuit model, which has been validated by the experimental measurements. We have successfully applied this sensor to measure very subtle mechanophysiology on human body, including the pulse pressure of the jugular vein and the temporal artery.

SESSION EL07.08: Biosensors and In Vitro Platforms

4:00 PM EL07.08.01
Late News: Intrinsically Stretchable, Self-Adhesive, Conductive and Biocompatible PDA-PAM Hydrogel Electrode Enabled in Long-Term Continuous Electrophysiological Monitoring with Minimizing Motion Artifacts and Skin Irritation Fengjie He, Sijia Li, Yingtao Jiang and Shengjie Zhai; University of Nevada, Las

Vegas, United States

Since cardiovascular diseases (CVDs) are the number one cause of death in the US, long-term continuous electrocardiogram (ECG/EKG) monitoring has evolved to the forefront as a golden standard of ambulatory cardiac monitoring for precise CVDs diagnosis. However, the current commercial gel-type silver/silver chloride (Ag/AgCl) electrodes used in continuous ECG monitoring systems inevitably induce motion artifacts (noise signal) and occasionally cause signal loss. It is ascribed to the irregular impedance changes in the conductive layer between electrodes and skin resulting from the weak stretchability and decreased adhesiveness of the electrodes under intense human motion. On the other hand, some clinical cases reported that the commercial electrodes could cause severe skin irritations and allergies after long-term direct skin contact. Therefore, a self-adhesive, stretchable, and biocompatible hydrogel is highly desirable.
Polydopamine-polyacrylamide (PDA-PAM) hydrogel as a highly self-adhesive and stretchable biomaterial has been attracting tremendous attention. In particular, our previous experiments exhibited that PDA-PAM hydrogel has intrinsic electroconductive capacity due to a large amount of water (more than 70%) and abundant molecules and ions in the hydrogel. Thus, the PDA-PAM hydrogel is a perfect candidate to be integrated into ECG electrodes for continuous health monitoring. In this study, we successfully fabricated the PDA-PAM hydrogel-based ECG electrodes that can be readily connected to conventional ECG devices. As a proof of concept, three male and two female human subjects (age between 25-30 years) were employed to evaluate the proposed ECG electrodes' long-term continuous monitoring performance in this study. The ECG experimental acquisition successfully indicated that the proposed PDA-PAM-based ECG electrodes could simultaneously record continuous ambulatory ECG signals and minimize the motion artifacts under intense exercises, including running, stair climbing, butterfly sleeve, chest expansion. Besides, a 3-hour continuous wearing of the PDA hydrogel-based ECG electrodes test also showed that the ECG signal's quality did not degrade over time, and skin irritation such as itching or redness was not observed among all five human subjects. Notably, the signal-to-noise ratio (SNR) results of PDA-PAM-based ECG electrodes for different exercises demonstrated significant improvement compared to the commercial electrodes results (up to 59% improvement obtained from the running exercise). This significant improvement was attributed to the remarkable tissue adhesiveness and stretchability of the PDA-PAM hydrogel, which enabled the contact areas between electrode and skin to maintain consistent upon skin deformation during exercise and in turn minimized the motion artifacts in the collected signals. In summary, the developed PDA-PAM-based ECG electrodes were successfully employed in the continuous ECG monitoring with high SNR, low motion artifacts, and minimal skin irritation. Undoubtedly, the proposed PDA-PAM hydrogel will serve as a promising hypoallergenic conductive biomaterial for bioelectronics to record long-term continuous high-quality electrophysiological signals.

4:15 PM EL07.08.02
Sapphire-Supported Nanopores for Low-Noise DNA Sensing Pengkun Xia, Jiawei Zuo, Shinhyuk Choi, Xiahui Chen, Jing Bai and Chao Wang; Arizona State University, United States

Low-noise biomolecule sensing has proven to be a crucial method in biology, diagnostics, prognosis, etc. Solid-state nanopores have attracted considerable interest as a potentially high-speed, portable and low-cost solution for detecting a variety of biomolecules, such as proteins, RNA and DNA, as well as studying molecular interactions.
The high capacitive noise from conventionally used conductive silicon (Si) substrates, however, has seriously limited both their sensing accuracy and recording speed. To minimize the stray capacitance of the Si chip, conventional techniques introduce a thick insulating material at the nanopore vicinity. However, these fabrication schemes require complex, and manual processing techniques**,** such as selective membrane thinning, silicone/photoresist printing, glass bonding, *etc*, and thus are expensive, slow, and difficult to reproduce. Another approach is to replace conductive silicon with an insulating material, such as glass. The amorphous nature of glass substrates, however, prevents the formation of uniform membranes, and involves complex fabrication schemes, such as multiple lithography steps, as well as deposition and etching processes on individual chips. Accordingly, the broad availability of such glass-supported nanopore chips are very limited, primarily due to their low fabrication yield, poor reproducibility, and low throughput.

A new approach is proposed here for forming thin nanopore membranes on crystalline and insulating sapphire wafers as a means to eliminate stray capacitance from substrate conductance for low-noise biosensing. The method involves creating sapphire-supported (SaS) nanopore membranes by wet and anisotropic etching of 2-inch sapphire wafers in concentrated sulfuric and phosphoric acids, a process similar to bulk alkaline etching of Si, that has been widely used in MEMS and biosensing applications. Uniquely, we design a triangular membrane by leveraging the three-fold symmetry of the hexagonal c-plane sapphire lattice and developed a controllable process to produce nanopore membranes over a 2-inch wafer with average size as small as 10.6 μm with 6.8 μm deviation, which corresponds to picofarad level chip capacitance even considering nanometer-thin membranes in high-signal-to-noise-ratio (SNR) DNA detection. For validation, a SaS nanopore chip with a 100 times larger membrane area than conventional a silicon-supported (SiS) nanopore was tested, which showed 130 times smaller chip capacitance (10 pF) and 2.6 times smaller root-mean-square (RMS) noise current (18-21 pA over 100 kHz bandwidth, with 50 to 150 mV bias) when compared to a SiS nanopore (1.3 nF, and 46-51 pA RMS noise). Tested with 1k bp double-stranded DNA, the SaS nanopore enabled sensing at microsecond speed with a signal-to-noise ratio of 21, compared to 11 from a SiS nanopore.
By analyzing the device capacitance, noise current, and power density spectra of the SaS nanopore and comparing to the best reported SiS and glass-supported nanopores, we found our nanopore chips comparable to the best available low-noise sensors. In this work, the nanopore SNR in DNA sensing is mainly limited by the relatively large nanopore size (~7 nm) and relatively thick membranes (~30 nm). Further optimization in creating smaller nanopores (3-4 nm) and reducing membrane thickness, for example by integration with ultrathin 2D materials, is expected to greatly increase the sensitivity and boost the SNR. The SaS nanopore platform will find use in interrogating a variety of other biomolecules, and their molecular interactions at improved speed and accuracy. Beyond nanopores, our batch-processing compatible and potentially cost-effective manufacturing of the SaS membrane architecture, together with the high optical transparency of sapphire, may serve to establish a new fabrication and design strategy in bulk micromachining of sapphire wafers to broaden the applications in MEMS designs and optoelectronic devices.

4:30 PM EL07.08.03
Late News: Biomembrane Based Organic Electronic Devices for Probing Constituent Specific Changes in Supported Lipid Bilayers Samavi Farnush Bint E Naser, Han-Yuan Liu, Hui Su and Susan Daniel; Cornell University, United States

Supported lipid bilayers (SLBs) are extensively used to mimic and study membrane properties. However, they are generally formed on rigid, non-conducting supports which prevent label free sensing. Combing the insulating properties of biomembranes with bio-compatible conducting polymers (CPs) can enable the electrical detection of membrane disruptions and pathogen interaction. This type of sensing application broadens the use of organic electronic devices into biomedical engineering, biosensing applications, and fundamental membrane biophysics studies. To this end, we demonstrate the formation of lipid bilayers supported on a transparent, conducting polymer surface to investigate changes in membrane properties through constituent specific biomolecular interaction using both optical and electrochemical techniques. Specifically, we have studied methyl-β-cyclodextrin (MβCD) induced cholesterol transfer to and from SLBs and the binding of cholera toxin B subunit (CTB) to lipid bilayers containing GM1 receptor. For our investigation, we used PEDOT:PSS as the CP support because of its high conductivity, optical transparency, easy processing, and excellent biocompatibility. SLBs were formed on this conducting polymer via solvent assisted method since this method bypasses vesicle preparation, does not require vesicle affinity to CP surface, and is applicable to a wide range of lipid mixtures and compositions for which vesicle fusion is difficult. We confirmed the presence of the specific constituents, i.e., cholesterol and GM1 receptors in the lipid bilayers visually using fluorescence microscopy. Next, we explored the sensing capabilities of the developed platform through EIS measurements performed on PEDOT:PSS/ITO electrodes on glass substrates. We report on the successful detection and quantification of the changes in membrane properties, such as, diffusivity and resistance, resulting from cholesterol addition/deletion and receptor specific toxin binding activity using the CP supported SLBs. Our results demonstrate the tremendous potential of these platforms in biosensing application, such as, studying the therapeutic effects of βCD derivatives, drug-screening and examining drug delivery efficiency to prevent receptor specific toxin

interaction with the cell membrane.

4:45 PM *EL07.08.04
Shepherding Tissue Growth and Healing Using Bioelectric Interfaces Daniel J. Cohen; Princeton University, United States

Living cells have a remarkable capacity known as ‘electrotaxis’ where they can sense DC electric fields and orient their migration or growth along field lines. Such fields are surprisingly common *in vivo* and can be critical during embryonic development, wound healing, infection response, and tissue assembly. Essentially, ion gradients give rise to electrochemical DC fields (~1V/cm) where the field direction orients cellular motion and the strength determines migration speed. The importance of such fields *in vivo* raises the question of whether we can develop bioelectric interfaces to mimic or manipulate these fields in order to literally program and ‘herd’ cellular growth and motion to heal injuries faster, grow bespoke tissues, or manipulate diseased tissue. This is an exciting opportunity, but many key challenges remain to be elucidated, especially at the material level. Firstly, new materials are required for the stimulation interface to reduce electrochemical damage and improve the resolution and subtlety of electrical control. I will discuss and highlight some of these challenges using the SCHEEPDOG platform—a multi-axis, microfluidic electrobioreactor developed in my laboratory—to emphasize both the extraordinary control electrotaxis affords and critical material limitations holding back more advanced interfaces. A second key challenge area is to relate bioelectric inputs to living material outputs as a tissue reconfigures itself in response to bioelectric stimuli. Here, I will introduce new work underlining the difficulties and limitations of using bioelectric cues to impose an external behavior on a living tissue material when the target behavior clashes with the natural behavior of the tissue. Overall, this talk will provide an attempt to provide a comprehensive introduction to electrotaxis spanning the basic biointerface biology of how DC fields are transduced by living cells, the design and constraints on DC bioelectric interfaces, and key challenges and opportunities in the field for the broader materials community.

5:10 PM EL07.08.05
Late News: Reliable, Low-Cost, Fully Integrated Hydration Sensors for Monitoring and Diagnosis of Inflammatory Skin Diseases in Any Environment Surabhi Madhvapathy[1], Heling Wang[1], Jessy Kong[1], Michael Zhang[1,2], Jongyoon Lee[1], Junbin Park[1], Hokyung Jang[1], Zhaoqian Xie[1,3], Jingyue Cao[1], Raudel Avila[1], Chen Wei[1], Vincent D'Angelo[1], Jason Zhu[1], Ha Uk Chung[1], Sarah Coughlin[1], Manish Patel[1,4], Joshua Winograd[1], Jaeman Lim[1], Anthony Banks[1], Shuai Xu[1], Yonggang Huang[1] and John A. Rogers[1]; [1]Northwestern University, United States; [2]Vanderbilt University, United States; [3]Dalian University of Technology, China; [4]University of Illinois at Chicago, United States

Present-day dermatological diagnostic tools are expensive, time-consuming, require substantial operational expertise, and typically probe only the superficial layers of skin (~15 μm). We introduce a soft, battery-free, noninvasive, reusable skin hydration sensor (SHS) adherable to most of the body surface. The platform measures volumetric water content (up to ~1 mm in depth) and wirelessly transmits data to any near-field communication-compatible smartphone. The SHS is readily manufacturable, comprises unique powering and encapsulation strategies, and achieves high measurement precision (±5% volumetric water content) and resolution (±0.015°C skin surface temperature). Validation on $n = 16$ healthy/normal human participants reveals an average skin water content of ~63% across multiple body locations. Pilot studies on patients with atopic dermatitis (AD), psoriasis, urticaria, xerosis cutis, and rosacea highlight the diagnostic capability of the SHS ($P_{AD} = 0.0034$) and its ability to study impact of topical treatments on skin diseases.

5:25 PM EL07.08.06
Late News: An Aerosol-Jet-Printed Graphene Biosensing Platform for Rapid Electrochemical Detection of Proteins and Small Molecules Sonal Rangnekar[1], Kshama Parate[2], Cicero Cardoso-Pola[2], Deyny Mendivelso-Perez[2,3], Dapeng Jing[2], Shaowei Ding[2], Ethan Secor[1], Emily Smith[2], Jesse Hostetter[2], Carmen Gomes[2], Jonathan Claussen[2] and Mark C. Hersam[1]; [1]Northwestern University, United States; [2]Iowa State University, United States; [3]U.S. Department of Energy, United States

Inexpensive and rapid diagnostic biosensing is needed more than ever and may be achieved through the development of disposable electrochemical sensors. Graphene films are an ideal material for electrochemical biosensing due to their high electrical conductivity, large surface area, and biocompatibility. However, graphene films fabricated through chemical vapor deposition are too expensive for single-use applications, and low-cost manufacturing alternatives, such as screen and inkjet printing of graphene inks, do not provide sufficient control over electrode geometry to achieve favorable electrochemical sensor performance. In this work, aerosol jet printing (AJP) is leveraged to pattern solution-processed graphene inks into high resolution interdigitated electrodes (IDE) on a flexible polyimide substrate. After thermally curing in air, the IDEs are heated in CO_2 to create additional oxygen moieties on the graphene surface that are then reacted with EDC-NHS chemistry. The resultant graphene biosensing platform can be functionalized with arbitrary antibodies and blocking agents to create a highly sensitive and specific biosensor. This platform has been demonstrated for electrochemical detection of cytokines interleukin-10 (IL-10) and interferon-gamma (IFN-γ) to monitor immune system function (i.e., diagnosis of paratuberculosis in cattle) and for detection of histamine in food safety applications (i.e., determining fish spoilage). The limits of detection for each analyte (IL-10: 46 pg/mL; IFN-γ: 25 pg/mL; histamine: 31 µg/mL) and sensing ranges (IL-10: 0.1-2 ng/mL; IFN-γ: 0.1-5 ng/mL; histamine: 6-200 µg/mL) are appropriate for the respective applications. Furthermore, the biosensors are mechanically robust enough to withstand hundreds of bending cycles at high curvatures (R = 3-11 mm) with minimal change in electrical and electrochemical signals. Overall, the low cost of manufacturing and short testing time (~30 min to soak and sense) motivate the expansion of this printed graphene biosensor platform into other sensing applications, including wearable health monitoring and human health diagnostics.

5:40 PM EL07.08.07
Late News: Electrostatic Modulation of Signaling at the Cell Membrane—Waveform- and Time-Dependent Electric Control of ERK Dynamics Quan Qing; Arizona State University, United States

The dynamics of extracellular-signal-regulated kinase (ERK) signaling regulates a wide variety of stimulated cellular processes and plays an important role in cell survival, motility, differentiation and proliferation. Here we show that a new range of alternative current electric field (AC EF) in the tens of KHz could non-invasively activate EGFR-Ras-ERK signaling pathway with precise timing and single-cell resolution, where electroporation or Faradaic processes have been deliberately avoided by using high-k dielectric passivated microelectrodes. We have shown that the ERK activities can be synchronized with the response time independent of the distance from the electrodes, suggesting that the inter-cellular communication and diffusion-limited processes are not involved. Series of blocker tests pinpointed that the ERK activation were triggered by EF induced EGF-independent phosphorylation of EGFR without changes in pH, Ca^{2+} concentration or reactive oxygen species. Interestingly, we also discovered that the cell response was sensitive to the waveform and timing of the EF, and that inhibition of ERK could also be controlled with different dynamic characteristics, strongly suggesting the electrostatic nature of the coupling between AC EF and the membrane protein. Our work suggests a new exciting possibility that the dynamic signaling initiated by membrane proteins can be non-invasively and locally modulated by specifically tuned EF.

Adaptive Self-Recoverable Electronic Epineurium Donghee Son; Sungkyunkwan University, Korea (the

Republic of)

Soft neuroprosthetics capable of bi-directionally monitoring sensory signals and delivering feedback motor information have pursued the perfect replacement for damaged nerves. Although such valuable efforts have been made to the long-term stability of the peripheral neural interfaces, nerve compression and tissue-induced device fatigue issues still remain challenging due to the lack of optimal materials that simultaneously meet tissue-device modulus matching, biocompatibility, and electrical/mechanical self-recovery. Here, we report a tissue-adaptive self-recoverable electronic epineurium that can prevent its electrical degradation induced by repetitive, non-uniform, and severe structural deformation occurred at a rat's sciatic nerve as well as undesired nerve compression. Such performances originate from its unique mechanical properties: i) spontaneous rearrangement of a ligand-decorated Au nanoshell-coated Ag flakes dispersed in a tough self-healing polymer matrix and ii) dynamic stress relaxation of the electronic epineurium enabling its mechanical adaptation to nerve modulus. Through these properties, we successfully demonstrate stable bidirectional neural recording and stimulation *in vivo* even under the harsh mechanical deformation.

8:10 AM EL07.09.03
A Protein-Based Free-Standing and Proton Conducting Transparent Polymer as a Sustainable Material for Large Scale Sensing Applications Nadav Amdursky; Technion–Israel Institute of Technology, Israel

In a world of depleted resources, and with our current acceptance that the materials we make can have a severe impact on the world, we now understand that we need to reconsider our strategy of making new materials. Accordingly, two materials-related approaches have been formulated. The first approach focusing on the environmental impact of the materials, also known as environmental chemistry, while the second approach is making/synthesizing new materials using green chemistry principals, also known as sustainable chemistry. The use of carbon-based polymers is a good example for the endeavor of making environmentally friendly materials, though not all polymers are environmentally friendly and many of them are not being synthesized in a green chemistry approach. In here, we are focusing on polymers exhibiting efficient ion transport capabilities, and specifically, proton conduction. Inspired by the natural role of mediating protons, we use proteins as the sole starting material for the formation of the polymer. Unlike synthetic polymers, protein-based polymers have inherent biocompatibility and biodegradability properties that promote their use in biomedical applications, either on the skin or in vivo. However, to date, protein-based proton conducting polymers cannot be translated to real applications due to two main reasons. The first being the low reported conductivity values compared to common synthetic proton conducting polymers, whereas the measured conductivity (at ambient conditions) across protein-based polymers are usually <1 $mS\bullet cm^{-1}$, while the one of common polymers is >5 $mS\bullet cm^{-1}$. The second most important challenge to overcome is the material formation protocol, whereas most of the conductive protein-based polymers have used genetically expressed proteins, which is not a viable solution as it is costly and time-consuming, even upon upscaling, and accordingly, cannot result in having highly affordable proteins in bulk quantities needed for the formation of materials in large scale. Here, we introduce a new sustainable approach of making proton conducting polymers using affordable and naturally available bovine serum albumin (BSA) proteins, which is in part due to being a 'waste product' of the extensive bovine industry. Hence, our choice of protein is both sustainable in terms that we are recycling waste products, in oppose of synthesizing or expressing something new, as well as highly economical with a commercial price tag of less than 2 $USD\bullet gr^{-1}$ of the protein starting material. An added novelty of our new approach here is in its simplicity, which is a one-pot process involving merely dissolving the protein at the right solvent mixture, polymerization and casting it. We show that by using our new methodology, we can form free-standing (self-supporting), insoluble transparent films with high measured proton conductivity at ambient conditions of ~5 $mS\bullet cm^{-1}$, and highly attractive mechanical properties of the polymer, capable of stretching ~5 times its length. We show that an added value of using proteins as the building blocks is the breadth of functional groups, which are the amino acids residues, allowing performing a variety of post synthetic modifications, and in here we use them to increase the proton conductivity across the polymer. Taking into consideration the polymer stretchability, water containing, biocompatibility and biodegradability nature, we foresee its direct translation in various biomedical applications. Here, we show an immediate application route for our new polymer by its use as a solid-state ion

conducting polymer in electrical sensing of physiological signals, replacing the current cumbersome use of a conductive gel.

Flexible Graphene-Based Wireless mHealth System for Non-Invasive Stress Monitoring Jiaobing Tu, Rebeca Torrente-Rodriguez, Yiran Yang, Jihong Min and Wei Gao; California Institute of Technology, United States

Prompt and accurate detection of stress is essential to human performance analysis, stress-related disorder diagnosis, and mental health monitoring. Current approaches such as questionnaires are very subjective. To avoid stress-inducing blood sampling and to realize continuous, non-invasive, and real-time stress analysis at the molecular levels, we investigate the dynamics of a stress hormone, cortisol, in human sweat using an integrated wireless sensing device based on laser-enabled flexible graphene sensors that are mass producible at low cost. Highly sensitive, selective, and efficient cortisol sensing is enabled by a flexible sensor array that exploits the exceptional performance of laser-induced graphene for electrochemical sensing. We report a strong correlation between sweat and circulating cortisol and demonstrate the prompt determination of sweat cortisol variation in response to acute stress stimuli. Moreover, we demonstrate, for the first time, the diurnal cycle and stress-response profile of sweat cortisol, revealing the potential of dynamic stress monitoring enabled by this mHealth sensing system.

Control of the Debye Length at the Electrolyte-Oxide Interface of bioFETs with Tunable Surface Electric Fields Ie Mei Bhattacharyya[1] and Gil Shalev[1,2]; [1]Ben Gurion University of the Negev, Israel; [2]The Ilse-Katz Institute for Nanoscale Science & Technology, Ben Gurion University of the Negev, Israel

Biosensors based on field-effect devices (bioFETs) have gained immense research over the past few decades because of their numerous advantages over existing technologies. Yet, their commercialization remains very limited. The biggest challenge for bioFET realization is the extremely short Debye screening length at high ionic strengths. This problem becomes significantly more severe at the solution-oxide interface due to high ion concentration induced by the charged oxide surface groups which cripples any attempt to use field-effect mechanism to detect the presence of the target analytes. In this work, we propose an electrostatic approach to remove the excess concentration of counterions at the double layer (DL), thereby forcing the DL ion concentration to match the bulk concentration [1]. This consequently forces bulk screening length at the DL, thus ‘exposing’ target biomolecules to the underlying FET. In order to achieve this, local tunable surface electric fields are introduced to the DL using surface passivated-metal electrodes. The effect of these electric fields on the DL ion distribution are examined numerically and analytically. Also, the feasibility of the proposed approach is demonstrated numerically for a fully-depleted silicon-on-insulator based bioFET. We show how a significant twofold increase in the threshold voltage shift is achieved due to the presence of target molecules upon the removal of the surface excess ion population.

Detecting Cancer Biomarkers Electrically Using Single-Molecule Techniques—Understanding Electrical Fingerprints at the Nucleic Acid Bioelectronic Interface Keshani G. Pattiya Arachchillage, Subrata Chandra and Juan M. Artes Vivancos; University of Massachusetts Lowell, United States

Cancer kills more than 8 million people per year and it is one of the most frequent causes of death globally.[1] Cancer biomarkers are promising for detecting cancers early.[2] There are various methods to analyze biomarkers

and liquid biopsy is one of them.[3] Blood samples, or other body fluids, can contain circulating free tumor nucleic acids (ctNA) that can be used as cancer biomarkers.[3] Detecting ctNA in the blood is challenging, because of the low ctNA concentration and the low frequency of mutations compared to wild-type sequences.[3] Nanotechnology bioelectronics methods can help to address this challenge. In particular, the Scanning Tunneling Microscopic (STM)-assisted break junctions method (STM-BJ)[4] has recently allowed the first demonstration of detection and identification of RNA from E.Coli via single-molecule conductance.[5] This is an ideal method for liquid biopsy bioelectronics since it could detect cancer biomarkers such as ctNAs in liquid biopsy samples non invasively and quantify them with high sensitivity and specificity.[3]

In this work, we characterize ctNAs using the STMBJ to measure and compare the bioelectronics fingerprints of these ctNAs. The main hypothesis of the study is that the sequences of ctNAs can be used to detect cancers, by finding their unique electronic fingerprints. We focus the study on KRAS, BRAF, and Nras as effective cancer biomarkers, based on the recent literature.[6,7] We have obtained some preliminary data for RNA sequences for a few candidate biomarkers and we expect to understand the bioelectronics interface between genetic material(ctNA) and nanostructured electrodes. Our results pave the way for the early detection of bioelectronics fingerprints from biomarkers, such as ctDNA and ctRNA,[3] through liquid biopsy using nanotechnology. These methods may allow beginning treatments early, potentially saving many lives from cancer patients in the future.

Polydopamine as a Soft Material for Integration of Metabolically Active Photosynthetic Bacteria in Bioelectronics Danilo Vona[1], Gabriella Buscemi[1,2], Roberta Ragni[1], Francesco Milano[2], Gianluca M. Farinola[1] and Massimo Trotta[2]; [1]Università degli Studi di Bari Aldo Moro, Italy; [2]Consiglio Nazionale delle Ricerche, Italy

Photosynthetic microorganisms and their subparts represent a very promising tool for the integration of biological photo transducers in bioelectronics and bioelectronic devices. [1,2] Light absorbed by these organisms can be converted into several energy forms exploitable for many external processes. Collect, extract, and transfer electrons from the photosynthetic microorganisms to electrodes represent one of the main issues in *Extracellular Electron Transfer* (EET). Unfortunately, EET often reduce microorganism's viability or leave bacteria in quiescent states inhibiting their reproduction. We present here a procedure for improving the communication between the bacterial cells and the electrode that does not jeopardize the activity and the viability of the bacteria. Cells from the purple non-sulphur bacterium *Rhodobacter sphaeroides* grown under photosynthetic conditions were used as model to test the ability of polydopamine to function as coating material that does not produce detrimental effect nor to the morphology of the cell, nor its basic metabolism, similarly to what previously reported in polygallic acid [3].

Integration of Bacterial Photoenzymes onto Electrodes—Towards Photosynthesis-Driven Optoelectronics
Gianluca M. Farinola[1], Gabriella Buscemi[1], Marco Lo Presti[1], Roberta Ragni[1], Rossella Labarile[1], Francesco Milano[2], Danilo Vona[1] and Massimo Trotta[3]; [1]Università degli Studi di Bari Aldo Moro, Italy; [2]CNR-ISPA, Italy; [3]CNR-IPCF, Italy

Photosynthetic microorganisms and their molecular components represent attractive tools for harvesting and conversion of solar light in integrated bioelectronic transducers [1].
We have recently investigated several approaches for adressing the Reaction Center (RC) photoenzyme, extracted from the purple non sulfur photosynthetic bacterium *Rhodobacter sphaeroides*, in optoelectronic devices for conversion of solar energy into photocurrent [2]. The RC has been covalently anchored on molecular organic semiconductors with reactive linkers, and the resulting active layer has been used in photodetector configuration [3]. A supramolecular approach based on specific interaction with another protein (Cytochrome C) has been used to create an oriented layer of RC on the gate electrode of an organic transistor device, resulting in the first example of light-driven Electrolite Gated Organic Field Effect Transistor (LEGOFET) based on a photoenzyme [4]. More recently, we have used polydopamine (PDA) for attaching RC directly onto ITO electrodes, by simple polymerization of dopamine in aqueous media [5]. However, this convenient approach suffers from the low transparency of PDA, which limits the light absorption of the embedded RC. To overcome this issue, PDA has been tailored into a more transparent copolymer by using a degradative functionalization with ethylendiamine. After the encapsulation of RC into polydopamine, the diamine additive modifies the polymer structure, conferring modulable fluorescence properties to the RC-PDA nanoparticles, reducing their size and increasing the general transparency of the polymer. This leads to an enhancement of the light response of RC, with augmented production of charge separated states.

9:10 AM EL07.09.12
Self-Healable, Recyclable and Reconfigurable Wearable Electronics Jianliang Xiao; University of Colorado Boulder, United States

Stretchable/flexible electronics has attracted tremendous attention in the past 2-3 decades due to the

combination of its superior mechanical attributes and electrical performance. It can be applied in places that are not accessible by traditional rigid printed circuit boards (PCBs), such as seamless integration with soft tissues and organs of human body for healthcare, bio-inspired curvilinear imagers and artificial skins that mimic the mechanical and electrical properties of natural skin. Among all the exciting applications, wearable electronics represents one of the most important, as it is the most accessible to people, and can be integrated onto the surface of human body to provide many useful functions, including physical activity tracking, health monitoring, drug delivery, human-computer interface, and virtual/augmented reality. More recently, various chemistry and mechanisms have been explored to enable self-healability and degradability in wearable electronics.
All these developments could lead to an exciting bright future of applying technological advancements to improve the wellbeing of people and the society. However, on the other hand, mass production and application of electronics generate a large amount of electronic waste. By 2021, the total electric waste is estimated to reach 52.2 million tons, and the majority of the waste cannot be appropriately recycled. The consequence is that a large amount of heavy metals and other hazardous substances have been entering the eco-system, causing serious environmental problems and human health issue*s*. To resolve this issue, we here report a fully recyclable multifunctional wearable electronic system, which can simultaneously provide excellent mechanical stretchability, self-healability and reconfigurability. Such wearable electronics is achieved by heterogeneous integration of rigid (chip components), soft (dynamic covalent thermoset polyimine) and liquid (eutectic liquid metal) materials through advanced mechanical design and low-cost fabrication method. In such wearable electronic system, off-the-shelf chip components provide high-performance sensing and monitoring of the human body, including physical motion tracking, temperature monitoring, and sensing of acoustic and electrocardiogram (ECG) signals. They are interconnected by intrinsically stretchable and robust liquid metal circuitry, and encapsulated by dynamic covalent thermoset polyimine matrix. Bond exchange reactions in the polyimine network, together with the flowability of liquid metal, enable the wearable electronics to self-heal from damage and to be reconfigured into distinct configurations for different application scenarios. Furthermore, through transimination reactions, the polyimine matrix can be depolymerized into oligomers/monomers that are soluble in methanol and are separated from the chip components and liquid metal. All recycled materials and components can be reused to fabricate new materials and devices.

Wireless Power Transfer System for Smart Contact Lenses Taiki Takamatsu, Hu Lunjie, Xiao Te, Qi Zhang and Takeo Miyake; Waseda University, Japan

Electronic contact lenses have been attracted much attention as health monitoring biosensors, wearable displays, and electrically-stimulated eye accommodation devices. Recent examples of their use are glucose sensing, lactate sensing, intraocular pressure measuring, light-emitting diode (LED) displays, and corneal electroretinogram recordings. As electrical lenses make continuous contact with the eyeball surface, their power source and all components must be flexible and safe. Constructing power sources on contact lenses is especially challenging, because the power device must be mounted on the restricted area of the lens without obstructing the vision. Here, we have developed wireless power transfer (WPT) system for smart contact lenses. The WPT system is based on two types of inductance(L)-capacitance(C) resonant circuits at the resonant frequency of 13.56 MHz [1]. Recently, we have developed a hybrid power generation device comprising a wireless power transfer system and a bioabsorbable metal–air primary battery, which provides a multifunctional direct current (DC) and/or alternating current (AC) output [2].

Late News: Design of Novel Conjugated Polymers for Organic Electrochemical Transistor Biosensors
Maximilian Moser[1], Sahika Inal[2] and Iain McCulloch[1,2]; [1]University of Oxford, United Kingdom; [2]King Abdullah University of Science and Technology, Saudi Arabia

Organic electrochemical transistors (OECTs) are bioelectronic devices that have gained significant attention recently, as they have shown excellent performances as biomolecule sensors, implantable brain signal recorders, neuromorphic computing elements and many other biomedical applications.[1] Currently, the aqueous dispersion, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS), has established itself as the OECT benchmark material, predominantly due to its commercial availability. PEDOT:PSS-based OECTs however display several disadvantages; namely i) their moderate OECT performances (quantified by the material-only dependent figure of merit μC^*), ii) their depletion-mode of operation, iii) their inability to conduct electrons and iv) PEDOT:PSS' highly complex structure preventing the formulation of structure-property relationships for future material design.[2] Based on these limitations, this work focuses on synthesizing novel, cheap and solution processable glycol-ether (GE) functionalized conjugated polymers to advance OECT and hence biosensor performance, while concomitantly also establishing design-rules for the development of future OECT materials.

Several molecular design strategies are investigated. These range from tailoring the GE side chain length, to varying the nature of the aromatic building blocks and modifying the chemical composition of the solubilizing chains.[3–5] Ultimately, we show how judicious optimization of the molecular structures, involving polymer energy level, polymer morphology and polymer electroactive swelling modulation, allows us to achieve unprecedented performance and stability benchmarks with μC^* values of 522 F V^{-1} cm^{-1} s^{-1} (*c.f.* typically ~40 F V^{-1} cm^{-1} s^{-1} for the PEDOT:PSS benchmark)[6] and devices retaining 98% of their initial current over 2 h of continuous electrochemical cycling.[4] We then proceed to show how the combined performance and stability advances of our newly developed materials can be exploited in the fabrication of higher performing biosensors, including better sensitivity and lower power consumptions.

Late News: Flexible Complementary Logic Circuit Featuring Two Identical Organic Electrochemical Transistors

Lorenzo Travaglini[1], Adam Micolich[1], Claudio Cazorla[1], Erica Zeglio[2], Antonio Lauto[3] and Damia Mawad[1]; [1]University of New South Wales, Australia; [2]KTH Royal Institute of Technology, Sweden; [3]Western Sydney University, Australia

Conjugated polymers are commonly used as the electroactive channel in organic electrochemical transistors (OECTs).[1] Combination of *p*-type and *n*-type materials allow the realization of complementary logic circuits that would drastically impact on the sophistication of organic electronic devices. Improved functionalities can be achieved by building complementary circuits featuring two or more OECTs. To date, this aim is strictly related to the development of organic materials with respectively reliable hole and electron transport.[2] Coupling these two types of materials in circuits is challenging because of the requirement to have matching charge transport properties. While *p*-type OECTs are widely available, *n*-type OECTs are less common mainly due to poor performances and stability of the active material in aqueous electrolyte.[3]
In this study, we build a complementary logic circuit using a pair of OECTs featuring only polyaniline (PANI)

as the channel material in both transistors.[4] PANI is chosen due to its unique behavior exhibiting a peak in current versus gate voltage when used as an active channel in an OECT. The voltage-transfer characteristic demonstrates the ability to switch from 0 to the supply voltage ($V_{DD} = \pm 0.2$ V) within a potential window suitable for physiological media, obtaining excellent performances with gain up to 7. We investigate concurrently the electrochemical and optical properties as the OECT was in operation to better understand the transfer characteristics of PANI. We further demonstrate the engineering of the complementary circuit into a flexible bioelectronic that operates in aqueous electrolyte.[4] Our approach of using one material simplifies the synthesis and processing design and eliminates the need of sourcing a material with matching performance.

9:50 AM EL07.09.16
Late News: Solid-State Organic Electrochemical Transistors (OECTs) with Biomaterials for Electronic and Neuromorphic Applications Tung Nguyen-Dang, Kelsey Harrison, Alana Dixon, Alexander Lill, Erin Lewis, Shantonu Biswas, Yon Visell and Thuc-Quyen Nguyen; University of California, Santa Barbara, United States

Organic Electrochemical Transistors (OECTs) have emerged as a promising technology for the development of future bioelectronic and wearable devices. Indeed, a wide range of applications of low-operating voltage and low-power consumption OECTs in electronics are demonstrated, including flexible integrated circuits, wearable biosensors and in implantable brain recording devices. High-performance OECTs require high ionic conductivity and consequently, the majority of current work focus on the device physics and the applications of devices with liquid electrolytes. Nevertheless, liquid components in the transistors could severely impede their long-term stability and complicate their miniaturization. Tremendous attention has therefore been drawn to the development of solid-state materials for solid-state OECTs, among which biomaterial electrolytes are attractive candidates, thanks in part to their biocompatibility and environmental friendliness.Thus far, however, biomaterial-based OECTs have not been systematically studied. There still remains uncertainty surrounding the nature of the doping/dedoping process in the working principle of biomaterial-based OECTs, and as a result, there is a lack of strategies to enhance the performance of these transistors for applications. Here, we present a systematic study of biomaterial-based solid-state OECTs in which biogels consisting of gelatin and glycerol, two food-grade materials, are chosen as the model solid electrolyte. Such gels are fundamentally attractive for bioelectronics and wearable applications due to their superior and tunable electrical and mechanical properties. Their highly processability allows for the fabrication of all-solid-state organic transistors in conventional top-gate-bottom contact configuration and in novel printing-oriented floating-gate coplanar-contact configuration. By analysing the temperature dependence of the biogel OECTs and that of the gel electrolytes, we reveal the role of protonic doping/dedoping in the operation of these transistors. We then establish a relation between morphology and protonic-conductivity of the gels, allowing for the fabrication of gel-based OECTs with high performance. To illustrate this unique flexibility in tuning biogel OECT performance, we demonstrate solid-state organic transistors with high ON/OFF ratio and transconductance, possible ms-switching speed, and six-month stability in ambient air. Understanding ion-conduction in biogel OECTs also leads to better control of their state-retention property, enabling their employment as artificial synapses with various synaptic functions, such as frequency-based short-term and long-term plasticity. With advances in stretchable wearable electronic devices and in solid-state neuromorphic devices, we believe that naturally occurring gels, and gelatin-glycerol gels in particular, will play an essential role in the next generation of sustainable, bio-compatible electronics. As such, our study herein paves the way for the development of biomaterial-based electronics by providing guiding principles for future works that employ biomaterials in OECTs.

10:00 AM EL07.09.17
Late News: Tuning Strain Sensor Performance via Programmed Thin-Film Crack Evolution Juan Zhu,

Xiaodong Wu, Jasmine M. Jan and Ana C. Arias; University of California, Berkeley, United States

Stretchable mechanosensors with specific mechanosensitivity and stretchability are ideal for a wide range of applications, from large deformation monitoring to subtle vibration detection. Currently, it is still a great challenge to fabricate stretchable mechanosensors with highly tunable stretchability and sensitivity with facile fabrication techniques. In this work, multifunctional sensors made from a metal film supported on an elastomer in conjunction with a novel programable cracking technology are reported. The cracking mechanism of the metal film can be effectively regulated by the surface chemistry of the elastomer, which results in finely controlled crack morphologies, allowing for strain sensors with well-defined sensitivity and stretchability. Benefitting from this strategy, our sensors demonstrate distinctive characteristics including unprecedented tunability, high sensitivity (Gauge Factor (GF) > 10000), broad stretchability (up to 100%), fast frequency response (5.2 Hz), and good cyclic stability (over 1000 cycles). Based on their superior performance, the sensors can be used for monitoring both subtle and drastic deformations in real-time. The fabrication process presented here, with one material system and a single approach, demonstrates a facile and efficient method for fabrication and regulation of strain sensors, making it an attractive approach for potential applications in wearable sensors, electronic skin and health monitoring platforms.

10:10 AM EL07.09.18
Late News: Stable and Conductive PEDOT:PSS:MXene Composites for Bioelectronics Shofarul Wustoni and Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

Poly(3,4-ethylenedioxythiophene) (PEDOT) doped with poly(styrene sulfonate) (PSS) is the most commonly used conducting polymer in organic bioelectronics. However, electrochemical capacitances exceeding the current state-of-the-art are required for enhanced transduction and stimulation of biological signals. The long-term stability of conducting polymer films during device operation and storage in aqueous environments remains a challenge for routine applications. In this work, we electrochemically synthesize a PEDOT composite comprising the water dispersible two-dimensional conducting material Ti_3C_2 MXene. We find that incorporating MXene as a co-dopant along with PSS leads to PEDOT:PSS:MXene films with remarkably high volumetric capacitance and stability, outperforming single dopant-comprising PEDOT films, *i.e.*, PEDOT:PSS and PEDOT:MXene electropolymerized under the same conditions on identical surfaces. Furthermore, we demonstrate the use of a PEDOT:PSS:MXene electrode as an electrochemical sensor for sensitive detection of dopamine (DA). The sensor exhibited an enhanced electrocatalytic activity toward DA in a linear range from 1 μM to 100 μM validated in mixtures containing common interferents such as ascorbic acid and uric acid.[1] PEDOT:PSS:MXene composite is easily formed on conductive substrates with various geometries and can serve as a high performance conducting interface for chronic biochemical sensing or stimulation applications.

Late News: Amplification with Microfluidics Integrated N-Type Organic Electrochemical Transistor Sensor Anil Koklu, David Ohayon, Shofarul Wustoni, Adel Hama, Xingxing Chen, Iain McCulloch and Sahika Inal; King Abdullah University Science and Technology, Saudi Arabia

The organic electrochemical transistor (OECT) can translate biochemical binding events into an electrical signal with particularly high amplification. We herein present a compact and self-sufficient glucose sensor based on an *n-type* OECT.[1] The *n-type* polymer cast at the channel and on the gate electrode has specific interactions with the enzyme glucose oxidase, allowing for direct detection of glucose rather than hydrogen peroxide. The OECT was integrated with a microfluidic system, enabling higher channel current and transconductance, which, in turn, resulted in higher detection sensitivity, lower detection limit and an enhanced signal to noise ratio (SNR) compared to its microfluidic-free counterpart. Owing to the low noise endowed by the microfluidics, the low

magnitude gate current changes (~pA) upon enzymatic reaction could be resolved, revealing that while the relative changes in gate and drain currents are similar, the drain current output has a higher SNR. Our microfluidic-integrated design provides new insights into the mechanisms allowing for high sensor sensitivities, while the combination of redox enzymes and *n-type* polymers presents a new avenue for the development of portable and autonomous lab-on-a-chip technologies.

2:20 PM *EL08.01.01
The Search for the Most Conductive Interconnect Metal <10 nm Daniel Gall; Rensselaer Polytechnic Institute, United States

The effective resistivity of conventional Cu interconnect lines increases by more than two orders of magnitude as their width decreases from 30 to 6 nm. Alternative metals have the potential to mitigate the resulting resistivity bottleneck by (a) facilitating specular interface scattering with an insulating lattice-matched liner, (b) increasing the grain size or the grain boundary transmission through Fermi surface matching, and (c) choosing a metal with a low product of the bulk resistivity times the bulk electron mean free path. Electron transport measurements on epitaxial metal layers in combination with first-principles simulations are used to quantify the resistivity scaling for a series of metals including Cu, W, Ru, Mo, Co, Rh, and Ir, and to provide insight into the interface structure and chemistry requirements that lead to specular electron scattering and therefore a low resistivity for narrow interconnect lines.

Direct Printing of Metallic Interconnects at Micro/Mesoscale Using Localized Electrodeposition Md Emran Hossain Bhuiyan and Majid Minary; The University of Texas at Dallas, United States

Device integration in modern electronics has become complicated with increasing complexity in new generation of devices. Photolithography based conventional techniques are widely used for patterning materials for various electronics applications. These conventional techniques require multiple steps and high vacuum processing, which increase the fabrication cost. Direct printing of metallic interconnects in room temperature without mask and post processing step (high temperature thermal annealing) to achieve the electrical properties close to bulk can significantly reduce the manufacturing cost. Along with low manufacturing cost, superior quality of the printed metal is also highly demanding to be fit in the electronics applications.
Here, an additive printing process based on localized electrodeposition (LED) is demonstrated to print pure metallic interconnects at micro- and meso-scale on rigid and flexible substrates. LED is a 3D electrochemical nano-, micro-, meso- scale printing technology that allows the direct printing of high density, high aspect ratio, and good quality 3D metals and alloys structures at room environment. In the LED process, a nozzle containing the electrolyte of the metal or alloy of interest functions as the printing tool bit. A combination of SEM, XRD, FIB, AFM, nanoindentation, DSC, and electrical characterizations was used to characterize the structure and the properties of the printed interconnections. Microscopy and spectroscopy showed that the printed metal is solid with no porosity, smooth, and with low impurities. Electrical resistivity close to the bulk (~2-time) was obtained without any thermal annealing. Mechanical characterization confirmed the mechanical strength close to the bulk with good adhesion strength of the printed interconnects to the silicon wafer. Thermal analysis further confirmed the melting point of the printed interconnects is close to the bulk. Promising electrical, thermal, and mechanical properties and good adhesion strength make this process attractive candidate for next - generation integrated circuit (IC) applications. Using this process, Cu or Ni micropillar bumps can be directly printed for flip chip interconnections and microscale interconnections for device integration. Such a process can also be used to fabricate functional devices.

Advances in Lateral Copper Electroplated Metallic Tracks—Production and Applications by Using Hydrogen Evolution Assisted Electroplating Sabrina Rosa and Arash Takshi; University of South Florida, United States

Recently we have demonstrated that hydrogen evolution assisted (HEA) electroplating can be used for rapid lateral growth of copper across a gap between two copper traces on a printed circuit board (PCB). In this work, the HEA approach has been applied for growing copper traces on three different fabrics of 1000 Denier Coated Cordura Nylon, Laminated Polyester Ripstop, and 100% Virgin Vinyl. To provide the conductive path for the electroplating, first, the desired pattern was applied as a template on the fabric using a conductive ink including multiwalled carbon nanotubes (MWNTs). The template was then metalized by lateral coating with copper. The fastest copper growth rate was achieved in 1000 Denier Coated Cordura Nylon sample (370.96 μm/s), while 100% Virgin Vinyl sample showed the slowest growth rate of 99.57 μm/s. Further study of the morphologies using the scanning electron microscopy technique showed that the material and the texture of the fabric directly affect the morphology of the electroplated copper. The results are very promising for developing a new method of fabricating wearable electronics by direct printing copper on different fabrics.

Two-Step Approach for Conformal Chemical Vapor-Phase Deposition of Ultra-Thin Conductive Silver Films Sabrina M. Wack, Petru Lunca Popa, Noureddine Adjeroud, Christèle Vergne and Renaud Leturcq; Luxembourg Institute of Science & Technology, Luxembourg

In the fabrication of microelectronic devices, which include DRAM capacitors, transistors, and back-end-of line

(BEOL) interconnects, copper (Cu) films are widely studied. However, in this field, silver (Ag) is of particular interest due to its low electrical resistivity and low residual stress compared to Cu. Moreover, a downscaling to less than 100 nm is possible without a considerable increase in resistivity. [1] All these arguments impose Ag as a potential replacement of Cu for contacts and interconnects. Besides microelectronics field, the outstanding optical properties of silver make it a good choice for several applications including optical coatings for plasmonics, windows or lenses, mirrors or sensors, while its chemical reactivity is used in antibacterial surfaces. More and more of these applications require a conformal growth of ultra-thin silver layers, which represents a challenge for most deposition methods. [2]

The deposition of highly uniform and conformal conductive ultra-thin films is also of great interest in the microelectronics industry where the miniaturization of semiconductor devices introduces complex three-dimensional structures with high aspect ratio. [3,4] Consequently, one of the main challenges is to be able to uniformly fill the metallic films into these structures. Conductive ultra-thin silver films are commonly deposited by line-of-sight methods (mainly sputtering) that do not allow conformal deposition on 3D structures with complex morphology such as in microelectronic devices, and have strong uniformity limitations for non-flat substrates such as curved glass. On the other hand, non-line-of-sight methods, such as chemical vapor deposition or atomic layer deposition, usually produce non-electrically-conductive films for low thickness, due to island growth mode. [4,5]

Our new approach relies on an original two-step plasma-enhanced chemical vapor-phase deposition [2], allowing us to reach the electrical performances of silver films obtained by physical approaches without the need of additional wetting layer. Indeed, we synthetized highly conductive and uniform Ag films with a critical thickness lower than 15 nm and a sheet resistance of 1.6 Ω/sq. for 40 nm thin film, corresponding to a resistivity of 6.4 μΩ.cm. The high reflectance (up to 94%) and low absorbance (3%) in the infrared region further demonstrate the optical quality of the films, despite a still large rms roughness of 8.9 nm and justify the relevance of the product for high-performance IRR coatings. Moreover, we successfully demonstrate the high conformality of the deposited film on complex lateral high aspect ratio structures (up to 100), with better coverage than the one reported up to now for atomic layer deposition of silver.

This new processing approach opens a very promising route for the use of ultra-thin silver films for electronic and optoelectronic applications, and could be extended to other metals deposited from metal-organic precursors, in particular copper and gold, for which the deposition using chemical vapor based methods is a very active field.

3:30 PM *EL08.01.05
New Frontiers in Metrology for Advanced Interconnect Technologies Kavita Shah; Nova Measuring Instruments, United States

The recent years have proven to be a prime time for materials scientists, process and integration engineers working on interconnect technologies. Even a cursory look at the interconnect roadmap for the next 5 – 10 years will reinforce the observation that a sizeable portion of the periodic table is at play! The semiconductor industry continues to address several daunting challenges at an aggressive dimensional scale by introducing new materials and novel processes to meet modern processor requirements. These changes are not limited to just critical dimension interconnects. We also see rapid evolution for far-back-end technologies. Across the board, the challenge is developing new materials and techniques while meeting more stringent requirements for reliability, variability, and process control. However, identifying the sources of variability and resolving these

issues is becoming more difficult as the complexity evolves. New metrology techniques are needed to address these challenges; however, the mindset for process control back-end-of-line process control lags behind the materials' engineering advances. Fabs either live with older technologies or, in many cases, run the processes blind. The introduction of new integration schemes such as Selective Deposition further extends the need for novel metrology capabilities. We will explore the advent of new metrology techniques with better sensitivity and higher resolution to solve challenges for advanced interconnects in my talk. We will also discuss the unique implementation of materials and dimensional metrology techniques across a few different application types and highlight future development needs in metrology, algorithms, and machine learning techniques to advance the interconnect technology roadmap.

High Mobility Monolithic InAs Integration on Amorphous Substrates at Low Temperature Jun Tao, Debarghya Sarkar, Ragib Ahsan and Rehan Kapadia; University of Southern California, United States

Heterogeneous and scalable back-end-of-line (BEOL) compatible integration of high-quality crystalline III-V semiconductor materials and devices are fundamentally limited by two factors: (i) the lack of a crystalline growth surface and (ii) the <400°C thermal budget. Here, we demonstrate high electron mobility single-crystal InAs templated mesas can be monolithically integrated on amorphous substrates at a growth temperature of 300°C by low temperature templated liquid phase (LT-TLP) method. Importantly, a room temperature mobility of 5880 cm^2/V-s and peak mobility of 6750 cm^2/V-s at 50 K are measured, the highest mobility reported for any thin-film semiconductor material system directly grown on a non-epitaxial substrate. Detailed modeling of the scattering mechanisms in the grown material indicates that mobility is limited by surface roughness scattering, not the intrinsic material quality. The projected room temperature mobility can reach 10,000 cm^2/V-s when reducing the RMS surface roughness of InAs from 1.8 to 1 nm, and result in ~20,000 cm^2/V-s at 0.5 nm RMS surface roughness, essentially identical with unencapsulated InAs thin films hetero-epitaxially grown by MOCVD or MBE. These results pave the way for the growth of high-mobility materials directly onto the back end of silicon CMOS wafers, and other non-epitaxial substrates such as glass, and polymers for flexible electronics.

Low Temperature Direct Bonding Mechanisms Vincent Larrey; Univ. Grenoble Alpes, CEA, LETI, France

Low temperature direct bonding became a mass production technology used for various applications in the microelectronics and microsystems industries. From the first optical system elaboration in the sixties to emerging and promising 3D applications, processes continue to grow in maturity thanks to a progressive understanding of the direct bonding mechanisms. Nevertheless, many research areas still deserve further investigations.
We will first review the general requirements and the most common characterizations needed to track important parameters influencing the quality and reliability of bonded structures. Bonding strength energy measurement, acoustic microscopy, X Ray Reflectivity and Fourier Transform Infrared Spectroscopy, to name a few, are most useful help to fully understand the role of various process parameters.
Silicon and thermal silicon dioxide have been widely studied for the last thirty years as their assembly without

any added layers is required for SOI fabrication. These stable and reproducible materials are very interesting to describe the chemical and mechanical mechanisms at play in confined bonding interfaces. We will put some emphasis on the key role water has during and after bonding. Adsorbed water on the surfaces is indeed trapped at the bonding interface. A post bonding annealing is usually performed to strengthen the structures. It is then quite obvious that water management plays a key role. Hydrophilicity, asperities hydrolization, silanol to siloxane bonds conversion and water stress corrosion are fundamental notions to depict and understand the behavior of bonded structures. We will also describe the common surface preparation technics used to improve the bonding strength and quality.
However, many microelectronics and microsystems applications require other material at the bonding interface. Previous considerations remains exact, however. New behaviors, models and mechanisms will benefit from such a background. Simply replacing thermal oxide with deposited oxide is not so easy, for instance. We will then have to deal with silanol groups in the oxide layer, as they will have an impact on water management. Other researches focus on alternative dielectrics and we will describe the specificity of alumina, silicon nitride and porous ultra low k materials.
We will then present some of the specificities of metallic direct bonding, with a focus on copper-to-copper direct bonding mechanisms. This technology can indeed address the growing 3D market, as it yields electrical contacts between microelectronic devices. To achieve such stacking, perfect hybrid surfaces (Silicon oxide and Copper) have to be prepared, aligned and contacted. We will discuss the surface topologies requirements and the latest bonding alignment improvements yielding stacks with connection pitches as low as 1µm.
Finally, we will discuss the main advantages and drawback of direct bonding compared to other bonding solutions, in order to propose a guideline to choose the best assembly technic.

5:40 PM EL08.02.02
Atomic Precision Advanced Manufacturing (APAM) of Ultra-Doped Nanostructures for Advanced CMOS Devices and Interconnects David A. Scrymgeour, Esther Frederick, Connor Halsey, DeAnna Campbell, Evan Anderson, Scott Schmucker, Andrew Leenheer, Xujiao Gao, Jeffrey Ivie, Tzu-Ming Lu, Lisa Tracy and Shashank Misra; Sandia National Laboratories, United States

Atomic precision advanced manufacturing (APAM) is a promising platform for creating quantum structures and advanced silicon based electrical devices at the absolute limit of doping in silicon – at activated concentrations higher than achievable by ion implantation. In this process, a hydrogen-terminated Si(100) surface is patterned by selectively removing the bound hydrogen with an scanning tunneling microscope tip in chosen areas, leaving behind a depassivated (bare silicon) pattern. Subsequent exposure to phosphine molecules leads to dissociative chemisorption of phosphine molecules in the depassivated regions only, then the entire pattern is then protected with an epitaxial silicon cap. This creates a 2D delta layer of highly conductive phosphorous in silicon that can carry 2 mA/µm of current. This ultra-doping of Si provides unprecedented electronic behavior, virtually unrecognizable to traditional Si devices, and enables its future use in advanced silicon devices and interconnects.

Our recent work focuses on exploring various aspects of integrating APAM directly into CMOS architectures, as well as the consequences of APAM on potential Beyond Moore silicon devices. Our first focus involves overcoming traditional cryogenic temperature limitations of APAM devices, and we have recently demonstrated the use of APAM phosphorus nanostructures at room temperature, overcoming previous limitations. Our second goal is to assess the compatibility of APAM delta layers with operational CMOS conditions. We recently performed accelerated aging studies at high temperatures and drive currents and will discuss the robustness and failure mechanisms of the APAM materials. Lastly, we are exploring the chemical selectivity of hydrogen and silicon depassivated surfaces to achieve patterned atomic precision deposition (APD) and etch (APE).

Cryogenic Etching Applied to Next Generation Interconnects Remi Dussart, Thomas Tillocher and Philippe Lefaucheux; Université d'Orleans - CNRS, France

Cryogenic etching process was introduced more than 30 years ago by a Japanese team [1]. The idea was to cool the substrate to a very low temperature (-100°C) in order to freeze the chemical reactions on vertical sidewalls while maintaining them with silicon at the structure bottom submitted to the ion bombardment. A plasma of SF_6 was used to perform these experiments. However, it was shown later that oxygen was playing an important role by forming a SiOxFy passivation layer at the sidewalls [2]. Oxygen contamination was probably coming from SiO_2 sputtering in the reactor. SF_6/O_2 plasmas in interaction with a cooled silicon wafer can be used to form high aspect ratio structures. However, until recently, Bosch process [3] was usually preferred by companies to etch high aspect ratio silicon microstructures, for its better robustness and because it is a room temperature process, which does not require any liquid nitrogen to cool the substrate. Etching at low temperature of the substrate may have many advantages: reactions of interest mainly occur on cooled surfaces, higher etch rate can be obtained, it can be used for nanometric patterns and surface diffusion can be minimized … [4] Moreover, new chillers are now available to cool down the wafer to very low temperatures without using liquid nitrogen. These assets make cryoetching generate more and more interest in the semiconductor industry.
In particular, cryogenic etching offers new opportunities for next generation interconnects. It can be used to anisotropically etch porous low-k materials. It is well known that ultra low-k material, which is used for the first levels of interconnection in CMOS technology, can be strongly damaged by plasma etching processes. Porous SiOCH is a typical low-k material used in microelectronics. Methyl depletion due to radical diffusion and reactions through the pores are some of the observed unwanted effects. Ion bombardment and VUV exposure can also damage the low-K material, leading to an increase of the k value [5]. In order to reduce Plasma Induced Damage, a technique based on the cryogenic process was introduced in 2013 [6]. It consists in cooling the substrate to a low temperature in order to reduce species diffusion and create a passivation layer on the sidewalls and on the pore surface. Several processes have been successfully tested involving C_4F_8/SF_6 plasma chemistry at -120°C. [7, 8]. The idea was to fill in the porous material by condensation of C_4F_8 before etching, and prevent plasma damage of the low-k material. Anisotropic etched profiles were obtained with an enhanced selectivity in SF_6/C_4F_8 plasma process at low temperature. The effect of the low temperature was clearly observed on the equivalent damage layer (EDL), which was evaluated by ex situ Fourier transform infrared (FTIR) spectroscopy and in situ ellipsometry. An anneal step at 350 °C was also used to completely desorb the remaining CF_x species from the pores. An equivalent process at higher temperature was proposed using organic molecules having a higher boiling point (HBPO – Higher Boiling Point Organic).

6:20 PM EL08.02.04
Late News: Effect of Non-Corrosive Gas Mixture on Etching of Nanometer-Scale Patterned Cu Thin Film Using Pulsed Modulated RF Source Plasma Ji Soo Lee, Eun Taek Lim, Sungyong Park, Yun Seong Park, Sung Hoo Cho and Chee Won Chung; Inha university, Korea (the Republic of)

As the critical dimensions of semiconductor devices are reduced for high performance, fast speed, and low operating power, copper has been used as the interconnect metals because it has low resistance and less electromigration. For the realization of copper interconnect into the devices, the etching of copper thin films are

necessary. However, the conventional dry etching of copper is difficult because conventional etching gases such as Cl_2, HCl, HBr are formed nonvolatile by-products on the copper films. Currently, the damascene process is used for copper pattering. However, as the critical dimensions are further reduced down to 10s nm scale, the damascene process shows its limitation. Therefore, new etch process containing new gases needs to be developed.
In this study, the copper thin films were etched using non-corrosive gas mixture in pulse-modulated RF plasma. We investigated the effect of pulse-modulated RF plasma etching on etching characteristic compared to using the conventional continuous wave (CW) plasma etching. This modulated plasma can provide the specific plasma conditions modified by special matching system that can change on-off duty ratio of 13.56 MHz RF power and frequency on the specific duty ratio. In this research, the etching characteristics of copper thin film masked with nanometer-scale patterns were investigated in non-corrosive gases using pulse-modulated inductively coupled plasma reactive ion etching (ICP RIE). The effects of on-off duty ratio and frequency of pulsed plasma on the etch characteristics of copper were examined. Then, the etch profiles of copper thin films were observed by scanning electron microscopy and the etch mechanism was investigated using optical emission spectroscopy and X-ray photoelectron spectroscopy.
Acknowledgments
This research was supported by the MOTIE(Ministry of Trade, Industry & Energy (10080450) and KSRC(Korea Semiconductor Research Consortium) support program for the development of the future semiconductor device.

6:25 PM EL08.02.05
Late News: Inductively Coupled Plasma Reactive Ion Etching of Nanometer-Scale Patterned Copper Thin Films Using Organic Materials Sungyong Park, Eun Taek Lim, Ji Soo Lee, Yun Seong Park and Chee Won Chung; Inha University, Korea (the Republic of)

Coper interconnect, which has low resistivity, high electromigration resistance, and good mechanical properties, has replaced aluminum interconnect as the semiconductor devices are scaled down. However, copper interconnect could not be patterned by the conventional plasma etching technics because copper has very low reactivity and its etch byproducts are nonvolatile. Thus, copper patterning has been accomplished using 'damascene' process. However, as the critical dimensions of the devices decreased to nm scale, the resistivity of copper interconnect increased than that of the bulk resistivity. It occurs due to the surface scattering and grain boundary scattering of the copper as its dimensions are shrunk. Therefore, conventional dry etching method which can directly utilize low resistivity of the copper films should be developed.
Previously, dry etching of copper films using various halogen gases such as Cl_2, $SiCl_4$, HCl, and CCl_4 was performed, and the results were unsatisfactory due to the copper halide byproducts which were remained on the copper surface. On the other hand, organic chelator materials such as hexafluoroacetylacetone was used to the dry etching of the copper. Recently, inductively coupled plasma reactive ion etching using several organic materials were performed and good etching profile in the mm-scale copper line pattern was achieved.
In this study, nanometer-scale patterned copper thin films have been etched using organic chelate materials with additives in inductively coupled plasma reactive ion etching. The influences of etch parameter such as gas concentration, ICP source power, bias voltage to the substrate, and process pressure have been investigated. The etch rate, etch selectivity, and etch profile of the copper film were examined by surface profilometer and field emission scanning electron microscopy. Then, the etch mechanisms were investigated using X-ray photoelectron spectroscopy and optical emission spectroscopy.

Low Dielectric Constant SiCOH Films by Plasma Enhanced Chemical Vapor Deposition of tetrakis(trimethylsilyloxy)silane and cyclohexane Precursors William Wirth, Jacob Comeaux and Seonhee

Jang; University of Louisiana at Lafayette, United States

In semiconductor industry, SiCOH films with low dielectric constant ($k \leq 4.0$) have been widely used as inter-metal dielectric (IMD) materials in the interconnects of semiconductor chips, to reduce a resistance-capacitance delay. In this study, the SiCOH films were deposited on silicon substrates using the plasma enhanced chemical vapor deposition of tetrakis(trimethylsilyoxy)silane (TTMSS) and cyclohexane (CHex) precursors. The chemical structure and materials performances of the SiCOH films strongly depended on deposition temperatures and flow rate ratios of TTMSSS/CHex. Deposition temperatures varied in the range between room temperature and 400 ºC. The flow rate ratios of TTMSS/CHex were determined by the control of argon carrier gas which transports each vaporized precursor from the bubblers to a process chamber. Physicochemical structures including porosity, density, and chemical composition of the SiCOH films affected their mechanical and electrical properties. The chemical bonds and compositions of the SiCOH films were investigated using Fourier transform infrared spectroscopy and X-ray photoelectron spectroscopy. The chemical bonds related with hydrocarbon and Si-O were the main characteristics of the SiCOH films. The mechanical properties including hardness and elastic modulus were measured by using a nanoindentation. The *k* values and leakage current density were determined by capacitance-voltage (C-V) and current-voltage (I-V) curves. The competition among hydrocarbon and Si-O bonds depending on deposition conditions affected the *k* values and mechanical strengths of the films. The enhanced mechanical and electrical performance with the optimized deposition conditions suggested the possibility of applying SiCOH films as IMD materials.

6:45 PM EL08.02.07
Design of Mechanically Reliable and Fracture Resistant Low-K Dielectric Hybrid Glasses for Next Generation Interconnects Karsu I. Kilic and Reinhold Dauskardt; Stanford University, United States

Despite their unusual properties, the reliable integration of low-k dielectric hybrid organosilicate glasses into interconnects for microelectronic device technologies is challenging due to their poor elastic and fracture properties. It is therefore crucial to explore the structure-property relationships of these materials to be able to design mechanically stiff and fracture resistant low-k dielectric hybrids for their successful integration into next generation interconnects. With our computational modeling, which is based on molecular dynamics simulations, we can generate highly accurate models of low-k dielectric hybrid organosilicate glasses with a wide range of structural characteristics and explore the effects of these structural characteristics on the resulting elastic and fracture properties. Our model low-k dielectric hybrid glasses have a range of different mean network connectivity, condensation degree and porosity; and they are derived from precursor molecules with a variety of geometrical features in terms of precursor chain length, molecular planarity and symmetry. Using molecular dynamics simulations, we can predict the structural stiffness of the model glass networks we generate and relate aforementioned structural features to the resulting elastic properties. As for the fracture properties, we have developed an algorithm named *Min-Cut Cohesive Fracture Model* which is based on a novel graph-theory approach to predict the fracture bond density and fracture morphology of our model hybrid glasses. In this approach, the glass network is treated as a graph where nodes and edges in the graph become atoms and bonds respectively. The algorithm operates on this mathematical framework and predicts the fracture path of the glass network to be the minimum cut that separates the graph, allowing us to explore fracture bond density and fracture patterns of several different low-k dielectric hybrid glass networks. Similar to elastic properties, we observe significant variations in the fracture path properties of low-k dielectric hybrid glass networks depending on their structural features. Remarkably, our results demonstrate that the hyperconnected low-k dielectric hybrid glass networks that are derived from cyclic and planar precursor molecules simultaneously enhance elastic and fracture properties. Specifically, the use of hyperconnected and cyclic planar precursors lead to *ultrastiff networks* which are stiffer than fully dense silica, and up to three times stiffer networks in comparison to traditional examples of low-k dielectric glasses such as the ethane-bridged oxycarbosilane (Et-OCS) glasses, while maintaining low density and low dielectric coefficient. Likewise, such networks also tend to exhibit more planar fracture paths (less fracture path meandering) with higher fracture bond density thereby significantly improving the fracture energy. This is a very important step towards the design of mechanically reliable and fracture resistant hybrid organosilicate low-k dielectric glasses for their successful integration to next generation

interconnects in microelectronic applications.

Low Temperature Deposition of Extremely Thin Barrier for Metallization Technology Mayumi Takeyama; Kitami Institute of Technology, Japan

In Si-LSI metallization technology and 3D-LSI, it is very difficult to obtain materials around metallization at low temperature and in a structurally- and thermally-stable state, because stability and temperature are generally inversely proportional. We have succeeded in forming at low temperatures insulating barriers and diffusion barriers. In particular, the sputtering method using radical reaction can form a thin film with excellent thermal stability without heating. I will explain the characteristics of the barrier film obtained by these technologies and an example of research on low-temperature deposition of barriers using the latest technology.

Late News: Electrical Breakdown and Morphology Dependent Charge Transport Properties in Single TiO2 Nanotubes Sourav K. Kajli, Debdutta Ray and Somnath C. Roy; Indian Institute of Technology Madras, India

Understanding the electrical conduction properties of a single nanostructure is essential for an insight into the fundamental charge transport through the 1D materials and also for exploring the collective behavior of an array of such nanostructures. TiO_2 nanostructures, such as electrochemically grown nanotubes, have been widely studied in recent times for several applications. The electrolyte plays a vital role in deciding the morphology, which, in turn, govern charge transport behavior. Here we present a comparative study of the charge transport through a single TiO_2 nanotube grown by electrochemical anodization using Ethylene Glycol and Dimethyl Sulphoxide electrolytes. The individual nanotubes are assembled into nanodevices using photolithography without relying on complex and sophisticated processes like electron beam lithography or focused ion beam deposition. The electric field dependent charge transport properties show Schottky emission at lower field regime and Poole-Frenkel emission in the higher region. The temperature-dependent electrical conduction (110K - 410K) is mediated by two thermal activation processes, attributed to shallow impurities in the low-temperature range ($T < 230$ K) and to the donors at deep intermediate levels at higher temperatures ($T > 230$ K). The activation energies for EG based nanotubes are found to be higher than that of DMSO nanotubes owing to the doubled wall morphology of the formed tubes. Also, the study of the electrical breakdown phenomena of these nanotubes reveals three distinct categories of collapse. ‘Model A’ type breakdown is characterized by a stepwise rise of current up to the breakdown point and fall to zero following a non-uniform step by step decrement, which is driven by crack formation near the electrode interface and it’s propagation. ‘Model B’ shows a transient rise and fall in current, leading to breakdown due to electromigration. Whereas ‘Model C’ type breakdown observed in a bundle of nanotubes shows a mixed trend of ‘Model A’ and ‘Model B.’ The data and analysis provide insight into the current limit through an individual nanotube or bundle of nanotubes and will be useful for designing prototype nanodevices from titania nanostructures.

Amorphous Si-Rich W Silicide as a New Barrier and Contact Material for Advanced CMOS Naoya Okada, Noriyuki Uchida, Shinichi Ogawa and Toshihiko Kanayama; National Institute of Advanced Industrial Science and Technology, Japan

The electrical resistance in the back-end-of-line (BEOL) and middle-of-line (MOL) is becoming a critical factor more and more with recent shrinkage of Si CMOS. For interconnects, a thinner barrier film is required to keep the conductance in a narrower structure. Many researchers have already addressed this problem using various materials against Cu diffusion; yet, a new barrier material is strongly required. For the source/drain in transistors, Co is now a promising electrode; however, Co has a very high diffusivity in Si and a low reaction temperature easy to form silicide with Si; additionally, the Co/Si direct junction has a high contact resistance arising from a high electron Schottky barrier height (SBH) of ~0.6−0.7 eV for *n*-Si, owing to the Fermi-level pinning effect at the Si interface. The Co/Si junction therefore needs a diffusion barrier layer capable of the low SBH for Si. A promising solution is to use an atomically designed and engineered ultrathin barrier film.
In this work, we demonstrate a novel barrier material with excellent barrier properties against Cu and Co diffusions and the low SBH for the Co/Si junction: the WSi_n ($n \leq 12$) composed of W-atom-encapsulated Si_n cage clusters.[1] The WSi_n film was prepared by the newly developed Cluster-Preforming Deposition (CPD) method.[2] In a hot-wall thermal deposition system, hydrogenated W-atom-encapsulated WSi_nH_x clusters with well-controlled n values ($n \leq 12$) are preformed by reaction of WF_6 and SiH_4 in the gas phase. The WSi_nH_x clusters are then deposited onto a substrate, where they are thermally dehydrogenated and coalesce to the WSi_n film with less hydrogen content. The formed films have an amorphous structure similar to the hydrogenated amorphous Si, but they are extremely stable against annealing up to 1100 °C. We also confirmed that the WSi_n film exhibits an excellent step coverage over a high-aspect-ratio hole array with 40-nm diameter and 2-μm depth. [1]
The barrier properties of the WSi_n film against Cu diffusion were investigated using the two test structures with Cu electrodes: MOS capacitors with a 20-nm thermal oxide and p^+-n diodes (junction depth of 100 nm) with and without the WSi_n insertion (n = 12, thickness = 5 nm). The WSi_n film exhibited excellent diffusion barrier properties for Cu contact; from the TDDB lifetime of the Cu MOS capacitors, the diffusion barrier height was estimated to be 1.33 eV under 5 MV/cm stress and the Cu on Si diodes were stable against annealing up to 600 °C.[3]
The contact properties for *n*-Si were investigated using the Co/Si Schottky diode with the WSi_n insertion (n = 8, thickness = 5 nm). Insertion of the WSi_n film reduced the electron SBH to 0.43 eV at Co/*n*-Si junctions. This is because the film is a semi-metal with a low work function close to the conduction bend edge of Si.[4] These junctions have an excellent stability against annealing up to 700 °C, leading to no appreciable interdiffusion. We directly observed that the WSi_n film prevented the Co diffusion by cross-sectional TEM and EDX.[5] These excellent diffusion barrier properties are because in the WSi_n film, all the Si atoms are strongly bonded to the W atoms forming W-atom-encapsulated clusters, suppressing the diffusion of Co and Cu atoms.
In conclusion, the WSi_n film exhibited excellent diffusion barrier properties for Cu and Co: a high barrier stability against annealing up to 600−700 °C. Consequently, this film is a promising barrier and contact material in advanced CMOS.

Late News: Reliability Failure in Microelectronic Interconnects by Electric Current Induced Chemical Reaction Sumit Kumar, Randhir Kumar, Praveen Kumar and Rudra Pratap; Indian Institute of Science Bangalore, India

The electric current-induced chemical reaction in Cr thin film by a micro/ nano-probe has been recently reported with detail characterization. Although the phenomenon has been employed for micro-nano fabrication

and the technique is called electrolithography, this acts as a reliability failure of interconnection lines in the structure, where Cr is used as an adhesion layer, or main interconnects in microelectronic circuits. Here, for the first time, we present an investigation on the role of electric current density for such failure using a specifically designed sample. A 100 µm width, and 100 nm thin Cr film was deposited perpendicular to the Pt film of similar dimensions. The anode probe (20 µm diameter) was placed onto the Pt film whereas cathode probe onto the Cr film. The chemical reaction for an applied voltage initiated at the edge of the Pt film and not at the cathode probe. The analysis based on the COMSOL multiphysics simulation shows that the chemical reaction evolves at the high current density locations. The localized chemical reaction causes to damage the interconnection line. The study also builds a fundamental understanding of the mechanism of evolution of micro-nano patterning by electrolithography.

Electroless Ni Plating—A Viable Approach for Fine-Pitch, Large Aspect-Ratio Vertical Interconnection Fabrication for 3D-LSI Integration and Packaging Mariappan Murugesan, Takafumi Fukushima and Mitsumasa Koyanagi; Tohoku University, Japan

The low-cost, high-throughput electro-less (EL) plating method has several potential advantages over the commonly used atomic layer deposition or physical vapor deposition processes to uniformly deposit barrier and seed metal layers inside the high aspect-ratio (AR) through-Si-via (TSV) interconnections for their immense applications in both the 2.5 D and 3D (three-dimensional) heterogeneous integration. By using an all-wet approach for TSV metallization, we have been able to fill the 8~10 mm-width Cu-TSVs with AR > 10 in Si-interposer for packaging applications. Also, the successful solid-filling of the sub-micron sized TSVs with AR close to 20 by EL plating of Ni enables one to achieve the vertical interconnections on 300 mm LSI wafer for the 3D-IC integration. Micro-structural and resistivity data on both sub-µm as well as 10 µm-width conventional Cu-TSVs with AR 12 to 17 revealed that the conformal Ni layer formed by EL-Ni plating is a very good seed layer for Cu electroplating. It is also evident from the morphological and the elemental analysis data that the EL-Ni plating forms nearly-uniformly thick metal layer all along the TSV sidewall and TSV bottom, which is otherwise difficult to realize by the even sophisticated PVD tool. Therefore, the EL plating method is proved to be a highly promising method for the conformal formation of barrier/seed layers inside the high AR TSVs for future 3D integration and packaging applications.

10:00 AM *
Atomic Layer Deposition of Ferroelectrics Based on HfPO2—Polycrystallinity, Polar Domains and Interfaces Paul McIntyre; Stanford University, United States

This tutorial will start with a general introduction to the atomic layer deposition (ALD) technique for industrial applications, the use of super-cycle ALD for fluorite structure oxides such as hafnium oxide and their nanolaminate and alloyed variants, and ferroelectricity therein. Afterwards, the main focus will be on microscopic aspects of such nanoscale, polycrystalline ferroelectrics for memory applications. Memory write and read operations require local reorientation and sensing of polar crystallographic domains, respectively. We will discuss the impact of such structural aspects on the miniaturization of the memory devices, physical principles relevant to polar domains, and methods for characterizing nanoscale domain structure in order to obtain a local picture for interpreting electrical data measured from ferroelectric memories. Lastly, we will elucidate the role of the interface layer structure, polarization charge screening, interface states and fixed charges on the performance and reliability of ferroelectric field-effect transistor based memories.

11:30 AM *
Ferroelectric Field-Effect Transistors for 28nm Node and Beyond Sven Beyer; GlobalFoundries, Germany

With the discovery of ferroelectricity in HfO2 based thin films 2011 and the co-integration of ferroelectric field effect transistors (FeFET) into standard high-k metal gate (HKMG) CMOS platforms 2016/17 by GLOBALFOUNDRIES, the FeFET has emerged from a theoretical dream to an applicable reality. Maturing in the beginning as a low-cost, low power eFLASH replacement, the FeFET yet is much more than a classical stiff eNVM cell. With its great HKMG CMOS compatibility, its flexibility and its unique switching properties, it is rather to be seen as a new versatile device that promises to open up new worlds. Especially the neuromorphic design community has shifted focus towards this novel device with game-changing potential. In this talk we will discuss the actual status of GLOBALFOUNDRIES FeFET technology, look into the operation and use of this device and sketch a potential roadmap.

Ferroelectric Negative Capacitance Jorge Iniguez; Luxembourg Institute of Science and Technology, Luxembourg

We will discuss the effect known as “negative capacitance”, whereby some ferroelectric materials display an anomalous dielectric response (a negative permittivity) when subject to suitable electric boundary conditions. We will describe our current theoretical understanding, from both phenomenological and atomistic perspectives, drawing a clear distinction between equilibrium and transient negative-capacitance responses. We will also review the experimental evidence for both flavors of negative capacitance, and briefly present its expected technological applications (most notably in field-effect transistors, because of the concomitant “voltage amplification”). Finally, we will give our view of the current challenges and opportunities in the field.

2:15 PM BREAK

2:30 PM *
Numerical Models for Ferroelectric Memory Devices Kai Ni; Rochester Institute of Technology, United States

Ferroelectric memories based on the doped HfO2 ferroelectric, including capacitor based 1T1C FeRAM and transistor based 1T FeFET, have received significant interests recently. The excellent scalability and CMOS compatibility of ferroelectric HfO2 has allowed its integration into 2x technology node. Such scaling reveals novel physical phenomena not observed before in perovskite ferroelectric devices, such as degraded device variation with scaling, switching stochasticity, switching probability accumulation. In order to understand such phenomena and exploit them for novel energy efficient computation, accurate device models would be indispensable. In this lecture, we will present ferroelectric memory models developed so far, covering computationally efficient compact models, Monte Carlo models, and computationally intensive phase field models. By comparing with experimental data, the application range of each model will be identified and the potential for scaling/miniaturization of ferroelectric devices will be discussed.

SESSION EL09.01: Negative Capacitance
Session Chairs: Asif Khan and Pavlo Zubko
Sunday Morning, April 18, 2021
EL09

11:00 AM *EL09.01.01
Negative Capacitance Sayeef Salahuddin; University of California, Berkeley, United States

Thermodynamics dictate that charge in an ordered system can be switched with lower energy than the Boltzmann limit known for non-interacting systems. Thinking about how to exploit it for computing led to the identification of negative capacitance in materials that show (anti)ferro-electric order [1]. In this presentation, we shall discuss this connection. Stabilization of negative capacitance needs careful consideration of electrostatic boundary condition. Especially, accounting for screening by metal electrodes is very important. In this regard, intuitive theoretical reasoning and simple schematics have often led to much confusion. We shall discuss our views on how to design experimental systems that are conducive to achieving the appropriate boundary conditions. While a single domain theory was used to elucidate the effect for simplicity, negative capacitance is not limited to single domains, as it has been pointed out early [2], and later by many authors [3,4].

Going back to the thermodynamic origin of switching more charge with less energy, the increase in capacitance has remained to be the simplest macroscopic test of the negative capacitance effect. However, modern imaging techniques allow probing the internal electric fields in a polar system with atomistic resolution. These experiments have revealed local energy maxima stabilized in the material, providing a direct imaging of stabilized negative capacitance [5]. These experiments confirm the prediction of local nature of the negative capacitance. In addition, they confirm the fact that negative capacitance originates in the regions of suppressed polarization.

One of the implications of Negative Capacitance is the possibility of subthermal (<kT/q) subthreshold swing in a MOSFET[6]. However, observation of subthermal swing has often been accompanied with Hysteresis or such swing has only been seen at very low currents. These led to questions such as: (i) Is subthermal subthreshold behavior intimately connected to Hysteresis? (ii) Does not observing this behavior mean that negative capacitance effect is fundamentally incorrect? In fact, in our view, most questions, confusions and so-called controversies can be traced back to these two questions. We will discuss these scenarios- specifically, the fact that these scenarios can be predicted from Landau's energy expressions together with appropriate boundary

conditions, as it has been discussed by many authors in literature. Therefore, observation of subthermal subthreshold swing is really a function of the properties of the channel material and he (anti)ferroelectric oxide and not observing it does not constitute a fundamental question on the negative capacitance effect itself. In fact, I will discuss other non-classical subthreshold behavior that ensues from negative capacitance, even if a subthermal subthreshold swing is not present. Such non-classical behavior is clearly observed in experiments,.

Negative capacitance could find applications in different areas such as supercapacitors for energy storage, batteries, as enhanced capacitor for Dynamic Random Access Memory (DRAM) scaling, for back end capacitors in microchips, in addition to reducing supply voltage in transistors. I shall discuss some of our recent results in this regard. Specifically, I shall discuss experimental data that show how the original thermodynamic motivation of switching more charge with less energy can now be achieved[7,8] in the most advanced transistors, which could lead to supply voltage reduction and/or enhanced scaling capability beyond the roadmap.

Enabling New Functionalities and Energy Efficiency with Negative Capacitance in 2D Devices Adrian Ionescu; Ecole Polytechnique Fédérale de Lausanne, Switzerland

In this talk we will present novel progress in the device functionality and energy efficiency when applying gate stacks with negative capacitance (NC) features to 2D devices. We will explore NC as technology booster for 2D/2D tunneling FETs based on WSe 2/SnSe 2 vdW heterojunctions, from low to high temperatures, including the energy losses per switching operation, together with the analysis of the advantages and challenges of using NC in doped high-k dielectrics like Si:HfO2. We will report both DC and pulsed experiments trying to have further insights in recent controversies concerning the negative capacitance regime and the dynamics of nucleation processes in ferroelectrics.

11:50 AM *EL09.01.03
Static Reversible Negative Capacitance in Ferroelectric Nanodot with Domains and Topological Excitations Igor Lukyanchuk[1], Yurii Tikhonov[1], Anais Sene[1], Anna Razumnaya[2] and Valerii Vinokur[3]; [1]University of Picardie, France; [2]Southern Federal University, Russian Federation; [3]Argonne National Laboratory, United States

The idea of ferroelectric-based devices with negative capacitance (NC) in low-power nanoscale electronics triggered explosive activity in the field. This revived the thoughts of engineers of the early 1930-s on the possibility of negative circuit constants and the 40-years old fundamental question raised by Rolf Landauer, whether the capacitance can be negative, that is if the increase in the charge of the capacitor can decrease its voltage. Having stated that ferroelectrics can harbor the NC during the transient processes of switching, Landauer indicated that the very existence of the static NC as a part of steady-state is challenged by instability against spontaneous domain formation. For today, most of the research addressed transient NC, leaving the basic question of the existence of the steady-state NC unresolved. Here we demonstrate* that the ferroelectric nanodot capacitor hosts a stable two-domain state realizing the static reversible NC device.

Local Negative Permittivity and Topological-Phase Transition in Polar Skyrmions Ramamoorthy Ramesh; University of California, Berkeley, United States

Topological solitons such as magnetic skyrmions have drawn attention as stable quasi-particle-like objects. The recent discovery of polar vortices and skyrmions in ferroelectric-oxide superlattices has opened up new vistas to explore topology, emergent phenomena, and approaches for manipulating such features with electric fields. Using macroscopic dielectric measurements, coupled with direct scanning convergent-beam electron diffraction (SCBED) imaging at the atomic scale, theoretical phase-field simulations, and second-principles calculations, we demonstrate that polar skyrmions in $(PbTiO_3)_n/(SrTiO_3)_n$ superlattices are distinguished by a sheath of negative permittivity at the periphery of each skyrmion. This enhances the effective dielectric permittivity compared to individual $SrTiO_3$ and $PbTiO_3$ layers. Moreover, the response of these topologically protected structures to electric field and temperature show a reversible phase transition from the skyrmion state to a trivial uniform ferroelectric state, accompanied by large tunability of the dielectric permittivity. Pulsed-switching measurements show a time-dependent evolution and recovery of the skyrmion state (and macroscopic dielectric response). The interrelationship between topological and dielectric properties presents an opportunity to simultaneously manipulate both of them by a single, and easily controlled, stimulus, the applied electric field.

Domains in ferroelectric materials have been at the forefront of recent scientific research, mostly due to the fascinating properties of their boundaries, domain walls. As well as enhancing the macroscopic properties of ferroelectrics, domain walls exhibit symmetry and properties different from the bulk material, offering novel functionality. One scalable method to control domain wall configurations in ferroelectrics is epitaxial strain. Epitaxial strain and the interplay between electrostatic and mechanical energy allow for the formation of novel domain structures, such as regular arrays of flux closure domains or chiral vortex centres.

Here, we show that a stable supercrystal phase comprising a 3D ordering of nanoscale domains with tailored periodicities can be engineered in $PbTiO_3/SrRuO_3$ ferroelectric-metal superlattices under tensile strain. A combination of x-ray diffraction, piezoresponse force microscopy, transmission electron microscopy and phase-field simulations reveals a complex hierarchical superstructure, which consists of alternate vertical and horizontal flux closure patterns, and forms in order to minimize the elastic and electrostatic energy. Large local deformations of the ferroelectric lattice are accommodated by periodic lattice modulations of the $SrRuO_3$ layers, presenting a paradigm for engineering correlated materials with tailored modulated structural and electronic properties.

Optimizing Steady-State Negative Capacitance Jorge Iniguez[1,2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]University of Luxembourg, Luxembourg

My group is interested in the behavior of ferroelectric materials that, in particular circumstances, display a persistent voltage drop that opposess the overall applied DC bias; that is, they behave as a static negative capacitance [1]. More precisely, we investigate PbTiO3/SrTiO3 ferroelectric/dielectric superlattices as a convenient model system [2,3], using second-principles simulation methods [2,4] to monitor their behavior as a function of the available control knobs: temperature, applied electric field, epitaxial strain and layer thickness. This allows us to better understand the factors affecting the negative-capacitance response of the PbTiO3 layers, and thus identify strategies to optimize it. In this talk I will review our most recent results, focusing on the possible persistence of negative capacitance down to very low temperatures and the evolution of the differential capacitance as a function of applied electric field.

2:05 PM EL09.02.04
Electric Field Control of Chiral Domains in PbTiO3/SrTiO3 Multilayers Piush Behera[1], Molly May[2], Margaret McCarter[1], Sujit Das[1], Archana Raja[3], Markus Raschke[2] and Ramamoorthy Ramesh[1,1]; [1]University of California, Berkeley, United States; [2]University of Colorado Boulder, United States; [3]Lawrence Berkeley National Laboratory, United States

Chirality, when an object cannot be superimposed on its mirror image, has been seen across a multitude of fields in materials science. From biological molecules to magnetic spin textures, chirality has played a key role in determining the functional properties of such systems. However, it is only recently that the chiral objects have appeared in ferroelectric materials systems. In $PbTiO_3/SrTiO_3$ (PTO/STO) thin film multilayers, boundary conditions set by epitaxial strain from the substrate and paraelectric layers of STO results the continuous rotation of electric dipoles in the PTO layer in the form of polar vortices.[1] Similar to magnetic vortices, the sense of rotation of the dipoles and the orientation of the axial polarization of the vortices can be used to classify them as left-handed or right-handed.[2] Although chirality and topology has been observed in a number of ferroic systems, the manipulation of the sense of chirality with electric fields has remained elusive.
Using second harmonic generation circular dichroism (SHG-CD), we show that these vortices organize together to form chiral domains over length scales of 100s of nanometers. Each chiral domain consists of a multitude of vortex tubes of the same handedness, separated by a mobile chiral boundary. Using in-situ SHG-CD, we map chiral polar vortex domains as a function of in-plane electric field. We show that these domains can be elongated along the field direction, when the electric field is applied along parallel to the vortex tube. Moreover, by applying an electric field along the direction of rotation, we deterministically switched the chirality of the film by translation of the chiral boundary. Ab-initio and phase field simulations were used to show that the chiral switching arises from a reversal in the buckling of these vortices. In addition, piezoforce microscopy studies were performed to relate how the chirality arises from polarization of domains. This work illustrates the

first evidence of chiral switching in any materials system using an applied electric field, and highlights the use of lab-based mesoscopic probes of nanoscale chiral objects.

Effective Ferroelectric Permittivity in Metal-Ferroelectric-Insulator-Semiconductor (MFIS) Heterostructures—The Implications of Hard and Soft Domain Walls Atanu Kumar Saha and Sumeet Gupta; Purdue University, United States

The negative capacitance effect in ferroelectric (FE) based devices has not only attracted a significant research interest due to the possibility of achieving steep switching in transistors [S. Salahuddin et al., Nano let. 8, 2008], but has also intrigued a broader research community aimed at understanding the fundamental origin of such intriguing properties. In a microscopic sense, the ferroelectricity originates from the non-centrosymmetric crystal structure where the spontaneous displacement of atoms (and the corresponding electron gas and ion core) leads to a non-zero spontaneous polarization (P), which yields the minimum energy bi-stable states of the FE. However, in a heterogeneous system (*e.g.* FE-DE-semiconductor or MFIS stack), the value of P is determined by the minimum energy of the whole system rather than the energy of the FE itself. In such systems, the P-induced bound charge in the FE-DE interface induces a depolarization electric field in the FE layer. Such a depolarization effect tends to reduce the P magnitude of the FE layer causing an increase in its free energy. However, in this scenario, the fundamental electrostatics suggests the formation of multi-domain (MD) states that suppresses the depolarization effect without any significant increase in its free energy [A. Kopal et al., Ferroelectrics 223, 1999]. Moreover, the suppression of depolarization and free energy occurs in the cost of gradient energy (which is elastic in nature) due to the P gradient near the domain wall (DW). Therefore, the formation of the MD state appears as an interplay among different energy components for obtaining the minimum energy configuration [A. K. Saha et al., Sci. Rep. 10, 2020].

To investigate the MD state formation and its effect on the effective permittivity of FE, we have developed a phase-field simulation framework for Metal-Ferroelectric-Insulator-Metal (MFIS) heterostructure by self-consistently solving the Ginzburg-Landau equation, Poisson's equation, and semiconductor charge equations [A. K. Saha et al., Sci. Rep. 10, 2020] . According to our analysis, the applied voltage-driven P switching in the MD state is strongly dependent on the features of its DW. This further depends on the elastic, electrostatic, and physical properties of the FE layer and the dielectric/semiconductor layers that it interacts with. We show that, in the case of low elastic coupling (low gradient energy coefficient), the types of DWs are hard and the domain density depends on material parameters and physical dimensions of the heterostructure. In the hard DW regime, P-switching is hysteretic and can take place as a combination of domain nucleation and DW motion. During such a P-switching, the effective permittivity of FE becomes negative. However, even without P-switching (with voltages < coercive voltage), the effective permittivity of the FE layer can increase (but remain positive) due to the electrostatic interactions among domains. This effect is more dominant when the domain density is large. As the domain becomes denser, the effective permittivity keeps increasing within the limit of hard-DW. On the other hand, for a sufficiently high elastic coupling (high gradient energy coefficient), the DW can become soft and the corresponding soft domain-wall displacement leads to non-hysteretic characteristics. In such a scenario, the effective permittivity of the FE layer becomes negative in a non-hysteretic fashion.

6:30 PM *EL09.03.01

Negative Capacitance in HfO_2 Based Ferroelectric Materials Michael Hoffmann[1,2], Stefan Slesazeck[1] and Thomas Mikolajick[1,3]; [1]NaMLab gGmbH, Germany; [2]University of California, Berkeley, United States; [3]Technische Universität Dresden, Germany

The feasibility of ferroelectric negative capacitance devices for ultra-low power electronics hinges on the availability of materials which are scalable and compatible with established semiconductor manufacturing technologies. Ferroelectrics of fluorite-structure based on the binary oxides HfO_2 and ZrO_2 fulfill both of these criteria. Recently, negative capacitance was observed in HfO_2 based ferroelectrics using pulsed electrical measurements. However, relatively large applied voltages have been necessary to observe negative capacitance in this material system so far. To move towards applications in negative capacitance devices, much lower operating voltages are needed. Furthermore, the microscopic domain dynamics underlying the negative capacitance effect in HfO_2 based ferroelectrics is still not understood, which hampers physical modeling and device design. Here, we discuss the available experimental data and outline pathways to move towards improving our understanding of negative capacitance in HfO_2 based ferroelectrics and prospective applications.

6:55 PM EL09.03.02

Differential Charge Boost in Hysteretic Ferroelectric-Dielectric Heterostructure Capacitors at the Steady State Nujhat Tasneem[1], Prasanna Venkatesan Ravindran[1], Zheng Wang[1], Jorge Gomez[2], Jae Hur[1], Shimeng Yu[1], Suman Datta[1] and Asif Khan[1]; [1]Georgia Institute of Technology, United States; [2]University of Notre Dame, United States

The ferroelectric (FE)-dielectric (DE) heterostructure is one of the commonly used model systems to probe negative capacitance effects.[1,2] In such a system, the change in charge due to a change in source voltage can be larger than the change in charge when the same change in source voltage is experienced only by the constituent DE capacitor. Such a differential charge boost, when achieved without a hysteresis, can lower the power supply voltage and the energy dissipation in a negative capacitance field-effect transistor (NCFET). However, there is an ongoing debate on whether the charge boost in such a heterostructure is a transient phenomenon or a steady state one.

According to a transient model[3] of ferroelectric negative capacitance, the charge boost in an FE-DE capacitor is a consequence of (1) the mismatch between the time scales for polarization switching and the screen charge dynamics in the FE, and (2) a charge imbalance between the FE and the DE. The change in the DE charge, $\triangle Q$ in such a scenario is expected to be larger than $C_{DE}\triangle V$ resulting in the so-called charge boost. The fundamental aspect of the transient model is that as the screening charges balance out the polarization charges, the boost in both V_{FE} and Q diminishes to values that are expected from a series combination of two positive capacitors, thereby leading to charge boost only in transience. Hence, $\triangle Q$ will be larger than $C_{DE}\triangle V$ only for a short amount of time. Whereas, if the charge boost was in fact a steady state response, then the charge boost stemming from it will prevail for the entire duration of the voltage pulse. Hence, the key test for transient and steady state model of negative capacitance is as follows: for a given change in voltage $\triangle V$, is the charge supplied by the voltage source to a FE-DE capacitor $\triangle Q$ larger than $C_{DE}\triangle V$ only for a short duration of time (transient state) or an extended period of time (steady state)?

To answer this question, we present an experiment that tests the nature of the charge boost: steady-state or transient. To that end, we study a ferroelectric-dielectric (FE-DE) heterostructure with FE $Hf_{0.5}Zr_{0.5}O_2$ (10nm) and DE HfO_2 (5nm). We adopt a modified form of the well-known, positive up negative down (PUND)

technique where 'long' voltage pulses are applied on the FE-DE capacitor to measure its polarization vs voltage (P-V) characteristics. We find that the device under test (DUT) exhibits a differential charge boost of steady-state nature i.e., the charge boost remains intact after the initial transient effects subside and all the voltages in the system reach constant values and steady states. A SPICE-based model of the system that accounts for the multi-domain polarization switching dynamics in the FE-DE stack was also used to verify our experimental results.

In summary, the results obtained from the modified PUND measurement technique on an FE-DE structure reveals that the charge boost in a hysteretic FE-DE structure is prevalent for the entire pulse duration and hence a steady state response. The experimental results match with the predictions based on a multi-domain ferroelectric model eliciting the importance of domain dynamics in obtaining the ideal stabilized negative capacitance. Investigating NCFETs and NC Capacitors using this method will provide more insights into the charge dynamics of the systems which can be used to advance the designs and study the physics of these devices.

Can NCFET Work as Steep-Slope Device for Ultralow-Power Logic Applications? Qianqian Huang, Mengxuan Yang, Chang Su, Huimin Wang and Ru Huang; Institute of Microelectronics, Peking University, China

Power dissipation is one of the most critical issues for nanoelectronic circuits. For low-voltage and low-power logic applications, novel steep-slope device concepts, which can break the fundamental limitation of subthreshold swing (SS) in MOSFETs (60mV/dec at room temperature), have attracted lots of attention. By utilizing the voltage amplification effect induced by the negative capacitance (NC) in the gate stack, the ferroelectric FET (FeFET) also has the capability of sub-60 SS, which is considered as NCFET. However, the NC effect in ferroelectric film has aroused great scientific controversy due to its unclear physical picture and lacking of direct experimental evidence.
Here we experimentally observed the NC effect in HfO2-based ferroelectric film and systematically studied its fundamental physics from the perspective of material features including both relaxation polarization and transient polarization. Different from the stabilized NC, the observed NC effect of HfO2-based FE material in this work is not a steady but a dynamic behavior, which is very sensitive with sweeping voltage and can be existed only under an extremely stringent operating frequency range. Moreover, even under this required frequency range, it is found that the SS of NCFET will inherently degrade with the increased gate voltage, which is not preferred for low-voltage logic operation.
Besides, it is found that the hysteresis theoretically exists, and there is an intrinsic optimization conflict between SS and hysteresis, which is a big challenge for logic applications. In addition, the hysteresis shows a strongly non-monotonic dependence on voltage sweeping rate, coupled with sweeping range, and can be even larger than the hysteresis of standalone FE capacitor for high-frequency applications. The possibility of NCFET as a steep-slope device for high-speed and low-voltage logic operation needs to be carefully re-assessed.

Enhancement and Origin of Intrinsic Transient Negative Capacitance During Ferroelectric Switching
Bin Xu[1,2], Sergey Prosandeev[2,3], Charles Paillard[4,2] and Laurent Bellaiche[2]; [1]Soochow University, China;

[2]University of Arkansas–Fayetteville, United States; [3]Southern Federal University, Russian Federation; [4]Université Paris-Saclay, France

The reversal of polarization in a ferroelectric material involves overcoming an energy barrier and has been previously proposed and found to yield transient negative capacitance (NC) in the intermediate states of the switching process [1-3]. Homogeneous switching was assumed to interpret the experimental results of NC; however, inhomogeneous switching is a more abundant mechanism than homogeneous switching, but its possible effect on NC is basically unknown. Here, we use first-principles-based effective Hamiltonian techniques to investigate the occurrence of NC during these two types of switching processes in the super-tetragonal phase of $BiFeO_3$, which can be realized by changing the magnitude of the electric field. We find NC in both cases, but with the magnitude of the inverse of the capacitance being drastically larger in the inhomogeneous (nucleation limited) switching, as compared to the homogeneous switching. We further analyze the origin of the different NC effects, and point to the different energetic trajectories between these two representative switching mechanisms [4]. In addition, we derive analytical formulas and show that the capacitance can be negative under perfect screening conditions and for very different materials and switching mechanisms [5].

Stability and Room Temperature Deposition of Ferroelectric Phase in Y-Doped (Hf, Zr)O_2 Films Hiroshi Funakubo[1], Takanori Mimura[1], Reijiro Shimura[1], Yoshiko Nakamura[1] and Takao Shimizu[1,2]; [1]Tokyo Institute of Technology, Japan; [2]National Institute for Materials Science, Japan

A discovery of ferroelectricity in doped HfO_2 films opens the door of the device application using very thin ferroelectric films because stable ferroelectricity is maintained below 10 nm even in polycrystalline films. We

demonstrate the fundamental understanding of HfO_2-based ferroelectric films using epitaxial films[1-8]. In addition, we demonstrate 1 mm-thick ferroelectric films that are useful for the piezoelectric applications[9-10]. Various devices including ferroelectric memories, ferroelectric tunnel junction, and piezoelectric transistors have been investigated. For these device applications, low temperature deposition of ferroelectric films is highly required to reduce the reaction between the film and the underlying layers.
In this study, we demonstrate the room temperature deposition of Y-doped (Hf, Zr)O_2 films by sputtering method[7]. Room temperature-deposited films showed almost similar ferroelectricity with the post heat-treated one above 800 ºC. In addition, wide variety of composition show the ferroelectricity even for the films deposited at room temperature. In my presentation, we discuss the determination factors for the room temperature deposition.

9:25 PM DISCUSSION TIME

9:40 PM EL09.04.04
Late News: Domain Patterns and Super-Elasticity of Freestanding BiFeO3 Membranes via Phase-Field Simulations Ren-Ci Peng[1], Xiaoxing Cheng[2], Bin Peng[1], Ziyao Zhou[1], Long-Qing Chen[2] and Ming Liu[1]; [1]Xi'an Jiaotong University, China; [2]The Pennsylvania State University, United States

Super-elasticity of functional ferroelectric oxides offers promises for integrating ferroelectric films into flexible electronics. However, super-elastic deformation is a complex phenomenon related to possibly multiple concurrent mechanisms. Fundamentally understanding how multiple mechanisms contribute to the super-elasticity of ferroelectric oxides is crucial to realizing their potential flexible electronic applications. Here, we employ phase-field simulations to model the dynamics of ferroelectric domain patterns of freestanding $BiFeO_3$ membranes to understand the origin of their super-elasticity under substantial bending deformation (5% strain). It is demonstrated that both a reversible Rhombohedral-Tetragonal (R-T) phase transition and a nearly reversible domain evolution of $BiFeO_3$ membranes contribute to accommodating the large deformation and thus their super-elasticity. The dynamics of domain evolution also reveal the formation of an exotic ferroelectric vortex and polarization rotation before the phase transition. We constructed a diagram of phases and domain patterns as a function of the membrane thickness and bending angle, which allows one to readily predict the emergence of T phase and ferroelectric vortex in bent BFO membranes. These results not only provide fundamental understanding of mesoscale super-elastic mechanisms but also reveal exotic domain states of ferroelectric membranes.

Exploring Mixed-Cation Niobates for High-Performance Dielectric Nanocapacitors Seunghyun V. Oh, Woohyun Hwang and Aloysius Soon; Yonsei University, Korea (the Republic of)

With the increasingly high demand for high-performance dielectric nanocapacitors in electronics and energy storage devices, huge research efforts have been placed in developing high-performance multilayer ceramic capacitors (MLCCs) with a particular focus on advanced functional nanomaterials design and development. In

particular, the search for lead-free, low-loss ferroelectric oxides are considered as one of the most promising material candidates for this technology. In this study, using first-principles density-functional (perturbation) theory calculations, we investigate the influence of A-site alloying in potassium niobate, (K,A)NbO_3 on its optoelectronic, polarization, and dielectric properties, where A = Li, Na, Rb, and Cs. Using the special quasi-random structure model, we consider various alloy compositions of (K,A)$NbO_3$and examine their mixing thermodynamics before moving on to characterizing their polar properties, establishing specific structure-property design rules for high-performance dielectric oxides. Together with complementary experimental findings, our work underscores the importance of how cation-exchange in these lead-free ferroelectrics on neoteric MLCC materials.

Negative Capacitance in Copper-Chlorine Boracite Joseph Guy[1], Charlotte Cochard[2], Roger Whatmore[3], Amit Kumar[1], Ray McQuaid[1] and Marty Gregg[1]; [1]Queen's University Belfast, United Kingdom; [2]University of Dundee, United Kingdom; [3]Imperial College London, United Kingdom

During switching, the microstructure of a ferroelectric normally changes to best align internal dipoles with externally applied electric fields. Dipolar regions (domains), that are favourably oriented, grow at the expense of those in unfavourable orientations and this is manifested in a predictable field-induced motion of the walls that separate one domain from the next. In copper-chlorine boracite, however, we have discovered that head-to-head charged 90º domain walls move in the opposite direction to that expected: the polarisation that is anti-aligned with the applied electric field increases as a result of the field-induced wall movement. Polarisation-field (P-E) hysteresis loops, associated with the movement of these walls, hence show negative gradients throughout the entire P-E cycle. Negative capacitance is therefore implied. We have measured switching currents, generated by the relative motion between domain walls and sensing electrodes, by employing charge gradient microscopy. Such measurements reveal that the signs of the switching currents are opposite to those expected conventionally. Moreover, the switching current behaviour can be analysed to allow the negative capacitance component to be extracted and probed as a function of frequency.

8:40 AM EL09.05.02
Electro-Mechanical Control of Ferroelectric Domains in $PbZr_{0.20}Ti_{0.80}O_3$ Sergio Gonzalez Casal[1,2], Xiaofei Bai[1], David Albertini[1], Nicolas Baboux[1], Bertrand Vilquin[1], Pedro Rojo-Romeo[1], Solene Brottet[1], Matthieu Bugnet[2], Ingrid Cañero Infante[1] and Brice Gautier[1]; [1]Institut des Nanotechnologies de Lyon, France; [2]MATEIS, France

The control of ferroelectric domains and domain walls is the basis of a promising approach to imagine novel electronic devices. While the control of ferroelectric domains by the application of an electric field has been extensively studied, the application of a mechanical load and its consequences over the ferroelectric properties have been seldomly explored. Mechanical switching of ferroelectric domains by the application of a local stress has already been observed [1], however a complete explanation of the phenomena involved in the process may depend on the properties of the material studied. In order to propose a complete description of the mechanisms at play during switching, flexoelectricity has to be taken into account [1] in addition to piezoelectricity, which is a common property of all ferroelectrics, and along with ferroelasticity [2] and electrochemistry [3].

In this contribution, we apply a mechanical stress by pressing the surface with the tip of an atomic force

microscope. We show that mechanical switching in sol-gel grown ferroelectric $PbZr_xTi_{1-x}O_3$ (x=0.2) thin films is possible under different conditions of mechanical stress up to large thicknesses (200 nm). We vary the experimental conditions that allow effective mechanical switching of layers of different thicknesses, and combine electrical and mechanical switching to modify the threshold force needed to switch the polarization. The results are supported by the cross-sectional observation of the films by scanning transmission electron microscopy (STEM), which brings information about the nanoscale structure and chemistry of the films.

Our results suggest two ways of controlling the threshold force. Firstly, the prior application of an electric field would modify the value needed to switch domains mechanically. This effect is probably due to charge trapping that decreases the magnitude of the electric field created by the applied stress. Secondly, the mechanical switching is affected by the presence of nanometer-scale cavities within the sample, either aligned in specific regions of the film or randomly distributed as evidenced by STEM images, which modify the boundary conditions of the domains created by mechanical stress and their stability. The combination of both external electrical field and cavities tends to show that it is actually possible to tune the force threshold to suit the desired purpose. We will discuss these results with the aim to provide a larger understanding of means to exploit the mechanical switching in integrated ferroelectric devices. [4]

8:55 AM EL09.05.03
Free-Standing Ferroelectric Oxide Superlattices Yaqi Li[1], Edoardo Zatterin[1,2], Alexander Björling[3], Michele Conroy[4], Kalani Moore[4], Adam Clancy[1], Sungmyung Kang[1], Marios Hadjimichael[1], Dirk Groenendijk[5], Edouard Lesne[5], Anastasiia Pylypets[6], Fedir Borodavka[6], Andrea Caviglia[5], Jiri Hlinka[6], Ursel Bangert[4], Steven Leake[2] and Pavlo Zubko[1]; [1]University College London, United Kingdom; [2]European Synchrotron Radiation Facility, France; [3]Lund University, Sweden; [4]University of Limerick, Ireland; [5]Delft University of Technology, Netherlands; [6]The Czech Academy of Sciences, Czechia

Ferroelectric oxide thin films and superlattices have attracted broad interest on account of their novel physical and functional properties. The strong coupling between strain and polarization in these materials allows mechanical and electrical boundary conditions to be utilized to induce novel polar phases, unusual polarization textures and surprising behaviour, as exemplified by the negative capacitance phenomenon. In such heterostructures, an epitaxial strain is usually induced through a lattice-parameter mismatch between the epitaxial layers and a monocrystalline substrate. This substrate-imposed strain is an invaluable tool, which plays a crucial role in determining the domain structures and the resulting properties; however, it also presents significant limitations to accessing a wealth of yet unexplored phase transitions in complex oxide heterostructures and hinders their applications in flexible electronics and integration in semiconductor electronic circuits.

With the development of new methods for releasing thin films from the underlying substrate, free-standing complex oxide heterostructures become excellent candidates to explore and harness the full potential of strain engineering. In this work, ferroelectric-dielectric superlattices with ordered nanoscale domains were released from the substrate, allowing the thin-film oxide components to share the strain elastically with each other. The free-standing superlattices were studied with a combination of laboratory and synchrotron x-ray diffraction, piezoresponse force microscopy, transmission electron microscopy and Raman spectroscopy. Our measurements show that the spatial distributions of strain are introduced, which lead to the three-dimensional deformation of films. The released superlattices adopt a new, complex polarisation structure with an unexpected

local anisotropy, which is correlated with the local film curvature.

9:10 AM EL09.05.04
Giant Piezo-Driven Magnetoelectric Coupling in (011) PMN-PT Membrane Heterostructures Shane Lindemann[1], Julian Irwin[1], Gi-Yeop Kim[2], Kitae Eom[1], Bo Wang[3], Jianjun Wang[3], Jiamian Hu[1], Long-Qing Chen[3], Si-Young Choi[2], Chang-Beom Eom[1] and Mark S. Rzchowski[1]; [1]University of Wisconsin–Madison, United States; [2]Pohang University of Science and Technology, Korea (the Republic of); [3]The Pennsylvania State University, United States

Relaxor ferroelectrics, such as (1-x)Pb($Mg_{1/3}Nb_{2/3}$)O_3-(x)$PbTiO_3$ (PMN-xPT), exhibit giant piezoelectricity which arises from the presence of multiple symmetries near a Morphotropic Phase Boundary (MPB). The MPB in PMN-xPT lies around x = 35% and separates a Rhombohedral (R) phase, with spontaneous polarization along the <111> crystallographic directions, from a Tetragonal (T) phase whose polarization lies along <100>. For compositions near the MPB, the presence of bridging Monoclinic (M) and Orthorhombic (O) phases help to facilitate large lattice distortions as the spontaneous polarization rotates between the competing symmetries in order to align with the applied field.
Bulk studies using (011) oriented PMN-PT single crystals have been used to demonstrate non-volatile 71/109 degree switching between in-plane and out-of-plane R polarization directions. Such switching can result in distinct strain states and forms the basis of low-power, ultrafast, memory storage devices when coupled with a ferromagnetic (FM) material [1,2]. Achieving low power, however, necessitates the use of thin films of PMN-PT. Additionally, the films must be removed from their substrates in order to prevent substrate clamping that eliminates their giant piezoelectricity. Here we demonstrate growth of epitaxial (011) PMN-PT thin films, followed by removal of the substrate via etching of a sacrificial layer. By coupling with a FM Nickel overlayer, we achieve manipulation of in-plane magnetic anisotropy under 3V applied bias across the PMN-PT film, which is much lower than the >100V needed using bulk PMN-PT. However, we do not see evidence of the 71/109 degree switching as observed in the bulk studies. Instead we find that the piezo-driven coupling is dominated by polarization rotation from the nominally <111> oriented R state towards the [011] O state along the applied field direction. Our findings have significant implications on the design of strain-mediated devices based on relaxor-ferroelectrics such as PMN-PT.

9:25 AM *EL09.05.05
Complex Polarisation Texture and Emergent Functionalities at Twin Domain Crossings in Ferroelectric Thin Films Patrycja Paruch; University of Geneva, Switzerland

Ferroelectric materials can host a wider range of novel functional properties as well as unusual structural features, potentially useful for nanoelectronics applications. At domain walls or in regions with high strain gradients, in particular, the complex interaction between polarisation, electrostatics, and strain can lead to localised chiral polarisation textures, electrical conductivity, and charge or chemical segregation. One promising highly strained structure is the intersection between ferroelastic twins.

In Pb(Zr0.2Ti0.8)O3 thin films, investigating such twin domain intersections with a combination of scanning probe microscopy and nonlinear optical microscopy, we find a characteristic localised piezoelectric and response and evidence of a more complex rotational or closure structure in second harmonic generation polarimetry analysis. The heart of the twin domain crossing presents an extremely high susceptibility to local application of electric bias or pressure, dominating the polarisation switching dynamics in this region. We also observe distinct mechanical properties and enhanced electrical conduction at the intersection.

Domain Switching and Imprint in Ferroelectric HfO_2 Capacitors Alexei L. Gruverman; University of Nebraska, United States

Application of HfO_2-based films to ferroelectric memory and logic devices has generated considerable interest as they allow overcoming significant problems associated with poor compatibility of perovskite ferroelectrics with CMOS processing. However, detailed studies of such application-relevant properties as imprint and polarization switching dynamics with respect to the electrode material and processing condition are still sparse. Here, we use a combination of Piezoresponse Force Microscopy (PFM) and pulse switching techniques to analyze the time- and field-dependent evolution of the domain structure in HfO_2-based thin film capacitors. Switching spectroscopy-PFM (SS-PFM) maps revealed the electrode-dependent spatial variations in the local potential landscape, which strongly affect the domain switching kinetics. It is shown that stronger oxidation reduces the internal imprint bias while also leading to an increase in the remanent polarization. Development of "fluid imprint" determined by the sample switching pre-history is reported. A particularly slow polarization reversal in the absence of an external field - termed as inertial switching - due to the interface entrapment of the charge injected during pulse application is shown to have a strong impact on polarization retention.

10:55 AM DISCUSSION TIME

11:10 AM EL09.06.03
Transient Negative Capacitance Behaviour in Constant Series R-C FETs Ashwani Kumar, Xiaoyao Song and Maria M. De Souza; The University of Sheffield, United Kingdom

Current research effort in transient negative capacitance phenomena is focussed on attempts to separate out the components arising from change in polarisation (dP/dt) in a Ferroelectric material from circuit components such as those expressed by the Miller model [1][2]. The phenomenon of transient negative capacitance, despite having completely disparate origins in the case of multi-domain as opposed to single-domain ferroelectric, remains closely interlinked with negative capacitance as governed by the Landau-Khalatnikov (LK) equation [3]. The single-domain regime, which is governed by the LK equation, can be expressed by a series R-C circuit in parallel with an oxide capacitor Cox, where C is non-linear and can attain negative values for a certain range of polarisation. In contrast, the multi-domain approximation is modelled by the Kolmogorov-Avrami-Ishibashi (KAI) model, which utilises a time-dependent polarisation [4] or the Miller model [5], which akin to the LK framework, can be equivalently described as a series R-C circuit. However, C in the Miller model remains strictly greater than 0. In different variations of such models at least one of the elements between R and C is always considered non-linear (with respect to polarisation) [6] to help explain the steep switching behaviour. Here we establish that the phenomenon of transient negative capacitance can be considered to be more general than reported earlier. We demonstrate the conditions for sub-60 mV/dec switching in an RC-FET, even if the R and C were constant. The voltage dropped across an equivalent series RC circuit can be represented as $Vox=R(dQ_{ch}/dt)+(Q_{ch}/C)$, where V_{ox} and Q_{ch} are the voltage across gate dielectric and sheet charge density in the channel, respectively. This leads us to the necessary condition for achieving a body factor $m<1$ along both forward and backward sweeps. However, when combined with the semiconductor charge $(dQ_{ch})/(d\Psi_s)=(q/(k_BT))Q_{ch}$, where Ψs is the surface potential, it is seen that sub-60 mV/dec switching is possible only if $Qch >0$ (i.e. when the transistor is ON) during the backward sweep. We believe this insight contributes further understanding to the causes of hysteresis in commonly used SPICE models of FE-FETs.

Dynamics Studies of Ferroelectric Switching on Hafnium Zirconium Oxide Peide P. Ye; Purdue University, United States

In this work, we present the first experimental determination of nucleation time and domain wall (DW) velocity by studying switching dynamics of ferroelectric (FE) hafnium zirconium oxide (HZO) according to the nucleation limited switching (NLS) model in ferroelectricity. Experimental data and simulation results were used to quantitatively study the switching dynamics. The switch speed can be degraded in high aspect ratio devices due to the longer DW propagation time or with dielectric interfacial layer due to the required additional tunneling and trapping time by the leakage current assist switch mechanism. The work is in collaborations with Xiao Lyu, Mengwei Si from Purdue University, Pragya R. Shrestha, Kin P. Cheung from NIST, Panni Wang, Shimeng Yu from GaTech.

11:50 AM EL09.06.05
Late News: Interplay of Negative Quantum Capacitance and Negative Ferroelectric Capacitance for Low-Power Transistor Operations Karpur Shukla, Meng-Ju Yu and Jimmy Xu; Brown University, United States

Since the initial proposal [1] of using ferroelectric negative capacitance to realize voltage transform for low-power transistors, substantial theoretical and experimental progress has been made in determining their fundamental properties and realizing negative capacitance transistors with improved device characteristics. Nevertheless, substantial gaps remain between observed performance and model expectations.

Most pressingly, model analyses [2,3] seem to imply substantial limits on the ability of ferroelectric negative capacitance to improve the subthreshold swing of well-designed transistors. Due to the small subthreshold gate capacitances of well-designed transistors, these models suggest that negative capacitance enhanced lowering of the subthreshold swing is only achievable with rather thick ferroelectric layers, at scales impractical for large-scale integration.

A central conclusion of these models is that the design space of negative capacitance FETs is constrained largely by the quantum capacitance of the channel, and thus that lowering the quantum capacitance of the channel allows for an expanded design space. In doing so, these models make the implicit assumption that the quantum capacitance of the channel remains positive. However, lowering the quantum capacitance exposes the channel to the prospect of negative *quantum* capacitance [4], itself a phenomenon of interest in enhancing low-power electronic device operation. Negative quantum capacitance can arise [5] in channels with strong electron correlation effects at a low electron density in a number of materials, including silicon.

Here, we discuss the effects of negative quantum capacitance in FET channels on the operations of ferroelectric negative capacitance FETs. In particular, we find that for small negative quantum capacitance values, the subthreshold swing begins exhibiting hysteresis. While hysteresis could be desirable in some neuromorphic applications, it puts a lower limit on the density of charge carriers in the channel for conventional low-power electronics. However, we further find that for larger magnitudes of the negative quantum capacitance, hysteresis

again disappears from the subthreshold swing. This adds a new region of design space to the fundamental model of ferroelectric negative capacitance FETs. We discuss the specific regime at which large negative quantum capacitance can provide steep-slope subthreshold switching, and examine the implications for ferroelectric negative capacitance FET design.

Switchable Photovoltaic Properties in PZT Epitaxial Thin Films Komalika Rani, Stéphane Gable, Thomas Maroutian, Philippe Lecoeur and Sylvia Matzen; Université Paris-Saclay, France

Epitaxial ferroelectric thin films are currently investigated for their potential in photovoltaic (PV) applications [1], mainly because of their large open circuit voltage and switchable photovoltaic effect. Indeed, in a ferroelectric film, the sign of the photovoltaic current can be controlled by the direction of the ferroelectric polarization, allowing in theory to achieve a 100% switchability of the photocurrent with the polarization, which is of great interest for potential applications, as photoferroelectric memories. However, switchability is not always achievable in integrated ferroelectric films between electrodes, because of extrinsic parameters, such as the nature of the electrode-ferroelectric interface (Schottky barrier) [2] or the amount of non-mobile charged defects. In addition, switchable photocurrent can also be affected by the migration of charged defects, such as oxygen vacancies, under applied electric field [3]. So, disentangling the impact of defects, electrodes, and polarization on the PV properties is not an easy task.
In this work, a careful study of the switchability of the PV properties of epitaxial lead zirconate titanate (PZT) thin films has been conducted in order to investigate the role played by the ferroelectric polarization. 100 nm thick PZT films were grown using pulsed laser deposition (PLD) and integrated in capacitor geometry between $SrRuO_3$ bottom and Pt top electrodes and the photoinduced current in the PZT devices were studied under UV illumination (above the PZT band gap), in different polarization states. A voltage pulse protocol was used to pole the device under increasing electric fields to reach different electrical states while measuring their polarization value. These results revealed the critical role of the depolarizing field as the driving force for the photocurrent and allowed us to extract to screening efficiency of electrodes. In addition, the contribution from electrode-ferroelectric interface was evidenced for particular photon energy, especially with ITO top electrodes.

Origin of the Ferroelectric Response in the Sr(Nb,Ta)O_2N Oxynitrides Juan S. Gelves Badillo[1], Aldo Romero[2,3] and Andres C. Garcia Castro[1]; [1]Universidad Industrial de Santander, Colombia; [2]West Virginia University, United States; [3]Benemérita Universidad Autónoma de Puebla, Mexico

Heteroanionic materials have recently positioned in the center of multiple investigations. The latter is motivated by the physical, optical, and chemical properties that can emerge when properly combining different, but compatible anions, within the same compound. Oxynitride perovskite compounds have shown to offer a wide range of different tunable properties depending on the O/N rate, for instance, the absorption of light in the visible regime makes them ideal candidates for photocatalysis applications where polar compounds offer a notable advantage [1].
In this study, we theoretically explored the origin of the polar and ferroelectric responses experimentally observed in perovskite oxynitrides $SrNbO_2N$ and $SrTaO_2N$ [2,3]. With this aim, first-principles calculations of the structural and vibrational properties were performed. We show that such ferroelectric behavior is extremely sensitive to the anionic ordering in both Sr(Nb,Ta)O_2N systems, where *cis*- and *trans*- orderings are identified as the most probable orderings in the crystals. Furthermore, We found that both *cis*- and *trans*- type can hold ferroelectricity, although the mechanisms in how such a stable phase emerges in each ordering are quite different. Aditionally, we show that spontaneous polarization characterizing such ferroelectric phases can be considerably enhanced by applying in-plane epitaxial strain, achieved by using strontium titanate as substrate.

Theoretical Investigation of the Electronic Properties of Ruddlesden-Popper Oxynitrides $Sr_2AO_{4-x}N_x$(A=Nb, Ta)(x=0.5, 1) Juan A. Pinto Castro and Andres C. Garcia Castro; Universidad Industrial de Santander, Colombia

In condensed matter, Ruddlesden-Popper (RP), considered as an intergrowth of n-layers ABX_3 perovskites with an AX layer with structure: $(AO)(ABO_3)$ have attracted a lot of attention due to their potential applications. As such, perovskites-like materials are notably at the vanguard of technological developments thanks to their versatility offered by the partial substitution of anionic sites as in the case of oxygen replacement by nitrogen sites (i.e. oxynitrides). These substitutions possible due to the similarities in electronegativity, polarizability, ionic radius, and coordination states and bringing modifications of their physical properties such as electrical, optical, catalytic, and magnetic responses [1]. Therefore, the study and research on new RP oxynitrides phases constitute an area of huge interest.

Here we present significance outcomes due to partial substitution of nitrogen for oxygen in structures $Sr_2AO_{4-x}N_x$(A=Nb, Ta)(x=0.5, 1), that show symmetry inequivalent structures that I have analyzed, These structures are more stable thermodynamically compared with oxides and nitrides structures, and the most stable is a trans-type configuration structure. The direct bandgap is reduced to benefit the performance of photocatalysis. Likewise, by researching the relationship of vibrational behaviour of trans-type configuration, it becomes evident that these RP-phases hold a ferroelectric response.

First-principles calculation reveals that strontium oxynitrides RP-phases are strongly correlated materials due to underestimation in the bandgap. So we have used, instead DFT, DFT+U for consistent results.

Dielectric Anomalies and Magnetodielectric Effect in Layered Perovskite-Type $Pr_2Ti_2O_7$ Single Crystal

Moein Adnani[1], Liangzi Deng[1], Melissa Gooch[1], Huiyuan Man[2], Alireza Ghasemi[2], Collin Broholm[2,2], Seyed Mojtaba Koohpayeh[2,2] and Ching-Wu Chu[1,3]; [1]University of Houston, United States; [2]Johns Hopkins University, United States; [3]Lawrence Berkeley National Laboratory, United States

The ternary oxides of the compound family with the general formula $A_2B_2O_7$, where A is a trivalent cation and B is a transition metal, have been widely studied because of their interesting physical properties and their technological applications. Among the relatively less explored members of this family are the rare-earth titanates ($RE_2Ti_2O_7$), which have a monoclinic layered perovskite-type structure and have been of interest for their ferroelectric, piezoelectric, non-linear optical, and photocatalytic properties and their high Curie temperature. Here we present our low-temperature dielectric study of high structural quality, stoichiometric single-crystal $Pr_2Ti_2O_7$. This compound has a monoclinic polar crystal structure ($P2_1$) that consists of four layers of corner-sharing TiO_6 octahedra separated by two layers of Pr cations. We will review the crystal structure and some of the magnetic and ferroelectric properties of the compound. We will then discuss our dielectric and magnetodielectric results, in particular the field-dependent anomalies in the dielectric constant and the mutual coupling between dielectric properties and magnetization in this compound.

The work in Houston is supported by US Air Force Office of Scientific Research Grants FA9550-15-1-0236 and FA9550-20-1-0068, the T. L. L. Temple Foundation, the John J. and Rebecca Moores Endowment, and the State of Texas through the Texas Center for Superconductivity at the University of Houston.
