Two-dimensional metal carbides and nitrides, known as MXenes, are the largest and yet quickly expanding family of 2D materials. Their diverse electronic, optical, and electrochemical properties have already distinguished them from other 2D materials. MXenes are produced by selective etching processes in which A layer atoms (i.e., Al, Si, Ga, etc.) are chemically removed from layered ceramics known as MAX phases or related layered carbides. MXenes have a general formula of $M_{n+1}X_nT_x$ where M is a transition metal (i.e., Ti, V, Nb, Mo, etc.), X is carbon and nitrogen, n can be from 1 to 4, and T_x indicates to presence of mixed surface terminations (O, OH, Cl, F, etc.) on the surface of outer transition metal layers of MXenes. MXenes can also contain two or more transition metals in the M sites in a random solid solution (such as $(Ti,V)_2CT_x$) or ordered (in-plane or out-of-plane, such as $Mo_2TiC_2T_x$) structure, which further expands their range of compositions and therefore, properties. The surface functional groups of MXenes provide them with chemical stability and control their electronic properties. Titanium carbide MXene, $Ti_3C_2T_x$, has metallic conductivity reaching over 15,000 S cm^{-1}, while some other MXenes showed 2-3 orders of magnitude lower values. The tunable electronic properties of MXenes along with their high mechanical stiffness (Young's modulus reaching ~0.4 TPa for $Nb_4C_3T_x$ MXene) and high bending rigidity as well as rapid ion-transport properties, redox-active surfaces, tunable electrochemical and optical properties have rendered these materials as promising candidates for various high-tech applications such as transparent conductive electrodes (TCE) for organic light-emitting diodes, smart and conductive textiles for sensing and energy-storing wearable devices, thin-film transistors, biomedical and biosensing, photovoltaics, and high energy and power density supercapacitors. Herein, we aim to discuss synthesis of MXenes, as well as effect of synthesis process parameters on surface chemistry and properties. Scalability of MXene synthesis and its processing from aqueous solutions by a variety of techniques will be addressed in detail.

AFM Additive Nanopatterning on Ionic Liquid Monolayer-Decorated Surfaces by Combined Mechanical and Electrical Stimuli Zixuan Li[1], Filippo Mangolini[1], Jerzy Sadowski[2], Raluca I. Gearba[1], Karalee Jarvis[1], Oscar Morales-Collazo[1], Andrei Dolocan[1] and Joan F. Brennecke[1]; [1]The University of Texas at Austin, United States; [2]Brookhaven National Laboratory, United States

The development of direct-write nanopatterning approaches enabling the accurate and reliable production of nanoscale architecture is critical for exploiting the unique functionalities of materials at reduced length scales. In the last few decades, several atomic force microscopy (AFM) lithography techniques, which use a sharp probe to write on a solid surface, have been developed as cost-effective methods for patterning with nanoscale resolution. Common AFM lithography techniques usually exploit the meniscus formed around the tip-substrate contact to dissolve and transfer the reactants for surface patterning. This mechanism can be problematic in large scale production due to the restricted ink capacity, as well as the inconsistency in the transfer process by varying experimental and environmental factors. Here we highlight a new AFM patterning method with which an adsorbed ionic liquid (IL) monolayer on the substrate will be used as the ink material. The unique interfacial properties of ILs combined with electrical and mechanical stimuli can realize nanoscale patterning without the reliance of the meniscus for ink transfer. The chemical nature and physical properties of the deposited material will be evaluated.

Rational Synthesis and Assembly of Transition Metal Dichalcogenide Nanocrystals with Tunable Optical Properties Tomojit Chowdhury[1], Erick Sadler[1], Kiyoung Jo[2], Todd Brintlinger[3], Deep M. Jariwala[2] and Thomas J. Kempa[1]; [1]Johns Hopkins University, United States; [2]University of Pennsylvania, United States; [3]U.S. Naval Research Laboratory, United States

Reducing the dimensionality of semiconducting transition metal dichalcogenides (TMDs) substantially alters their physical properties. Two-dimensional (2D) TMD crystals also exhibit electronic, magnetic, and optical properties which are sensitive to any manipulation of edge and strain states. We have introduced a rational chemical synthesis strategy that drastically improves control over the dimensions, morphology, and crystalline edges of 2D TMDs without the need for lithography and etching. TMD nanoribbons prepared through gas-phase growth on our designer surfaces exhibit atomically sharp edges and have enabled the exploration of anomalous exciton emission features. Moreover, we show that judicious assembly of mixed-dimensional architectures containing 2D TMD crystals and Si nanowires enables the introduction of nanoscale strain fields. Detailed nanoscale structural and optical characterization of these systems reveals unique edge and strain states that manifest localized photoluminescence with anomalous shifts in energy. Our results open a path toward the rational design of inorganic low-dimensional architectures with clear relevance for enabling future photonic and optoelectronic device studies.

Toward 2D Heat and Light in 2D Crystals Jiwoong Park; The University of Chicago, United States

2D crystals and superlattices possess extremely anisotropic structures originating from different in-plane intralayer and out-of-plane interlayer bondings. This extreme structural anisotropy leads to anisotropic transport of electrons, phonons and photons. Indeed, 2D materials have recently shown several exciting 2D electronic transport phenomena. However, its impacts on the transport of heat and light in different directions have not been fully explored. In this talk, I will discuss two recent results related to this topic. First, we will discuss extremely anisotropic thermal conduction in stacked multilayers of transition metal dichalcogenides, where interlayer rotations lead to air-like thermal insulation along the through-plane direction. This leads to a giant thermal conductivity anisotropy ratio ~ 900, which is much larger than that of graphite. Second, we will discuss

the long-range (~cm) guiding and non-linear switching of 2D photonic waves using a "delta-waveguide" built based on wafer-scale MoS2. We show that this becomes an optical analog of quantum mechanical delta potential trap with a single trapped wavefunction. If time allows, we will also discuss how to realize these novel anisotropic properties by synthesizing and integrating other, molecule-based 2D materials.

5:25 PM NM07.04.05
Atomic-Step-Induced Screw-Dislocation-Driven Spiral Growth of PVD SnS Yih-Ren Chang[1], Chien-Ju Lee[2], Tomonori Nishimura[1], Wen-Hao Chang[2] and Kosuke Nagashio[1]; [1]The University of Tokyo, Japan; [2]National Chiao Tung University, Taiwan

The in-plane piezoelectricity or ferroelectricity of two-dimensional (2D) materials can vanish due to the appearance of inversion symmetry with increasing flake thickness, which drastically limits the development of their energy-harvesting application. On the other hand, although screw dislocation has long been regarded as an undesired line defect in three dimensional materials, screw dislocation driven growth in 2D materials could result in non-centrosymmetric structure even in bulk materials. The non-centrosymmetric structure in 2D materials can bring about plenty of intriguing properties such as vertical conductivity through the screw dislocation core and nonlinear optical generation, piezoelectricity and ferroelectricity and these properties might be further used in various applications like memory devices or piezoelectric generators. [1-3] However, despite the fact that the inversion symmetry breaking characteristic in spiral structure may the solve above-mentioned problem in 2D materials, the control of spiral growth remains immature owing to random occurrence of screw dislocation which limits the development of applications based on spiral 2D materials by poor nucleation site control and low percentage of spiral flakes.

In this research, a novel mechanism to achieve high percentage of spiral SnS flakes with superior control of nucleation position is demonstrated. By introducing atomic steps on substrates, the screw dislocation can be easily formed when SnS partially grows across these steps and leads to over 90% of spiral SnS flakes grown by physical vapor deposition (PVD). Furthermore, the preference for SnS to nucleate at steps can introduce remarkable nucleation site control of spiral growth even on substrates with artificially transferred graphene atomic steps. Through second harmonic generation (SHG) spectroscopy and cross sectional STEM analysis, it turns out that the spiral SnS structure exhibits inversion symmetry characteristic. Contrary to common understanding that spiral 2D material with single screw dislocation and Burgers vector equaling single layer thickness would show non-centrosymmetric structure, single-spiral SnS flakes with Burgers vector equaling the thickness of single layer SnS exhibits centrosymmetric structure. One possible reason that lead to centrosymmetric structure in spiral SnS could be ascribed to its ferroelectricity, [4] indicating that the orientation switching of SnS layer and the formation of AB stacking structure could be induced by strain.

This is the first work to control the formation position of spiral 2D materials and point out 2D materials with single spiral morphology and Burgers vector equaling single layer thickness do not guarantee non-centrosymmetric structure. High spiral flake percentage and precise control of nucleation sites in this study will facilitate future development of spiral 2D materials.

Late News: WS2 Films Obtained with a Low Thermal Budget Sulfurization Process Dheryck S. Cabeda, Bruno C. Ferreira, Guilherme K. Rolim, Gabriel V. Soares and Claudio Radtke; UFRGS, Brazil

Transition metal dichalcogenides (TMDs) with lamellar structures similar to that of graphite have received

significant attention because some of them are semiconductors with sizable bandgaps and are naturally abundant. This offers opportunities for fundamental and technological research in a variety of fields including catalysis, energy storage, sensing, and electronic devices. Among them, bulk WS_2 exhibits an indirect band gap of 1.2 eV, while single-layer WS_2 exhibits a direct band gap of 1.8 eV. In order to fully exploit this versatility, obtaining layers of this material over large areas with the desired properties (in particular the number of monolayers composing the stack) is mandatory. Despite recent advances in the growth techniques of such a material, further investigation is needed especially in the basic mechanisms involved in the growth of WS_2 layers aiming at expanding their applicability. In view of this scenario, we sulfurized sputtered WO_3 films on SiO_2/Si substrates, varying the processing parameters. The objective was i) to identify the role of hydrogen added to the carrier gas in the sulfurization process and ii) to determine sulfurization parameters that result in fully sulfurized WO_3 films. For that, WO_3/SiO_2/Si stacks were introduced in a quartz tube where they were heated for variable times and temperatures. Pure Ar and a Ar:H_2 gas mixture were used as carrier gases. Sulfur powder was independently heated. X-ray Photoemission Spectroscopy (XPS), Rutherford Backscattering Spectrometry (RBS), and Raman Spectroscopy were used to characterize the products of the sulfurization process and also to infer about W loss from the sample during sulfurization. Results evidence that H_2 promotes an efficient sulfurization of the WO_3 film. Using pure Ar as the carrier gas, higher temperatures must be employed aiming at a complete sulfurization. Moreover, W loss takes place during sulfurization, if S is not supplied in a specific moment of the sample's heating ramp. This latter effect can be strongly suppressed by the use of H_2, which also significantly lowers the temperature needed for sulfurization. These results evidence a synthesis of WS_2 layers with a low thermal budget as well as details of the sulfurization process of WO_3 films. Such knowledge is fundamental for further improvements of WS_2 films' properties and to new applications of this material.

The Phonon Dispersion Relation as a Unique Identifier of Ordered BC_3 "Flower" Units in Graphene-Like Materials Devin McGlamery[1], Alexander A. Baker[2], Yi-Sheng Liu[3], Martin A. Mosquera[1] and Nicholas Stadie[1]; [1]Montana State University, United States; [2]Lawrence Livermore National Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States

Boron doped graphene and related materials, especially crystalline BC_3, have long been sought as promising materials for applications such as hydrogen and lithium-ion storage. Among the materials presented by experimentalists so far, boron presents as a notoriously difficult structural/chemical environment to unambiguously probe in the presence of carbon, frustrating the report of a successful synthesis of single-layer BC_3. Herein we report that the hexagonally symmetric C_6B_6 flower-like units that make up the structure of BC_3 exhibit a characteristic "breathing mode" detectable by Raman spectroscopy in the place of the usual D peak associated with graphene. This mode has a distinctly different dispersion relation, which is easily measured using a typical benchtop Raman spectrometer. Boron-substituted graphitic materials were synthesized by the direct route in the temperature range of 750 °C to 1100 °C across a range of compositions and levels of structural order, as characterized by a complement of techniques: Raman spectroscopy, X-ray diffraction, X-ray absorption spectroscopy, energy dispersive X-ray spectroscopy, and Auger electron spectroscopy. The dispersion relation was shown to be directly correlated with the structure and composition of the resulting materials, culminating in the detection of extended BC_3 units in samples of composition ~BC_5 prepared at 800 °C.

Manipulation of Magnetic Properties of van der Waals Crystals by Protons and Photons Srinivasa Rao Singamaneni; The University of Texas at El Paso, United States

van der Waals (vdW) engineering of magnetism is a topic of increasing research interest in the community at present. In the first part of my talk, I will present and discuss our recent efforts[1] in manipulating the magnetic properties of quasi-two-dimensional layered vdW $Mn_3Si_2Te_6$ (MST) crystals upon proton irradiation as a function of fluence 1×10^{15}, 5×10^{15}, 1×10^{16}, and 1×10^{18} H^+/cm^2. We find that the magnetization is significantly enhanced by 53% and 37% in the ferrimagnetic phase (at 50 K) when the MST was irradiated with the proton fluence of 5×10^{15}, both in *ab* and *c* plane, respectively. The ferrimagnetic ordering temperature and magnetic anisotropy retained even after proton irradiation.
In the second part of my talk, I will discuss on the electron spin resonance (ESR) properties[2] of $CrCl_3$ and CrI_3 single crystals upon photo-excitation in the visible range. We noticed remarkable changes in the ESR spectra upon illumination. In the case of $CrCl_3$, at 10 K, the ESR signal is shifted from g = 1.492 (dark) to 1.661 (light), line width increased from 376 to 506 Oe, and the signal intensity is reduced by 1.5 times. Most interestingly, the observed change in the signal intensity is reversible when the light is cycled on/off. We observed almost no change in the ESR spectral parameters in the paramagnetic phase (>20 K) upon illumination. Upon photo-excitation of CrI_3, the ESR signal intensity is reduced by 1.9 times; the g-value increased from 1.956 to 1.990; the linewidth increased from 1170 to 1260 Oe at 60 K. These findings are discussed by taking into account the skin depth, the slow relaxation mechanism and the appearance of low-symmetry fields at the photo-generated Cr^{2+} Jahn-Teller centers. Such an increase in the g-value as a result of photo-generated Cr^{2+} ions is further supported by our many-body wavefunction calculations. This work has the potential to extend to monolayer vdWs magnets by combining ESR spectroscopy with optical excitation and detection. Our work shows that it is possible to employ proton and photon excitation in tuning the magnetic properties of vdW crystals, and provide many opportunities to design desired magnetic phases.

6:55 PM NM07.05.02
2D Confinement Heteroepitaxy Metals—Atomistic Insights of Interface Structure and Layer Intermixing Hesham El-Sherif[1], Natalie Briggs[2], Joshua Robinson[2] and Nabil Bassim[1]; [1]McMaster University, Canada; [2]The Pennsylvania State University, United States

Confinement heteroepitaxy (CHet) is a fabrication technique for 2D heterostructure in which atoms are intercalated between defective epitaxial graphene and substrates of silicon carbide in a CVD process typically at 800 °C. The confined layers can be designed with the merit of intercalation in several combinations, including metals, refractory, nitrides, and oxides. With all of these combinations, the CHet layers attract interest for many next-generation 2D devices in the field of photonics, plasmonic, hot-electron transistors, and optical polarization substrates.

Using a double-corrected aberration electron microscope and many FIB cross-section samples, we noted that the CHet layers' structure is not a superficial metallic layer on a perfect 6H-SiC stacking. We found that the SiC terminations vary from terrace-to-terrace, including a significant 3C-SiC termination on the topmost layer. Accordingly, this termination variation is found to affect the Chet layers structure and physical properties. For example, the 2D metals – called half-Van der Waals metals –exhibit a non-centrosymmetric structure with a lateral direction variance of the staking order, structure, and the number of layers, which adds to the vertical direction bonding variance; from covalent (SiC) to metallic (Ga or In) to Van der Waal (Graphene). This makes

the 2D CHet surfaces a candidate for generating non-linear optical response and implemented as Surface-enhanced Raman Scattering substrates.

Besides, we observed a picometer-to-angstrom lattice spacing variation at the Si-metal interface. We also investigated epitaxial graphene samples, just before the intercalation process, to understand the Si-graphene and Si-carbon buffer layer interface. Here, we could provide the first direct microscopic evidence that the SiC termination induces Si sublimation from the topmost layer through controlled electron beam damage experiments. Our TEM observations were also consentient with many previous theoretical expectations that explained epitaxial graphene growth due to a pico-scale corrugation in the Si-face atoms due to a $(\sqrt{3} \times \sqrt{3})R30°$ reconstruction on hexagonal (0001) 6H-SiC.

With these observations, we could explain anomalous but repeatable STEM-HAADF images of 2D Gallium and indium interfaces. These images show a significant EELS signal of Ga and In co-located with the topmost SiC layer in addition to Si and C signal within the 2D Ga and In layer. This interface mixing is observed to be limited to the topmost SiC layer but could be propagated into few layers in severe cases. The Si-metal interface instabilities are essential to be fully understood to optimize the growth conditions to avoid them. However, the presence of few doped Si and C atoms within 2D Ga and In could also be exciting if it induces extra orbital hybridization that may generate local and confined magnetism from the metallic layer, which we are currently investigating.

7:10 PM NM07.05.03
Ambipolar Thermoelectric Measurements of Multilayer WSe_2 Victoria Chen, Hye Ryoung Lee, Cagil Koroglu, Connor McClellan, Alwin Daus and Eric Pop; Stanford University, United States

Layered, two-dimensional (2D) semiconducting materials are promising candidates for thermoelectrics [1,2]. Among them, WSe_2 has one of the lowest thermal conductivities [3], in part due to its heavier atoms, which is an important consideration. In addition, WSe_2 is one of the few 2D materials that has been demonstrated as both *n*- and *p*-type (i.e. ambipolar) [4], thus satisfying the need of a thermoelectric generator with one material. Despite these promising material characteristics, only a few experimental studies on the thermoelectric properties of 2D WSe_2 have been performed [5,6], and their dependence on thickness and temperature is still unknown to date.

In this work, we conduct thickness- and temperature- dependent in-plane thermoelectric measurements of WSe_2 films. In order to tune the Fermi level and modulate the carrier density in the channel, we use an ionic-liquid, 1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide (EMIM-TFSI), for electrolyte gating. WSe_2 flakes are exfoliated onto a glass substrate and contacted from the top with 50 nm of evaporated Pd. By using ionic-liquid gating, we are able to sweep across a large range of carrier densities with relatively low applied gate bias. Furthermore, the low thermal conductivity of both the ionic-liquid and substrate contribute to a larger lateral temperature gradient along the WSe_2, which is important for an accurate measurement of the Seebeck voltage. The thermoelectric measurements are conducted in vacuum, with on-chip Pd metal lines serving as resistive heaters and thermometers.

We sweep the gate voltage and measure the in-plane Seebeck coefficient ($S_{n,p}$) and electrical conductance of WSe_2 flakes with thicknesses from ~10 to 90 nm between 296 to 400 K. At room temperature, we measure S_p up to 700 μV/K for holes and S_n down to -400 μV/K for electrons in the same device, which are some of the largest reported for sub-100 nm WSe_2 [5,6]. In addition, we measure power factor values up to 50 $\mu W/K^2/cm$, which are comparable to bulk Bi_2Te_3, a common commercially used thermoelectric material, at room temperature [7]. We examine the trends of thermoelectric performance vs. electron and hole density as well as temperature and observe an increasing power factor with decreasing flake thickness. Overall, our results demonstrate the potential for WSe_2 to eventually compete with bulk materials for use in thermoelectric energy harvesters and we contribute to further understanding the fundamental properties of WSe_2.

Pyrene-tethered Poly(4-vinylpyridine) for Liquid Phase Exfoliation of Hexagonal Boron Nitride Allotropes and Their Thermal Conductive Nanocomposite Hyeokjung Lee, Seung Won Lee, Chanho Park, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Owing to its favorable solution processability, the development of a stable dispersion of two-dimensional (2D) boron nitride (BN) has received significant attention for cutting-edge optic/electronic applications. Herein, we report an efficient method to disperse BN nanosheets (BNNSs) in polar solvents via dual noncovalent interactions using pyrene-tethered poly(4-vinylpyridine) (P4VP-Py). As a dispersion agent, P4VP-Py enables dual-functionalization with BNNS through π−π and Lewis acid−base interactions arising from the pyrene and pyridine moiety, respectively, resulting in highly stable BNNS dispersions in different solvents. The blend of P4VP-Py-functionalized BNNS with the pristine P4VP matrix resulted in increased thermal conductivity and dielectric constant combined with superior thermal stability by forming a compatible interface between the P4VP-Py matrix and the BNNS adjacent to the P4VP-Py. We demonstrated that dual noncovalent functionalization of BNNSs based on molecular design presents a strategy to achieve high dispersion of 2D materials into various media, ranging from polar solvents to solid matrices, for the expansion of advanced optic/electronic applications using BNNSs.

7:28 PM NM07.05.06
ALD Growth of Wafer-Scale WS_2 Film and Device Applications with Non-Toxic and Less Corrosive Precursors Hanjie Yang[1], Yang Wang[1], Tao Chen[1], Rongxu Bai[1], Zecheng Wu[1], Zhongya Pang[2], Xingli Zou[2], Hao Zhu[1], Lin Chen[1], Qingqing Sun[1] and Li Ji[1]; [1]Fudan University, China; [2]Shanghai University, China

Tungsten disulfide (WS_2), as a member of two-dimensional transition metal dichalcogenides family, has attracted great attention due to its tunable band structure, excellent electrical transportation, unique optical properties and good air-stability. Despite the fact that WS_2 is a potential candidate for next-generation channel materials, preparing wafer-scale WS_2 film (8 inch or larger) with good uniformity and film quality remains challenging. Moreover, the bandgap of WS_2 with different layer numbers was tunable, which implied the necessity to precisely control the thickness. Chemical vapor deposition (CVD) is a common method to achieve high quality WS_2 films [1].However, it is difficult to synthesize 2-inch or larger size WS_2 films with precisely controllable thickness. Atomic layer deposition (ALD) is an effective method to achieve wafer-scale WS_2 film. The self-limiting growth mode enabled the thickness of WS_2 film to be accurately controlled through changing the cycle numbers. The S sources of most ALD WS_2 research works were H_2S, which was highly toxic and dangerous. In addition, F-based precursor were used in many studies[2-5], resulting in an accelerated degradation of deposition system due to the highly corrosive nature of F-based precursors. In this work, low-toxic and less-corrosive tungsten hexachloride and hexamethyldisilathiane ($(CH_3)_3SiSSi(CH_3)_3$, HMDST) were used as W and S precursors, respectively, to achieve wafer-scale and thickness-controllable WS_2 films. The annealing process was carried out to improve the crystallinity of WS_2 film at 800ºC for 2h. The XPS spectra, Raman spectra and plane-view and cross-sectional TEM indicated the good quality and controllable thickness of WS_2 film. Moreover, arrays of field-effect transistors based on WS_2 channel were further fabricated showing homogeneous electrical properties. The on/off ratio of WS_2 FET was nearly 10^5 and the average electron mobility of WS_2 FET was 3.5 $cm^2V^{-1}s^{-1}$. Our results paved a new path to synthesize wafer-scale and thickness-controllable WS_2 film in use of low-toxic and less-harmful precursors through ALD process, while the electrical properties demonstrated the attractive and promising potentials for WS_2 films in future nano-electronic device

integrations and applications.

7:31 PM NM07.05.07

An Effective Lattice Engineering Way of the Defect and Stacking Structure of Inorganic Nanosheets for Optimizing Their Electrode and Electrocatalyst Performances Tae-Ha Gu[1] and Seong-Ju Hwang[2]; [1]Ewha Womans University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

An effective chemical way to optimize the electrochemical functionalities of layered inorganic solids is developed by controlled restacking of exfoliated 2D nanosheet (NS). The fine-control of the stacking number and oxygen defect of restacked inorganic NSs can be achieved by employing diverse intercalants having various ionic sizes and charge densities. In contrast to conventional expectation, the supercapacitor electrode and electrocatalyst performances of inorganic NSs are well-correlated with their stacking numbers and oxygen defects, rather than with their basal spacings. The application of appropriate intercalant ion is quite effective in enhancing the electrode/electrocatalyst performances of restacked NSs via the creation of oxygen defect and the decrease of stacking number, resulting in improvement of catalysis kinetics and charge transfer property, and electrochemical surface area (ECSA). The present study highlights that the controlled restacking of exfoliated inorganic NSs can provide an effective way to optimize its electrochemical functionalities.

7:34 PM NM07.05.08

Exfoliated g-C_3N_4 Nanosheet as an Emerging Cationic Building Block for 2D Superlattice Bifunctional Catalyst Nam Hee Kwon and Seong-Ju Hwang; Yonsei University, Korea (the Republic of)

The interstratified superlattices of graphitic carbon nitride (g-C_3N_4)-molybdenum disulfide (MoS_2) monolayers with improved bifunctional catalytic performance are synthesized by an electrostatically-driven self-assembly between oppositely-charged exfoliated nanosheets (NSs). In contrast to other exfoliated inorganic NSs, the cationic form of g-C_3N_4 NS can be obtained via the tuning of suspension pH, which is applicable as a new type of cationic building block for superlattice nanohybrids. The resulting superlattice nanohybrids display strong interfacial interaction between restacked g-C_3N_4 and MoS_2 NSs, leading to creation of nitrogen vacancy, stabilization of 1T'-MoS_2 phase, and efficient interfacial electronic transition between the interstratified NSs. The superlattice g-C_3N_4-MoS_2 nanohybrids display remarkably enhanced bifunctionality as electrocatalysts for hydrogen evolution reaction and photocatalysts for visible light-induced N_2 fixation with high selectivity. The beneficial effect of hybridization on catalyst performances is attributable to the promoted adsorption of H^+/N_2, the provision of many active sites, and the enhancement of charge transfer kinetics, the charge separation, and the visible light absorptivity. The present study highlights that the application of g-C_3N_4 NS as a cationic building block provides valuable opportunity to widen the library of multifunctional NS-based superlattice nanohybrids.

7:37 PM NM07.05.10

Synthesis and Structural Characterizatioon of Graphene and Boron Nitride Angela Luis Matos[1], Vladimir Makarov[2,1], Brad Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]University of Puerto Rico, United States

Graphene and Boron nitride are 2D materials that has been widely investigated due to their excellent features and potential applications in optoelectronic devices because of their high absorbance and transmittance properties. Graphene has been grown by several methods such as chemical vapor deposition (CVD), chemical or plasma exfoliation from natural graphite, mechanical cleavage (exfoliation) from natural graphite, microwave synthesis, etc.
CVD has demonstrated to be the most remarkable process for large-scale graphene fabrication. When the thermal CVD process is carried out in a resistive heating furnace, it is known as thermal CVD, and when the process consists of plasma assisted growth, it is called plasma enhanced CVD or PECVD. In this work it is presented graphene growth by hot filament CVD. Here methane gas it is used as a carbon source which is decomposed with a filament at high temperature. In this technique it is possible to obtain a single to few layers graphene by adjusting the growth parameters. To characterize graphene one of the main techniques used is Raman spectroscopy. A nondestructive tool for investigating atomic vibrational properties. Using the important features such as the D, G and 2D band of graphene, can be distinguish the number of layers, the presence of defects, edge orientation and to monitor the temperature. In this work will be presented how the Raman spectra change depending on the substrate where graphene has been grown or transferred, as well as the dependence on the temperature of the G band in bilayer graphene. Also, hexagonal-boron nitride (h-BN) has been known as the best substrate dielectric for studying 2D physics of graphene and for the high-performance of graphene electronics, due to its atomically smooth surface, lattice constant similar to that of graphene, large optical phonon modes, and a large electrical band gap. H-BN have been used to encapsulate graphene to avoid the impurities and as well to tailor the electronic properties of graphene. In this work, it will be presented the synthesis of h-BN and its structural characterization.

Alkalide-Assisted Direct Electron Injection for the Non-Invasive N-Type Doping of Graphene Sanghwan Park and Chang Young Lee; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Although the doping of graphene grown by chemical vapor deposition is crucial in graphene-based electronics, non-invasive methods of n-type doping have not been widely investigated in comparison with p-type doping methods. We developed a convenient and robust method for the non-invasive n-type doping of graphene, wherein electrons are directly injected from sodium anions into the graphene. This method involves immersing the graphene in solutions of $[K(15\text{-crown-}5)_2]Na$ prepared by dissolving NaK alloy in 15-crown-5 solution. The n-type doping of the graphene was confirmed by down-shifted G and 2D bands in Raman spectra and by the Dirac point shifting to a negative voltage. The electron-injected graphene showed no sign of structural damage, exhibited higher carrier mobilities than that of pristine graphene, and remained n-doped for over a month of storage in air. In addition, we demonstrated that electron injection enhances noncovalent interactions between graphene and metallomacrocycle molecules without requiring a linker, as used in previous studies, suggesting several potential applications of the method in modifying graphene with various functionalities.

Salt-Assisted Growth of 2D Transition Metal Dichalcogenides Shisheng Li; National Institute for Materials Science, Japan

Abstracts
Chemical vapor deposition (CVD) of 2D transition metal dichalcogenides (TMDCs) always involves the conversion of vapor precursors to solid products in a vapor-solid-solid (VSS) growth mode (e.g., $WO_3 + S \rightarrow WS_2 + SO_2$). This often requires very high temperatures to sublimate metal oxide precursors (e.g., WO_3).
Our pioneering work on salt-assisted CVD (**Salt 1.0 technique**) enables the growth of 2D WS_2 and WSe_2 monolayers in a mild condition (lower temperature and atmospheric pressure) [1,2]. In the last five years, the use of alkali (alkaline earth) metal halides (AH, A = Li, Na, K, Ba, Ca; H = F, Cl, Br, I) in CVD has demonstrated great success in growing tens of atomically thin metal chalcogenides, graphene & h-BN

monolayers [3,4]. This is due to the formation of volatile MO_uCl_v and non-volatile NaM_yO_z when alkali (alkaline earth) metal halides react with metal oxides. They are highly efficient precursors for growing 2D TMDC monolayers.
The recent discovery and use of non-volatile molten salts in CVD (**Salt 2.0 technique**) trigger the vapor-liquid-solid (VLS) growth of 1D/2D TMDC monolayers [5]. The Salt 2.0 technique shows great improvements in the high-efficient and reproducible growth of large-area, uniform, and high-quality 2D TMDC monolayers. The Salt 2.0 technique also demonstrates great potentials in growing 2D TMDC materials in the following aspects: wafer-scale single crystals, patterns, heterostructure, and alloys [6]. It represents a new trend in the CVD growth of 2D TMDC materials.

Layer-Controlled Nb Doped MoS_2 Thin Film with Wafer-Scaled Uniformity Jae-Hwan Jung[1], Ahrum Sohn[1], Changhyun Kim[2], Kyung-Eun Byun[2], Yeonchoo Cho[2], Hyeon Jin Shin[2] and Sang-Woo Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of)

Recently, due to the physical limitations of silicon-based transistors, studies using 2-dimensional (2D) materials as next-generation transistors have become more active. Graphene, widely known as a representative next-generation 2D material, has attracted a great deal of attention due to its high electrical conductivity, thermal conductivity and stiffness coefficient. However, since it does have zero-bandgap, it is limited to use as a semiconductor. Molybdenum disulfide (MoS_2), one of the TMD materials consisting of chalcogenide elements on both sides of the transition metal, has been reported to have n-type property, a direct band gap of 1.9 eV in a single layer and high absorptivity. Synthesis of MoS_2 films with a different carrier type is a very desirable technology because it can overcome the scaling issues in the further CMOS technology. However, most doping techniques of MoS_2 are difficult to satisfy well-controlled the number of layers, and large-scaled uniformity at the same time. Herein, we propose that an outstanding method with two steps enables us to obtain 2-inch wafer sized MoS_2 thin film with controlled the number of layers and even metal-doped MoS_2 with different carrier type in significantly short time. Various experiments have verified the quality of grown MoS_2 including thickness-dependent electrical behavior, and especially an innovative TEM analysis has confirmed an existence of dopants regardless of an atomic size.

Controlling Two-Dimensional Growth Through Interfacial Interactions and Dynamics Maria Sushko, Jinhui Tao, Biao Jin, Praveen Thallapally, James J. De Yoreo and Jun Liu; Pacific Northwest National Laboratory, United States

Solution synthesis may prove to be one of the most scalable synthesis methods of 2D materials providing that the thermodynamic and kinetic drivers that determine the phase, nucleation, and growth kinetics, and the degree of perfection, can be understood and controlled. A combination of in situ characterization and simulations of crystallization pathways demonstrated the dependance of specific pathways on local chemical environments. Using well-defined model systems these studies identified the factors for particle morphology control during homogeneous nucleation and growth and highlighted the importance of interfacial precursor kinetics and surface stress in inducing asymmetric growth. In particular, fast ion deposition kinetics at twin planes was shown to promote the growth of nanoplates in pure precursor solution. In ligand assisted homogeneous and heterogeneous growth ion- and ligand-induced interfacial strain relief was found to control the growth of asymmetric nanoparticles and single-layer metal organic framework films, respectively. The detailed analysis of the dependence of crystallization pathways on synthesis parameters (pH, precursor and ligand concentrations, temperature) and the systematic approaches to control synthesis of 2D materials using homogeneous and heterogeneous solution-based synthesis will be discussed.

Late News: Imaging Strain Fields in Moiré Heterostructures Daniel K. Bediako; University of California, Berkeley, United States

Strain plays a key role in defining both the electronic and chemical behavior or materials. The properties of two-dimensional (2D) materials are particularly susceptible to strain and the controllable creation and analysis of strain in such systems is critically important to understand their behavior. In recent years, moiré superlattices that are formed by a small lattice mismatch or the azimuthal misorientation (interlayer twist) of two 2D layers have emerged as some of the most fascinating platforms to probe a host of emergent phenomena. Twisted bilayer graphene, with one sheet twisted relative to another, results in a moiré superlattice with a wavelength that is inversely proportional to the twist angle. Because of the variation in stacking of AA vs AB/BA sites in the two graphene layers, the individual sheets strain from the graphene hexagonal lattice in order to minimize free energy. This talk will discuss our work to precisely map this atomic reconstruction and measure the resultant strain in twisted bilayer graphene using a new methodology called Bragg interferometry based on 4-dimensional scanning transmission electron microscopy (4D-STEM). Intralayer strain and reconstrcution mechanics are determined from mapping the displacement vectors between the graphene lattices by acquiring diffraction patterns at each position of the scanning electron probe. By quantitatively mapping strain tensor fields we uncover two distinct regimes of structural relaxation—in contrast to previous models depicting a single continuous process—and we disentangle the electronic contributions of the rotation modes that comprise this relaxation. Further, we find that applied heterostrain accumulates anisotropically in saddle point regions to generate distinctive striped shear strain phases. Our results thus establish the reconstruction mechanics underpinning the twist angle dependent electronic behaviour of twisted bilayer graphene, and provide a new framework for directly visualizing structural relaxation, disorder, and strain in any moiré material.

9:15 PM NM07.06.03
Enhanced Electronic Quality of Monolayer WS_2 via Re-Doping Leyi Loh, Michel Bosman and Goki Eda; National University of Singapore, Singapore

It is known that the electronic quality of monolayer transition metal dichalcogenides (TMDs) is strongly compromised by the presence of chalcogen vancancy defects. These defects are commonly present in densities

of > 10^{13} cm^{-2} and result in unintentional n-type doping and sub-gap optical emission features. In this study, we report suppression of sulfur vacancy formation during chemical vapor deposition of monolayer WS_2 by means of intentional in-situ Re-doping. Using aberration-corrected scanning transmission electron microscopy (STEM), we reveal that the sulfur vacancy density consistently decreases by up to 52% with increasing Re content. Interestingly, despite the possible electron-doping behavior of substitutional Re, we find the Re-doped WS_2 to be less n-type, indicating the suppresion of unintentional doping effects of sulfur vacancies and high activation energy of Re impurities. We further show that substrate-induced exciton line broadening and sub-gap emission features are strongly suppressed in Re-doped samples, demonstrating their high electronic quality.

9:30 PM NM07.06.04
Strategies to Induce Selectivity in 2D Material Chemical Sensors Through Integration with Covalent Organic Frameworks Lucas K. Beagle[1,2], Ly D. Tran[1,2], Rahul Rao[1], Luke A. Baldwin[1] and Nicholas Glavin[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Chemical and biological sensing using 2-D nanomaterials has been an area of intense investigation including inorganic materials that exhibit high sensitivity, however it has been limited as a field due to the lack of selectivity among analytes. While 2D inorganic materials can readily decipher between donor/acceptor groups, strategies to incorporate selectivity in these devices is crucial. Organic 2D materials known as covalent organic frameworks are large porous and repeated organic frameworks which have been shown to act as selectivity agents due to functionalization and porosity. This research focuses on the association of COFs with 2-D nanomaterials using top-down microwave-assisted activation of TMDs and deposition of COF particles. Several known COF species have been examined in order to understand the fundamental surface interactions between 2-D nanomaterials and COFs. Kinetics and mechanistic studies were used to determine the manner of association of the inorganic and organic substrates.

9:45 PM NM07.06.06
Metal Atoms on WTe_2—Surface Diffusion, Interactions with Defects and Clustering Peter V. Sushko, Zexi Lu, Micah P. Prange, Yang Wang and Zdenek Dohnalek; Pacific Northwest National Laboratory, United States

Electronic properties of 2-dimensional (2D) van der Waals materials can be modified by adsorbing and intercalating metal atoms. Controlled aggregation of isolated atoms into clusters and other low-dimensional features can be used to generate new functional properties with potential applications in electronic devices and energy storage and conversion. Our ability to utilize these possibilities are predicated on the development of new synthesis strategies that, in turn, require detailed understanding of diffusion and aggregation pathways of adsorbed species on surfaces of these materials.
Here we report on binding, diffusion, and aggregation of transition metal atoms (Pd, Cu, Fe) adsorbed on a prototype 2D transition metal dichalcogenide (TMD) WTe_2 investigated using ab initio (density functional theory) simulations. While we find four distinct surface binding sites, the diffusion activation barriers between them differ dramatically, creating an asymmetry in surface migration. Metal dimers are only marginally more stable (~0.1 eV) than isolated adsorbed atoms; however, clusters of three atoms are stabilized by as much as ~0.4 eV. Further increase of the cluster size up to 11 atoms is not significantly favored on the non-defective surface, which suggests that such clusters can decompose under mild thermal treatment. In contrast, adsorption of metal atoms at the Te vacancy sites is strongly favored. This is particularly evident in the case of Pd, which is slightly more electronegative than Te. As the size of the vacancy bound Pd cluster increases, the amount of the electron charge transferred to the cluster from the surface Te increases as well. This charge redistribution is accompanied by Pd atoms displacing Te atoms from their lattice sites leading to significant lattice damage. Finally, we investigated pathways for Te substitution with the adsorbed metal species on pristine surfaces. Our results suggest that formation of transient Pd dimers and trimers can trigger Te-to-Pd charge transfer sufficient to destabilize surface Te atoms and induce Pd for Te substitution. These results are consistent with the formation of two types of small Pd clusters on WTe_2 observed using scanning tunneling microscopy and their responses to thermal treatment. We discuss the similarities and the differences in behavior of the adsorbed metal species and their effect on the electronic properties of WTe_2 as well as implications for functionalization of

other TMDs.

10:00 PM NM07.06.08
Evidence of Large Absorption in the UV-Vis Region from Chemically Exfoliated MoS_2 Nanoparticles
Wafa Alnaqbi[1], Juveiriah M. Ashraf[1], Ayman Rezk[1], Aisha Alhammadi[1], Sabina Abdul Hadi[2] and Ammar Nayfeh[1]; [1]Khalifa University of Science and Technology, United Arab Emirates; [2]University of Dubai, United Arab Emirates

Molybdenum disulphide (MoS_2) is a transition metal dichalcogenide (TMD) semiconductor that has unique optical and electronic properties making it attractive for future electronic and photonic devices [1]. Due to the quantum confinement effect in 2D MoS_2, it has a tuneable band gap which increases as the size decreases. Bulk MoS_2 has an indirect band gap of ~1.2eV, while 2D MoS_2 has a direct band gap of ~1.8eV. In this work, we present MoS_2 nanoparticles (NPs) synthesized using a chemical exfoliation method and investigate the optical properties . First, we disperse 0.5 grams of MoS_2 powder in 50 mL of N-Methyl-2-pyrrolidone (NMP). Next, sonication using a probe set at 50% amplitude, and 10/2 seconds duty cycle for 6 hours in an ice bath maintained at 0 °C. The dispersion is then centrifuged at 1500 rpm for 60 min to remove unexfoliated particles, then at higher speed (7500 rpm) for 30 min to remove soluble impurities from the dispersion. The NMP is then removed, and the MoS_2 nanoparticles are filtered and re-dispersed in 25 mL of IPA. In order to first characterize the chemically exfoliated MoS_2 (ce-MoS_2) nanoparticles, we first deposit them on 3 cm x 3 cm pieces of fused silica by spin coating. Three coats of 100 µL were deposited with a total of 300 µL. The samples were left to dry for 1 hour between each coat at room temperature. The spin coating was conducted at 150 rpm for 40s. Optical microscopy of the samples under ultra-violet (UV) illumination showed a homogenous distribution of the MoS_2 NPs, exhibiting a red photoluminescence (PL) which is correlated to the quantum-confinement effect in MoS_2 at the nanoscale where direct band gap transitions can occur with a stable tunable PL depending on the NPs size. The films showed a smooth layer at low particle densities with cluster sizes below the resolution of the microscope (< 300 nm). At higher particle densities, larger clusters begin to form, with an approximate size of 1 µm and above, with a majority of clusters in the range of 2-5 µm in diameter.
Both reflection and transmission spectra are measured after each coat using a UV–VIS spectrophotometer (Lambda 850, PerkinElmer) to investigate the behaviour of MoS_2 NPs, and the effect of the number of coats applied on the reflectance of the substrate. The corresponding reflection spectra were captured as a function of the incident wavelength, ranging from 250 nm to 1500 nm. Coated samples show a severe reduction in transmission to almost ~0% at UV-Vis (250 to 850 nm) and ~ 10% at NIR (850 to 1500 nm) after three coats. However, reflectance was around ~20% for UV-Vis and increased to ~50% at NIR. Which got absorption to increase from ~0% to ~80% at UV-Vis and ~40% at NIR after the third coat. We also deposited the MoS_2 on low temperature PECVD Ge films grown on (100) P doped (n-type) Si described in detail in our previous work [2]. A large drop in reflectance below 800 nm is seen which can be attributed to absorption in the MoS_2 nanoparticles. Above 800 nm, reflectance increases. This asymmetrical behaviour, which will be investigated further, can be explained by increased scattering in the non-absorption region. To summarize, in this work, we investigate the optical properties of chemically exfoliated MoS_2 NPs on fused silica and PECVD Ge films. The results show a large reduction in reflectance due to absorption in the MoS_2 in the UV-Vis region. Moreover, these results show that MoS_2 can have potential applications in photonics and PV-based devices.

Electrical and Chemical Control of Magnetism in van der Waals Ferromagnetic Materials Goki Eda[1,1,2]; [1]National University of Singapore, Singapore; [2]Centre for Advanced 2D Materials, Singapore

Recent discoveries of gate-tunable magnetism in ferromagnetic two-dimensional (2D) materials such as $CrI_3$and Fe_3GeTe_2 highlight the unique potential of this class of materials for novel spintronic devices. Understanding the interplay between magnetic order, free electron density, and electric field in the 2D limit is essential for uncovering the full potential of these materials. In this talk, we will first discuss electrical control of magnetism in $Cr_2Ge_2Te_6$ (CGT), a van der Waals ferromagnetic semiconductor, in an electric double-layer transistor (EDLT) geometry. We show that degenerately electron-doped CGT exhibits enhanced Curie temperature of up to 200 K, and rotation of its easy axis from out-of-plane to in-plane orientation. We demonstrate that similar changes in Curie temperature and easy axis can be induced by Na intercalation, which is accompanied by heavy electron doping of the host. We will further discuss our exploration of magnetism in other van der Waals materials such as $NbFeTe_2$ and magnetically doped transition metal dichalcogenides.

8:30 AM NM07.07.02
Thickness-Dependent Ambient Effects on the Curie Temperatures and Magnetic Domains of Metallic Two-Dimensional Magnets Ti Xie[1], Yeonghun Lee[2], Jinling Zhou[1,3], Alemayehu S. Admasu[4], Nagarajan Valanoor[3], John Cumings[1], Sang-Wook Cheong[4], Ichiro Takeuchi[1], Kyeongjae Cho[2] and Cheng Gong[1]; [1]University of Maryland, United States; [2]The University of Texas at Dallas, United States; [3]University of New South Wales, Australia; [4]Rutgers, The State University of New Jersey, United States

The emergent magnetic two-dimensional (2D) materials provide ideal solid-state platforms for a broad range of applications including miniaturized spintronics and magnetoelectric sensors. Owing to the general environmental sensitivity of 2D magnets, the understanding of ambient effects on 2D magnetism is critical. Apparently, the nature of itinerant ferromagnetism potentially makes metallic 2D magnets insensitive to environmental disturbance. Nevertheless, our systematic study showed that the Curie temperature of metallic 2D Fe_3GeTe_2 decreases dramatically in the air but thick Fe_3GeTe_2 exhibits self-protection. Remarkably, we found the air exposure effectively promotes the formation of multiple magnetic domains in 2D Fe_3GeTe_2, but not in bulk Fe_3GeTe_2. Our first-principles calculations support the scenario that substrate-induced roughness and tellurium vacancies boost the interaction of 2D Fe_3GeTe_2 with the air. Our elucidation of the thickness-dependent air-catalyzed evolution of Curie temperatures and magnetic domains in 2D magnets provides critical insights for chemically decorating and manipulating 2D magnets.

8:45 AM NM07.07.03
Atomic-Scale Understanding of Defect Dynamics in Phosphorene Under Ion Bombardment Saransh Gupta[1], Prakash Periasamy[2] and Badri Narayanan[1]; [1]University of Louisville, United States; [2]LAM Research Corporation, United States

The unique opto-electronic properties of two-dimensional monolayer of phosphorus (namely phosphorene) makes them lucrative for a variety of applications in nano-scale electronic devices, including field-effect transistors, photovoltaic junctions and thin-film solar cells. In particular, the lure of phosphorene arises from its semiconducting nature, thickness-dependent electronic band gap (1.5 eV in monolayer to 0.3 eV in bulk), high hole mobility (~10^5 $cm^2/V/s$), and large drain current modulation. The properties of phosphorene can be further

engineered by precise introduction of defects via ion bombardment or electron-irradiation. For instance, isolated mono-vacancies can induce hole doping as well as local magnetic moments; which can be leveraged to achieve specific functionality in opto-electronic devices. Despite this promise, precise defect engineering of phosphorene via ion/electron beams has remained challenging due to lack of fundamental understanding of the atomic-scale mechanisms underlying production, accumulation, and subsequent annealing of defects during irradiation. Indeed, previous first-principles modeling and electron microscopy studies provide insights into the atomic structure of defects, their thermodynamic stability, and threshold ion energy required to produce them. However, the effect of dose on defect accumulation, atomistic details of temporal evolution of defects, and defect dynamics under irradiation as well as subsequent annealing are largely unclear. Here, we employed reactive molecular dynamics (MD) simulations to unravel the dynamical atomic-scale processes underlying formation, accumulation, and re-organization/annealing of defects during Ar-ion bombardment of phosphorene. We found that radiation dosage strongly influences the type of defects that form, as well as their subsequent annealing. At low doses (10^{13} Ar^{+}ions/cm^2 at 25 keV), the predominant defects that form are isolated mono-vacancies or Stone-Wales type defects that largely retain the planarity of the sheet. Interestingly, even small voids (1-2 nm) that form at these low doses can be healed by subsequent annealing; such healing proceeds via local re-arrangement of rings. Beyond a critical dosage (10^{14} Ar^{+} ions/cm^2 at 25 keV), large nanopores form whose edges are stabilized by formation of 3D structures consisting of P_4 tetrahedra. During subsequent annealing, these 3D structures facilitate the coalescence of nanopores, which further degrades the structure. These results will be discussed in the context of designing novel routes to precisely tune opto-electronic properties of phosphorene-based devices using ion beams.

8:50 AM NM07.07.08
Spatial Defects Nanoengineering for Bipolar Conductivity in MoS2 Annalisa Calo[1,2]; [1]University of Barcelona, Spain; [2]Institute for Bioengineering of Catalonia, Spain

Two-dimensional transition metal dichalcogenides show great potential as a new class of atomically thin semiconductors for electronics and optoelectronics. Understanding the atomistic origin of defects in these materials and their impact on the electronic properties, as well as finding viable ways to dope them is matter of intense scientific and technological interest. In particular, controlling defects could be envisioned as a strategy for the design of ad-hoc electronic and optoelectronic properties. Here, we demonstrate a new integration of thermochemical scanning probe lithography (tc-SPL) with a flow-through reactive gas cell to achieve a nanoscale control of the local thermal activation of defects in monolayer MoS_2. The tc-SPL activated nanopatterns can present either p- or n-type doping on demand, depending on the used gasses, allowing the realization of field effect transistors, and p-n junctions with precise sub-mm spatial control and a rectification ratio over 10^4. Doping and defects formation mechanisms are elucidated at the molecular level by means of X-Ray photoelectron spectroscopy, scanning transmission electron microscopy, and density functional theory. The p-type doping of locally heated MoS_2 in HCl/H_2O atmosphere is found to be related to the rearrangement of sulfur atoms and the formation of new protruding covalent S-S bonds on the surface, which produce a band structure with p-character. Alternatively, local heating MoS_2 in N_2 produces n-character.

Strong and Flaw-Insensitive Two-Dimensional Covalent Organic Frameworks Qiyi Fang[1], Chao Sui[1], Chao Wang[1], Tianshu Zhai[1], Jing Zhang[1], Jia Liang[1], Hua Guo[1], Emil Sandoz-Rosado[2] and Jun Lou[1]; [1]Rice University, United States; [2]U.S. Army Research Laboratory, United States

Recently, two-dimensional covalent-organic-frameworks (COFs), an structural analogue of graphene, have attracted great interests because of their tailorable structures lacking in other 2D materials. The topological design principles of monomers enable researchers to control the pore size and the unit cell geometry of 2D COFs allowing for highly tunable functionalities and properties. The unique structural features make 2D COFs possess exciting multifunctional properties with broad applications in liquid/gas separation, water filtration, energy storage/conversion, catalysis and ionic conduction, etc. However, the understanding of its mechanical properties and fracture mechanisms remains elusive. Here we report a quantitative in-situ tensile study of ultrathin COFs films. The fracture strength was measured to be 0.75±0.34 GPa, and the tensile modulus was measured to be 10.38±3.42 GPa, with a nominal density of 0.393 g/cc, thus having specific strength equivalent to Kevlar(2 GPa cc/g), and specific modulus comparable to titanium alloys (23 GPa cc/g). Additionally, the fracture toughness was measured to be 0.55±0.09 MPa$\sqrt{m}$, and it was found that the crack propagation could be insensitive to the pre-crack when the size of pre-crack is below a critical value, leading to intriguing flaw insensitivity in such ultrathin nanomaterials. This work provides in-depth insights into the fracture properties of 2D COF films and lays a foundation for their future applications.

11:10 AM NM07.08.03
Recycling of Two-Dimensional Materials for van der Waals and Remote Epitaxy Dongheun Kim, Yeonhoo Kim, Eric Auchter, Enkeleda Dervishi-Whetham and Jinkyoung Yoo; Los Alamos National Laboratory, United States

The absence of surface dangling bonds on two-dimensional (2D) materials mitigates materials compatibility issues of heterostructuring. Conventional materials synthesis on 2D materials have been prepared by van der Waals (vdW) and remote epitaxy techniques. In principle conventional or other 2D materials epitaxially grown on a 2D materials can be feasibly delaminated from the 2D layer as a substrate via applying mechanical force. Previous reports have shown that semiconductor nanomaterials and thin films for device applications can be prepared on 2D materials, especially graphene. Then the grown materials were detached from the host substrate, and applied for flexible devices. However the 2D layer in between the grown materials and the host substrate has not been thoroughly investigated. The 2D layer as a substrate or interlayer for vdW and remote epitaxy techniques has been considered as damaged. Thus there was no systematic characterizations of 2D layer after the epitaxy procedures and no attempt to recycling the 2D layer multiple times.
In the presentation recycling graphene and transition metal dichalcogenides layers for vdW and remote epitaxy will be demonstrated and discussed. Surface morphology and optical characteristics of the recycled 2D layers along repetition of the vdW and remote epitaxy were studied. Moreover the electrical/optical characterizations of semiconductors/2D heterostructures were performed to obtain insights of 2D/conventional materials interfacial properties.

11:25 AM NM07.08.04
Optimizing the Schottky Barrier at Metal-MoS_2 Junctions Through Metal Selection and Annealing Meghan Bush, Timothy Ismael, Kazi Islam, Claire Luthy and Matthew Escarra; Tulane University, United States

Monolayer molybdenum disulfide (MoS_2) is an attractive semiconductor for nano-optoelectronic devices due to its direct bandgap, open-air stability, and potential for large-scale synthesis. To optimize the electrical performance of these devices for applications such as photovoltaics, the relationship between the semiconductor and metal contacts must be fully understood and optimized.

The Schottky barrier height, denoted as Φ_B, is a potential energy barrier that exists at the junction of a metal and a semiconductor due to the difference in work functions. This directly impacts device performance, as a higher barrier decreases minority carrier transport since electrons cannot easily flow back into the semiconductor. We report here the experimental measurements of Φ_B between monolayer MoS_2 and a number of metals with varying work functions and process conditions. Large-area monolayer MoS_2 is grown using chemical vapor deposition (CVD) and metal contacts are deposited using electron beam evaporation on patterns written by electron beam lithography.

Different metals have different electrical performances and Schottky barriers resulting from their interaction with a semiconductor. The metals used for contacts are Ti and Sc (low work functions) and Pt (high work function). Here, the barrier height is extracted using the thermionic emission model, which implies that the Schottky barrier is temperature dependent. With an applied source-drain bias of 1 V, a source-drain sweep is taken for the nanoscale transistors over the gate voltage range -30 V to 30 V. These sweeps are repeated at 25 K temperature increments over 100-400 K. This data is plotted on an Arrhenius plot, with logarithmic gate voltages on the y-axis and the inverse of temperature on the x-axis. The initial linear slopes are related to the barrier height using the thermionic emission model, which results in an approximate barrier vs gate voltage plot from which the actual Schottky barrier height is extracted.[1,2] So far, we have experimentally determined the Schottky barrier height of titanium, $\Phi_{Ti} = 0.21$. We will be repeating this process with the other metal contacts listed above to fully document how our CVD grown 2D MoS_2 interacts with these metals.

Thermal treatments have been used for decades to improve electrical performance in traditional III-V solar cells and semiconductor devices. Building on this, we posit that there are optimal annealing parameters that can improve the desired transport properties in electron and hole-selective Schottky barriers between 2D materials and metals. This annealing is done using a Rapid Thermal Annealer (RTA) to expose the device to high temperatures for short periods of time. Since RTA is scalable, it directly translates to manufacturing for large area 2D PV. By comparing the Schottky barrier heights without annealing and after various annealing conditions, we will establish a better understanding of how this process impacts the metal-semiconductor junction. The ability to tune the barrier height allows devices to be further customized with improved performance.

Understanding the barrier of the MoS_2-metal junction will allow for more complex devices to be designed and fabricated, including but not limited to photovoltaics, photo-emitters, photodetectors, etc. Future work entails optimizing device preparation and treatment to result in Schottky barriers for different 2D electronic applications. These measured barrier heights are also being included in a computational device model to study various MoS_2-based optoelectronic devices.

Collective Modes in Substitutionally Doped 2H-NbS_2 Amin Azizi[1], Mehmet Dogan[1,2], Jeffrey D. Cain[1,2], Kyunghoon Lee[1,2], Xuanze Yu[1], Marvin L. Cohen[1,2] and Alex Zettl[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Metallic transition-metal dichalcogenides (TMD) are rich material systems in which the interplay between strong electron-electron and electron-phonon interactions results in a variety of instabilities such as charge density waves (CDWs). While most metallic TMDs exhibit coexistence of superconductivity and CDWs, 2H-NbS_2, with a superconducting transition temperature (T_C) of ~6K, shows no CDW order. Most recently, the

existence of an incommensurate CDW pinned by atomic impurities (such as vacancies) has been reported in 2H-NbS_2. Substitutional dopants, depending on their atomic number and electronic state, can considerably affect electronic behavior in these systems.
Here, we substitutionally dope 2H-NbS_2 with heavy atoms via chemical vapor transport. Using aberration-corrected scanning transmission electron microscopy (STEM) imaging, we confirm the 2H phase of NbS_2 and determine the distribution and concentration of dopant atoms. Using a combination of low temperature transport measurements and density functional theory calculations, we demonstrate how heavy dopant atoms can modify the collective electronic states (such as superconductivity and CDW) in 2H-NbS_2.

Late News: Exfoliation and Optical Properties of Near-Infrared Fluorescent Silicate Nanosheets Gabriele Selvaggio[1,2], Milan Weitzel[2], Nazar Oleksiievets[2], Tabea A. Oswald[2], Robert Nißler[1,2], Ingo Mey[2], Volker Karius[2], Jörg Enderlein[2], Roman Tsukanov[2] and Sebastian Kruss[1,2,3]; [1]Ruhr University Bochum, Germany; [2]University of Göttingen, Germany; [3]Fraunhofer Institute for Microelectronic Circuits and Systems, Germany

The near-infrared (NIR) region of the electromagnetic spectrum presents optimal characteristics for imaging of complex (biological) samples due to reduced light scattering, absorption, phototoxicity and autofluorescence. However, despite their clear potential over commonly employed visible fluorophores, only few NIR fluorescent materials are known so far, and even less are suitable for biomedical applications. For this reason, it is of great interest to identify novel NIR fluorophores and use them for biomedical applications.
Here, we exfoliated a class of layered silicates: Egyptian Blue ($CaCuSi_4O_{10}$, EB), Han Blue ($BaCuSi_4O_{10}$, HB) and Han Purple ($BaCuSi_2O_6$, HP). These pigments fluoresce in the NIR ($\lambda_{emi} \approx$ 920-950 nm) with a long excited state lifetime ($\tau \approx$ 10-100 µs). By milling, tip sonication and several centrifugation steps, small and monodisperse 2D nanosheets (NS) could be exfoliated. The morphology of such NS was then fully characterized by atomic force (AFM) and scanning electron microscopy (SEM). Most interestingly, the intense NIR fluorescence emission of the bulk counterparts is retained in these nanostructures. In comparison to state-of-the-art fluorophores, EB-NS show no bleaching while displaying outstanding fluorescence intensity. These qualities of EB-NS enabled us to inject them into systems of biological relevance such as developing *Drosophila* embryos, and perform *in vivo* single-particle tracking and microrheology measurements. Furthermore, because of their high biocompatibility, it is possible to use them for NIR imaging in plants. [1]
The above mentioned three silicate NS are very bright and can be imaged through several cm of tissue phantoms, which demonstrates the potential for (bio)photonics. Finally, we used the microsecond fluorescence lifetimes of EB-NS, HB-NS and HP-NS for micro- and macroscopic fluorescence lifetime imaging (FLIM). The results show that lifetime engineering of these silicate nanostructures is possible and can be used for lifetime-encoded imaging. [2]
In summary, we present a new exfoliation route that yields NIR fluorescent nanosheets with high potential for bioimaging and photonics.

12:00 PM NM07.08.08
Late News: Strain Tuning of the Optoelectronic Properties of Two-Dimensional Crystals Elena Blundo[1], Marzia Cuccu[1], Pettinari Giorgio[2], Cinzia Di Giorgio[3], Tanju Yildirim[4], Paulo E. Faria Junior[5], Marco Felici[1], Fabrizio Bobba[3] and Antonio Polimeni[1]; [1]Sapienza, University of Rome, Italy; [2]National Research Council, Italy; [3]University of Salerno, Italy; [4]National Institute for Materials Science, Japan; [5]Universität Regensburg, Germany

The variegated family of two-dimensional materials comprises crystals that have attracted great interest for diverse characteristics and peculiarities. Among them, semiconducting transition-metal dichalcogenides (TMDs) possess alluring optoelectronic and spin properties when reduced to the single layer. In particular,

TMD monolayers are characterised by a direct bandgap, resulting in an efficient light emission in the visible/infrared range, which renders them appealing for optoelectronic devices. Furthermore, a strong spin-orbit coupling makes them interesting candidates for valley- and spin-tronics. Indeed, the inherent plane-confined nature of these materials -coupled to their exceptional mechanical flexibility and robustness- makes them highly sensitive to external stimuli. Methods to tailor their unique properties on demand have been thus sought after, and protocols based on controllable external perturbations such as mechanical deformations have shown promise in this respect.

Here, we present a novel technique to induce controllable strain-fields in TMD monolayers and study their effect on the optical and spin properties. Localised strains are created via low-energy hydrogen-ion irradiation of bulk TMDs, leading to the production and accumulation of molecular hydrogen in the first interlayer region. The trapped gas coalesces, leading to a local blistering of the material, and thus to the formation of one-monolayer-thick micro/nano-bubbles, which stud the crystal surface and locally turn the dark bulk material into an efficient light emitter. [1] Electron-beam-lithography-based approaches allowed us to achieve control over the formation process of the bubbles, and to create them in ordered arrays and with the desired dimensions (from few tens of nm to few microns). [1-2] These bubbles are durable and incredibly robust [3] and host complex strain fields, evaluated numerically, that cause dramatic changes in the TMD optoelectronic properties. Photoluminescence steady-state and time-resolved studies enabled the characterisation of the strain-induced band-structure modifications and revealed intriguing phenomena, such as bandgap crossovers enabling the creation of exciton states with long lifetimes. [4] Magneto-optical experiments allowed us to achieve unprecedented information on the spin and valley properties of strained TMDs, and led to the observation of hybridisation mechanisms between different band states.

Recently, the interest for TMD monolayers has surged due to the possibility to stack them via weak van der Waals forces to create heterostructures. TMDs have also been coupled with other semiconducting two-dimensional materials, such as post-transition-metal chalcogenides. Novel excitonic states -referred to as interlayer excitons- have been observed in TMD-based heterostructures, in which the two oppositely charged carriers forming the exciton are localised in different monolayers. Here, we exploit the same approach used for the formation of single monolayer bubbles to strain-tune the electronic properties of novel van der Waals heterostructures, and show how strain can play a crucial role by changing the relative band alignment of the stacked materials.

Our results unveil unprecedented information on the strain effects on TMDs and their heterostructures, the understanding of which represents an essential step towards their integration into flexible electronic devices.

1:00 PM NM07.09.01
Late News: Zero-Dimensional Graphene and Its Behavior During Mechanochemical Activation of Nanoferrites Monica Sorescu[1], Alice Perrin[2] and Michael McHenry[3]; [1]Duquesne University, United States; [2]MIT, United States; [3]Carnegie Mellon University, United States

Nickel ferrite nanoparticles were subjected to mechanochemical activation for ball milling times ranging from 0 to 12 hours. The milling was performed with and without the addition of equimolar concentrations of graphene nanoparticles. Characterization of resulting nano-powders was undertaken by Mossbauer spectroscopy and magnetic measurements. The hyperfine magnetic field was studied as function of milling time for octahedral and tetrahedral sites. An additional quadrupole split doublet represented the occurrence of superparamagnetic particles in the as-obtained and milled specimens. A new phase was obtained in the graphene-milled set of samples, which could be assigned to carbon-rich particles. The degree of inversion and canting angle were derived from the Mossbauer measurements and studied as function of ball milling time. The degree of inversion was found to decrease with milling time, especially for the set without graphene and evidenced a transition from inverse to normal spinels. The canting angle decreased with time for the graphene milled nanoparticles. The recoilless fraction was determined as function of milling time and was consistent with the observation – for the first time in literature – of a distribution of recoilless fractions in the studied specimens. The saturation magnetization, remanence magnetization and coercive field were derived from the hysteresis loops, recorded at 5K and 5T. The zero-field-cooling-field-cooling measurements were obtained in a magnetic field of 200 Oe and the blocking temperature was determined. Our results show new features of the behavior of nickel ferrite nanoparticles under mechanochemical activation with and without graphene.
Cobalt ferrite nanoparticles were exposed to mechanochemical activation, with and without equimolar amounts of graphene nanoparticles, for time periods ranging from 0 to 12 hours. Their structural and magnetic properties were detailed from Mossbauer spectroscopy and magnetic measurements. The Mossbauer spectrum corresponding to the unmilled cobalt ferrite powder was analyzed using 2 sextets, corresponding to the tetrahedral and octahedral sites of ferrites. The rest of the spectra was deconvoluted using an additional quadrupole-split doublet, with an abundance close to 30% and was assigned to superparamagnetic particles. Moreover, the spectra corresponding to milling with graphene at the longest times needed a third sextet, which could be assigned to iron carbide. The degree of inversion was determined from the Mossbauer spectra and found to decrease with milling time, both for the set with and that without graphene. The canting angle was derived and studied as function of the ball milling time for both sets of samples. Hysteresis loops were recorded at 5 K in an applied magnetic field of 5 T and was found to exhibit a constricted shape. Magnetization was plotted as function of temperature in the range 5-300 K with an applied magnetic field of 200 Oe using zero-field-cooling-field-cooling (ZFC-FC) measurements. These made it possible to determine the blocking temperature of the samples. Our data exhibit new characteristics of the cobalt ferrite nanopowders milled with and without graphene nanoparticles.

Acoustic Transport of Room Temperature Excitons in Monolayer WSe_2

Kanak Datta[1], Zidong Li[1], Zhengyang Lyu[1], Takashi Taniguchi[2], Kenji Watanabe[2] and Parag Deotare[1]; [1]University of Michigan–Ann Arbor, United States; [2]National Institute for Materials Science, Japan

In recent years, monolayer transition metal dichalcogenides (TMD) have garnered widespread interest from the research community across the world due to their exciting optical properties and strong light-matter interaction. As the optical properties of these materials are extremely sensitive to external mechanical stimuli, controlled static strain has been successfully applied to tune the light-matter interaction in these materials [1]. However, the interaction of excitons with the travelling strain and piezoelectric field generated by surface acoustic wave remains widely unexplored. Here, we experimentally investigate exciton transport in monolayer WSe_2 under surface acoustic wave.
We generate high-frequency Rayleigh type surface acoustic wave (SAW) by patterning interdigitated electrodes (IDTs) on 128^0 Y-cut piezoelectric lithium niobate ($LiNbO_3$) substrate using standard photolithography methods. The SAW resonators are designed for a resonance frequency of 600 MHz (SAW wavelength ~ 6 μm). We characterize the transport of excitons in hexagonal boron nitride (hBN) encapsulated WSe_2 monolayer using phase locked time correlated single photon counting (TCSPC). Upon RF excitation the travelling hydrostatic strain wave of the SAW modulates the conduction and valance band of the monolayer WSe_2 in opposite phase resulting in localized potential pockets, commonly referred as type – II bandgap modulation [2]. The resulting

potential pockets can capture and result in long-range transport of excitonic species.
We observed strong coupling of monolayer exciton species to the travelling strain field generated by the surface acoustic wave that resulted in remote recombination of the transported excitons. Using measured exciton lifetime of 1.27 ns, we estimate the exciton velocity under acoustic modulation to be 0.78×10^3 ms^{-1}. Using experimentally reported value of strain mobility in monolayer WSe_2 [3], we estimate the hydrostatic strain on the monolayer to be 0.4%. Our observations show that the transport distance is mostly limited by the intrinsic exciton mobility and lifetime in monolayer WSe_2.

Late News: Structural and Spectroscopic Investigation of Layered Semiconductor-Iron Phosphorus Trisulfide-$FePS_3$
Adam K. Budniak[1], Szymon J. Zelewski[2], Magdalena Birowska[3], Tomasz Wozniak[2], Tatyana Bendikov[4], Yaron Kauffmann[1], Yaron Amouyal[1], Robert Kudrawiec[2] and Efrat Lifshitz[1]; [1]Technion - Israel Institute of Technology, Israel; [2]Wroclaw University of Science and Technology, Poland; [3]University of Warsaw, Poland; [4]Weizmann Institute of Science, Israel

Binary layered semiconductors, especially transition metal dichalcogenides (TMDs), are among the most studied van der Waals (vdW) semiconductors. Recently ternary layered materials are drawing more attention due to their attractive properties.[1]

Amid ternary vdW semiconductors, iron phosphorus trisulfide - $FePS_3$ - is an interesting material. It belongs to a family of transition metal phosphorus trisulfides (TMTs) with general formula MPS_3. $FePS_3$ is magnetic semiconductor, absorbing in near IR, and it is also relatively stable in exfoliated form. Large $FePS_3$ crystals (almost centimeter size) have been obtained in big amounts (more than 70% chemical yield) via chemical vapor transport (CVT). Bulk material is investigated by X-Ray and ultraviolet photoelectron spectroscopy (XPS and UPS). Optical properties are carefully studied with temperature change. The results are further corroborated with DFT calculations. $FePS_3$ is both mechanically and liquid exfoliated and obtained products are compared by X-Ray diffraction (XRD) and then by conventional transmission electron microscopy (cTEM), carefully proceeded for chosen crystallographic directions with high-resolution analysis for both kinds of samples.[2] Here, a simple, one-step protocol for mechanical exfoliation directly onto transmission electron microscope grid is used as an efficient sample preparation method.[1,2,3] Finally, atomic resolution elemental maps are registered with high-resolution scanning transmission electron microscope (HR-STEM) and reveal directly the atom columns arrangement.[2]

At last, the large-scale project will be briefly described, where vdW materials are used for the first time for tunable X-Ray emission. The X-Ray radiation is produced from two combined mechanisms [called parametric coherent bremsstrahlung (PCB) collectively]: parametric X-ray radiation (PXR) and coherent bremsstrahlung (CBS). $FePS_3$ with other ternary vdW materials $CrPS_4$, $MnPS_3$, $CoPS_3$, $NiPS_3$, and also binary WSe_2, are mechanically exfoliated and transferred to electron microscopy grids. Next, they are irradiated by an electron beam inside a transmission electron microscope. The tunability of energy of emitted X-Ray is achieved both by adjusting electrons acceleration voltage or using different material as the emitter.[3]

1:35 PM NM07.09.05
Late News: Mobile Charges and Intertube Excitons in 1D van der Waals Coaxial Nano-Cables Maria Burdanova[1], Reza Kashtiban[1], Yongjia Zheng[2], Rong Xiang[2], Shohei Chiashi[2], Shigeo Maruyama[2] and James Lloyd-Hughes[1]; [1]University of Warwick, United Kingdom; [2]The University of Tokyo, Japan

Heterostructures built from atomically thin 2D crystals, and bound by the van der Waals force, are well known to exhibit attractive optoelectronic properties and exotic physics. For instance, the strong Coulomb interactions can create bind charges across an interface, creating interlayer excitons with longer lifetimes. However the quantum confinement of electrons in quasi-1D structures creates distinctly different possibilities than available in 2D, as can be seen by contrasting graphene (a semi-metal in 2D with no excitonic absorption) and carbon nanotubes (semiconducting for certain chiralities, and featuring strong excitonic absorption).

Here we report the structure, composition and optoelectronic properties of a 1D van der Waals heterostructure consisting of nano-scale coaxial cables [1,2]. Carbon nanotubes (CNTs) formed the "core" of the cable, and were wrapped by atomically-thin nanotubes of the insulator boron nitride, and then by molybdenum disulfide (MoS_2). The high quality of the composite was directly evident on the atomic scale from high-resolution transmission electron microscopy, and on the macroscopic scale by a study of its equilibrium and ultrafast optoelectronics [2].

We used THz spectroscopy to establish the good conductance of the CNT cores within the coaxial nano-cable, which can be therefore be regarded as a radial metal/insulator/semiconductor heterojunction. Via optical pump, THz probe spectroscopy we investigated the electron mobility of the MoS_2 nanotubes, finding that it was comparable to that of high-quality atomically-thin 2D crystals of MoS_2. The high mobility of the MoS_2 nanotubes highlights the huge potential of the coaxial "hetero-nanotube" growth platform for nanoscale optoelectronic devices [3].

Finally, we addressed the intriguing question: can the optical properties of such coaxial nano-cables be described by the average properties of each material in isolation, or do interactions between the materials lead to unique new properties? To investigate, we used multi-colour infrared pump, visible probe spectroscopy to selectively create excitons in the carbon nanotubes, while probing the response of the A and B excitons in the MoS_2 nanotube sheath. We observed a rapid and strong excitonic response of the MoS_2 to the presence of excitons in the carbon nanotube core. This observation is surprising as in the single-photon, single particle picture a photon from the infrared pump pulse (0.6eV) does not give an electron sufficient energy to cross the MoS_2 excitonic gap (1.9eV). Further, charge transfer processes are prohibited by the intermediate BN insulating layer. However, our experimental findings can be understood by considering the strong Coulomb correlations between the carbon nanotube core and the MoS_2 sheath, which created the intertube excitonic and biexcitonic absorption features observed in the transient spectra. This first observation of intertube excitons, analogous to the interlayer excitons of 2D heterostructures, further underscores the potential of 1D van der Waals materials for basic science and future applications.

1:50 PM *NM07.09.06
Van der Waals Heterostructure Magnetic Josephson Junction Philip Kim; Harvard University, United

States

When two superconductors are connected through a ferromagnet, spin configuration of the transferred Cooper pairs can be modulated due to the exchange interaction. The resulting supercurrent can reverse its sign across the Josephson junction, depending on the thickness of the ferromagnetic weak link. In this talk, we present Josephson phase engineering in van der Waals heterostructures of atomically thin magnetic insulator Cr2Ge2Te6 sandwiched between NbSe2 van der Waals superconductors. Employing a superconducting quantum interference device based on our magnetic insulator Josephson Junctions, we reveal a doubly degenerate nontrivial Josephson phase originating from the magnetic barrier. We find that these unusual magnetic Josephson junctions are formed by momentum conserving tunneling of Ising Cooper pairs of NbSe2 across the magnetic domains of atomically thin Cr2Ge2Te6. The doubly degenerate ground states in magnetic insulator Josephson junction provide a quantum two-level system which can be utilized as a new component for superconducting quantum devices

4:00 PM *NM07.10.01
Orbital Magnetism in Graphene Heterostructures Andrea Young; University of California, Santa Barbara, United States

Ferromagnetism arises from the interplay of the Coulomb repulsion between electrons and their fermionic statistics. The vast majority of magnets consist of ordered arrangements of the electron spins stabilized by the spin orbit interaction. In my talk, I will describe a new class of magnets based on the spontaneous alignment of electron orbitals. Such orbital ferromagnetism may be a generic phenomena, but has, to date, found its fullest expression in graphene heterostructures in which the two dimensional orbits of electrons in distinct momentum space valleys provide the underlying degree of freedom for magnetic order. These magnetic degrees of freedom arise directly from the band wavefunctions, making orbital magnets exquisitely sensitive to both the design of the electronic wavefunctions as well as in situ control parameters. For example, in systems in which interlayer lattice mismatches lead to a moire superlattice potential, the resulting superlattice band structure may feature nontrivial topology, which in conjunction with orbital magnetism can give rise to precise quantization off the Hall effect at zero magnet field. Remarkably, the conduction electrons themselves can also directly influence the magnetic order, leading to field-effect switchable magnetic moments. Finally, I will conclude with our progress towards using orbital magnetism to engineer "topologically ordered" states at zero magnetic field, in which the electron splits into fractionally charged anyons.

Late News: Molybdenum Disulfide Nanoribbons—Scalable Fabrication, Structure-Properties Correlation, Precision Manipulation and Applications Yun Huang[1], Kang Yu[1,2], Huaizhi Li[1], Kai Xu[3], Zexi Liang[1], Debora Walker[4], Paulo Ferreira[1,2,5], Peer Fischer[6,7] and Donglei (Emma) Fan[1,1]; [1]The University of Texas at Austin, United States; [2]International Iberian Nanotechnology Laboratory, Portugal; [3]University of Illinois at Urbana-Champaign, United States; [4]Harvard University, United States; [5]University of Lisbon, Portugal; [6]Max-Planck-Institute for Intelligent Systems, Germany; [7]University of Stuttgart, Germany

In the family of two-dimensional (2D) transition metal dichalcogenide (TMD) materials, molybdenum disulfide (MoS_2) has received immerse attention owing to its desirable electrical, chemical, and mechanical properties. Similar to single-crystalline MoS_2 nanostructures, polycrystalline MoS_2 structures also possess many desirable

properties for applications, such as outstanding catalytic properties. Recently we reported an innovative and scalable approach to synthesize MoS_2 nanoribbons with tunable dimensions and excellent dispersibility in suspension [1]. The obtained polycrystalline MoS_2 nanoribbons exhibit high chemical purity which endows them with much-enhanced surface reactivity compared to those of their single-crystal counterparts. They can be readily grafted with UV-triggered click-chemistry ; they effectively react and remove mercury contaminates from water. They also possess an ultrafast optoelectronic response from 450 nm to 750 nm that is the same as the single-crystal forms. In this presentation, we highlight these properties and describe in detail our newly obtained unpublished result on the electronic properties of the MoS_2 nanostructures and how these determine their manipulation and electro-rotation behavior. We show that the nanoribbons can be manipulated efficiently in a high-frequency electric field. They propel along arbitrary paths on a 2D surface, assemble rapidly on prepatterned microelectrodes, and rotate clockwise and counter-clockwise. Their mechanical behaviors reflect their semiconductor electronic type, distinct from those of metals or insulators, which provides additional support to their optoelectronic characterizations. The fabrication, manipulation, assembly, and unique properties of the obtained MoS_2 is useful for device fabrication, and applications of the TMD family.

4:40 PM NM07.10.03
Late News: Narrow Excitonic Lines and Large-Scale Homogeneity of Transition Metal Dichalcogenides Grown by MBE on hBN Wojciech Pacuski[1], Magdalena Grzeszczyk[1], Karol Nogajewski[1], Aleksander Bogucki[1], Kacper Oreszczuk[1], Aleksander Rodek[1], Julia Kucharek[1], Karolina E. Polczynska[1], Bartlomiej Seredynski[1], Rafal Bozek[1], Slawomir Kret[2], Takashi Taniguchi[3], Kenji Watanabe[3], Janusz Sadowski[1,2,4], Tomasz Kazimierczuk[1], Marek Potemski[1,5] and Piotr Kossacki[1]; [1]University of Warsaw, Poland; [2]Institute of Physics of the Polish Academy of Sciences, Poland; [3]National Institute for Materials Science, Japan; [4]Linnaeus University, Sweden; [5]Laboratoire National des Champs Magnétiques Intenses, France

Monolayer transition metal dichalcogenides (TMDs) are two-dimensional materials with exceptional optical properties such as high oscillator strength, valley related excitonic physics, efficient photoluminescence, and several narrow excitonic resonances. However, above effects have been so far explored only for structures produced by techniques involving mechanical exfoliation and for the best results, encapsulation in hBN, both proceedures inevitably inducing considerable large-scale inhomogeneity. On the other hand, techniques which are essentially free from this disadvantage, such as molecular beam epitaxy (MBE), have to date yielded only structures characterized by considerable spectral broadening, which hinders most of interesting optical effects.

We report for the first time on the MBE-grown TMD exhibiting narrow and fully resolved spectral lines of neutral and charged exciton. Moreover, our MBE-grown TMD exhibits unprecedented high spatial homogeneity of optical properties, with variation of the exciton energy as small as 0.16 meV over a distance of tens of micrometers. Our recipe for MBE growth [1,2] is presented for MoSe2 and includes extremely slow growth rate, the use of atomically flat hexagonal boron nitride (hBN) substrate and the annealing at very high temperature. Importantly, good optical properties are achieved for as-grown sample, without any post growth exfoliation and encapsulation in hBN. This novel recipe opens a possibility of MBE growth of TMD and their heterostructures with optical quality, dimensions and homogeneity required for optoelectronic applications.

Electrical Control of Strong-Light Matter Interactions in $MoTe_2$ Souvik Biswas[1], Zakaria Al Balushi[1,2],

Eoin Caffrey[1], Sergiy Krylyuk[3], Joeson Wong[1], Kenji Watanabe[4], Takashi Taniguchi[4], Albert Davydov[3] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]University of California, Berkeley, United States; [3]National Institute of Standards and Technology, United States; [4]National Institute for Materials Science, Japan

Light matter interaction between excitonic resonances in atomically thin TMDCs, which are highly susceptible to electrostatic stimulus, and cavity polaritonic modes can enable novel electro-optic functionalities. In this work, we investigated electrical control of strong light-matter interactions in molybdenum ditelluride via opto-electronic modulation of an h-BN encapsulated monolayer $MoTe_2$ gated heterostructure designed also as a 'Salisbury-screen' photonic resonant absorber.

Using low temperature reflection contrast and photoluminescence measurements at different Fermi-level values, we observed strong modulation of the A 1s, 2s and B 1s exciton and trion peaks. Our results can be primarily understood from increased electronic doping which gives rise to enhanced elastic Coulomb scattering and screening – resulting in oscillator strength shifts from excitons to trions and also spectral broadening of the individual resonances. Moreover, many body effects leading to band-structure renormalization were seen from the changes in the binding energy of the different excitonic species with increased charge density. We performed transfer matrix calculations to obtain the complex dielectric function of $MoTe_2$ at each Fermi level position. Notably, we observed unity-order refractive index modulation at the A1s exciton. Additionally, we also studied the influence of optical pumping by performing laser fluence dependent emission measurements. Spectral broadening of the excitonic features was observed, indicating exciton-exciton interaction at higher pump powers. Our results shed light on the strongly correlated many-body interactions in $MoTe_2$ and suggest paths for integration into active devices such as near infrared electro-optical modulators.

Fracture Toughness and Fracture Strain of Single-Layer Freestanding Graphene Extracted by On-Chip Testing Sahar Jaddi[1], Bin Wang[1,2], Mohammad W. Malik[1], Yun Zeng[2], Jean-Pierre Raskin[1] and Thomas Pardoen[1]; [1]UCLouvain, Belgium; [2]Hunan University, China

Graphene has attracted the attention of the scientific community for the last two decades, thanks to an astounding set of properties such as high thermal conductivity (5000 W/mK), superior electron mobility (250,000 cm^2/V-s), high modulus of elasticity (~1 T Pa), and ultra-high flexibility. Graphene's C-C bonds are sp^2 hybridized providing superior mechanical stability in the basal plane directions. Graphene appears as the perfect material constituent for a wide range of application fields, like in flexible electronics, in electromechanical devices, and in reinforced lightweight composites that rely on both electrical and mechanical performances. It remains crucial to determine the latter properties under realistic and well-controlled conditions to guide the fail-safe design of graphene-based applications.

While the mechanical behavior of graphene has been very much investigated numerically for both perfect and defected lattice structures [1,2], most experimental works remain partly inconclusive regarding the fracture resistance. Nanoindentation of a suspended single layer (SLG) and of multilayer graphene (MLG) on top of holes [3,4], and uniaxial tensile test using the so-called push-to-pull device, are mostly used to deform graphene [8,9]. Testing graphene using a valid fracture mechanics approach is very complex due to the nature of the fabrication, the difficulty of pre-cracking, and the delicate data analysis. Two reports on the fracture toughness of SLG have been published [5,6], while other data are for MLG [7, 8]. The aforementioned works have provided insight into the fracture mechanisms of graphene, using a notch as a starter crack. This can potentially lead to an overestimation of the fracture toughness with a dependence on the notch root radius, which is difficult to deconvolute. Furthermore, the notch is produced by a focus ion beam, which may introduce damage. These tensile and fracture tests relied on external equipment either for loading or sensing, leading to cumbersome manipulation and allowing only a few specimens to be tested, preventing statistical analysis.

In the present work, we report two novel extensions of methods developed in our laboratory to study the mechanical and fracture properties of freestanding SLG. The method relies on the use of residual tensile-stress involved in a beam layer called the actuator beam. This beam is attached to the graphene specimen. Removing the sacrificial layer induces the release of internal stress in the actuator, pulling then on the graphene specimen. Hence, the use of external (electro-)mechanical actuation is avoided. In a first configuration, the actuator layer is pulling on a dog-bone shape or rectangular graphene specimen, from which the uniaxial stress-strain curve is extracted up to fracture [10]. In a second configuration, two actuator beams pull on a notched specimen but using a crack arrest method to determine the fracture toughness suppressing the problem of notch blunting effect at crack initiation [11]. Benefiting from the lithography process, numerous devices have been fabricated hence providing statistically representative data. Our investigation shows fracture strains larger than 10% and tensile strength larger than 100 GPa for specimens with an area larger than 160 mm^2. Brittle fracture behavior is observed with fracture toughness value equal to about 4 MPa $m^{0.5}$ in agreement with literature.

Nanoscale Anisotropic Strain Dynamics in MoS_2 Imaged with Ultrafast Electron Microscopy Yichao Zhang and David Flannigan; University of Minnesota Twin Cities, United States

The large anisotropy of the bonding states in layered transition metal dichalcogenides (TMDs) provides an additional dimension to modulate materials properties [1,2]. For example, relatively weak interlayer van der Waals forces lead to distinctly different electronic, mechanical, vibrational, and electrochemical properties along the *c*-axis of MoS_2 compared to the basal plane. Efforts have been focused on probing photoinduced structural dynamics in the basal plane, where strong covalent bonding dominates the response of the material [3,4]. Comparatively few ultrafast studies have shown the different nature of photoexcited structural dynamics along the *c*-axis as compared to the in-plane behaviors [5,6]. In addition, defects play an important role in the nucleation of coherent strain waves studied with the bright-field imaging modality of ultrafast electron microscopy (UEM) [7-9].

Here, we report the combined study of direct imaging of photoinduced localized *c*-axis acoustic-phonon dynamics of a free-standing, multilayer MoS_2 flake with UEM and finite element transient deformation analysis with COMSOL. With nanometer-picosecond spatiotemporal resolutions in bright-field imaging, we observe and quantify the emergence and oscillation of two spatially localized interlayer breathing modes separated by a 10-nm thick step edge, with the difference in frequency due to the different thicknesses in the two respective regions. The onset of coherent contrast dynamics in the thicker region of the terrace is delayed by 2 to 3 ps, indicating a more rapid structural response to photoexcitation in the thin region of the terrace. Time-dependent finite element analysis on a terrace of the same dimensions as the specimen shows excellent agreement with experimental results. Photoexcitation was modeled by applying a spatially varying strain profile along the *c*-axis calculated based on the absorption of multilayer MoS_2 and the thickness of the terrace, leading to a discontinuity of the *c*-axis strain profile at the step edge. Both experiment and simulation captured a gradual decrease of 1 to 2 GHz of the oscillation frequencies starting 50 to 100 nm away from the step edge on both

sides of the terrace, likely due to the additional force component along the *c*-axis opposed to wave propagation because of the distortion of the basal-plane covalent bonds. These results provide insights into the local, nanoscale nature of transient lattice deformations and the associated impacts on phonon dynamics in layered materials [10].

Unconventional Superconductivity Mediated by Spin Fluctuations in Single-Layer $NbSe_2$ Wen Wan, Paul Dreher, Rishav Harsh, Francisco Guinea and Miguel M. Ugeda; Donostia International Physics Center, Spain

Van der Waals materials provide an ideal platform to explore superconductivity in the presence of strong electronic correlations, which are detrimental of the conventional phonon-mediated Cooper pairing in the BCS-Eliashberg theory and, simultaneously, promote magnetic fluctuations. Despite recent progress in understanding superconductivity in layered materials, the glue pairing mechanism remains largely unexplored in the single-layer limit, where electron-electron interactions are dramatically enhanced. Here we report experimental evidence of unconventional Cooper pairing mediated by magnetic excitations in single-layer $NbSe_2$, a model strongly correlated 2D material. Our high-resolution spectroscopic measurements reveal a characteristic spin resonance excitation in the density of states that emerges from the quasiparticle coupling to a collective bosonic mode. This resonance, observed along with higher harmonics, gradually vanishes by increasing the temperature and upon applying a magnetic field up to the critical values (T_C and H_{C2}), which sets an unambiguous link to the superconducting state. Furthermore, we find clear anticorrelation between the energy of the spin resonance and its harmonics (Ω_n) and the local superconducting gap (Δ), which invokes a pairing of electronic origin associated with spin fluctuations. Our findings demonstrate the fundamental role that electronic correlations play in the development of superconductivity in 2D transition metal dichalcogenides, and open the tantalizing possibility to explore unconventional superconductivity in simple, scalable and transferable 2D superconductors.

Multiscale Phonon Green's Function for Silicene with and without Lattice Defects and Its Applications
Vinod K. Tewary and Edward Garboczi; National Institute of Standards and Technology, United States

Since the advent of graphene, many new two-dimensional (2D) materials have been either fabricated or theoretically proposed. These new materials, the so called 2D materials beyond graphene, represent a revolutionary new development in the science and technology of materials. Silicene, a 2D allotrope of silicon, is one of these materials. Compared to the normal 3D solids, the electronic as well as phononic characteristics of these materials are quite unusual. It has a stronger spin-orbit coupling, which gives rise to quantum spin Hall effect. Further, it has an electrically tunable band gap, a property useful in the design of field effect transistors at room temperatures. Hence, there is a strong interest in silicene for solid state devices for diverse applications such as thermal management, thermoelectric energy conversion, quantum computing, and spintronic devices. A reliable and robust mathematical model is necessary for industrial development of new materials. It is needed

for development of their characterization and testing systems and for virtual experimentation for providing answers to “what if” type questions. The conventional modelling techniques based upon the continuum approximation of solids are not applicable to 2d materials. One obvious reason is that the solid has almost 0 thickness. This introduces a discontinuity in the derivatives of field quantities, in the direction of the thickness. Hence all components of the standard continuum parameters, like stress and strain tensors, are not rigorously defined for 2d materials. Modeling 2d materials is, therefore, a multiscale many body problem, which must be valid at the atomistic scales.
Further, it has been recognized that the performance and stability of quantum materials are sensitive to the presence of lattice defects. Lattice defects induce displacement field in the solid, which strongly affects thermal, optical and electronic parameters of the solid. The elastic displacement field due to a point defect in the plane of the solid has a logarithmic behavior, which introduces a size effect in the material parameters, which must be accounted for in modeling and interpretation of measurements. Hence a discrete atomistic scale model needs to be large in order to avoid spurious size effects.
Finally, the model should be able to simulate low frequency phonons and their interaction with the electrons, which make a significant contribution to the thermal and possibly even quantum response of the solid. All these requirements make modeling of silicene a highly challenging task for which special techniques are needed. A conventional molecular dynamics based model is computationally inefficient for modeling low frequency phonons in large crystallites because of rather poor mathematical convergence.
At NIST, we have developed a multiscale phonon Green’s function method, which is very efficient for modeling the phononic response of 2d quantum materials. Our method can simulate a million atoms over an extended time range on an ordinary desktop computer. The power of the Green’s function method arises from the fact that we retain up to second order terms in the expansion of the lattice Hamiltonian in terms of the atomic displacements. In contrast, only the first order terms are retained in standard molecular dynamics. The second order term is crucial for phonon applications because the phonon energies are determined by the second order term.
In this talk I will briefly describe our Green’s function method and its application to calculation of phonon related properties of 2d quantum materials with and without lattice defects, such as vacancy, lithium, phosphorous, and boron. Numerical results will be presented for silicene.

Theoretical Performance Limits of Graphene Hot Electron Emission Ragib Ahsan, Hyun Uk Chae and Rehan Kapadia; University of Southern California, United States

Electron emission devices with ultrahigh emission current density and ultrafast response are instrumental to applications including but not limited to electron microscopy, high power microwave generation, and free electron lasers. A key limitation to achieving the ultrahigh emission current density and ultrafast response lies in the 3D nature of electron emitters. In a 3D photoemitter, the photons are absorbed at a finite depth and the excited electrons need to transit to the emitting surface before they can be extracted. During this transit process, these high energy electrons lose their excess energy due to electron-phonon and electron-electron scattering. In a 2D material like graphene, the excited electrons are always at the emitting surface and therefore the transit length is effectively eliminated. In a recent experimental study, it has been demonstrated experimentally that a waveguide integrated graphene photoemitter can absorb nearly 100% of the photons traveling through the waveguide and the excited electrons can be extracted by applying a dc electric field with a quantum efficiency that exceeds 5 orders of magnitude compared to that of multiphoton and strong field photoemitters. In this work, we have performed a theoretical investigation of the performance limits of such a photoemitter by solving for the Monte Carlo Boltzmann Transport Equation (MCBTE) accounting for the scattering processes in graphene as well as the tunneling rates into the vacuum as a function of absorbed optical power density, photon energy and applied dc electric field. The rates of different scattering and tunneling processes were calculated by quantum mechanical theory using Fermi’s golden rule. We have shown that the theoretical model can reproduce the experimental results with good quantitative agreement. Our results predict two regimes of operation for graphene hot electron emitters: (a) single hot electron emission at lower power densities ($< 10^9$ W/m^2) and (2) ensemble hot electron emission at higher power densities ($> 10^9$ W/m^2) where the electronic temperature of

graphene increases beyond the lattice temperature. In the ensemble hot electron emission regime, it is possible to achieve a quantum efficiency that exceeds 100% with a response time below a picosecond. This theoretical study demonstrates an experimental roadmap towards realizing high efficiency electron emission with large emission current densities and ultrafast response times.

Atomistic Mechanism of Stress Modulated Phase Transition in Monolayer MoTe2 Wei Gao; The University of Texas at San Antonio, United States

Monolayer MoTe2, one of the 2D transition metal dichalcogenide (TMD) materials, exhibits two stable structural phases: semiconducting 2H phase and metallic 1T′ phase. The dynamic control of the transition between these two phases on a single atomically thin sheet holds promise for a variety of revolutionary device applications. Particularity, stress could be utilized to dynamically modulate such phase transition. To date, the atomistic and kinetic mechanism of the phase transition under stress is not clear. In this study, the finite deformation nudged elastic band method and density functional theory are applied to determine the phase transition barriers and pathways of monolayer MoTe2 as a function of applied stress. It is found that the stress can greatly influence the thermodynamics and kinetics of the phase nucleation and propagation. The results shed light on the phase engineering of 2D TMD materials with stress at the atomic leve

Mode-Dependent Thermal Conductivity and Size Effects in Planar SiC and h-BN Sheets Yuqing Huang, Anant Raj and Jacob Eapen; North Carolina State University, United States

Low-dimensional systems such as graphene and planar h-BN sheets exhibit anomalous size-dependent thermal transport. Non-equilibrium atomistic simulations using a constant heat current or a temperature gradient are ideal for analyzing this size dependency. Most analyses to date have employed the Fourier representation with complex normal mode coordinates to describe the phonon modes; while this representation is sufficient for computing the phonon dispersion relationships or spectral energy density, it lacks a precise capability to express the modal energy, and more importantly, a real modal heat current along a specified wave-vector. In this work, we adopt our recent non-equilibrium molecular dynamics approach [*J. Chem. Phys.*, **151**, 104110 (2019)], which employs a set of real asymmetric normal mode amplitudes that can unambiguously define the exact modal heat currents in a given direction, to extract the size-dependent modal thermal conductivity in planar SiC and h-BN sheets under a temperature gradient. We capture both the left-going and right-going modal heat current and phonon population independently, which is theoretically impossible with the traditional complex normal mode coordinates, and contrast their size-dependent behavior in planar SiC and h-BN sheets. While a modified Tersoff potential is used to describe the interatomic interactions in the planar SiC, the recently developed EXTEP potential is employed for h-BN. We anticipate that our approach would particularly be useful to characterize thermal transport in low-dimensional systems and molecular junctions where bulk or effective thermal properties are ill-defined or difficult to access.

Late News: Substitutional Doping of Fe on Magnetism in MoS2 and WS2 Monolayers Siwei Chen, Kyungnam Kang, Shichen Fu and Eui-Hyeok Yang; Stevens Institute of Technology, United States

The doping of two-dimensional (2D) semiconductors has been intensively studied toward modulating their electrical, optical, and magnetic properties. While ferromagnetic 2D semiconductors hold promise for future spintronics and valleytronics, the origin of ferromagnetism in 2D materials remains unclear. Here, we present that substitutional Fe-doping into MoS_2 and WS_2 monolayers to induce magnetic properties. The Fe-doped monolayers were directly synthesized *via* chemical vapor deposition. A Fe_3O_4 powder was sandwiched between a bare SiO2/Si substrate and the transition metal oxide-deposited substrate for the growth. After loading the substrates and precursors, Ar gas was supplied, and the furnace temperature was increased up to 900 °C. Fe substitutional doping was *successfully* achieved, as confirmed using scanning transmission electron microscopy. While both Fe:MoS_2 and Fe:WS_2 showed PL quenching and n-type doping, Fe dopants in WS_2 monolayers were found to assume deep-level trap states, in contrast to the case of Fe:MoS_2, where the states were found to be shallow. Unlike MoS_2 monolayers showing ferromagnetic behavior, WS_2 monolayers showed paramagnetic behavior upon Fe-doping. These contrasting magnetic behaviors caused by paired Fe atoms can be attributed to paired Fe atoms generating more accumulated electric charge in Fe:WS2 by pulling the Fe atoms apart. These findings allow us to control the material's magnetic properties layer-by-layer and can be applied for spintronics.

7:50 PM NM07.11.04
Late News: Quasi-Fermi Level Splitting in Monolayer Transitional Metal Dichalcogenides and Its Manipulation Thereof. Mike Tebyetekerwa, Daniel Macdonald and Hieu Nguyen; Australian National University, Australia

Quasi-Fermi level splitting ($\Delta\mu$) of any material under illumination symbolizes the maximum possible open-circuit voltage (*Voc*) that a photovoltaic device can reach if made out of that material in ideal conditions. We have experimentally quantified the $\Delta\mu$ (*Voc*) values of various monolayer transitional metal dichalcogenides (TMDs). Briefly, we employed optical non-destructive techniques of micro-photoluminescence and micro-absorption spectroscopy with reference to the generalized Planck law of emission. We report that the photovoltaic devices made of monolayer WS_2, MoS_2, WSe_2, and $MoSe_2$ can possibly yield *Voc* values of up to ~1.4, 1.12, 1.06, and 0.93 V at 1 Sun illumination, respectively. We further show some of the different possible ways to manipulate the reported *Voc* performance using external voltage and chemical molecules of aggregation-induced emission in Type-I heterostructures.

7:55 PM NM07.11.05
Late News: Small-Nanostructure-Size-Limited Phonon Transport within Composite Films Made of Single-Wall Carbon Nanotubes and Reduced Graphene Oxides Qiyu Chen[1], Xiaolu Yan[2], Leyuan Wu[2], Yue Xiao[1], Sien Wang[1], Guoan Cheng[2], Ruiting Zheng[2] and Qing Hao[1]; [1]University of Arizona, United States; [2]Beijing Normal University, China

Nanocarbon materials have been widely used for nanoelectronics and other energy-related applications. In the kinetic relationship, the phonon (lattice) thermal conductivity is given as $k_L \sim C_p v_g \Lambda$, with C_p as the phonon specific heat, v_g as phonon group velocity, Λ as phonon mean free paths (MFPs). Within general composite films made of reduced graphene oxides (rGO) and carbon nanotubes (CNTs), the existence of many nanocontacts results in a k reduction but the loss in k can be overshadowed by the significant advantages of using bulk composites for large-scale applications. Detailed thermal analysis of composite films made of rGO and CNTs is still lacking, particularly for the individual in-plane $k_\parallel$ contribution from each constituent material within the complicated 3D nanocarbons. In this work, composite films consisting of rGO nanosheets and varied weight percentage of single-wall CNTs (SWCNTs) are synthesized and studied for their in-plane thermal conductivities, in which increased SWCNTs percentage leads to a reduced $k_\parallel$. Different from pristine graphene and other composite nanocarbon films with decreased thermal conductivities above 300 K, the in-plane thermal conductivities of these composite films are found to follow the trend of the specific heat of graphene from 100 K to 400 K, i.e., monotonously increasing at elevated temperatures. For investigated samples, the extracted $k_\parallel$ can be matched by a scaled curve for the product $C_p v_g$ summed up for all phonon modes that are computed for pristine graphene. This indicates that the rGO nanosheets contribute significantly to the $k_\parallel$ but their MFPs are

largely restricted by the dense SWCNT-graphene junctions and additional graphene-graphene nanocontacts. Such a trend has seldom been observed for nanocarbon. This unique temperature dependence of thermal conductivities is attributed to the so-called small-nanostructure-size (SNS) limit, at which the phonon MFPs are simply restricted as the structure size. This SNS limit is often found at cryogenic temperatures where the majority bulk phonon MFPs are much longer than the sample size. But in this study, the intrinsically long phonon MFPs within the initial graphene sheets and the dense SWCNT-graphene/graphene-graphene nanocontacts result in $k \approx k_L$ following the SNS limit even up to 400 K. The highest in-plane thermal conductivity among samples with different synthesis conditions is 62.8 W/mK at 300 K which is significantly higher than amorphous materials with a similar temperature dependence of thermal conductivities. Such a high thermal conductivity, combined with its unique temperature dependency, can be ideal for applications such as flexible film-like thermal diodes based on the junction between two materials with a large contrast for their temperature dependence of the thermal conductivity.

8:00 PM NM07.11.06
Late News: Effect of Ti-Doping on Group-14 Elemental Two-Dimensional Materials as a Method for Improving the Quantum Capacitances Juven Rihm[1], Eun Seob Sim[1], Sung Beom Cho[2] and Yong-Chae Chung[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Electric double-layer capacitors (EDLCs) are one of the most promising candidates for environmentally friendly and sustainable energy storage systems due to their balanced energy-power density compared to conventional batteries and capacitors. As key materials for EDLCs, group-14 elemental two-dimensional materials (ETDMs) possess extremely large surface area for doping and ion adsorption, which is advantageous for maximizing the charge storage. However, one of the bottlenecks that limits the performance as EDLCs is the ETDMs' lack of density of states (DOS) near the Fermi level (E_F) that can store the charge transferred from the ions. In this study, to provide additional DOS near the E_F, Ti-doping was introduced to the ETDMs. The density functional theory (DFT) calculation revealed that additional DOS was provided to ETDMs by the d band of doped Ti atom. Since the surface charge densities increased due to the newly formed DOS near the E_F, the quantum capacitances were also enhanced. In addition, among the Ti-doped ETDMs, Ti-doped silicene is found to have superior characteristics at the low voltage range. These findings may provide practical guidelines for improving the performance of EDLCs.

8:05 PM NM07.11.07
Late News: Enhanced Metallicity in Defected Zigzag Graphene Nano Ribbons—Role of Oxygen Doping Sonal Agrawal, Anurag Srivastava and Gaurav Kaushal; Atal Bihari Vajpayee Indian Institute of Information Technology and Management, India

The effect of Oxygen (O) doping in Zigzag Graphene Nano ribbons (GNR) has been investigated in terms of their stability and electronic properties, using density-functional theory-based ab-initio approach. The Zigzag GNR has been subjected to mono vacancy and decorated with three possible sites of oxygen impurities around the MonoVacancy (MV). The stability of the systems has been analysed in terms of cohesive energy, and the electronic properties in terms of band structure, and density of states profiles. The cohesive energy calculations suggest that formation of the pyridine-type defects with oxygen doping, have nearly the same stability in the case of monovacancy introduced system. The electronic bandstructure and density of state profile observed that the metallicity of the ZGNR enhances with O doping, validated through increase in density of states at the fermi level. This enhanced metallicity in ZGNR, defends its application as metallic electrodes as well as interconnects in electronic industry.

8:10 PM NM07.11.08
Large-Scale Lithium-Intercalated Multilayer Graphene Production Joseph Andrade[1], Mohamed Boukhicha[2], Jan Folkson[1], Amanda Carr[1] and Matthew Eisaman[1]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

For more than 70 years, Graphite Intercalated Compounds (GICs) have been extensively studied, wherein LiC6 was discovered as a lead material for high-capacity electrical energy storage. With the recent surge of compact electronic devices in commercial production, we present a novel fabrication technique for ultra-thin LiC6 devices. Here we present a new transfer method, termed “bifacial float transfer”, which enables large-scale multilayer graphene transfer from both sides of a nickel growth catalyst [1]. Bifacial float transfer has the potential to reduce graphene production costs by transferring chemically vapor deposited (CVD) graphene films from both sides of their native nickel substrate, with one graphene film transferred to a polymer and the other graphene film transferred to another target substrate. In traditional transfer methods, the graphene on the “non-preferred” side, that is, the bottom of the substrate, is removed with oxygen plasma before removal of the metal catalyst in etchant solution. Although this treatment prevents undesired aggregation of the graphene films, it fails to utilize both sides of CVD-grown graphene. In this talk, we compare the quality of graphene transferred from both sides onto target glass and polymer substrates. The results of optical microscopy, confocal Raman spectroscopy, atomic force microscopy, and electronic transport measurements suggest that the quality of the multilayer graphene on the “non-preferred” side does not differ significantly from that of the “preferred” side. This method will allow more efficient and cost-effective use of graphene by doubling the usable graphene per area of growth substrate, and by eliminating the need for intermediate sacrificial transfer substrates such as poly(methyl methacrylate). By modifying the air-liquid interface, we also attempt similar polymer-free transfer of progressively thinner multilayer graphene films. The fabricated samples are then lithiated using the in-situ short-circuit direct contact method [2]. The ultra-thin LiC6 exhibits metallic behaviour at room temperature with low sheet resistance and improved optical transparency in the visible spectrum [3]. We present preliminary results on the fabrication and characterization of these large-scale, stable LiC6 films.

High Efficiency Hot Electron Emission from Waveguide Integrated Graphene Ragib Ahsan, Fatemeh Rezaeifar, Hyun Uk Chae and Rehan Kapadia; University of Southern California, United States

Electron emission devices are important for applications in electron microscopy, free electron lasers, radio frequency (RF) amplifiers, and accelerators. Photoemission plays an important role in realizing high efficiency electron emission by exciting lower energy electrons above the workfunction barrier. There are three fundamental limitations to improving the efficiency of photoemission from cathodes: (1) low optical absorption (2) large absorption depth leading to a large transit length to the emitting surface for the excited electrons and (3) high workfunction barrier to extracting the electrons. As a result, most of the works on photoemitters have focused ultraviolter photons with energy that exceeds the workfunction barrier (> ~5 eV), multiphoton absorption, and strong field photoemission processes to realize electron emission. In this work, we have addressed these limitations by using a waveguide integrated graphene electron emitter excited by subworkfunction photons (3.06 eV). While monolayer graphene absorbs only 2.303% of the free space incident light, a waveguide integrated graphene can absorb nearly 100% of the light traveling through the waveguide. In addition, the monolayer thickness of graphene ensures that the excited electrons are always at the emitting surface which eliminates the transit length and reduces the energy loss in electrons due to electron-phonon scattering and electron-electron scattering. This waveguide integrated graphene electron emitter absorbs photons at 3.06 eV which is significantly smaller than the workfunction barrier in graphene (~4.5 eV) and a dc electric field then assists these electrons to tunnel out of graphene before they lose energy. This device experimentally demonstrates an efficiency exceeding the efficiency of multiphoton and strong field photoemitters available in literature by 5 orders of magnitude. Finally, we have modified the graphene surface by introducing a coating of LaB_6 nanoparticles which have a low workfunction (~2.7 eV). This coating of LaB_6 nanoparticles further reduces the workfunction of graphene to 3.5 eV resulting in a tenfold increase in the hot electron emission efficiency. Therefore, we have addressed all three fundamental limitations of a photoemitter by (a) using the waveguide integrated structure that allows ~100% optical absorption (b) using monolayer

graphene that eliminates transit length for excited electrons, and (3) reducing the workfunction barrier with a LaB_6 nanoparticle coating. The strategy to this work can be extended to optical resonators which allows higher optical power densities and other 2D materials including transition metal dichalcogenides which may allow a further increase the efficiency of hot electron emission.

New Directions in Topological 2D Materials without Translational Symmetry Sinéad Griffin; Lawrence Berkeley National Laboratory, United States

Topological order is intimately connected to the presence of translational symmetries - these result in symmetry-protected phases in quantum materials and the resulting classification of topological materials. However, recent experiments have hinted at the presence of topologically protected states even in the absence of translational symmetry. In this talk, I will discuss how theoretical calculations have uncovered topological phases in materials without translational symmetry -- namely in a quasicrystal material and in an amorphous material. I will first describe how a two-dimensional Ta-Te chalcogenide quasicrystal and approximant hosts a layer-tunable topologically nontrivial electronic bandstructure. Next, I will show how introducing disorder into the BiTeI layered family of Rashba materials can induce a trivial-to-nontrivial topological phase transition. Finally, I will discuss the amorphous limit of this case where theory and ARPES measurements suggest topologically protected surface states in amorphous Bi2Se3.

Electrically Tunable 2D Ferromagnetic Semiconductors CrSBr and CrSeBr with High Curie Temperature Xiaofeng Qian; Texas A&M University, United States

Identifying intrinsic low-dimensional ferromagnets with high transition temperature and electrically tunable magnetism is crucial for the development of miniaturized spintronics and magnetoelectrics. Recently, monolayer CrI_3 and $Cr_2Ge_2Te_6$ semiconductors were found to exhibit long-range two-dimensional ferromagnetism with relatively low Curie transition temperature. Here we present our theoretical study of van der Waals layered magnetic semiconductors CrSBr and CrSeBr. Using first-principles electronic structure theory and renormalized spin-wave theory, we predict that monolayer CrSBr and CrSeBr exhibit highly anisotropic electronic structure with bandgap of 1.66 eV and 0.78 eV. More importantly, monolayer CrSBr and CrSeBr possess high Curie temperature of ~150K which was recently verified by experiments, well beyond that of CrI_3 and $Cr_2Ge_2Te_6$. The origin of the high Curie temperature is attributed to strong anion-mediated superexchange interaction and sizable spin-wave excitation gap due to large exchange and single-ion anisotropy. Our results also show that it may be possible to switch magnetization easy axis via electrostatic doping can, suggesting the possibility of realizing spin field effect transistor controlled by electrostatic doping. Finally, we will also discuss linear and nonlinear optical properties of van der Waals layered CrSBr and CrSeBr. Monolayer CrSBr and CrSeBr semiconducting ferromagnets offer long-desired alternatives to dilute magnetic semiconductors and provide unprecedented opportunities for 2D spintronics such as spin valves and spin FETs.

Understanding Carrier Mobility in Two-Dimensional Semiconductors Chenmu Zhang, Long Cheng and Yuanyue Liu; The University of Texas at Austin, United States

Atomically thin (two-dimensional, 2D) semiconductors have shown great potential as the fundamental building blocks for next-generation electronics. However, all the 2D semiconductors that have been experimentally made so far have room-temperature electron mobility lower than that of bulk silicon, which is not understood. Here,

by using first-principles calculations and reformulating the transport equations to isolate and quantify contributions of different mobility-determining factors, we show that the universally low mobility of 2D semiconductors originates from the high "density of scatterings," which is intrinsic to the 2D material with a parabolic electron band. The density of scatterings characterizes the density of phonons that can interact with the electrons and can be fully determined from the electron and phonon band structures without knowledge of electron-phonon coupling strength. Our work reveals the underlying physics limiting the electron mobility of 2D semiconductors and offers a descriptor to quickly assess the mobility. [1,2,3]

Late News: Van der Waals Hetero-Structures of 1H-MoS2 and N-Substituted Graphene for Catalysis of Hydrogen Evolution Reaction Lakshay Dheer; Jawaharlal Nehru Centre For Advanced Scientific Research, India

First-principles theoretical analysis of the catalytic activity of van der Waals hetero-structures of 1H-MoS_2 and graphene substituted with three chemical types of nitrogen species (i) Graphitic (G), (ii) Pyridinic (Pn), and (iii) Pyrrolic (Pr), for application in catalysis of hydrogen evolution reaction (HER) has been presented. Graphitic and pyrrolic N substituents result in n-type electronic structure, whereas substitution of pyridinic N imparts p-type electronic character to the hetero-structure. Work functions () of the hetero-structures suggest that graphitic N-graphene:MoS_2 hetero-structure () is expected to be effective in catalysing the reduction of H^+ to evolve H_2. 1H-MoS_2 monolayer in the hetero-structure contributes by enabling increased H_2O adsorption and offsetting the band edge energies optimal for the catalytic activity. Near optimum Gibbs free energy of H-adsorption () were obtained for graphitic (~ 0.29 eV) and pyrrolic (~ −0.2 eV) N-graphene:MoS_2 hetero-structures. Our work showcases how catalytic and electronic properties of the N-doped graphene:MoS_2 hetero-structure depends on the chemical identity of N-sites and uncovers a route to 2D hetero-structures with high catalytic activity.

Synthesizable Yet Unsynthesized Low Dimensional Materials Revealed by Data Science Gowoon Cheon, Evan Antoniuk and Evan J. Reed; Stanford University, United States

We have utilized data mining approaches to elucidate over 1000 2D materials and several hundred 3D materials consisting of van der Waals bonded 1D subcomponents, or molecular wires. We find that hundreds of these 2D materials have the potential to exhibit observable piezoelectric effects, representing a new class of piezoelectrics. A further class of layered materials consists of naturally occurring vertical hetero structures, i.e. . bulk crystals that consist of stacks of chemically dissimilar van der Waals bonded layers like a 2-D super lattice. We further combine this data set with physics-based machine learning to discover the chemical composition of an additional 1000 materials that are likely to exhibit layered and two-dimensional phases but have yet to be synthesized. This includes two materials our calculations indicate can exist in distinct structures with different band gaps, expanding the short list of two-dimensional phase change materials. We find our model performs five times better than practitioners in the field at identifying layered materials and is comparable or better than professional solid-state chemists. Finally, we find that semi-supervised learning can offer benefits for materials design where labels for some of the materials are unknown.

8:25 AM NM07.12.02
Late News: Theory-Based Strategy of Nitrogen Doping for Optimized Electronic Structure of Ti2CO2 Toward High Hydrogen Evolution Reaction Activity Hyunjun Nam[1], Eun Seob Sim[1], Minyeong Je[2], Heechae Choi[2] and Yong-Chae Chung[1]; [1]Hanyang University, Korea (the Republic of); [2]University of Cologne, Germany

Finding inexpensive and active catalyst is essential to produce renewable energy, hydrogen, in a sustainable method. MXenes have been reported as a potential hydrogen evolution reaction (HER) catalysts with the advantages of their unique surface properties and excellent electrical conductivity. Recent studies on MXenes, especially titanium carbide, have showed that nitrogen-doping improves the catalytic performances in HER. However, various nitrogen-containing by-products are formed on the surface of MXene during the doping processing, and the origins of catalytic performance variations or the theoretical optimal doping concentration have not been fully studied. In this study, to find the optimum nitrogen doping concentration of Ti_2CO_2, the adsorption energies of hydrogen and the conductivity, were investigated using the density functional theory (DFT) calculations. From the calculations of the doping formation energy, C-site of Ti_2CO_2 was found to be the most favored nitrogen substitution. To determine the optimum nitrogen concentration, the Gibbs free energy of hydrogen adsorption and the conductivity were calculated for various N doping concentration. As the doping concentration increased, both the Gibbs free energy of hydrogen adsorption and the conductivity were enhanced and reached an apex point at the specific doping concentration. As the doping concentration further increased, deterioration of the catalytic performance was expected as the values of the two properties decreased. Through these results, it can be inferred that the doping concentration of N at C site influences the catalytic properties of N-doped Ti_2CO_2 and that optimum catalytic performance can be achieved at the specific doping concentration. This study suggests a frame of systematic and theoretical predictions to optimize doping processing of MXene-based HER catalysts.

8:40 AM NM07.12.04
Late News: First-Principles Study of a MoS2-PbS van der Waals Heterostructure Inspired by Naturally Occurring Merelaniite Gemechis D. Degagaa[1], Sumandeep Kaur[2], Ravindra Pandey[2] and John A. Jaszczak[2]; [1]Oak Ridge National Laboratory, United States; [2]Michigan Technological University, United States

Vertically stacked, layered van der Waals (vdW) heterostructures offer the possibility to design materials, within a range of chemistries and structures, to possess tailored properties. Inspired by the naturally occurring mineral merelaniite, we investigate a vdW heterostructure composed of MoS_2 monolayer and PbS bilayer, using density functional theory. The results find such a heterostructure to be stable and possesses p-type semiconducting characteristics. Due to the heterostructure's weak interlayer bonding, its carrier mobility is essentially governed by the constituent layers; the hole mobility is governed by the PbS bilayer, whereas the electron mobility is governed by the MoS_2 monolayer. Furthermore, we estimate the hole mobility to be relatively high ($\sim 10^6\ cm^2V^{-1}s^{-1}$), which can be useful for ultra-fast devices at the nanoscale.

8:55 AM NM07.12.05
Flat Bands in Transition Metal Dichalcogenide with Strong Spin-Orbit Interaction Sudipta Kundu[1], Mit H. Naik[2], Indrajit Maity[1], Hulikal R. Krishnamurthy[1] and Manish Jain[1]; [1]Indian Institute of Science, India; [2]University of California, Berkeley, United States

Since the discovery of flat bands at magic angle in twisted bilayer graphene, the formation of flat bands has been predicted for several other materials, especially twisted transition metal dichalcogenides (TMD). WSe_2 possesses strong spin-orbit interaction which makes it different from other TMDs. Using a multiscale approach, based on classical force-fields for structural relaxation and density functional theory calculations for electronic structure, we study the effect of spin-orbit coupling on the formation of flat bands in relaxed twisted WSe_2. The spin-orbit interaction affects the flat bands with the twist angle close to 0° differently than those near 60°. The flat bands at valence and conduction band edge arise from K and Q points of the unit cell Brillouin zone

respectively. For twist angle near 60°, we find that the flattening of the bands arising from K point is a result of the atomic reconstruction in the individual layers and not due to interlayer coupling. On the other hand, for twist angle close to 0°, the interlayer interaction between the two layers becomes important. Additionally, we also find flat bands folded from the Γ point of the unit cell Brillouin zone. The wave function localization of the flat bands matches well with STM measurements from existing literature [1]. Furthermore, we find that the atomistic spin-orbit splitting in moiré remains unchanged from the monolayer. We extend our study to strain-induced moiré in homobilayer TMD. The mismatch in lattice constant gives rise to moiré pattern. Relaxation of the system distributes the strain unevenly in the moiré lattice with increased strain at the highest energy stacking. Several well separated flat bands emerge at both valence and conduction band edges and we observe a significant reduction in the band gap. Thus, both twist and strain engineered moiré generate pathway to manipulate holes and electrons in TMD.

P-Type van der Waals Contacts on 2D Semicondcutors Manish Chhowalla; University of Cambridge, United Kingdom

Ultra-clean van der Waals interfaces can be achieved between soft indium metal and monolayer 2D transition metal dichalcogenide semiconductors. Such interfaces lead to low contact resistance and n-type field effect transistors with high mobilities – in excess of 100 cm^2-V^{-1}-s^{-1}. It has been, however, challenging to make similarly clean interfaces between refractory metals with high work functions to achieve efficient hole injection. Here, I will present our efforts on realizing p-type contacts using high work function metals and their alloys. This method preserves the ultra-clean interface between the monolayer semiconductor and alloy while increasing the work function so that p-type devices can be realized. We also demonstrate clean interfaces using metals such as Pd and Pt via direct deposition. These interfaces reveal low contact resistance and also high performance p-type devices.

12:10 PM NM07.13.03
Deformed All-2D Electronics and Strain Engineering Enabled by 3D Deformation in 2D Monolayer Semiconductors Mohammad A. Hossain[1], Jaehyung Yu[2], Yue Zhang[1] and Arend van der Zande[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]The University of Chicago, United States

Emerging technologies like stretchable electronics and straintronics require materials that are highly deformable yet electronically active. With high breaking strain, high electronic mobilities and diverse properties, two dimensional (2D) materials are ideal for such applications. Moreover, due to their low bending stiffness, 2D materials are excellent candidates for engineering three-dimensional (3D) nanostructures to relieve strain or engineer inhomogeneous strain under compression. In crumpled systems, highly deformed surfaces of 2D materials lead to applications in wearable electronics and multifunctional surfaces. Engineering inhomogeneous strain gradients into device architectures enables access and control of strain-dependent quantum states like single quantum emitters, exciton diffusion and asymmetric valley states.

To fully realize the potential of 2D materials for deformable electronics or straintronics, it is necessary to tailor the transfer of strain into the materials and resulting morphologies. Here we demonstrate tuning of the

interfacial interaction between 2D membrane and elastomer substrate resulting in either crumpling through buckle delamination or conformal wrinkling, corresponding with low and high transfer of strain into the 2D membrane respectively. We then explore systems leveraging these tuned interactions resulting in strain resilient electronics from crumpled 2D heterostructures, and inhomogeneous or mechanically reconfigurable strain engineering from wrinkled 2D materials.

First, we demonstrate phototransistors from crumpled 2D heterostructures formed from graphene contacts to a monolayer transition-metal dichalcogenide (MoS_2, WSe_2) channel and quantify the membrane morphology and optoelectronic performance.[1] Under uniaxial compression, the heterostructure and constituent monolayers relieve the stress by creating nearly periodic delaminated folds whose spacing depends on the membrane type. The matched mechanical stiffness of the constituting layers allows the heterostructure to maintain a conformal interface through large deformations. Photoluminescence (PL) spectroscopy shows that the optical band gap of WSe_2 shifts by less than 2 meV under 15% biaxial crumpling, corresponding to a change in strain of less than 0.05%. Photocurrent revealed that the crumpled heterostructure behave as a phototransistor where photoresponsivity scaled as $P^{-0.38}$, with behavior similar to flat devices. Photocurrent maps reveal biaxial crumpling by 15% marginally increases the photoresponsivity, by only 20%. PL and photoresponse confirm that crumpling and delamination prevent the buildup of compressive strain leading to highly deformed materials and devices with similar performance to their flat analogs.

While crumpling leads to strain resilient structures, increased substrate interaction actually results in wrinkling and increased strain transfer. We demonstrate a method to tune the strain in 2D materials by wrinkling monolayer WSe_2 attached to a 15 nm thick Al_2O_3 support layer and compressing the heterostructure on a soft substrate.[2] The Al_2O_3 film stiffens the 2D material, enabling optically resolvable micron scale wrinkling rather than nanometer scale crumpling. Using PL spectroscopy, we show that the wrinkling introduces periodic modulation of the bandgap by 47 meV, corresponding with strain modulation from +0.67% tensile strain at the wrinkle crest to -0.31% compressive strain at the trough. Moreover, we show that cycling the substrate strain mechanically reconfigures the magnitude and direction of wrinkling and resulting band tuning.

Taken together, these results set a foundation for deformable all-2D heterostructure devices and circuitry for stretchable electronic applications, and articulate strategies for maximizing or minimizing strain transfer.

Mobile and Continuous Stress Monitoring Using Imperceptible Graphene E-Tattoos (GET) Robustly Connected to a Wristwatch Hongwoo Jang, Eunbin Kim, Siyi Liu, Xiangxing Yang, Kyoung-Ho Ha, Seungmin Kang, Rebecca Wang and Nanshu Lu; The University of Texas at Austin, United States

Mental stress negatively impacts more than 77% population in our modern societies. Continuous and objective assessment of stress level enables proactive management for depression, evasion, and suicidal tendency. Electrodermal activity (EDA), a.k.a. galvanic skin response (GSR), is an emotion-induced skin conductance change due to sweat gland activity. EDA has been widely used as a quantitative index of mental stress levels for decades. Palm has the highest density of eccrine sweat glands which are filled up under psychological stimuli, such as mental stress, primarily. However, state-of-the-art EDA monitors suffer from limitations such as obstructiveness, undesirable location, short-term wearability, motion artifacts, etc. Herein, we introduce a long-term wearable (e.g. 24 hours), high-fidelity palm EDA sensor using dry, sub-micron-thick graphene e-tattoos (GET). The filamentary-serpentine-shaped GET is so thin (only 150-nm-thick) and so soft that it is imperceptible optically, mechanically, and also physiologically. The GET can fully conform to the finest texture of human skin, resulting in an interface impedance even lower than wet Ag/AgCl gel electrodes as well as reduced susceptibility to motion artifacts. GET is laminated on the palm and extended to the wrist to connect to

a wristwatch which provides data acquisition, storage, and wireless transmission. The orders of magnitude mismatch of stiffness and thickness between the GET and the wristwatch poses an outstanding challenge for the connection in between. We propose a simple yet effective solution named “heterogenous serpentine ribbon (HSR).” Due to the ultimate conformability of GET, simply laminating serpentine GET ribbon on an ultrathin serpentine metal ribbon without any interfacial adhesive could yield a conductive and stretchable interface. Compared with contacts between straight GET and metal ribbons, HSR offers a ten-fold strain reduction. To achieve a mechanically robust and reversible electrical connection between the ultrathin metal ribbon and the wristwatch, a soft interlayer is added in between to serve as a mechanical insulator but electrical conductor. We have successfully applied such GET-watch-based wearable EDA sensor for long-term, continuous, and ambulatory EDA sensing during our daily activities as well as during sleep. We argue that our HSR plus soft interlayer structure is a generic solution to robustly connect any ultrathin and ultrasoft e-tattoos to smartwatches, which will significantly extend the sensing modalities of future smartwatches.

12:40 PM NM07.13.05
Structural Engineering of Two-Dimensional Nanomaterials for Electrocatalysis Zhiwei Fang and Guihua Yu; The University of Texas at Austin, United States

Research on beyond graphene two-dimensional (2D) nanomaterials is becoming critically important for wide-ranging technological applications. In parallel with the discovery of new candidate materials and exploration of their unique characteristics, there are significant interests to rationally control the properties of 2D nanomaterials to meet requirements for energy-related applications. Electrocatalysis powered by renewable energy is expected to play a pivotal role in achieving sustainable energy goals. Recent advances in structural engineering have demonstrated their ability to overcome intrinsic material limitations, showing great potential for promoting catalytic activity and stability to a new level. Here we will discuss several important strategies to provide insights into application-oriented tailoring of material properties, and focus on our recent progress in developing 2D nanomaterials with tunable pore sizes or multidimensional interconnection for catalyzing several key electrochemical reactions, such as oxygen evolution, hydrogen evolution, and nitrogen reduction. Constructing porous and/or hierarchical 2D nanosheets enables improved ionic/electronic transport to achieve high active surface area for reactant adsorption/desorption, and meanwhile maintains high structural stability. These works demonstrate valuable insights, regarding material selection, structural modification and electronic tuning, into developing earth-abundant 2D electrocatalysts as alternatives to noble metal catalysts for efficient and stable electrocatalysis.

12:55 PM NM07.13.06
Late News: Tailored Graphene Micropatterns by Wafer-Scale Direct Transfer for Flexible Chemical Sensor Platform Yeonhoo Kim[1], Taehoon Kim[2], Jinwoo Lee[3], Yong Seok Choi[2], Joonhee Moon[4], Seo Yun Park[2], Tae Hyung Lee[2], Hoon Kee Park[2], Sol A Lee[2], Min Sang Kwon[2], Hyung-Gi Byun[5], Jong-Heun Lee[6], Myoung-Gyu Lee[2], Byung Hee Hong[2] and Ho Won Jang[2]; [1]Los Alamos National Laboratory, United States; [2]Seoul National University, Korea (the Republic of); [3]Korea Institute of Materials Science, Korea (the Republic of); [4]Korea Basic Science Institute, Korea (the Republic of); [5]Kangwon National University, Korea (the Republic of); [6]Korea University, Korea (the Republic of)

Emerging novel technologies, such as flexible, rollable, and wearable electronics, need to meet their special requirements such as ease of controlling electronic properties, flexibility, and transparency. To date, metal and semiconducting materials have been used for conventional electronics, but the materials are brittle and nontransparent. In contrast, two-dimensional (2D) materials such as graphene and transition dichalcogenides have demonstrated great potential for flexible electronics and transparent electrodes due to their unique mechanical and electronic properties. In order to fully utilize 2D materials for the next-generation of flexible electronics, geometric micropatterns of 2D materials on flexible substrates such as polymer substrates are essential to fulfill technological purposes. However, due to harsh conditions such as cleaning, developing, and etching processes in the existing lithography procedure, defining elaborate micropatterns of 2D materials using the conventional microelectromechanical systems on polymer substrates is difficult to achieve.

Here, we demonstrate a novel strategy to obtain micropatterned graphene on flexible substrates, which is an alternative to the conventional wet transfer method. Graphene microchannels, which are prepared by the conventional lithography process are transferred by direct polymer curing transfer. With this method, entirely flexible, transparent, self-activated graphene sensor arrays are fabricated on 4-inch wafer-scale polymer substrates. A sensor array with four sensors using micropatterned graphene channels with noble metal decoration provides different sensing information and discriminates chemical species. Finite element method simulations were employed to investigate the potential of this patterning technique. The calculation results demonstrate that the performance of the sensors can be highly enhanced when the active channels are suspended and nanoscaled. This study provides higher reliability compared to the present state-of-the-art flexible electronic fabrication techniques and also demonstrates future-oriented flexible chemical sensor platforms.

1:10 PM NM07.13.08
Late News: Atomically-Thin Tellurene Based Biosensor for Selective and Sensitive Electrochemical Detection of Dopamine Ruifang Zhang and Wenzhuo Wu; Purdue University, United States

The effective and accurate sensing of dopamine (DA) has important implications due to its essential roles in the neurobiological system. The release process of dopamine is closely linked with neurological diseases such as Parkinson's, drug addiction, and attention deficit hyperactivity disorder (ADHD). Here we report a novel electrochemical biosensor based on atomically-thin tellurene, a 2D *p*-type semiconductor, for selective and sensitive detection of dopamine with a sensitivity for 2.81 mA/mM*cm^2, which is more superior to glassy carbon electrodes. Our device exhibits good linearity of oxidation current at the concentration of DA over a range of 1-2.875 mM, which presents the largest range reported in the literature. Enabled by the specific binding between Te and nitrogen atoms on biomolecules (DA), tellurene based sensors show greater selectivity of DA in the presence of uric acid and ascorbic acid. In addition, well-dispersed Au nanoparticles (Au-NPs) on 2D tellurene can enable excellent catalytic activity and a hospitable environment for biomolecules. We further demonstrated the successful sensing operation of tellurene/Au-NP based hybrid biosensors for the quantification of dopamine concentrations in human blood samples with satisfactory recoveries.

2:15 PM *NM07.14.01
Logic-in-Memory Based on an Atomically Thin Semiconductor Andras Kis; EPFL, Switzerland

The growing importance of applications based on machine learning is driving the need to develop dedicated, energy-efficient electronic hardware. Compared with von-Neumann architectures, brain-inspired in-memory computing uses the same basic device structure for logic operations and data storage, thus promising to reduce the energy cost of data-centric computing significantly. Two-dimensional materials such as semiconducting MoS_2 could stand out as a promising candidate to face this obstacle thanks to their exceptional electrical and mechanical properties. Here, we show that wafer-scale grown MoS_2 can be used as an active channel material for developing logic-in-memory devices and circuits based on floating-gate field-effect transistors (FGFET). The conductance of our FGFETs can be precisely and continuously tuned, allowing us to use them as building blocks for reconfigurable logic circuits where logic operations can be directly performed using the memory elements. We show that this design can be simply extended to implement more complex programmable logic and functionally complete sets of functions. Our findings highlight the potential of atomically thin semiconductors for the development of next-generation low-power electronics.

2:40 PM NM07.14.02

Device Integration of Atomically Precise Graphene Nanoribbons (GNRs) Oliver Braun[1,2], Jan Overbeck[1], Mickael Perrin[1], Gabriela Borin Barin[1], Maria El Abbassi[1,3], Qiang Sun[1], Sara Sangtarash[4,5], Akimitsu Narita[6], Klaus Müllen[6], Edward Ditler[1], Kristjan Eimre[1], Colin Daniels[7], Vincent Meunier[7], Hatef Sadeghi[4,5], Carlo Pignedoli[1], Colin Lambert[5], Oliver Gröning[1], Pascal Ruffieux[1], Roman Fasel[1] and Michel Calame[1,2]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]University of Basel, Switzerland; [3]Kavli Institute of Nanoscience, Netherlands; [4]University of Warwick, United Kingdom; [5]Lancaster University, United Kingdom; [6]Max Planck Institute for Polymer Research, Germany; [7]Rensselaer Polytechnic Institute, United States

Graphene nanoribbons (GNRs) have attracted considerable interest due to their largely modifiable electronic properties, including width-dependent bandgaps for armchair GNRs and spin-polarized edge states for GNRs with zigzag edges.[1,2,3,4] Manifestation of these properties requires atomically precise GNRs, which can be achieved through a bottom-up synthesis approach under ultrahigh vacuum conditions. We show that 5-atom wide armchair GNRs as well as pyrene-GNRs can be processed under ambient conditions and incorporated as the active material in a field effect transistor.[5,6] At room temperature, a film like behavior is observed while at cryogenic temperatures coulomb blockade and single electron tunnelling can be seen. Our recent results may enable the realization of devices based on carbon nanomaterials with exotic quantum properties.

High Yield, Bottom-Up/Top-Down CVD Synthesis of 2D Layered Metal Selenides—A Promising Class of Materials for Applications in Electronics and Electrochemistry Gilbert D. Nessim; Bar Ilan University, Israel

Since the excitement about graphene, a monolayer of graphite, with its 2010 Nobel Prize, there has been extensive research in the synthesis of other non-carbon few/mono-layers exhibiting a variety of bandgaps and semiconducting properties (e.g., n or p type). The main approaches to deposit few/monolayers on a substrate are: (a) bottom-up synthesis from precursors using chemical vapor deposition (CVD) or (b) top-down exfoliation (liquid or mechanical) of bulk layered material. Using a Lego approach of superposing monolayers, we can envisage the fabrication of heterojunctions with original electronic behavior.
Here we show a combined bottom-up and top-down approach where (a) we synthesize in one step high yields of bulk layered materials by annealing a metal in the presence of a gas precursor (sublimated selenium from selenium powder) using chemical vapor deposition (CVD) and (b) we exfoliate and deposited (dropcast or Langmuir Blodgett) few/mono-layers on a substrate from a sonicated mixture of our material in a specific solvent. It is interesting to note that, besides the structure being 2D layered, the properties of the nanomaterials synthesized slightly differ from the materials with the same stoichiometry synthesized using conventional chemical methods (e.g., solvothermal).
In this talk, we will discuss the chemical synthesis, the very extensive characterizations, and the lessons we learned in making multiple metal selenides (Ag-Se, Cu-Se, W-Se, Mo-Se). We will see how we integrated these new materials into sensors and into electrochemical devices (see selected published papers below).

Late News: A Homoepitaxial Approach of Large Scale, High Quality Boron Nitride Growth by MOVPE
Aleksandra K. Dabrowska, Mateusz Tokarczyk, Grzegorz Kowalski, Johannes Binder, Rafal Bozek, Roman Stepniewski and Andrzej Wysmolek; Faculty of Physics, Uniwesity of Warsaw, Poland

The importance of hexagonal boron nitride (BN) in the world of two-dimensional crystals (2D) is constantly increasing. This is due to the fact that it combines the properties of 2D materials, like a layered structure and possibility of exfoliation with those of classic nitrides – a wide bandgap and high chemical and physical resistance [1]. All of these aspects make it a perfect candidate for example for deep UV light source and detector, insulating barriers in van der Waals heterostructures or protecting layers for other, more sensitive materials [2]. Metal Organic Vapor Phase Epitaxy (MOVPE) is a very promising technique to obtain high quality boron nitride on the wafer-scale, which could facilitate the implementation of the before mentioned applications

The MOVPE growth of boron nitride requires careful selection of growth conditions – as this is a van der Waals material, effective synthesis is usually connected with a bad surface morphology and poor optical properties. Epitaxial material, oriented parallel to the sapphire substrate could be obtained basically with two different growth modes. The first mode is the Continuous Flow Growth (CFG) regime when the boron (TEB) and nitrogen (ammonia) precursors enter the reactor simultaneously, conducted at extremely high temperature (about 1300 °C) and with a large NH_3/TEB flow ratio resulting in thin, smooth BN layers [3]. The optical properties and surface morphology of such layers are satisfactory. Unfortunately the longer the growth, the more three-dimensional precipitates appear on the surface, thus the maximum thickness of a good quality layer, possible to obtain by this method is about 5 nm. The second growth regime is Flow-rate Modulated Epitaxy (FME) for which ammonia and TEB are delivered to the reactor in alternating pulses. This growth mode allows to obtain tens of nanometer thick BN but the supersaturation of boron in TEB pulses support the formation of structural defects, responsible for mid-gap luminescence [3].

The method we propose combines these two growth regimes by using CFG BN as a buffer layer for homoepitaxial growth of a FME layer on the top of it. This approach allows to obtain FME BN layers with much better optical and structural quality reaching a thickness of several tens of nanometers [4]. Moreover, this semi-homoepitaxial boron nitride exhibits high homogeneity on the entire two-inch surface. Further optimization of this method allows us to obtain better quality samples. The relationship between the growth parameters and the crystallographic structure, concentration of point defects and surface morphology of BN grown by this Combined Growth Mode (CGM) will be presented. Our results bring boron nitride significantly closer to large-scale applications.

Mixed-Dimensional MXene-Hydrogel Heterostructures for Electronic Skin Sensors with Ultrabroad Working Range Yichen Cai and Vincent Tung; King Abdullah University of Science and Technology, Saudi Arabia

Skin-mountable microelectronic devices (i.e., electronic skin, e-skin) are garnering substantial interest for various promising applications including human−machine interfaces, bio-integrated devices, and personalized medicines[1-3]. However, it remains a critical challenge to develop reliable, durable, and biocompatible e-skins to mimic the human somatosensory system in a full working range[4]. Herein, we present a multifunctional e-skin system with a heterostructured configuration that couples a vinyl hybrid silica nanoparticles (VSNP) modified polyacrylamide hydrogel (VSNP-PAM) with two-dimensional (2D) MXene. The VSNP-PAM hydrogel is engineered to achieve both high toughness and low hysteresis, serving as an elastic substrate for the e-skin that overcomes the toughness-hysteresis correlation. Then, a nano-bridging layer of 1D polypyrrole (Ppy) nanowires is applied to dynamically link the interfaces between the hydrogel substrate and the sensing layer of 2D MXene. These material configurations endow the e-skin with tunable sensing mechanisms, exhibiting an extraordinary stretchable working range (0−2,800%), ultrafast responsiveness (~90 ms) and outstanding resilience (~240 ms), good linearity (0−800%) and excellent reproducibility (>5,000 cycles). In parallel, this e-skin is capable of detecting, quantifying and remotely monitoring of stretching motions in multi-dimensions, pressure exertions (40 Pa-30 kPa), tactile and proximity sensing (from a distance of ~20 cm), temperature, and light variations, providing a promising platform for next-generation smart flexible electronics with a ultrabroad working range.

Experimental Demonstration of Room Temperature 2D TMD Excitonic Perfect Absorbers for High Efficiency Excitonic Solar Cells Joeson Wong, Tyler Colenbrander and Harry A. Atwater; California Institute of Technology, United States

We experimentally demonstrate near-unity absorption in monolayer WS_2 via a van der Waals heterostructure coupled to an optical cavity. To achieve this perfect absorption at the excitonic frequency, we match the WS_2 radiative and non-radiative excitonic decay rates, which impedance matches the exciton to free space. With the presence of an Ag back mirror, this impedance matching condition results in perfect absorption at the excitonic frequency. We show that this impedance matching condition can be readily achieved at cryogenic temperatures by lowering the non-radiative decay rate due to homogeneous broadening but can also be achieved at room temperature by increasing the radiative decay rate, via Purcell enhancement of the excitonic emitter. We further show theoretically that perfect absorption with multiple excitonic species (e.g. WS_2 and WSe_2) is possible, suggesting that solar cells comprised of multiple excitonic perfect absorbers can achieve detailed balance photovoltaic efficiencies surpassing the Shockley-Queisser Limit. We find that monolayer 2D perfect absorbers have potential for highly efficient van der Waals optoelectronic and photovoltaic devices.

4:05 PM NM07.14.08
Laser Photothermal Nano-assembly of Palladium Nanoparticles and 3D Porous Graphene for Wireless,

Flexible, High-Sensitive Hydrogen Detection Seung Min Lee[1], Minsu Kim[2], Byoung Gak Kim[2] and Pilgyu Kang[1]; [1]George Mason University, United States; [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

A simple and facile method to produce a hybrid nano-assembly of 3-dimensionally (3D) structured and palladium nanoparticles (PdNPs) embedded graphitic carbo with high-performance polymers would be highly desirable. All existing approaches to synthesize hybrid materials comprising graphene and metal NPs involve complicated processes; carbon nanomaterials are mostly fabricated based on chemical vapor deposition or reduction of graphene oxides methods and PdNPs are further integrated on carbon nanomaterials through thermal annealing or chemical processes. Recently, a scalable and fast laser photothermal method to generate laser-induced graphene (LIG) with high electrical conductivity and large specific surface area from commercial polyimide films has been demonstrated and triggered a significant research development in various applications, including energy storage, harvesting, and detection. The method has been further utilized to fabricate LIG based hybrids including heteroatoms-doped LIG, LIG-metal-sulfides nanocomposite materials, as well as LIG-metal-oxides nanocomposite materials for high-performance energy storage, detection, and generation. However, the application of the laser photothermal method in the fabrication of porous graphene-PdNPs nanocomposite material has yet been demonstrated especially for the hydrogen leakage system hence achieving the hybrid materials remains a challenge due to the processing requirements of high thermal/chemical energy, and the lengthy period of time consumption. Here, we report a one-step, fast laser photothermal nano-assembly method to synchronously Pd-NPs and porous graphene from polymer films of mixed Pd and carbon precursors. We used the polymers of intrinsic microporosity (PIM-1) as a precursor to obtaining porous graphene, which has polybenzodioxane structure with cyano groups, high solubility in a volatile solvent, and miscibility with inorganic materials enabling to fabricate homogeneous polymer films with evenly and highly dispersed Pd-ligands. We demonstrated a scalable laser photothermal method to form the nano-assembly of 3D porous graphene and PdNPs from the polymer film for wireless and flexible hydrogen detection systems with the limit of detection (LOD) of 1 ppm hydrogen gas concentration. With the combined advantages of high sensitivity/selectivity/surface of 3D porous graphene and rapid response/recovery speed of PdNPs, we could obtain high sensitivity with the fast response time at low H_2 concentration ranges (1-50 ppm). Moreover, the hybrids exhibit outstanding flexibility and durability under bending and twisting and the nano-assembly is further integrated with a wireless communication system via BLE protocol to transfer the monitored signal of conductance to the change of hydrogen concentrations to a mobile device. The innovative sensing technology based on laser nanomanufacturing of the nano-assembly for highly sensitive, flexible, wireless sensing systems has future potential for broad applications in various industries and military fields.

Late News: Broadband Photodetectors Based on Tellurene/CdS Quantum Dots Mixed-Dimension heterostructure Ruifang Zhang and Wenzhuo Wu; Purdue University, United States

Photodetectors capable of detecting light in a broad spectrum is central to diversified optoelectronic applications in spectroscopy, remote sensing, imaging, and optical communication. Two-dimensional (2D) materials, such as graphene, borophene, phosphorene, and transition metal dichalcogenides (TMDs), are good candidates due to their unique semiconductor and structural characteristics. Tellurene is an emerging 2D semiconductor boasting characteristics potentially relevant for photodetection.
However, the small bandgap of tellurene makes it more suitable to detect long-wavelength light. Here, we

demonstrate a highly sensitive, fast-response photodetector based on tellurene-CdS quantum dots mixed-dimension heterostructures, which enables the efficient separation of the photogenerated electron-hole pairs and inhibits the rate of undesirable recombination. The heterostructured device exhibits a low dark current (0.4 nA) and good quantum efficiency. A systematic characterization of the device performance indicates that such mixed-dimensional heterostructured photodetector exhibits superior photodetection performance with a broadened spectrum response, improved response speed, sensitivity and responsivity.

CVD-Grown 2D Material Schottky Photovoltaics with Interlocking Asymmetric Contacts Timothy Ismael, Kazi Islam, Meghan Bush, Claire Luthy and Matthew D. Escarra; Tulane University, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) have received increased attention in recent years for optoelectronics due to their strong light-matter interactions. This includes ultra-thin molybdenum disulfide (MoS_2), which is a suitable material for flexible, wearable, and high specific power photovoltaics (PV)[1]. Obtaining high efficiency PV through doping of 2D materials has been a challenge; however, Schottky PV is an alternative route to overcoming this challenge. In this work, we present a Schottky-type photovoltaic device using 2D MoS_2 films and asymmetric contacts.
Chemical vapor deposition (CVD) is utilized to synthesize MoS_2 films on sapphire substrate, with MoO_3 and S as the precursors, carried by Ar. High-quality monolayer films with sparse bi-layer regions are obtained, and film uniformity, optical performance, and electronic quality are confirmed through transmittance and photoluminescence spatial mapping. Ti contact MoS_2 transistors and photodetectors were fabricated from which an external quantum efficiency (EQE) of 25% at 620 nm laser illumination and a carrier mobility of 3.3 $cm^2/V.s$ was obtained, indicating high quality CVD grown MoS_2.
For the Schottky PV device, Ti is selected as one of the asymmetric metal contacts due to its work-function of 4.33 eV, while Pt is selected as the second contact due to its relatively high work-function of 5.64 eV. These Schottky PV device contacts are fabricated on SiO_2/Si substrates as an asymmetric interlocking-finger type design onto which the MoS_2 films are transferred using a surface energy assisted transfer technique. The MoS_2/metal configuration maximizes the PV active area by eliminating contact shading losses and utilizes lateral transport to minimize electrical shunts between contacts. A band offset of -0.9 eV arises between the Fermi levels of Ti and MoS_2 at their interface while an offset of 0.41 eV arise at the Pt-MoS_2 interface. The resulting selectivity of Ti to electrons and of Pt to holes in the Ti-Pt asymmetric contact device creates the condition for photo-generated carrier separation.
The 300 µm X 400 µm active area Schottky PV shows a V_{OC} of 260 mV under 660 nm laser illumination with a 1.07 uA/cm^2 J_{SC}, while 125 mV V_{OC} was obtained under 1 sun AM1.5G illumination using a solar simulator with J_{SC} of 0.17 uA/cm^2). Device modeling using COMSOL Multiphysics (Semiconductor Module) shows that a V_{OC} of 900 mV and 41 uA/cm^2 [EMD1] J_{SC} is attainable for a Pt-Ti asymmetric contact 2D PV device. The low photocurrent and poor J_{SC} obtained from the fabricated asymmetric contact device can partly be attributed to the small diffusion length of carriers in these CVD-grown films, especially for holes. Furthermore, relatively large sheet and contact resistance was identified in the device through transmission line measurement (TLM). However, the relatively high V_{OC} and absorption, the promising carrier mobility obtained from the symmetric contact devices, and the device modeling all indicate that efficient photovoltaic devices are attainable.
Current efforts towards improving PV device performance include contact engineering, film growth/thickness, and device architecture optimization guided through spatial mapping of device properties. Atomistic investigation of interfaces through density functional theory, PV device modeling, and contact selection supported through Schottky barrier height extraction and work function measurements will also support the realization of high efficiency 2D PV.

Tuning the Electrical Properties of Monolayer TMDs via Chemical Doping and Interface Engineering

Siyuan Zhang and Christina A. Hacker; National Institute of Standards and Technology, United States

The fundamental properties of two-dimensional (2D) materials, as well as the quality of 2D films and device interfaces, give rise to inherent limitations in their device performance. The ultrathin nature and large surface area of two-dimensional (2D) materials make them quite sensitive to their surrounding environments, which enables their optical and electrical properties to be tuned through surface modification. Developing processes to controllably dope transition-metal dichalcogenides (TMDs) and their electrical contact interfaces are critical to achieving commercial viability for optical and electrical applications. Previously, we successfully expanded the application of electron-transfer doping using molecular reductants and oxidants to various TMDs, including monolayer MoS_2, $MoSe_2$, WS_2, and WSe_2. The chemical doping is introduced onto the 2D material by exposing it to solutions of molecular reductant (n-dopant) or oxidant (p-dopant). Both n- and p-type transport properties were achieved in all four monolayer-TMDs, and both non-degenerate and degenerate regimes are accessible.[1] The degree of doping can be finely controlled by choice of dopants, treatment time, and the concentration of doping solution. Detailed physical characterization was conducted to study the doping effect and to understand the underlying mechanisms. MoS_2 is known to show stubborn n-type behavior due to its intrinsic band structure and Fermi level pinning. Here, we investigate the combined effects of molecular doping and contact engineering on the transport and contact properties of the monolayer (ML) MoS_2 devices. Our study showed that p-type MoS_2 can only be achieved by combining molecular doping with high-work function Pd contacts.[2] Molecular doped p-FETs show effective hole mobilities of 2.3 $cm^2 V^{-1} S^{-1}$, an on/off ratio exceeding 10^6, and improved contact resistance of ≈482 kΩ μm. Devices with low work function Ti metal contacts only showed ambipolar behavior. It was shown that the contact resistance and Schottky barrier heights can be effectively modulated through doping of the channel materials and by changing the contact metal. A relatively low hole injection barrier of ≈156 meV was obtained for p-doped MoS_2 with Pd contacts. A MoS_2 inverter based on pristine (n-type) and p-doped monolayer MoS_2 was fabricated, demonstrating the potential application of 2D-based complementary electronic devices. In summary, we have demonstrated a solution-based charge transfer doping on several 2D semiconductors. This technique provides a simple yet effective route to tailor the band structure of the 2D materials and control the resulting electrical and optical properties.

Graphene Oxide as a Catalytic Agent in Polymer Electrolyte Membrane Fuel Cell Shristi Silwal, Abdelrahman Elkhatib, Olabode Ajayi, Jayson Treml, Puteri M. Hamari and Bhushan V. Dharmadhikari; Minnesota State University, United States

Platinum (Pt) is commonly used as a catalyst in fuel cell production. Platinum being an expensive metal, makes commercialization of fuel cells uneconomical. Many research groups are working on finding the alternative catalytic material. Graphene and carbon based nanomaterials have potential to replace Pt as catalyst in polymer electrolyte membrane fuel cell (PEMFC) due to their properties such as broad electrochemically active surface area, fast carrier mobility, high conductivity, and ability to stabilize and increase the durability of fuel cells. Proton conducting Polymer Electrolyte Membranes (PEMs) are used in PEMFCs to allow protons (H+) to pass through the electrodes. An effective PEM should be able to facilitate ion transfer in fuel cells. Nafion is one of the most widely used electrolytes in PEMs due to its high ionic conductivity and highly resistance to chemical reactions such as corrosion. However, water retention in Nafion membrane give rise to fouling effect, which reduces the ion transfer and performance of PEMFC. The amount of water retained also causes the polymer to swell, therefore, decreasing the efficiency of fuel cells. To overcome this drawback, hydrophobic Polycaprolactone (PCL) is being considered a potential electrolyte in this study. The objective of our research is to use Graphene Oxide as catalyst in electrodes of PEMFC and find alternative for Nafion membrane by using electrospun PCL nanofibers instead. The use of carbon based nanomaterials has delivered commendable performance making commercialization of fuel cell products possible in near future.

5:35 PM NM07.15.12
Strong Interfacial Interaction of Prussian Blue and Inorganic Nanosheet with Improved Supercapacitor Performance Xiaoyan Jin and Seong-Ju Hwang; Yonsei University, Korea (the Republic of)

An efficient interfacial interaction between Prussian blue (PB) nanocrystals and exfoliated inorganic nanosheets (NSs) enables to synthesize strongly-coupled composite materials with remarkably improved electrode functionality for supercapacitor. The highly porous nanohybrids of PB-inorganic NS are synthesized by crystal growth of PB nanocrystals on the inorganic NSs. The coordinative bonding between cyanide ligand of PB and inorganic NS induces significant interfacial charge transfer and the increase of the metal oxidation state of PB. The obtained nanocomposites possess expanded surface area than does the pristine PB material, indicating the enhancement of porosity by the hybridization. Of prime importance is that the present nanocomposites show larger specific capacitances with better cyclability and better stability than does the MnO_2 free-PB material, underscoring the beneficial effect of incorporated inorganic NS on the electrode functionality of PB. The present study clearly demonstrates that the composite formation of PB nanocrystals with inorganic NSs can provide an effective way to explore high performance electrode for supercapacitor.

5:40 PM NM07.15.15
Flexible Piezotronic Transport Behavior and Transistors from 2D Zinc-Oxide Nanosheets Corey Carlos, Kevin J. Berg, Yizhan Wang and Xudong Wang; University of Wisconsin–Madison, United States

Since graphene, the growing family of 2-dimensional (2D) materials spanning transition-metal dichalcogenides (TMDs), metal-organic frameworks (MOFs), oxides, and organics, has led to the broader development of nanomaterials and creative use of nanotechnology. Often, it is this reduced dimensionality that enables enhanced structure-property relationships necessary for advancing the field. Wearable flexible electronics is one research area that has seen tremendous growth in recent decades and has benefited by advances in 2D nanomaterials. Considered a fundamental building block, transistors are ubiquitous in modern technology. We demonstrate a novel approach for utilizing the piezoelectric and semiconducting properties of 2D zinc-oxide (ZnO) nanosheets (NS), synthesized via Ionic Layer Epitaxy (ILE), as strain-gated flexible transistors. We examine the effects of strain and immobile piezoelectric surface charge on the semiconducting properties of ZnO-NSs. Given the polar structure of ZnO, we show that the accumulation of piezoelectric charge can change depending on the crystallographic orientation with the respect to the gated contacts of the flexible transistor. As a consequence, the Schottky barriers at the metal-semiconductor interface can be asymmetrically modulated through the application of strain.

5:45 PM NM07.15.16
Low-Voltage Operating 2D MoS_2 Channel Based Electron Devices Using Lead-Free High-k/Ferroelectric $Ba_xSr_{1-x}TiO_3$ Yeonsu Jeong, Hye-Jin Jin, Ji Hoon Park and Seongil Im; Yonsei University, Korea (the Republic of)

Combinining lead-free high-k materials and two dimensional (2D) semiconductor has been attracted many attentions owing to need for environmental-friendly and low-voltage operating devices. Especially, low voltage switching ferroelectric memory devices are rare in report. Here, we have successfully fabricated low-voltage operating field effect transistor (FET) and ferroelectric switching memory transistor using 2D MoS_2 channel and high-k/ferroelectric dielectric $Ba_xS_{1-x}rTiO_3$ (BST). Ferroelectricity of BST can be controlled by changing composition ratio of Ba and Sr in the BST film. In this study, $Ba_{0.5}Sr_{0.5}TiO_3$ (50BST, x=0.5) and $Ba_{0.8}Sr_{0.2}TiO_3$ (80BST, x=0.8) have been used as dielectric materials for low-voltage operating FET and nonvolatile ferroelectric memory transistor, respectively. Mechanically exfoliated MoS_2 flakes were transferred on PMMA brush-treated 50BST and 80BST oxide. The 5 nm-thin PMMA brush was used for reduction of the surface roughness of BST. As a result, we have successfully demonstrated extremly low voltage operating MoS_2 FET, which uses only 0.5 V gate voltage for ON/OFF switching due to high-k 50BST. And using 80BST, MoS_2 based ferroelectric memory transistor has been well operated in a nonvolatile manner under ±3 V pulses. Since

employed high-k dielectric and ferroelectric oxides are lead-free in particular, the approaches applying high-k BST gate oxide for 2D MoS_2 FET are not only novel but also practical towards future low voltage nanoelectronics and green technology.

2D Transistors—Promises, Pitfalls and Prospects Xiangfeng Duan; University of California, Los Angeles, United States

Two-dimensional (2D) semiconductors have attracted tremendous interest as an atomically thin channel for the continued transistor scaling. However, despite many proof-of-concept demonstrations, the full potential of 2D transistors remains elusive. To this end, the fundamental merits and technological limits of 2D transistors need a critical assessment, reality check and objective projection. In this talk, I will briefly review the promises and the current status of 2D transistors, and highlight the widely used device parameters (e.g., carrier mobility, contact resistance) could be frequently misestimated or misinterpreted, and may not be the most reliable performance metrics for benchmarking 2D transistors. We suggest the saturation or on-state current density, especially in the short channel limit, could provide a more reliable measure for assessing the potential of diverse 2D semiconductors, and should be applied for cross-checking different studies, especially when milestone performance metrics are claimed. We next summarize the key technical challenges in optimizing the channel, contacts, dielectric and substrate interfaces and outline the potential pathways to push the limit of 2D transistors; and lastly conclude with a prospect on the critical technical targets, the key technological hurdles to enable the lab-to-fab transition, and the potential opportunities arising in these atomically thin semiconductors.

9:25 PM *NM07.16.02
Ultrathin Electronic Tattoos Based on PtSe2 and PtTe2 Dmitry Kireev[1,1], Emmanuel Okogbue[2,2], Jayanth RT[1], Tae-Jun Ko[2], YeonWoong Jung[2,2,2] and Deji Akinwande[1,1]; [1]The University of Texas at Austin, United States; [2]University of Central Florida, United States

In this work, we present the unique ultrathin platinum-based two-dimensional dichalcogenide (Pt-TMDs) based electronic tattoos. These ultrathin electronic tattoos are fabricated utilizing large-scale CVD-grown platinum diselenide ($PtSe_2$) and platinum ditelluride ($PtTe_2$). The growth is performed at moderate temperatures, at about 400°C, allowing for direct coating onto temperature-sensitive polymers, such as Kapton. Confirming the quality of TMD materials, we show a thorough characterization of $PtSe_2$ and $PtTe_2$'s electrical and electrochemical properties along with advanced healthcare-related applications. First of all, both $PtSe_2$ and $PtTe_2$ tattoos were found to have lower sheet resistance and electrode-skin impedance compared to graphene-based tattoos. Among themselves, $PtTe_2$ tattoos were found to be the most attractive, with sheet resistance as low as 13 Ohm/sq and electrode-to-skin impedance averaging at 4.94±1.61 kΩ (@10 kHz), clearly outperforming the state-of-the-art gold tattoos and even medical-grade Ag/AgCl gel electrodes. We used these ultrathin tattoos for a plurality of human physiological vital signs monitoring, such as the heart and the brain's electrical activity, muscle contractions, eye movements, and temperature. Moreover, to showcase an advanced application of the Pt-TMDs for human-machine interfacing, we built a multi-tattoo system that can easily distinguish eye movement and identify sight direction.

Late News: Controlled and Scalable Fabrication of Non-Stoichiometric 2D Bi2S3 and Its Intriguing

Optoelectronic Properties Jagadeesh Suriyaprakash and Lijun Wu; School of Information and Optoelectronic Science and Engineering, China

Two-dimensional (2D) materials are considered as ground-breaking foundations for novel optoelectronic devices owing to their tunable optoelectronic features, which rely on band/strain/defect engineering. However, early studies have limitations of precise tuning of new chemical composition correlated with electronic and crystal structure, which provides the space for developing a new strategy. In this context, we fabricated the novel non-stoichiometric Bi_x-$Bi_{2-x}S_{3-y}$ 2D-layered materials by simple e-beam lithography. Furthermore, an *in-situ* HRTEM study reveals that newly formed Bi metallic nanocrystals on the edge of $Bi_{2-x}S_{3-y}$ 2D layer show structural dynamics behavior followed by surface and structural transformation. We observed the nucleation, coagulation and Ostwald ripening process in the metallic nanocrystals with respect to the irradiation time. This functional material shows unique electronic structures, which can be manipulated by the non-stoichiometric ratio (Fermi level changes: p-type → n-type → quasi metallic). X-ray photoelectron spectroscopy studies supported the results of *in-situ* TEM analysis. Also, complete optoelectronic characteristics of newly synthesized materials were studied. We propose the possible mechanism involving the Auger decay of sulfur and local bond-breaking phenomenon in Bi_2S_3 material by considering the specimen heating effect and radiolysis process. This *in-situ* study opens the new corridor to the materials researchers to design the novel 2D transition metal chalcogenides materials by the one-step route and tune their physicochemical properties precisely.

10:05 PM NM07.16.05
Conductor-Free Anode of Transition Metal Dichalcogenide Nanosheets Self-Assembled with Graft Polymer Binder Chanho Park, Hyeokjung Lee, Seung Won Lee, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

The development of anodes for lithium-ion batteries (LIBs) has garnered considerable interest. In particular, anodes based on liquid-phase-exfoliated two-dimensional transition metal dichalcogenide (TMD) nanosheets are studied extensively because their intrinsic capacity is higher than graphite. As most semiconducting TMDs possess low electrical conductivity and lithium-ion diffusivity, costly processes are needed—such as the addition of conductive fillers, chemically converted metallic phase transformation, and topological nano-fabrication—to decrease the ion diffusion length and increase the surface area. Here, we introduce a novel conductor-free TMD nanosheet anode with graft-polymer ionic channels that ensures high stability and rate capability of the LIB. The fluorinated polymer binder grafted with ionomers allows not only the efficient exfoliation of TMD nanosheets in the liquid phase to guarantee stable sheet-to-sheet separation but also provides self-assembled ionic channels through which lithium ions in the electrolyte readily arrive close to the surface of the nanosheets. Efficient electrochemical reduction of lithium ions occurs on the surface of our simple binary anode of MoS_2 nanosheets, self-assembled with graft binder ionic channels, resulting in a high-performance LIB with stability (90% retention rate after 1,000 cycles), rate capability (50% at 5 A/g), and high cell capacity (933.1 mAh/g at 0.1 A/g). Our TMD anodes that do not require additional processes for enhancing electric as well as ionic conductivity offer a novel strategy for developing high performance large-scale TMD-based LIBs.

QD Hybridized 2D Material Based Nanoscroll—A New Paradigm for Efficient Light-Harvesting and Polarized Emission Rapti Ghosh[1], Ya-Ping Hsieh[1] and Yang-Fang Chen[2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

The light-matter interaction in the 2D materials can greatly be enhanced by exploiting their flexural strength. These materials either be twisted[1] or wrinkled[2] in order to decrease the substrate interaction. This generates enhanced carrier mobility in the suspended material and strong light confinement due to multiple internal reflections. Spirally rolling of 2D material (eg. MoS_2, WS_2) strictly restricts the electronic motion in a uniaxial direction. This encapsulated structure after getting hybridized with high yield QDs form type-II band alignment

at the heterostructure interface. The photo-generated excitons after getting dissociated at the QD/2D interfaces transferred to the conductive 2D channel. The subsequent presence of QDs as a strong photoabsorptive material and multiple reflections at the inner wall of the nanocavity increase the photoconductivity in the nanoscale regime. Nanoscroll (NS) stimulates coherent lasing action with an unprecedently low lasing threshold and enhances the photosensitivity almost 3000 fold[1] compared to the nanosheet counterpart. This spirally rolled helical structure predominately generates polarized photosensitivity due to preferential excitons localization along the circumference of the scroll. Our approach of QD hybridized NS formation thus enables feasible ways to discover exotic physical phenomena and to develop novel high-performance flexible devices toward realistic applications.

8:00 AM NM07.10.09
Mitigating the Substrate Effect on Two-Dimensional Molybdenum Disulfide Kory Burns; University of Florida, United States

Valley excitons has proven to play a significant role in the photoconductivity and light emission processes of two-dimensional (2D) Molybdenum Disulfide (MoS_2). Exploring ways to manipulate energy levels of excitons opens the possibility to tune quantum degrees of freedom such as electron spin, layer pseudospin, and valley pseudospin. In this contribution, we first introduce a new method to produce single-layer sheets of MoS_2 using miscible organic solvents to minimize the exfoliation energy in the fabrication process. The atomically thin membranes were suspended on four different epitaxial substrates and analyzed using Raman spectroscopy, Photoluminescence (PL), Atomic Force Microscopy (AFM) and X-ray photoelectron spectroscopy (XPS). We report on the strain induced from the lattice mismatch between the substrate and the material, correlate the effect this has on the binding energy of MoS_2, and lastly explore the impact substrates have on the optical properties of MoS_2 by measuring the exciton binding energy, spin-orbit coupling, and optical and electronic band gap. This work serves as a foundational piece to assist researchers with choosing a formidable substrate to build field effect transistors.

8:00 AM NM08.01.01
Late News: Experimental Observation of Quasi-Ballistic Thermal Transport of Surface Phonon-Polaritons Over Hundreds of Micrometers Yunhui Wu, Jose Ordonez-Miranda, Laurent Jalabert, Saeko Tachikawa, Roman Anufriev, Sebastian Volz and Masahiro Nomura; The University of Tokyo, Japan

At the nanoscale, enhancing the propagation distance of heat carriers in solids attracts intensive attention for improving the thermal performance in micro- and nanoelectronics. However, the major heat carriers, phonons, propagate ballistically over the distances shorter than one micrometer above room temperature. To compensate this limited propagation range, we propose a novel heat carrier, surface phonon polariton (SPhP), which is generated from the hybridization of the optical phonon and the photon and propagate in the range of a few hundred micrometers. In this study, we conduct a 3ω measurement of SiN suspended submicron films to investigate the thermal transport by SPhP in hundreds of micrometers range.

As a result, we report the thermal conductivity (TC) measurements in silicon nitride (SiN) films with different thicknesses (h = 30, 50, 100, and 200 nm) measured in the 300 - 400 K temperature range. We detect the higher TC with the sensor further from the heater (d = 200 μm) in thin films (h = 30, 50 nm). This phenomenon suggests that the heat propagation due to SPhPs remains quasi-ballistic in the hundreds of micrometers range, which is consistent with our previous study [1]. When the 30-nm-thick film heats up to 400 K, we detect approximately 13% enhancement of the TC compared to 300 K. Meanwhile, for 100- and 200-nm-thick membranes, the TC is nearly independent of both temperature and the distance. The results presented here have potential applications in the fields of heat transfer, thermal management, near-field radiation, and polaritonics.

Late News: Thickness Dependence of Surface Phonon-Polariton Propagation Length in SiO2/Si/SiO2 Structures Saeko Tachikawa[1], Jose Ordonez-Miranda[2], Yunhui Wu[1], Laurent Jalabert[2], Roman Anufriev[1], Sebastian Volz[2] and Masahiro Nomura[1,2]; [1]IIS, the University of Tokyo, Japan; [2]The University of Tokyo, Japan

Surface phonon-polaritons (SPhPs) are surface waves generated by the coupling of electromagnetic waves and optical phonons at the interface of polar materials. In suspended nanofilms, SPhPs propagate over typical distances of a few hundreds of micrometers along their interfaces [1], which positions them as powerful energy carriers to transport energy along the plane of nanomaterials. However, such nanometric films are mechanically unstable and hence their practical application is limited. In this work, we study the SPhP propagation along a three-layer structure made up of a Si film, acting as a mechanical support, sandwiched by two nanofilms of SiO_2, which is the SPhP active material. This is done by determining the SPhP propagation length as a function of the spectral frequency and thicknesses of the Si and SiO_2 films. Longer propagation lengths are obtained for

thinner SiO_2 films, due to the reduction of energy absorption [2]. By contrast, as the Si film thickness reduces, the propagation length increases (decreases) for thicknesses smaller (greater) than the SPhP wavelength. This behavior is generated by the tradeoff between the energy absorption and coupling of SPhPs propagating along the top and bottom SiO_2 layers. It is shown that the resulting SPhP contribution to the in-plane thermal conductivity of the considered structure exhibits a minimum value for a given Si film thickness. The obtained results thus shed light on the physical understanding of the propagation of SPhPs and the modulation of their thermal transport inside a layered and mechanically stable structure.

Late News: Near-Field Radiative Heat Transfer Mediated by Graphene Plasmons Behrad Zeinali Tajani and Sheila Edalatpour; University of Maine, United States

Radiative heat transfer is said to be in the near-field regime when the separation distance between the heat exchanging media is smaller than or comparable to the dominant thermal wavelength ($\lambda_{max} \approx 10$ mm at room temperature). Near-field radiative heat transfer can be quasi-monochromatic and exceed the blackbody far-field limit by several orders of magnitude. The enhancement beyond the blackbody limit is due to the extraneous contribution to radiative heat transfer by evanescent waves that are confined to a distance of about the thermal wavelength from the surface of the thermal emitter. Near-field radiative heat transfer can be quasi-monochromatic when the heat exchanging media support surface phonon and plasmon polaritons. These unique properties of near-field regime of radiative heat transfer are highly promising for many advanced and state-of-the-art technologies such as waste heat recovery, nanoscale-resolution imaging, nanomanufacturing, thermal management of electronic devices, and thermal rectification through a vacuum gap. The quasi-monochromatic behavior of near-field radiative heat transfer plays a central role in these technologies. Development of the near-field applications requires materials with plasmonic or phononic resonances in the mid-infrared where these modes can be thermally excited.
The number of materials with plasmonic/phononic resonances in the mid-infrared is very limited, and the spectral location (wavelength) of these resonances does not often match the ones required by practical applications. Graphene supports surface plasmons in the mid-infrared and terahertz ranges. It is thermally very stable, and due to the two-dimensional nature of graphene, free electrons or holes can effectively be induced into this material using chemical doping or electrical gating rendering dramatically tunable optical properties. Due to these advantages, graphene has recently gained significant attention for increasing or modulating thermal radiation in the near-field regime. In this presentation, the possibility of tuning the spectrum of near-field radiative heat transfer using graphene-based materials is discussed. Radiative heat transfer between graphene sheets of various chemical potentials, temperatures, and separation distances is analyzed. The dispersion relation of graphene plasmons is derived, and the conditions under which graphene plasmons can result in quasi-monochromatic near-field conductance is discussed.

Late News: Phonon Hydrodynamics for Resistive Dominated Materials F. Xavier Alvarez, Albert Beardo Ricol, Lluc Sendra Molin, Juan Camacho and Javier Bafaluy; Universitat Autonoma de Barcelona, Spain

Phonon hydrodynamics is the framework to understand thermal transport in materials where momentum conservation is important. This is the case of 2D materials like graphene or transition metal dichalchogenides but also 3D materials like graphite and diamond. In these materials, momentum conservation is granted by the dominance of the normal phonon-phonon collision.
In the last decades, phonon hydrodynamics has been shown to offer also an explanation for the anomalous thermal behaviour of semiconductors like silicon or germanium, where normal scattering is not dominant. Despite also based in the momentum conservation, the appearance of hydrodynamics in materials like silicon is related to surface and interface physics. In this case, a boundary layer is created that is the responsible to transfer momentum between the surfaces and the inner regions of the materials. In that layer, conservation rules

are also crucial and modify the heat equations. The final result is that a hydrodynamic equation like Guyer and Krumhansl is also valid to describe these materials.
We present a multiscale analysis going from the microscopic fundamentals for the appearance of a hydrodynamic behaviour in silicon to the experimental evidences in favour of using the Guyer and Krumhansl equation to describe this kind of materials. We will also demonstrate that in the samples where this happens, traditional approaches based on an effective Fourier equation are completelly ruled out.
Moreover, the proposed framework allows to understand why using a Fourier approach, a size dependent thermal boundary resistance at nanoscale contacts between metals and substrates is required. It will be shown that this size dependence understood through the hydrodynamic behaviour of the substrate near the metal line.

Late News: Observation of a Hydrodynamic Relaxation Time Scale Governing the Thermal Evolution of Nanoscale Heat Sources in Silicon Substrate Albert Beardo Ricol[1], Lluc Sendra Molin[1], Joshua Knobloch[2], Brendan McBennett[2], Travis D. Frazer[2], Javier Bafaluy[1], Jorge Nicolas Hernandez Charpak[2], Begoña Abad Mayor[2], Henry Kapteyn[2], Margaret Murnane[2], F. Xavier Alvarez[1] and Juan Camacho[1]; [1]Universitat Autònoma de Barcelona, Spain; [2]University of Colorado Boulder, United States

Recent experiments revealed non-Fourier thermal conduction in general semiconductors like Silicon [1-3]. The use of a hydrodynamic heat transport equation has shown to capture thermal transport beyond Fourier's law through new phenomena like phonon vorticity and viscosity [4-6].

We focus on the process of energy release from a nanoscale heat source towards a Silicon substrate. By monitoring the heater thermal relaxation through EUV-scatterometry techniques [2], we demonstrate that the heater temperature follows a double exponential decay [7]. This system response cannot be explained if using Fourier's law with effective parameters to model the substrate conduction, which provides a single exponential thermal decay followed by a power law. In contrast, the hydrodynamic model with geometry independent parameters naturally predicts the two exponential decay and provides analytic expressions for each characteristic time scale. The shorter time scale (~100ps) is dominated by the interfacial resistance and the second one (~1ns) is dominated by hydrodynamic effects in the substrate. The geometry dependencies of the second characteristic time accurately predict the observed slower relaxation of the heater by reducing its size. Furthermore, the model provides a simple analogy based in an electrical circuit to illustrate the heater thermal evolution.

Late News: New Formalism to Derive a Hydrodynamic Heat Transport Equation for General Semiconductors from the Phonon Boltzmann Equation Lluc Sendra Molin, Albert Beardo Ricol, Javier Bafaluy, F. Xavier Alvarez and Juan Camacho; Universitat Autònoma de Barcelona, Spain

We present a new formalism that solves the Boltzmann Transport Equation (BTE) and derives a hydrodynamic heat transport equation (Guyer-Krumhansl equation) [1] similar to Navier-Stokes, which generalizes the Fourier's law [2]. This generalization applies from systems dominated by momentum-preserving collisions to kinetic materials dominated by resistive collisions. Therefore, it can be applied to general semiconductors like Silicon, in contrast to the common belief [1]; and arbitrary complex geometries by using Finite elements

methods at a low computational cost.
This contrasts with other approaches, where efforts have been made to use Fourier's law with effective coefficients depending on the physical situation [3,4] or through alternative solutions of the phonon BTE [5,6], whose complexity only allows to face simple geometries.
Our model allows the understanding of the experimentally observed Fourier's law breakdown at small length and time scales by using geometry independent parameters calculated from ab initio, resulting in a predictive model [7-9].
Furthermore, it supplies a connection between microscopic variables (phonon properties) and mesoscopic ones (temperature, heat flux, …), providing an explicit solution for the nonequilibrium phonon distribution function. Furthermore, this approach allows to derive consistent boundary conditions for arbitrary complex surfaces and interfaces between different materials.

Late News: Mechanical Tuning of the Thermal Conductance of Molecular Junctions Mohammadhasan Dinpajooh and Abraham Nitzan; University of Pennsylvania, United States

Understanding the thermal conductance in molecular junctions offers important insights in designing future thermoelectric devices. One of the most interesting features in molecular junctions is the possibility to exert external control through mechanical forces. We use non-equilibrium molecular dynamics simulations to study the steady state thermal conductance of different molecular junctions consisting of finite macromolecules at various end-to-end distances/electrode displacements. We find that the nature of the thermal conductance along such polymer chains strongly depends on mechanical tuning, leading to significantly different heat conductions and temperature profiles along the chain in the compressed-chain and stretched-chain limits. This transition between modes of behaviors appears to be a threshold phenomenon: at relatively small end-to-end distances/electrode displacements, the thermal conductance remains almost constant as one stretches the polymer chain. At given critical end-to-end distances/electrode displacements, thermal conductances start to increase, reaching the fully extended chain values. In addition, we find that the thermal conductances of molecular junctions sandwiched between metal leads significantly depend on the nature of metal leads and are much smaller than the corresponding intrinsic thermal conductances, i.e. in the absence of metal leads. We then address how the thermal conductance is correlated with the vibrational density of states and study the metal-molecule coupling and anharmonic effects upon stretching. We also conduct similar studies for disordered polymer chains and bundles of several polymer chains, which show remnants of the same behaviors of the aforementioned systems.

Geometry-Modulated Metamaterials for Enhanced Thermoelectric Effects and Decreased Thermal Conduction Xanthippi Zianni; National and Kapodistrian University of Athens, Greece

Geometry-modulated nanostructures consist a class of metamaterials promising for efficient thermoelectric applications and nanoscale heat management. In these metamaterials, it is possible to achieve enhanced thermoelectric effects and decreased thermal conductivity by designing the geometry-modulation in the nanometric scale. We indicated this possibility in 2010 when we proposed diameter-modulated nanowires for enhanced thermoelectric efficiency [1]. We showed that coupling between propagating waves and resonances of the modulation units modifies the carriers transmission coefficients and results in enhanced thermoelectric power factor and decreased electron and phonon thermal conductions [2,3,4]. Electron and phonon scattering can be controlled by designing the shape of the geometry-modulation [5,6]. Ballistic or diffusive transport effects may dominate depending on characteristic dimensions of the geometry modulation [7,8]. We will discuss physics aspects of electron and phonon transport in geometry-modulated metamaterials based on our work and the evolution of the research in this field that is currently gaining increased interest for advanced applications.

10:55 AM NM08.02.03
Late News: Ba1/3CoO2, a Promising Candidate for Oxide Thermoelectric Material Yuqiao Zhang[1], Yugo Takashima[1], Liao Wu[1], Jiake Wei[2,3], Bin Feng[3], Yuichi Ikuhara[2,3], Hai Jun Cho[1] and Hiromichi Ohta[1]; [1]Hokkaido University, Japan; [2]Kyoto University, Japan; [3]The University of Tokyo, Japan

Layered cobalt oxide such as $Na_{0.75}CoO_2$ and $Ca_3Co_4O_9$ are known as good candidates for oxide thermoelectric material. Although layered cobalt oxides have several advantages such as environmental compatibility and thermal-chemical stabilities compared to heavy metal-based chalcogenides like Bi_2Te_3 and PbTe, their *ZT* is low as compared to that of heavy metal-based chalcogenides, mainly due to rather high thermal conductivity. In order to overcome the difficulty, we hypothesized that the thermal conductivity of layered cobalt oxide can be reduced by heavier ion substitution[1]. Firstly, we fabricated $Na_{0.75}CoO_2$ epitaxial films on sapphire or YSZ substrate by the R-SPE method[2]. Then, the Na ions were exchanged with Ba ions by the ion exchange treatment. The resultant film was $Ba_{1/3}CoO_2$, which was clarified from the XRD patterns and HAADF-STEM images. Although $Na_{0.75}CoO_2$ is unstable at high temperature in air, the resultant $Ba_{1/3}CoO_2$ epitaxial films show excellent thermal stability at high temperature (700 °C) in air. The room temperature thermal conductivity of $Ba_{1/3}CoO_2$ epitaxial films along the layered structure was ~3 W m^{-1} K^{-1}, which is approximately half of that of $Na_{0.75}CoO_2$ (~5.5 W m^{-1} K^{-1}), indicating that our hypothesis is true. Since the power factor was almost unchanged, the *ZT* was greatly improved (*ZT* = 0.11[3] at room temperature and 0.2 at 200 °C). These *ZT* values are the highest among oxides ever reported as a "reliable value". The present result clearly indicates that $Ba_{1/3}CoO_2$ shows rather large *ZT* at high temperatures in air, exerting a potential high temperature application prospect.

Origin of Unexpectedly Low Thermal Conductivity In AMg_2X_2 (A = Mg, Ca, Yb, X = Sb, Bi) Jingxuan Ding[1], Tyson Lanigan-Atkins[1], Mario R. Calderon Cueva[2], Alexandra Zevalkink[2] and Olivier Delaire[1,1]; [1]Duke University, United States; [2]Michigan State University, United States

Thermoelectric materials enable direct conversion of waste heat into electrical energy. The conversion efficiency is inversely proportional to the thermal conductivity, which is generally dominated by phonons in semiconductors. Zintl compounds AMg_2X_2 constitute a class of new thermoelectric compounds with excellent thermoelectric performance in n-type $Mg_3(Sb,Bi)_2$ alloys, with zT values up to 1.6 reported so far. Mg_3Sb_2 exhibits very low lattice thermal conductivity (~1-1.5 W/m/K at 300K), comparable with PbTe and Bi_2Te_3, despite a much lighter average ionic mass. We report on neutron scattering and first-principles studies of the lattice dynamics of AMg_2X_2. Inelastic neutron scattering measurements provided the temperature dependence of the phonon density of states (DOS). Extra peaks and overall softer phonons were found at low frequency in Mg_3Sb_2 and Mg_3Bi_2 compared to $CaMg_2X_2$ or $YbMg_2X_2$. Combined with simulations, we highlight the importance of a specific soft Mg-X chemical bond that suppresses phonon group velocities and drastically enlarges the scattering phase-space, enabling the threefold suppression in thermal conductivity.

Nanokelvin-Resolution Band-Edge Thermometry at Room Temperature Amin Reihani, Edgar Meyhofer and Pramod Sangi Reddy; University of Michigan, United States

High-resolution thermometry is essential in calorimetry and bolometry with broad applications in studies of dissipation in electronics and quantum systems [1, 2], metabolism in biological systems [3], and millimeter-wave sensing for astronomy [4]. Achieving high-resolution thermometry combined with small device size, at room temperature, is highly desirable. In this presentation, we will describe a novel thermometer capable of <100 nK resolution in a 0.1 Hz measurement bandwidth. Our thermometer is composed of a microfabricated suspended GaAs device with lateral sensing dimensions of <200 μm and employs an optical readout scheme. The temperature sensing mechanism is based on the Fabry-Pérot resonance at the Urbach edge of direct band-gap semiconductors, where the optical properties of the medium, namely the absorption coefficient and refractive index, change abruptly by variation of incident photon energy relative to the band gap [5]. We show that the temperature dependence of band gap provides a highly temperature-sensitive reflection or transmission signal at the Fabry-Pérot resonance peaks. The device we describe here represents a first demonstration of a micro-thermometer for all-optical, nano-Kelvin thermometry at and above room temperatures.

11:40 AM NM08.02.06
Cathodoluminescence Nanothermometry for Thermal Transport Measurements Kelly W. Mauser[1], Magdalena Solà-Garcia[1], Matthias Liebtrau[1], Benjamin Damilano[2], Pierre-Marie Coulon[3], Stéphane Vézian[2], Philip Shields[3], Sophie Meuret[4] and Albert Polman[1]; [1]AMOLF, Netherlands; [2]Université Côte d'Azur, France; [3]University of Bath, United Kingdom; [4]CEMES/CNRS, France

As structures in nanodevices approach the size of the phonon mean-free-path of materials, studying thermal transport properties becomes increasingly difficult due to the need for nanoscale thermal probes. Many different techniques exist to study these nanoscale effects, however, measurement speed and/or the diffraction limit of

light is often a limiting factor. Here, we present new methods for measuring temperature and thermal conductivity of semiconductor nanostructures rapidly with nanometer resolution using cathodoluminescence spectroscopy in a scanning electron microscope (SEM).

First, we demonstrate the first measurements, to our knowledge, of cathodoluminescence (CL) nanothermometry in semiconductors. In semiconductor CL, a 5-30 keV electron beam from a scanning electron microscope excites electrical carriers, that recombine and emit radiation at energies near their bandgap, which is then collected and analyzed [1]. We perform CL imaging of 7-micron-long, 200-nm-diameter GaN nanowires, made by a top-down approach based on sublimation under vacuum, which are suspended across a 6.5 micron hole in a TEM membrane. The wires are thermally clamped on both sides using focused ion beam deposition of Pt and we record the bandgap emission near 3.4 eV at every position in the SEM image. By precisely measuring shifts in the bandgap, we map the temperature as the electron beam is scanned over the wire by using the Varshni relation fit to calibration data. We find a 6 K temperature resolution with our samples, limited primarily by small doping variations in the wires which can be corrected for by mapping the doping profile with a low-current electron beam with nm-resolution[2]. Using low-current electron beams which deposit less than 1 μW of power into the wire, we can measure temperature in a non-perturbative way. Using large currents of 70 nA which can deposit 100's of μW of power, we can heat the wires by over 400 K.

Next, we will discuss three techniques for measuring thermal conductivity using this novel method of CL nanothermometry. The first two use a continuous electron beam current scanned over the wires with the beam acting as both a delta-function-like heat source and local temperature probe with resolution of the electron cascade. We fit the temperature rise as a function of position, correcting for doping variations in the wire. The final method uses an electrostatic beam blanker[3], with which we measure the frequency dependence of the thermal response of the GaN nanowires to electon beam heating in the range of 100 Hz to 5 MHz in a matter of minutes. We develop a theoretical model to fit the data and find a cut-off frequency of ~500 kHz from which we derive a thermal conductivity of 54 ± 13.2 W/m*K, which agrees within error with the other techniques we discuss. We will discuss the advantages and limitations of each technique and future directions. With minor modifications, the underlying principles of methods like time-domain thermo-reflectance are applicable to CL nanothermometry experiments, especially with the rise of electron microscopy with fs-photoexcited field-emission guns[4]. Because of the nanoscale nature of these measurements, CL nanothermometry methods could prove useful for probing thermal transport and phonon properties at small dimensions, including ballistic thermal transport, near-field heat transfer, or in studies of thermal contact resistance.

Direct Electrocaloric Measurements via ThermoReflectance Layla Farhat[1,2], Mathieu Bardoux[1], Stéphane Longuemart[1], Ziad Herro[2] and Abdelhak Hadj Sahraoui[1]; [1]Université du Littoral Côte d'Opale, France; [2]Université Libanaise, Lebanon

Electrocaloric (EC) effect refers to the isothermal entropy or adiabatic temperature changes of a dielectric material induced by an external electric field. This phenomenon has been largely ignored for application because only small EC effects (2.6K) have been detected in bulk materials such as $Pb_{0.99}Nb_{0.02}(Zr_{0.75}Sn_{0.20}Ti_{0.05})_{0.98}O_3$. The discovery of a giant electrocaloric effect by Mischenko et al. in thin films (up to 12°C with E=480kV.cm^{-1}) renewed interest in electrocaloric materials and related cooling technologies. It is indeed the development of thin structures that has made it possible to obtain high dielectric rigidity and significant electrocaloric effects.

Several methods have been developed to characterize EC effect. "Direct methods" measure the EC temperature

change or released heat in the material on application or withdrawal of the electric field. ‘‘Indirect method’’ employs Maxwell equations to calculate the EC effect from the change of polarization with temperature.

In fact, ferroelectric thin films exhibit significant dielectric losses ($\tan\delta>0.1$). Furthermore, EC thin layer being deposited on a solid substrate, the thermal capacity of the assembly is very high compared to that of the thin layer alone. Thus, even if the change in specific entropy following the application of an electric field is very large, the change in total entropy is almost undetectable because of the very low volume of the thin films. The temperature variation will also be hardly detectable because of the rapid dissipation of the heat in the substrate that is behaving as a heat sink. Due to these limitations, till now it has been difficult to present experimental values of electrocaloric properties in thin films from direct measurements, only estimates by indirect characterization are accessible. It is therefore imperative to study these materials using instruments offering high resolution.

To overcome these difficulties, we propose a novel characterization method based on thermoreflectance for measuring directly the electrocaloric effect. This method allows the study of systems such as thin films, multilayers, and nanoparticle. It is a non-contact and non-destructive measurement method with a very large temporal dynamic, which allows the study of extremely rapid phenomena. It exploits the temperature-dependent reflectivity of a surface which is probed using the intensity variation of a reflected laser beam. We report laser-based direct measurements of ECE in various solid ferroelectric materials in the form of multilayered capacitor and thin films as a function of the applied electric field. Using appropriate model, the signal can be used to retrieve Electrocaloric properties of embedded or stacked electrocaloric layers.

Thermal Switching via the Thermal Chiral Anomaly in the Magnetic-Field Induced Ideal Weyl Phase of $Bi_{1-x}Sb_x$ Topological Insulators Dung D. Vu and Joseph Heremans; The Ohio State University, United States

The chiral anomaly in Weyl semimetals has a thermal analog [1]. In electrical measurements, an electric field applied parallel to a magnetic field and parallel to the direction of separation of the Weyl points produces a charge transfer between the Weyl points that results in an anomalous charge current and a negative magnetoresistance; this is the chiral anomaly. In thermal measurements, there is no charge transfer between the Weyl points, but an energy transfer, which produces an anomalous heat current and an increase in thermal conductivity in magnetic field. We unambiguously demonstrate this experimentally in the topological insulator bismuth-antimony alloys ($Bi_{89}Sb_{11}$ and $Bi_{85}Sb_{15}$) driven into an ideal Weyl semimetal state by a Zeeman field, with the chemical potential pinned at the Weyl points, and in which the Fermi surface has no trivial pockets. The experimental signature is a 300% enhancement of the electronic thermal conductivity in a 9T applied magnetic field parallel to the thermal gradient that follows the Wiedemann-Franz law above 60 K. The same material shows an equally strong decrease in thermal conductivity in a magnetic field applied perpendicularly to the direction of Weyl point separation. The talk will emphasize how the material is potentially useful in heat switches in applications, such as adiabatic demagnetization refrigeration, where an external magnetic field is already being used to induce ordering in a paramagnetic salt.

Ultrafast Spin Seebeck Measurements on Rare-Earth Iron Garnets Victor Ortiz, Michael Gomez, Yawen Liu, Mohammed Aldosary, Jing Shi and Richard B. Wilson; University of California, Riverside, United States

Understanding the thermal generation of spin currents in magnetic materials is an important goal for the field of spin caloritronics. Among magnetic materials, rare earth iron garnets (REIG) display intriguing magnetic transport properties as result of strong antiferromagnetic exchange interactions and low magnetic damping. We report on ultrafast longitudinal spin Seebeck effect (LSSE) experiments on thin film REIG / heavy metal (HM) heterostructures (RE: Y, Tm, Eu, Tb; HM: Au). We use time-resolved magneto optic Kerr effect measurements to directly observe the transfer of magnetization from the REIG into the HM on femto-second timescales, allowing us to selectively probe the interfacial SSE. We observe a factor of 4 difference in the magnitude of the LSSE among the different REIG samples. Our results provide insight regarding the different contributions to the spin current from the different REIGs and the relevance of the interface between the REIG and the HM layers. This work was supported by the U.S. Army Research Laboratory and the U.S. Army Research Office under contract/grant number W911NF-18-1-0364; and SHINES, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award SC0012670.

Thermal Conductivity Study of Piezoelectric PZT Stack Brandi Wooten and Joseph Heremans; The Ohio State University, United States

We present new data on the polarization-dependent thermal conductivity of ferroelectric materials, and a new hypothesis on its possible physical origin. Hopkins and colleagues [1] report that piezoelectric materials have a thermal conductivity that is a function of the external electric field. Further, they assert that the decrease as the field is applied is due to an increase in ferroelectric domain wall density, which increases the phonon scattering. While their experiment is conducted on a thin film, we investigate the field and temperature dependency of thermal conductivity on a PZT stack with interwoven electrodes. We present data that are consistent with [1], but with a sensitivity to the applied field that is an order of magnitude larger. The thermal conductivity changes are hysteretic and follow the polarization of the material, but the signal is too large to be explained by volume or sound velocity changes. Our data hint at an alternate hypothesis, in which local thermal fluctuations of the polarization in the material may carry heat, by analogy to magnons carrying heat in ferromagnets [2].

PHONONICA—An Object-Oriented Code for Probing Phonon Modes and Interactions Jacob Eapen and Anant Raj; North Carolina State University, United States

The traditional normal mode analysis, which employs complex normal mode coordinates, cannot distinguish the normal (N) phonon interactions from the Umklapp (U) interactions. In our recent work [*Sci. Rep.* **9**, 7982 (2019)], we have demonstrated that both N and U processes can be resolved from atomistic simulations by adopting a set of real asymmetric normal mode amplitudes. In the current work, we have developed an object-oriented code – Phononica, which when dynamically paired with the popular molecular dynamics (MD)

simulator – LAMMPS, transforms the atomistic trajectories, on the fly, to real normal mode amplitudes that can be used for analyzing phonon interactions, and phonon modes in non-equilibrium thermal transport. Additionally, Phononica can read-in the dynamical trajectories from *ab initio* MD codes such as VASP or Quantum Expresso for phonon analysis; using the recently developed ZTR-2 method [*Comp. Phys. Comm.* **238**, 124 (2019)], both crystalline and disordered materials can be analyzed even when the mean displacements are not defined or known. Phononica is particularly suited for (*i*) computing phonon dispersion curves, (*ii*) analyzing elementary phonon-phonon interactions, (*iii*) computing phonon modal conductivities from equilibrium and non-equilibrium simulations using our approach outlined in *J. Chem. Phys.*, **151**, 104110 (2019), (*iv*) analyzing defect-phonon interactions, and (*v*) modeling phonon transport across low dimensional molecular junctions and interfaces. In this talk, we summarize the capability of Phononica by elucidating the phonon and heat current modes in representative bulk and low-dimensional materials in both equilibrium and non-equilibrium conditions.

Atomistic Simulation of Phonon Behavior in Crystalline Cellulose Iβ Zhiyu Liu, Gaurav Kumar and Peter Chung; University of Maryland, College Park, United States

Cellulose is an inexhaustible naturally occurring plant-based polymer. Because of its sustainability and renewable properties, it has drawn significant research interest recently including simulation-based studies of thermal [1] and mechanical properties [2]. However, the phonon behavior in Crystalline Cellulose Iβ, especially the anharmonicity, is less studied. In this work, we investigate the intrinsic anharmonicity of Cellulose Iβ by calculating both harmonic and anharmonic phonon behaviors using molecular dynamics simulation using a reactive molecular forcefield (ReaxFF). To improve the performance of geometry optimization and get better energy conservation, a modified version of ReaxFF [3] is used in our study. The contributions of different phonon modes towards thermal conductivity and the mediating effects of anharmonicity are shown using both diffusive and ballistic models. Comparisons of the results using different models reveal the unconventional way heat is transported by phonons in Cellulose Iβ and help to understand nanoscale thermal transport mechanisms in this highly complex crystal. Moreover, similar to other organic molecular crystals, such as α-RDX [4], we show the unusual role of certain phonon-phonon scattering processes. Unlike ordered crystal, our study will demonstrate the diffusive behaviors of phonon in complex organic crystals. These results indicate complex materials like Cellulose Iβ can diverge strongly from accepted multiscale and multiphysical notions of phonon contributions to the macroscale thermal transport behavior.

Late News: Causal Phonon Green□s Function for Simulation of Thermal Transport in Nanomaterials
Vinod K. Tewary and Edward Garboczi; National Institute of Standards and Technology, United States

The development of nanomaterials has revolutionized the materials industry. In order to exploit the full industrial potential of these materials, it is necessary to have a reliable mathematical model to simulate the physical processes that are relevant for specific applications. Such a model is needed, for example, for their characterization and testing and for virtual experimentation, useful for designing new devices.
Thermal transport in nanomaterials is a subject of strong topical interest because of its wide-ranging practical

applications. Examples are thermoelectric energy conversion as well as heat management systems. Almost all solid-state electronic devices are sensitive to heat and require efficient heat dissipation mechanisms. The conventional modeling techniques based upon the continuum approximation of solids are not applicable to nanomaterials. This is because phonons play a major role in the thermal transport and their mean free path is comparable to the interatomic spacing and the device dimensions.
Another modeling challenge is that the thermal transport characteristics of solids, specifically their thermal conductivities, are sensitive to the low frequency (GHz - MHz) phonons. These quasiparticles require modeling of a many particle system over extended times. The iterative numerical techniques, based upon the use of conventional molecular dynamics (MD), suffer from poor temporal convergence. They are, therefore, limited to small times and are more suitable for simulating high frequency phonons. For example, the basic MD formulation is limited to a few picoseconds, whereas simulation of GHz -MHz phonons need the simulations to extend to nano-micro seconds.
At NIST, we have developed a causal phonon Green's function (CGF) method, which is very efficient for modeling the phononic response of nanomaterials at the atomistic length scales and large temporal scales. In the conventional MD, a typical function Z(r,t) in the Hamiltonian is expanded to first order in the space variable 'r', as well as the time variable 't'. The differentials are approximated by finite differences. In our CGF method, we first make the problem mathematically more complicated by expanding the Z(r,t) to quadratic powers in 'r' but not in t. Then we exploit the fact that the CGF for Hamiltonian with quadratic dependence on r can be calculated analytically. This enables us to construct the CGF to obtain an exact solution in 't'. It breaks the limitation of the small time steps in temporal integration.
We still need to iterate because of the need to include the anharmonic (cubic and higher) terms in Z(r,t). This introduces some constraints on the iteration steps but they are much less severe than those in the conventional MD. For some idealized cases, we had shown that our CGF technique can model the temporal processes over an unprecedented wide range from femto to microseconds.
One problem was that the calculation of CGF needs diagonalization of an N x N matrix, where N is the number of atoms in the model. This can be done for symmetric lattices but becomes computationally expensive for lattices with defects and disorders. We have now developed an ICGF (Iterative CGF) scheme for calculating the CGF for realistic nanomaterials without invoking any symmetry. We have tested the validity of the ICGF by applying it to a model problem, for which exact results are available for comparison.
The CGF is useful for a variety of modeling problems in nanomaterials. For example, it gives pair correlation functions and is useful for solving problems on scattering of quasi particles. The poles of the CGF give phonon frequencies and the imaginary part of its diagonal elements give the frequency spectrum. In this talk I will briefly describe our CGF and ICGF techniques and discuss their efficacy and validity by giving a numerical example.

Late News: Linearized Peierls Boltzmann Transport Solution of Heat Accumulation at Interfaces
Abhishek Pathak[1], Avinash Pawnday[2], Aditya P. Roy[2], Amjad Aref[1], Gary Dargush[1] and Dipanshu Bansal[2]; [1]University at Buffalo, The State University of New York, United States; [2]Indian Institute of Technology Bombay, India

Interfaces impede phonon transmission and cause heat accumulation. This heat accumulation degrades the performance of nanoscale transistors and microprocessor chips used in our everyday life. Hence effective thermal management strategies are desirable to control the heat carriers both at an atomic scale and at the device level. Several phenomenological elastic phonon transmission models, such as the acoustic mismatch model, diffuse mismatch model, atomistic Green's function, are proposed to spectrally resolve the phonon conductance across the interface[1]. More recently, the conductance is shown to have a significant (~50%) contribution from inelastic phonon transmission assisted by interfacial modes[2]. Moreover, within both elastic and inelastic phonon transmission, phonons can retain or lose their coherency[3]. Simulation of these elastic and inelastic models at the device level is necessary to design effective thermal management strategies.
To this end, we have developed a variance-reduced Monte Carlo solver for linearized Peierls Boltzmann transport equation in three-dimensions[4]. Using phonon dispersions and lifetime from inelastic scattering

experiments, ab-initio simulations, or empirical models, we simulate domains ranging from a few nanometers to hundreds of microns. Simulations are performed on both periodic and non-periodic geometries. Since phonons scatter differently from physical domain boundaries, interface, impurity, and other phonons, we simulate boundary scattering, three-phonon processes, two-phonon processes, and impurity scattering independently. A frequency-dependent transmission probability and interface roughness (specularity) capture the size-effects and device-level conditions. Grain-boundary scattering models and interface transmission models are incorporated separately. Our interface modeling strategy is not limited to elastic energy transport and allows us to include inelastic transport across the interface by energy exchange between high- and low-frequency modes. We compare our interface conductance results in quasi-ballistic and diffusive regimes measured using near-IR pump EUV/X-ray probe experiments[5,6,7]. The spectrally-resolved contribution to temperature and flux at the interface provides critical insights into the heat accumulation. We are presently simulating interfacial conductance in layered materials to compare with available near-IR pump and X-ray probe experiments[8]. We anticipate our code will further find applications in evaluating the nano-structuring and nano-patterning efficiency to thermal conduction properties of mesoscale devices.

Late News: Ultrafast Thermo-Optical Dynamics for Thermal Boundary Resistance Measurements on Single Nano-Objects Michele Diego[1], Romain Rouxel[1], Fabio Medeghini[1], Aurélien Crut[1], Francesco Rossella[2,3], Paolo Maioli[1], Fabrice Vallée[1], Francesco Banfi[1] and Natalia Del Fatti[1]; [1]FemtoNanoOptics Group, Universite de Lyon, CNRS, University Claude Bernard Lyon 1, Institut Lumiere Matiere, France; [2]NEST, Scuola Normale Superiore, Italy; [3]Istituto Nanoscienze-CNR, Italy

Michele Diego, Romain Rouxel, Fabio Medeghini, Aurélien Crut, Francesco Rossella, Paolo Maioli, Fabrice Vallée, Francesco Banfi and Natalia Del Fatti

Single-particle optical spectroscopy methods have enabled quantitative investigations of the optical [1], electronic [2], and vibrational [3,4] responses of nano-objects in the recent years. In this work, we exploit single-particle pump-probe optical spectroscopy to investigate the cooling dynamics of individual gold nanodisks supported on a sapphire substrate. Although this topic has already been theoretically investigated in the past [5,6], quantitative measurements have so far proved very challenging. We here show time-resolved signals encompassing the temporal evolution of the single nanodisk temperature following its impulsive excitation [7]. By comparing the experimental signals (measured on individual nanodisks with different sizes) to the results of analytical [4] and finite-element simulations, we are able to retrieve the thermal boundary resistance at the single gold nanodisk-sapphire interface, which limits the nanodisk cooling rate. The present findings pave the way for quantitatively characterizing the temperature-dependent optical response of a single nano-object by investigating the probe-wavelength dependence of time-resolved signals, and for correlating the nano-object thermal properties to its specific morphology and composition. Moreover, it bears great relevance

for post-processing inspection of nanopatterned metal nano-objects [8].

Lattice Thermal Conductivity Enhancement at the Ferroelectric Phase Transition in GeTe Ivana Savic[1] and Djordje Dangic[2,1]; [1]Tyndall National Institute, Ireland; [2]University College Cork, Ireland

Materials near structural phase transitions usually have large phonon anharmonicity and low lattice thermal conductivity. The proximity to structural phase transitions in IV-VI materials is one of the main reasons for their low thermal conductivity and high thermoelectric figure of merit [1,2]. However, experiments indicate that the lattice thermal conductivity of germanium telluride (GeTe) actually increases near the ferroelectric phase transition around 600-700 K. In this work, we elucidate this unexpected effect using first principles calculations [3].

We first compute the lattice thermal conductivity of GeTe for a range of temperatures using the temperature dependent effective potential method [4] and the standard Boltzmann transport equation. We find that, although anharmonicity increases near the phase transition in the low symmetry phase (below the Curie temperature), the phonon group velocities increase as well, leading to a rise in the lattice thermal conductivity. Furthermore, anharmonicity decreases in the high symmetry cubic phase, further enhancing the phonon lifetimes and thermal conductivity.

Strong anharmonicity near the phase transition induces non-Lorentzian shapes of the phonon power spectra, which exhibit large softening of the peaks for soft phonon modes near the phase transition. To account for these effects, we implement a novel method of calculating lattice thermal conductivity based on the Green-Kubo approach [3]. Using this approach, we find that the Boltzmann transport equation underestimates the lattice thermal conductivity of GeTe near the phase transition. Our findings elucidate the influence of structural phase transitions on lattice thermal conductivity and provide guidance for design of better thermoelectric materials.

This work is done in collaboration with Djordje Dangic, Olle Helman and Stephen Fahy. The work is supported by Science Foundation Ireland PI Award 15/IA/3160.

High Asymmetric Heat Transport in Multilayer Phase Change Materials Timm Swoboda[1], Katja Klinar[2], Andrej Kitanovski[2] and Miguel Muñoz Rojo[1]; [1]University of Twente, Netherlands; [2]University of Ljubljana, Slovenia

In this work, we determine how a multilayer structure made of different types of nanoscale phase change materials results in a highly non-linear and asymmetric heat flow depending on thermal bias directionality. This will set the basis of solid-state thermal diodes that can be scaled up for integration in energy management, conversion or storage applications. Thermal diodes (TD) or rectifiers are capable to manage heat in a similar manner as how electronic diodes control electricity, propagating heat preferably in one direction.[1] The rectification ratio is defined as, $RR = (Q_{fwd}-Q_{rev})/Q_{rev}$, where Q_{fwd} and Q_{rev} correspond to the heat flux in the forward and reverse direction, respectively. Unfortunately, current solid-state thermal diodes typically present moderate *RR*s, complex fabrication designs, and/or lack of operating temperature tuneability.[1]

Phase change materials (PCM) have become popular for the development of TDs due to their thermal conductivity (k) change during the phase transition at a critical temperature (T_{crit}), e.g. VO_2 (k_{low} = 1.5 W/(m×K) to k_{high} = 3.5 W/(m×K) at T_{crit}~340 K).[1,2] These materials are often combined with phase invariant materials (PIM) to develop TDs.[1] As an example, in a PIM/PCM structure based on VO_2, when the heat source is at temperatures $T > T_{crit}$ and close to the PCM side, both PIM and PCM conduct the heat well (Q_{fwd}). The situation is reversed when the heat source is applied to the PIM (Q_{rev}). This typically leads to *RR* larger than those found for individual PCMs.[1]

Here, we used finite element modeling (COMSOL®) to develop a versatile TD based on a novel multilayer PCM/PIM structure. Our design includes an alternating combination of two PCM layers with two PIM layers. The total length of the multilayer structure was set to 1 μm, while the thickness of the individual layers was varied at the nanoscale. We selected carefully different types of PCM and PIM materials, whose experimental thermal properties were extracted from literature, to find the optimum PCM/PIM configuration that led to the highest *RR*. Then, we applied a temperature difference across the two ends of this structure. *RRs* larger than 100% were observed when we used Si and SiO_2 as PIMs and Ag_2Te and $Ag_2S_{0.6}Se_{0.4}$ as PCMs with transition temperatures at 420 K and 360 K, respectively.[3] Compared to the state of the art[1] of PCM/PIM diodes, this configuration represents one of the highest *RRs* at room temperature as well as offers new possibilities for advanced thermal control. Additionally, from the point of view of applicability, this thermal diode offers numerous advantages over previously reported TDs, including simple design, scalability and operating temperature tunability.

To determine the potential of this thermal device for solid state refrigeration, we analyzed the effect of integrating this TD into a magnetocaloric (MC) device. For that purpose, we used a one-dimensional MC device consisting of gadolinium as MC material with two TDs at their ends, sandwiched between the heat sink and the heat source. The presence of TDs avoids the heat to flow back to the heat source improving the efficiency of the MC device.[4] We selected a PIM/PCM structure that worked optimally for the MC system operating temperature and we considered quasi-steady-state operation in an alternating magnetic field with 1 T change. We observed that the integration of this TD enables higher operating frequencies compared to the conventional active magnetic regeneration process, increasing the cooling power density. Beyond MC refrigeration, this

versatile and unique TD can be used in other solid state refrigeration, heat pump and energy harvesting technologies to improve their performances or efficiencies.[1,4]

Phonon Softening Near Topological Phase Transitions Shengying Yue and Bolin Liao; University of California, Santa Barbara, United States

Topological phase transitions occur when the electronic bands change their topological properties, typically featuring the closing of the bandgap. While the influence of topological phase transitions on electronic and optical properties has been extensively studied, its implication on phononic properties and thermal transport remains unexplored. In this work, we use first-principles simulations to show that certain phonon modes are significantly softened near topological phase transitions, leading to increased phonon-phonon scattering and reduced lattice thermal conductivity. We demonstrate this effect using two model systems: pressure-induced topological phase transition in $ZrTe_5$ and chemical composition induced topological phase transition in $Hg_{1-x}Cd_xTe$. We attribute the phonon softening to emergent Kohn anomalies associated with the closing of the bandgap. Our study reveals the strong connection between electronic band structures and lattice instabilities and opens up a potential direction towards controlling heat conduction in solids. This work is based on research supported by DOE under the award number DE-SC0019244 and the UC Santa Barbara NSF Quantum Foundry funded via the Q-AMASE-i program under award DMR-1906325.

Role of Coherent Phonons on Thermal Transport in Lead Sulfide Nanocrystal Superlattice Cheng Shao and Junichiro Shiomi; The University of Tokyo, Japan

Colloidal nanocrystal superlattices that are made of uniform-sized quantum dots (QD) connected by organic ligands have shown promising applications for photon detectors, solar cells, and thermoelectrics, among many others. Due to the secondary periodicity, the nanocrystal superlattice is also an ideal platform for phonon engineering, and the existence of coherent superlattice phonon mode is confirmed through the inelastic neutron scattering measurement recently. [1] However, it is also found that such coherent phonons are sensitive to the rotational motions of the building block [2], [3], and the surface morphology. [4] In this work, based on molecular dynamics simulation techniques, we explored the preconditions that are required to sustain the coherent phonons in the lead sulfide nanocrystal superlattice and the possible margins to engineering the thermal conductivity by manipulating such coherent phonons. We found that the mean free paths of the low-frequency coherent modes are tens of nanometers. However, those coherent modes, of which the frequency is less than 0.2 THz, carrier negligible amount of heat due to their small weights in the overall vibrational spectrum. We have shown that phonon in the frequency range of 0–5 THz dominates the thermal transport. In this frequency range, the interatomic vibrations of QDs have the maximum overlapping with the translation and bending modes in the ligands. We also identified the ligand coverage ratio as the key parameter that will affect

the morphology of the nanocrystal superlattice and thus dictate the thermal transport.

Late News: Anisotropic Heat Conduction of Coherent Phonons in Defect-Free Superlattices Hai Jun Cho and Hiromichi Ohta; Hokkaido University, Japan

Heat conduction due to phonons is usually dominated by diffuse scattering processes from crystal defects and anharmonicity. As such, doping and grain boundary engineering have been the primary approach for controlling the heat conduction in solids. While the contributions from coherently scattered low frequency phonons are not significant, they are challenging to control since they are not sensitive to crystal defects and therefore, remain as a major challenge for mastering the conduction of heat in solid. As such, understanding the propagation of coherent phonons is of fundamental interest in thermal management technologies. Superlattices in this regard provide an excellent platform since its heat conduction is attributed to coherent phonons. Experimental studies are typically performed on artificial superlattices, but they exhibit dislocations at interfaces, which increases anharmonicity and affect coherent scattering processes. For this reason, there has been some discrepancies between experimental and theoretical research efforts. In this study, we investigated the heat conduction in defect-free $InGaO_3(ZnO)_m$ superlattice films to experimentally demonstrate several important concepts in phonon engineering, including the discrepancy between coherence length and mean free path, scattering mechanism changes according to the coherence length, specular phonon propagation along the in-plane direction, and the suppression of Umklapp processes.

Enhanced Environmental Scanning Electron Microscopy for Analyzing Material Dynamics in High-Pressure Gaseous Environments Lenan Zhang[1], Jinlong Zhu[2], Ryuichi Iwata[1], Lin Zhao[1], Kyle Wilke[1], Xiangyu Li[1], Zhengmao Lu[1], Yang Zhong[1] and Evelyn Wang[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Illinois at Urbana-Champaign, United States

Environmental scanning electron microscopy (ESEM) is an important micro-to-nanoscale inspection tool to image diverse wet or insulating samples, such as liquid, polymer, and biomaterials in a gaseous environment. However, the presence of gas induces intensive electron-gas collisions, which leads to significant degradation of imaging quality. For this reason, the operating pressure of ESEM is typically below 1000 Pa. In this work, we enhanced the performance of ESEM by referring to the phase and scattering force of electron. Much higher contrast of ESEM images was obtained from the phase and scattering force reconstruction without any hardware changes. The limit of operating pressure was also extended up to 2500 Pa. More importantly, a close connection between the sample morphology and scattering force distribution was observed, which promises to advance the quantitative analysis using ESEM. To demonstrate the effectiveness of this enhanced ESEM technique, we studied the nucleation site distribution during droplet condensation, which cannot be precisely probed in previous studies due to the micro/nanoscopic nature of nucleation. We show that the population of nucleation sites is governed by the Poisson distribution while the nearest neighbor distance follows the Rayleigh distribution, instead of the commonly used Poisson distribution. Our work provides a simple approach to enhance the performance of ESEM and can be widely used to study a variety of material dynamic processes in

gaseous environments.

Late News: Maximum Evaporating Flux of Molecular Fluids from a Planar Liquid Surface Zhi Liang and Eric Bird; California State University, Fresno, United States

Fast evaporation of liquids is a process of great importance to many industrial applications such as evaporative cooling of gas turbines, efficient combustion in engines, and superfine inkjet printing. Accurate prediction of the maximum evaporation flux from a condensed phase is one of the basic problems in the study of fast evaporation processes. The maximum evaporation flux occurs during the evaporation into a vacuum. In spite of the extensive work on the process of evaporation into a vacuum in the past decades, most of modeling studies only focused on the evaporation of monatomic substances. Whether these modeling results on monatomic fluids can be applied to predict the maximum evaporation flux of more complex fluids such as water and polymers is questionable. To address this question, one must have a fundamental and quantitative understanding of how the internal motions including rotations and vibrations of polyatomic fluid molecules affect the evaporation process and the maximum evaporation flux.

In this work, we use the kinetic theory of gases (KTG) to develop a theoretical model to understand the role of internal motions of molecules on the maximum evaporation flux from a planar liquid surface. The kinetic theory is applied to study the evaporation of molecular fluids into a vacuum and predict the dimensionless maximum evaporation flux ($J_{R,max}$, i.e. the ratio of the maximum evaporation flux to the molar flux emitted from a liquid surface). The key assumptions regarding the velocity distribution function (VDF) of polyatomic molecules in the highly non-equilibrium vapor near the evaporating surface are validated by the VDF obtained directly from molecular dynamics (MD) simulations. Our KTG-based analysis show that $J_{R,max}$ is affected by the specific heat ($c_{V,int}$) associated with internal degrees of freedom of fluid molecules. When the maximum evaporation flux is reached, the isotropic evaporating vapor far from the liquid surface moves at its speed of sound regardless of whether it is a monatomic vapor or polyatomic vapor. To fundamentally understand the evaporation of a molecular fluid into a vacuum, we solve the Boltzmann transport equation (BTE) to obtain the temperature, density, and flow speed distributions in the highly non-equilibrium evaporating vapor flow. Our BTE solutions indicate that there are several universal features of the evaporating vapor when the maximum evaporation flux occurs. In particular, we find that the evaporating vapor flow speed reaches the maximum value of sqrt(1.5) times the most probable thermal speed in the vapor flow direction at the vacuum boundary, and this maximum value is independent of fluid properties. All theoretical predictions in this work are verified by the MD simulation results of the evaporation of the model liquid Ar and the model liquid n-dodecane into a vacuum, and existing experimental data.

Interfacial Thermal Transport in Spin Caloritronic Material Systems Frank Angeles and Richard B. Wilson; University of California, Riverside, United States

Interfaces often govern the thermal performance of nanoscale devices and nanostructured materials. As a result, accurate knowledge of thermal interface conductance is necessary to model the temperature response of nanoscale devices or nanostructured materials to external heating. We report the thermal boundary conductance between metals and insulators that are commonly used in spin-caloritronic experiments. We use time-domain thermoreflectance to measure the interface conductance between metals such as Au, Pt, Ta, Cu, and Al with garnet and oxide substrates, e.g. NiO, YIG, EuIG, Cr_2O_3, and sapphire. We find that, at room temperature, the interface conductance in these types of material systems range from 50 and 300 MW m^{-2} K^{-1}. We also measure the interface conductance between Pt/YIG at temperatures between 80 and 350 K.

7:35 PM NM08.05.07
Late News: Influence of the Crystallization on the Thermal Resistance of the GST-Based Structures Kazimierz J. Plucinski; Military University of Technology, Poland

Correct estimation of the thermal resistance of the PCM memory structure is crucial due to the optimization of its parameters. The thermal resistance of PCM memory consists of thermal boundary interface resistances and GST bulk resistance. After entering the reset state, the crystallization of bulk GST begins and as a result a composite of GST crystallites distributed in an amorphous GST matrix is formed and thermal conductivity of such composite depends on the stage of the crystallization. Influence of the time-spatial distribution of the function defining the volume of the transformed fraction of the GST on the thermal resistance of the GST-based PCM structure is presented.

Control of Periodic Structure in a Homologous Series of Titanium Oxide Bulk Crystals in Atomic Scale
Shunta Harada[1,2], Shunya Sugimoto[1], Miho Tagawa[1] and Toru Ujihara[1]; [1]Nagoya University, Japan; [2]Japan Science and Technology Agency, Japan

Control of heat conduction through the manipulation of phonons as coherent waves have been attracted great interest for the advanced thermal management. Although smooth interfaces were reported to be obtained in artificial superlattices, preparation of coherent interfaces for terahertz phonons having nanoscale periodicity with atomic-scale perfection are still challenging since MOCVD and MBE were nonequilibrium growth process. Therefore, we focus on natural superlattice titanium oxides, in which periodic structures are obtained as thermodynamically stable phases. A homologous series of the titanium oxides is so-called crystallographic shear (CS) structure, in which planar faults are periodically introduced in the mother rutile structure with their spacing depending on the oxygen. Recently we have revealed that the titanium oxide with CS structure possesses the periodicity and the interface with high perfection and the coherent interface for almost all phonons are formed. In the present study, we demonstrated the control of the period of the CS structure in titanium oxides by the addition of chromium oxides to form oxygen deficiency.
The polycrystalline crystals of the titanium oxides with the addition was fabricated by the following process: firstly mixture of titanium and chromium oxides were sintered and obtained ceramics were melted by arc melting in an argon atmosphere and subsequently annealed in air for homogenization and oxidization of the crystals. The structure of the crystals were investigated by x-ray diffraction (XRD) as well as scanning transmission electron microscopy (STEM) with atomic-scale observation.
Judging from the XRD measurement, it seemed that the obtained crystals were of single phases and the structure was systematically changing according to the chromium content. Atomic-scale STEM observation revealed that the interval of the interfaces in the crystals were decreasing with increasing chromium content and we obtained the titanium oxides with the different interval of the interfaces ranging from 1.2 to 2.0 nm. From the STEM observation, not only the interval but also the atomic structure of the interfaces were changing depending on the chromium content. We have successfully control the periodic structure in a homologous series of titanium oxide bulk crystals. The current results indicates that the tuning of phonon band gap formation at higher frequency is possible in titanium oxide natural superlattices.

Late News: Generalized Law of Heat Conduction Including the Intrinsic Coherence of Thermal Phonons
Zhongwei Zhang[1], Yangyu Guo[1], Masahiro Nomura[1], Jie Chen[2] and Sebastian Volz[1]; [1]The University of Tokyo, Japan; [2]Tongji University, China

While coherent effects in solid heat conduction have recently been exemplified in superlattices and disordered structures [1-3], those evidences have remained essentially qualitative because the understanding of the intrinsic coherence of thermal phonons remains unclear. We propose a formalism supported by theoretical arguments and direct atomic simulations, which takes into account both the conventional phonon gas model and the internal wave nature of thermal phonons. By naturally introducing wavepackets in the heat flux from fundamental concepts, we derive an original thermal conductivity formula including coherence times and lifetimes. We then estimate the deviation between the predictions of the conventional model and ours by using atomic simulations to highlight significant effects in graphene. This contribution establishes a new frame for

understanding and quantifying the intrinsic coherence of phononic heat carriers, which has a general impact on the estimation of the thermal properties in nanostructures as well as in bulk materials.

Anchor-Shaped Surfactants Enhance Evaporation on a Flat Liquid-Vapor Interface Xiaoman Wang[1], Jiong Chen[2], Jonathan Malen[1] and Alan McGaughey[1]; [1]Carnegie Mellon University, United States; [2]Zhejiang University-University of Illinois at Urbana-Champaign Institute, China

Surfactants are amphiphilic molecules that can be used to control the evaporation rate on a liquid-vapor interface. Previous experimental work has shown that molecular monolayers can reduce the evaporation rate on a flat liquid-vapor interface, while surfactant-modified sessile droplets show an increased evaporation rate due to changes in their wetting properties. A surfactant-induced increase in evaporation rate on a flat interface has yet to be demonstrated.

We applied molecular dynamics (MD) simulations to study the evaporation of a Lennard-Jones liquid with a variety of surfactants. A non-equilibrium MD (NEMD) simulation with a temperature difference was designed to directly extract the evaporation mass flux. Surfactants are added to the liquid-vapor interface. We found that an anchor-shaped surfactant with a flat hydrophobic top and hydrophilic chains enhances the evaporation rate by a factor of around 1.4 compared to the pure liquid.

To determine the origin of the evaporation rate enhancement, additional equilibrium MD simulations of the pure liquid and liquid-surfactant systems were performed to calculate thermal conductivities, diffusion coefficients, latent heats, vapor pressures, and mass accommodation coefficients. The results cumulatively point towards the evaporation enhancement being a result of liquid structuring around the surfactant, which lowers the thermal resistance to evaporation. Different surfactant sizes and structures are currently being investigated to further elucidate the origin and limits of the enhanced evaporation rate.

The Effect of Electrochemical Lithium Insertion on Thermal Transport of Titanate-Based Thin Films Azat Abdullaev, Bakhtiyar Soltabayev, Berik Uzakbaiuly, Almagul Mentbayeva, Zhumabay Bakenov and Zhandos Utegulov; Nazarbayev University, Kazakhstan

Understanding the heat transport in intercalated layered materials has attracted significant interest in Li-ion battery (LIB)-based electrochemical energy storage devices because they act as electrode materials. Heat dissipation affects a battery lifetime. Moreover, thermal runaway is one of the main faults of modern LIBs [1]. Therefore, tuning thermal conductivity in these devices becomes a key challenge. Chemical intercalation has proved to be an effective approach to control thermal transport in this application [2,3].
In our recent work, we have demonstrated thermal conductivity variation across amorphous Si thin films during Li intercalation [4]. In the present work, we further extend this research on titanium oxide and lithium titanate electrode materials, which were proved to be good alternatives for high power applications due to high cycling stability and long lifetime [5]. To study the effects of Li intercalation on their subsurface thermal conductivity, a picosecond time-domain thermoreflectance (TDTR) [4,6] was employed. Corresponding thin films were deposited by RF magnetron sputtering system and galvanostatic cycling was used between 0.5 and 3 V for Li insertion. Raman microscopy measurements were exploited to study chemical evolution during Li insertion into lithium titanate samples.
Thermal conductivity measurements revealed an average 50% increase in as-deposited TiO_2 thin films upon lithiation. Raman spectra indicated the formation of Li_xTiO_2 phase formation. Also, samples with different annealing temperatures have been prepared to study the effect of crystallinity on thermal conduction during Li

intercalation.

Nano- and Micro-Scale Thermal Conduction in AlN and Si_3N_4 Ceramics Irradiated by Swift Heavy Ions
Ainur Koshkinbayeva[1], Azat Abdullaev[1], Vinay Chauhan[2], Mostafa Valadkhani[3], Ruslan Rymzhanov[4], S. Mehdi Vaez Allaei[3], Marat Khafizov[5], Vladimir Skuratov[4] and Zhandos Utegulov[1]; [1]Nazarbayev University, Kazakhstan; [2]Intel Corporation, United States; [3]University of Tehran, Iran (the Islamic Republic of); [4]Joint Institute for Nuclear Research, Russian Federation; [5]The Ohio State University, United States

Displaying unique thermal, mechanical, electrical and magnetic properties [1], nitride ceramics have been widely used in nuclear engineering [2] and microelectronics applications [3]. In particular, the effect of swift heavy ion (SHI) irradiation on thermal transport of radiolysis-resistant nitride ceramics is a matter of interest [4]. However, there has been no prior study of the impact of SHI irradiation on the thermal conductivity of these materials on the subsurface scale.

AlN and Si_3N_4 polycrystalline ceramics were irradiated at the U-400 FLNR JINR cyclotron facility in Dubna, Russia by 167 MeV Xe and 700 MeV Bi ions ions at fluences between 1×10^{11} and 1×10^{14} cm^{-2}. The projected ion ranges were 13.6 (Si_3N_4) and 13.2 (AlN) μm as calculated using SRIM 2013 in full cascade mode. Structural analysis with corresponding molecular dynamics (MD) simulations revealed formation of ion induced tracks in Si_3N_4, while no tracks were observed in AlN.
We report the results of cross-plane heat transport measurements of SHI irradiated aluminum nitride and silicon nitride ceramics as a function of ion dose by femtosecond laser pulse-based time-domain thermo-reflectance (TDTR) and continuous laser wave-based modulated thermoreflectance (MTR) techniques on nano- and micro-meter subsurface scales, respectively. TDTR technique revealed thermally probed region extending down to hundreds of nanometers, where the electronic stopping / ionization processes dominate over nuclear stopping, while MTR approach has revealed thermal wave penetration depths down to microns. Thermal transport in these sub-surface domains irradiated by Xe and Bi ions for the given fluences has degraded by the factor of ~ 3 compared to non-irradiated as-received sample for both nitrides.
Using theoretical modeling based on Debye approximation and Klemens analytical thermal transport model [5], we analyzed defects concentrations extracted from experimentally measured thermal property data fitted to thermal diffusion model. In addition MD simulations were employed to model phonon scattering at ion tracks in Si_3N_4 ceramics. Given TDTR probed sub-surface region overlapped with ionization depth determined by SRIM calculation, whereas MTR probed region spanned nuclear displacive domain.

Thermal Transport Properties of Dried Colloidal Silicon Nanoparticle Films by Micro-Raman Spectroscopy

Bayan A. Kurbanova[1], Gauhar Mussabek[2], Victor Timoshenko[3] and Zhandos Utegulov[1]; [1]Nazarbayev University, Kazakhstan; [2]Al-Farabi Kazakh National University, Kazakhstan; [3]Lomonosov Moscow State University, Russian Federation

We report on the heat conduction properties of smooth layers prepared from dried colloidal pure crystalline silicon (Si) nanoparticle (NP), which were probed by weak continuum wave (cw) laser light-induced heating with simultaneous Raman scattering detection under atmospheric conditions. The same approach of heating measurement was applied for the bulk silicon at high laser powers [1, 2]. Low thermally conductive Si NP films are envisioned as heat insulators for thermal management of optoelectronic devices. Laser heating causes softening of the first-order Raman Si-Si transverse optical phonon mode and a decrease in the corresponding phonon lifetimes [3]. The temperatures of laser-heated Si NP films were assessed from measured ratio of Stokes-to-Anti-Stokes integrated peak intensities of the Raman probed phonon mode and were compared with the external heater-heated temperature and temperature evaluation for cw-laser heated bulk crystalline Si [4]. It was revealed that the evaporation rate of the colloidal Si NP droplets and heating of deposited thin layers of variable thickness were heavily influenced by the thermal conductivities of the substrates, on which the films were deposited. It is suggested that the heat conduction of nanostructured layers is governed by the ballistic transfer of phonons across the boundaries of nanoparticles and varied with an increase in the layer thickness [5]. Our experimental results are in good agreement with theoretical molecular dynamics calculations [6] and Raman measurements in meso-porous nanocrystalline Si layer [7]. Micro-Raman-based thermal conduction measurements in our Si NP films are discussed in the light of variation of deposited colloidal NP film thickness, NP size, heating laser beam diameter and the substrate type.

Phonon Heat Conduction Regime Map Gang Chen; Massachusetts Institute of Technology, United States

Beyond the Fourier diffusion theory on heat conduction, the classical size effects---the Casimir regime---caused by phonon boundary scattering is well known and extensively studied. However, over the last three decades, new regimes beyond the Fourier and the Casimir pictures of heat conduction have been demonstrated. In this talk, I will discuss different phonon heat conduction regimes, including the Knudsen regime, the hydrodynamic regime, the quantization regime, the coherence and localization regimes, and the divergence regime. The Knudsen regime expands Casimir's picture to many other quasi-ballistic transport geometries, and is being exploited to develop phonon mean free path spectroscopy techniques. Phonon hydrodynamic transport happens when the normal scattering dominates over the resistive scattering, which is a condition difficult to satisfy and only observed at a narrow temperature range less than 20K. However, recent experiments have observed second sound---a consequence of phonon hydrodynamic transport---at much higher temperatures, while simulations point to possibility of observing hydrodynamic heat conduction even at room temperature. Quantized phonon transport was observed at very low temperatures. Signatures of coherent heat conduction, including localization, will be discussed, together with experimental evidences. Divergent thermal conductivity, implying thermal superconductors, is predicted to be possible in low-dimensional materials, although no experiments have provided conclusive evidence. These different phonon heat conduction regimes will be summarized in a regime map, demonstrating the rich phonon transport physics rivaling that of electrons.

Ray Phononics for Advanced Heat Flux Manipulations in Ballistic Regime Roman Anufriev and Masahiro Nomura; The University of Tokyo, Japan

Manipulation of thermal fluxes is essential in modern science and technology. Modern thermal phononics tries to achieve coherent control of heat conduction based on the wave interference of phonons that occurs in periodic nanostructures, called phononic crystals. However, the past decade of the research demonstrated that such a coherent control of heat is truly efficient either at sub-kelvin temperatures or in nanostructures with features at atomic scale.
In this work, we propose an alternative concept of heat manipulation based on the particle picture of phonons and their ballistic transport. We call this concept ray phononics as a thermal analogy of ray optics. Our simulations demonstrate the formation of directional thermal fluxes in phononic crystals due to the stochastic phonon motion in phononic crystals. We illustrate possible application of such directional fluxes for emitting directional heat rays, filtering the phonon spectrum, and even protecting a specific region from a thermal gradient.
Finally, we show that the proposed concept is not bound to only low temperatures, and ray-phononic nanostructures can control heat fluxes even at room temperature using modern materials like boron arsenide. Moreover, ray phononics is free from limitations of the traditional thermal phononics and enables creating and guiding thermal fluxes in realistic nanostructures regardless of their surface roughness. This makes us believe that advances in material synthesis may soon enable creation of devices capable of thermal guiding, emitting, filtering, and shielding using the proposed ray-phononics principles at room temperature.

Phonon-Phonon Interactions: Selection Rules and Higher-Order Processes David Broido[1] and Navaneetha Krishnan Ravichandran[2]; [1]Boston College, United States; [2]Indian Institute of Science, India

Applying a first-principles theory that includes both the lowest-order three-phonon and the higher-order four-phonon processes to zinc blende semiconductors, we find that the lowest-order theory of phonon-phonon interactions drastically overestimates the measured thermal conductivities, *k*, for many of these materials, while inclusion of four-phonon scattering gives significantly improved agreement with measurements [1]. We identify new selection rules on the phase space of three-phonon processes that help explain many of these failures in terms of anomalously weak anharmonic phonon decay rates predicted by the lowest-order theory competing with four-phonon processes. We also show that zinc blende compounds containing boron (B), carbon (C), or nitrogen (N) atoms have exceptionally weak four-phonon scattering, much weaker than in compounds that do not contain B, C, or N atoms. This new understanding helps explain the ultrahigh *k* in several technologically important materials like cubic boron arsenide, boron phosphide, and silicon carbide. At the same time, it not only makes the possibility of achieving high *k* in materials without B, C, or N atoms unlikely, but it also suggests that it may be necessary to include four-phonon processes in many future studies. Finally, we show that the hidden influence of selection rules on three-phonon scattering can be exposed through anomalous signatures in the pressure (*P*) and temperature (*T*) dependence of the *k* of certain compounds [2]. In particular, boron phosphide reveals such underlying behavior through an exceptionally sharp initial rise in *k* with increasing *P*, which may be the steepest of any material, and also a peak and decrease in *k* at high *P*. These features are in stark contrast to the measured behavior for many solids, and occur at experimentally accessible conditions.

First Principles Predictions of Four-Phonon Scattering and Related Thermal Conductivity and Radiative Properties Xiulin Ruan; Purdue University, United States

For decades, the three-phonon scattering process had been considered to govern thermal transport in solids, while the role of higher-order four-phonon scattering had been persistently unclear and so ignored. However, recent quantitative calculations of three-phonon scattering had often overestimated thermal conductivity as compared to experimental data. We developed a rigorous perturbation method to predict four-phonon scattering rates and investigated its significant impact on thermal conductivity and infrared thermal radiative properties. We show that four-phonon scattering is generally important in solids. For silicon and diamond, the predicted thermal conductivity is reduced by 30% at 1000 K after including four-phonon scattering, bringing predictions in excellent agreement with measurements in the entire temperature range. For the projected ultrahigh-thermal conductivity material, BAs, a competitor of diamond as a heat sink material, four-phonon scattering is found to be strikingly strong as three-phonon processes have an extremely limited phase space for scattering. The four-phonon scattering reduces the predicted thermal conductivity from 2200 to 1400 W/m K at room temperature. The reduction at 1000 K is 60%. Our prediction on BAs has been confirmed by three independent experimental breakthroughs. Four-phonon scattering also significantly reduces the thermal conductivity of ZA phonons in graphene due to the fact the reflection symmetry does not restrict four-phonon scattering. Moreover, we find that four-phonon scattering universally plays a significant or even dominant role on the zone-center optical

phonon linewidth over three phonon scattering, for a wide range of materials including diamond, Si, Ge, GaAs, boron arsenide (BAs), cubic silicon carbide (3C−SiC), and α-quartz. This is enabled by the large four-phonon scattering phase space of zone-center optical phonons. Raman measurements on BAs were conducted, and their linewidth verifies our predictions. The predicted infrared optical properties through the Lorentz oscillator model, after including four-phonon scattering, show much better agreement with experimental measurements than those three-phonon-based predictions.

Enhanced Controllability of Coherent Phonon Heat Conduction by Non-Random Aperiodic Nanostructures Junichiro Shiomi; The University of Tokyo, Japan

How and how much we can control transport of thermal phonons by nanostructures utilizing their wave nature is a central issue in science and engineering of nanoscale heat conduction. Phonon-particle scattering can impede heat conduction but, for that, large disorder needs to be introduced, which makes it inherently difficult to balance the impact with those on other quasi particles like electron and magnons. Furthermore, in the best scenario, the wave interference should be superior to particle scattering in impeding phonon transport as the former allows localization. The general difficulty in realizing interference by artificial nanostructure particularly for phonon transport is that the coherent lengths of phonons are typically quite short at room temperature, but thanks to the efforts of the researchers in the field, the control of phonon coherent heat conduction can be realized in heterostructures with nanometers lengths and clear interfaces like the semiconductor superlattices. Over the last few years we Thermal Energy Engineering Lab (TEEL) at the University of Tokyo, together with the collaborators, have been pushing the limit of controllability of coherent phonon heat conduction by exploring the effect of "non-random aperiodicity" in the superlattice. Since the design of aperiodic superlattice involves vast degrees of freedom, one of the key tools has been the machine learning, where we are now capable of efficiently handing extremely large search space using various machine learning schemes [1, 2] and hardware such as quantum annealer [3]. We performed a thorough demonstration from designing the structure by coupling coherent phonon transport calculation and machine learning to experimental fabrication and characterization for the GaAl/GaAs superlattice [4]. We further found a large controllability by the non-random aperiodicity in graphene/MoS_2 heterostructure [5]. An interesting finding here is that non-random aperiodic structure performs better than random aperiodic structure. Each part of the aperiodic structure selectively imposes interference of specific phonon band, allowing the overall structure to act on the entire thermal phonon spectrum. Here, competition with Anderson localization, which works best with full randomness, becomes important and we find that non-random structure is superior when the sample length/thickness is at nanoscale.

Fast Simulations of Thermal Transport in Complex Materials using Machine Learning and Bayesian Force Fields Anders Johansson, Jonathan Vandermause, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

Controlling thermal conductivities of materials is important for a wide range of applications, from thermoelectrics for clean energy generation to electronic devices and thermal barrier coatings. The thermal conductivity is commonly estimated using molecular dynamics simulations within the Green-Kubo formulation. This requires a force field that is both 1) an accurate estimate of the interatomic interactions and 2) fast enough to allow simulations with sufficiently large length and time scales. Traditionally, only empirical force fields have fulfilled both of these requirements, which severely limits the applicability of the method.

In this work, we employ the Gaussian Process-based FLARE force field, which automatically learns the interactions of more complex materials than empirical force fields. The resulting model can then be mapped to a low-dimensional, computationally efficient model. Through GPU-acceleration with LAMMPS and the Kokkos library, we achieve excellent performance and obtain well-converged estimates for the thermal conductivity. Furthermore, we investigate state-of-the-art sampling and spectral denoising methods for further acceleration of the simulations.

11:10 AM NM08.07.03
Machine Learning Interatomic Potentials from Small Dataset for Grain Boundaries—A Case Study for Graphene Ruiqiang Guo, Sangyeop Lee and Amirreza Hashemi; University of Pittsburgh, United States

Grain boundaries (GBs) often control a variety of properties of polycrystalline materials, which are widely used for practical applications. Atomistic simulations are helpful for understanding the relationship between GBs and materials properties. However such a simulation is largely limited by the lack of accurate and computationally efficient interatomic potentials. Machine learning has recently demonstrated its ability to develop interatomic potentials at first-principles level accuracy while costs a few orders of magnitude cheaper computational expense. However, for disordered structures like GBs, developing a high-fidelity machine learning interatomic potential (MLIP) usually requires a large training dataset to cover most of atomistic configurational space. Building the training dataset typically from first-principles calculations is very time-consuming. Here, we propose an efficient scheme for developing MLIPs for GBs from small dataset, while covering the entire atomistic configurational space. Using graphene GBs as an example, we show that the trained MLIP can achieve first-principles accuracy in the prediction of a broad range of structures and properties, including grain boundary energies, elastic constants, phonon spectra, etc. Our MLIP shows the almost same level of accuracy even for GBs not included in the training dataset, demonstrating an excellent transferability. We expect the proposed scheme will facilitate the efficient and rationale development of MLIPs of general GBs, enabling large-scale simulations of GB systems with high accuracy and low computational cost.

11:25 AM *NM08.07.04
Low, High and Switchable Thermal Conductivity in Soft Materials David Cahill; University of Illinois at Urbana-Champaign, United States

A century of experiment and theory have produced a thorough understanding of heat conduction by phonons in simple inorganic crystals. By contrast, basic understanding of heat conduction by molecular vibrations in soft materials (amorphous and crystalline polymers, small molecule solids, and biological materials) is much less mature. Complex, non-periodic structures spanning multiple length scales are difficult to characterize and model. Low thermal conductivity, fiber morphologies, poor control of defects, and anisotropy created by molecular order create daunting challenges for experiment. I will discuss our past work on the thermal conductivity and elastic constants of a wide variety of polymeric materials in the form of thin films and fibers that span a factor of 300 range in thermal conductivity, 0.06 to 20 W/m-K. Time-domain thermoreflectance (TDTR) provides a common experimental platform for these studies; varying the thickness and modulation frequency changes the relative sensitivities of the TDTR measurement to thermal conductivity and heat capacity. Our recent work has employed light-activated changes in the morphology azo-polymers to switch the thermal conductivity by a factor of 3 between a low conductivity amorphous state and higher thermal conductivity crystalline state. We are developing frequency-domain probe beam deflection and optical-fiber

based TDTR measurements to provide new capabilities for measurements of the thermal effusivity and thermal diffusivity of small volumes of soft materials.

11:50 AM NM08.07.05
Strong Localization of Diffusons in Low-Coordinated Amorphous Networks Kiumars Aryana[1], Derek Stewart[2], John Gaskins[1], Joyeeta Nag[2], John Read[2], David Olson[1], Ashutosh Giri[3], Michael Grobis[2] and Patrick Hopkins[1,1,1]; [1]University of Virginia, United States; [2]Western Digital Corporation, United States; [3]University of Rhode Island, United States

Amorphous chalcogenide alloys are key materials for optical/electronic data storage and thermoelectric applications due to their threshold switching and low lattice thermal conductivity. Here, we report on a mechanism to suppress the thermal transport in a representative system, silicon telluride (SiTe), nearly by an order of magnitude via systematically engineering the cross-linking network between the atoms. As such, we experimentally demonstrate that in fully dense amorphous silicon telluride the thermal conductivity can be reduced to as low as 0.1 ± 0.01 W/m/K for high tellurium content with a density nearly twice that of amorphous silicon. With no fitting parameter, our estimation for thermal conductivity using ab-initio simulations integrated with lattice dynamics shows excellent agreement with the empirical measurements. We attribute the ultralow thermal conductivity of SiTe to suppressed contribution of propagons and a large shift in the mobility edge -a factor of five- towards lower frequency modes, leading to strong localization of extended modes of vibration, namely diffusons. This localization is the result of large atomic mismatch and a transition from over-constrained amorphous network to under-constrained atomic structure.

12:05 PM NM08.07.06
Effects of Medium Range Order on Propagon Thermal Conductivity in Amorphous Silicon Amirreza Hashemi[1] and Sangyeop Lee[2,2]; [1]University of Pitsburgh, United States; [2]University of Pittsburgh, United States

Several recent experimental and computational studies show that the thermal conductivity of amorphous silicon varies with sample size.[1–4] This suggests that phonon-like propagating vibrational modes (propagons) carry a significant amount of heat in amorphous silicon. The previous computational studies used the continuous random network (CRN) atomistic structure that represents an ideal random structure without medium- and long-range orders. However, recent spectroscopy results reveal that the actual atomistic structure of amorphous silicon contains medium-range order (MRO) that the CRN structure does not.[5] In this work, we show the dependence of the propagon thermal conductivity on the MRO which has not been discussed in the previous studies. We compare the extent of MRO and the propagon thermal conductivity in several model amorphous silicon structures using simulated fluctuation electron microscopy, dihedral angle distribution, and molecular dynamics simulation. The results indicate that the structures with MRO show significantly larger propagon thermal conductivity (over 50 %) than the structures without MRO. As the extent of MRO depends on the material preparation methods, our study suggests that the thermal conductivity of amorphous Si also should depend on the material preparation method.[6]

Late News: Understanding Thermal Transport in Nanostructured Polymers Yu Guo and Yanfei Xu; University of Massachusetts Amherst, United States

A continuous increase in power density and miniaturizing electronics makes heat dissipation one of the most important and complex technological challenges [1]. A major issue is that vast amounts of waste heat generated during device operation leads to overheating problems [2, 3]. A need for new materials to manage overheating arises. Polymers have been used for electronics packaging, thanks to their unparalleled properties: light weight, electrical insulation, chemical resistance and easy processability [4]. However, common polymers are generally regarded as thermal insulators with low thermal conductivity and are undesirable for efficient heat dissipation [5]. Understanding thermal transport in polymers and turning polymer insulators into heat conductors are needed for better thermal management [5, 6]. In this poster, we will present the recent work on improving thermal conductivity of polymers and understanding the relationships between thermal conductivity and polymer structures [5, 6]. We have developed polyethylene films with a high thermal conductivity of ~62 W m^{-1} K^{-1}, which is two orders of magnitude greater than that of traditional polymers (~0.1 W m^{-1} K^{-1}) and is higher than that of many metals (e.g. 304-stainless steel ~15 W m^{-1} K^{-1}) and ceramics (e.g. aluminum oxide ~30 W m^{-1} K^{-1}). Unlike conventional approaches focusing on crystalline phase in polymers that can only marginally increase the thermal conductivity, we have engineered the non-crystalline chains through disentanglement and alignment and achieved a remarkably high thermal conductivity of ~16 W m^{-1} K^{-1} [5]. We will also discuss our current work on investigating the relationships between thermal conductivity and polymer structures such as chain morphology and radius of gyration [6].

Thermal Transport in 2D Materials—Few-Layer Membranes and Heterostructures Clivia Sotomayor-Torres[1,2] and Marianna Sledzinska[1]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]ICREA, Spain

Two-dimensional materials offer a wide range of options to study thermal transport in the nanoscale. The current understanding of thermal transport by phonons will be reviewed considering a few exemplary cases. We will discuss the case of free-standing polycrystalline membranes of MoS2 where the grain size, their orientation and its distribution all play important roles to control the thermal conductivity, for which we have carried out

experiments and simulations. We explore the case of single crystal membranes containing few monolayers in which the sample preparation is crucial to eliminate effects of imperfections and contamination focusing on the thickness dependence of the thermal conductance. The role of the surface and interfaces will be discussed using the example of MoS2/hBN heterostructures. Recent laser Raman thermometry data obtained from MoS2 crystalline membranes supported on patterned substrates, with patterns covering the crossover range of phonon confinement to ballistic transport and from supported single-layer membranes of PtSe will be reported. In the former the focus is on the impact of phonon hybridization between the membrane and the patterned substrate, which has been observed and discusses in free-standing Si membranes on a phononic crystal, on the thermal transport. In the latter material, new challenges emerge and these will be discussed. On the methodological part, the sources of errors in the determination of thermal properties and outstanding questions concerning phonon transport in TMDCs will be discussed with view to find reliable figures of merits for a future benchmarking. Work in collaboration with M. Sledzinska, E. Chavez Angel, A. El-Sachat, X. Peng, M-J Esplandiu, R. Quey, B. Mortazavi, B. Graczykowski, M. Placidi, D. Saleta Reig, F. Alzina, L. Colombo, S. Roche, F. Bonell and M. Jamet.

Thermal Characterization of MoS2 Mono/Few Layers Using Scanning Thermal Microscopy C. Mateo Frausto Avila[1,2], Victor Manuel Arellano Arreola[1], J. Martin Yañez Limon[1], Andres De Luna-Bugallo[1], Severine Gomes[2] and Pierre-Olivier Chapuis[2]; [1]Cinvestav Queretaro, Mexico; [2]CNRS-CETHIL, France

Molybdenum disulfide (MoS_2) is a promising material for optoelectronics that belongs to the Transition Metal DiChalchogenide (TMDC) family and that can be grown in monoloyers. Studies of such materials have led to a broad range of values for thermal conductivity and thermal contact conductance, both on simulation [1] and experimental [2] sides, probably due to the variety of configurations considered. Scanning Thermal Microscopy (SThM) is an Atomic Force Microscopy-based technique dedicated to the thermal investigation of micro and nanometric structures such as membranes, grains, films, etc, especially useful for cross-plane transport studies [2]. In this work, we apply the technique to characterize MoS_2 monolayers grown by Chemical Vapor Deposition (CVD) on Silicon Dioxide SiO2_300nm/Si substrates. Our technique employs a self-heated resistive probe that is brought into contact with the surface of the sample to be characterized. Scanning the sample surface provides simultaneously the topography and thermal contrast images of sample. Using either the Wollaston microprobe or the Palladium nanoprobe in ambient environment, we find that SThM images show a clear thermal contrast between the substrate and MoS2. Based on a calibration of the SThM probe using reference bulk materials and an original set of {oxide films on silicon substrate} samples of varying thickness, we are able to trace back to the effect of the MoS2 layers. We find that the boundary dominates heat conduction on supported samples, and provide estimates of associated thermal contact resistance. Simulations reproducing the full {SThM probe + MoS2 sample} experiment allows to clarify heat conduction in such systems.

Understanding and controlling interfacial heat transport is crucial for several applications in nanoelectronics, photonics, and energy conversion. Over the past few years, ultrafast optical techniques have enabled high-accuracy measurements of the thermal boundary conductance. Typically, these measurements are performed on systems that are thick compared to atomic lengthscales (at least several nm), and lack the ability to distinguish materials on both sides of the interface. The emergence of two-dimensional (2D) materials and heterostructures has revealed the need for techniques that can provide *angstrom-scale*, *material-selective* characterization of heat flow on picosecond timescales. Here, using mega-electron-volt ultrafast electron diffraction (MeV-UED), we present time-resolved measurements of thermal transport across type-II heterojunctions of monolayer 2D materials. Such heterostructures are of significant interest due to ultrafast (<100 fs) charge separation that is known to occur following photoexcitation. However, it has remained unclear how these electronic processes dissipate energy to the lattice. In this work, we prepare electron-transparent samples of 2D heterostructures, and selectively excite layer(s) within the stack using a tunable wavelength source. Layer-specific heating is subsequently monitored through the time-dependent dimming of Bragg peak intensities, thereby enabling picosecond tracking of energy flow across angstrom-scale junctions. Using ab initio calculations, we uncover the fundamental coupling between the electronic and lattice degrees of freedom in van der Waals 2D heterostructures.

1:55 PM NM08.08.04

Van der Waals Binding Effect Mediated Optimal Heat Transfer Through 2D Heterostructures Yang Zhong[1], Lenan Zhang[1], Xin Qian[1], Qichen Song[1], Jiawei Zhou[1], Long Li[2], Liang Guo[2], Gang Chen[1] and Evelyn Wang[1]; [1]Massachusetts Institute of Technology, United States; [2]Southern University of Science and Technology, China

Two-dimensional (2D) materials and their heterogeneous integration promise to advance the applications in electronics and photonics. However, the high thermal resistance at the interfaces bonded by weak van der Waals (vdW) interaction largely limits the energy dissipation, which may induce significant temperature rise and large thermal mismatch, and therefore degrades the device performance. Considering the practical tunability of vdW binding for 2D heterostructures reported by experimental studies, we investigated the thermal transport through an MoS_2-amorphous silica (a-SiO_2) heterostructure using molecular dynamics (MD) simulation, where the effects of vdW binding on both the in-plane and the cross-plane heat transfer are considered. We model the vdW interaction between MoS_2 and a-SiO_2 using the Lennard-Jones (LJ) potentials and scale the binding energy of the LJ force field. The in-plane thermal conductivity of the MoS_2 monolayer was calculated using the Green-Kubo formalism from the equilibrium MD simulation. The cross-plane thermal conductance between the MoS_2 monolayer and the a-SiO_2 substrate was calculated by the thermal circuit model using the approach-to-equilibrium MD. We show that the increase of vdW binding energy leads to a decrease of in-plane thermal conductivity and increased cross-plane thermal conductance. In particular, we observed saturation of the cross-plane thermal conductance at high vdW binding energy, which is attributed to the substrate-induced localized phonon modes in the MoS_2 with high phonon relaxation times and low participation ratios. The insights gained at the atomistic level lead to a device level optimization strategy of heat dissipation in the solid-state 2D nanodevice thermal management. Through the finite element analysis based on MD-calculated thermal properties, we show that three length scales, i.e., the hotspot size, the size of the 2D film, and characteristic length of the lateral heat spread, determine the device level thermal transport and the optimal vdW binding energy that maximizes heat dissipation. We identified two distinct heat transfer regimes that are characterized by the coupling of in-plane and cross-plane heat transfer and the cross-plane heat transfer, because of the interplay among the three length scales. At each regime, the optimal heat transfer for device operation was analyzed. Our study elucidates how the vdW binding affects the thermal transport through the 2D heterostructure from the atomistic level to the device level, which provides a general guideline to optimize the heat dissipation of high-performance 2D nanoscale devices.

Mapping Nanoscale Thermal Transport Properties with Deep Learning Algorithms Sanghamitra Neogi, Artem Pimachev and Morgan Henderson; University of Colorado Boulder, United States

Confining heat carriers at the nanoscale significantly affects thermal transport in materials, even resulting in the breakdown of Fourier's law. For example, the thermal conductivities (TC) of one- and two-dimensional (1D and 2D) materials exhibit anomalous size dependencies and anisotropies. Confinement and surface roughness due to oxidation, amorphization, and nanostructuring have similar effects and have been investigated extensively as means for TC reduction, especially for thermoelectric applications. The end of conventional transistor scaling inspired extensive reasearch on alternative integrated chip (IC) architectures to meet these increasing computing demands. Samsung announced limited manufacturing of a 3nm node IC featuring a new nanosheet architecture (Multi-Bridge-Channel FET). The greatest challenge in practically implementing such devices is the emergence of thermal bottlenecks that arise due to nanoscale structuring and material interfaces associated with tightly packed transistors, greatly reducing device performance. Although the nanoscale heat transport processes in semiconductors could be drastically different, as highlighted above, thermal modeling of these ICs is mostly done at the continuum level. New designs with controlled thermal environments guided by microscopic phonon physics models will directly impact the performance of nanostructured devices. To gain control over thermal transport processes in nanostructures, it is essential to fully map the vibrational properties of the materials. However, sampling of a high-dimensional parameter space is unavoidable to design nanostructured materials with controlled phonon transport properties due to the large variability of their geometric features, broad spectra of vibrational modes, and thermal transport properties; making analysis via first-principles models highly expensive. On the other hand, the rich dynamics of data in these spaces makes the problem of establishing a phonon-control design strategy ideal for the application of data-driven techniques. To understand thermal buildup in the active structures within modern field-effect transistor (FET) devices, we combine atomistic modeling techniques and first-principles calculations for constituent components with novel machine learning (ML) approaches to predict the thermal properties of the structures themselves. We generate temperature profiles for material components of several FET structures and identify phonon modes that contribute strongly to thermal transport in them using atomistic lattice dynamics calculations. We then establish a relationship between component features, temperature profiles, and corresponding phonon dynamics using a machine learning (ML) algorithm. Once the algorithm has been trained, the relationship is used to predict the full phonon dynamics of the FET structures. We acknowledge funding from the National Science Foundation [Award No.: HDR-DIRSE-1940153].

Nanoscale Thermal Transport in Hybrid Materials and Across Interfaces Zhiting Tian; Cornell University, United States

Understanding nanoscale thermal transport processes is essential to design nano-materials and devices with desired thermal transport properties for thermal energy conversion and management. Despite the significant progress in thermal transport of inorganic crystals, thermal transport in more complicated materials and across material interfaces remains largely unexplored. In this talk, I will present my research group’s efforts to understand nanoscale thermal transport in hybrid organic-inorganic materials and across interfaces, using atomic modeling and experimental characterization. I will start with our study on phonon dynamics in hybrid

perovskites using inelastic x-ray scattering. It provides useful insights into their ultralow thermal conductivity. I will then share our recent development on anharmonic atomistic Green's function, which allows us to capture the importance of inelastic scattering at the interfaces. Lastly, I will share our latest work on phonon Anderson localization and quantum thermal rectification.

4:25 PM NM08.09.02
Optimizing Top-Side Device Cooling via Metal/Nanocrystalline Diamond Interfaces Henry Aller[1], Nicholas Golio[1], Karl Hobart[2], Tatyana Feygelson[2], Alan McGaughey[1], Andrew Gellman[1] and Jonathan Malen[1]; [1]Carnegie Mellon University, United States; [2]U.S. Naval Research Laboratory, United States

Top-side device cooling methods, e.g., diamond heat sinks on top of the metal contacts, facilitate heat removal from hot spots near the gate, directly lowering local and global temperature rises. Because the top-side surface of modern devices is often complex and rarely flat, conformal nanocrystalline diamond (NCD) growth techniques are critical to maximize the contact area between the device and the heat sink. Weak adhesion at this interface will cripple thermal transport, acting as a large thermal resistance. As a result, thin adhesive metal layers are often deposited between the device and the heat sink. The effectiveness of heat sinks is directly dependent on the thermal boundary conductance of the metal/NCD interface. In this study, we seek to optimize thermal transport across Au/Cr/Pd/NCD stacks. Cr was chosen for its thermal merits. Excellent adhesive properties and high maximum phonon frequencies has enabled Cr to produce some of the largest thermal boundary conductance interfaces for materials like Diamond, Al2O3, and AlN. Despite this, Cr is predicted to react with NCD to form enthalpically favorable carbides, which will lower the thermal boundary conductance. We hypothesize that a thin non-reactive Pd layer can eliminate these reactions and preserve the metal/NCD thermal boundary conductance in heated conditions. Pd and then Cr layers are deposited as perpendicular wedges with thickness of 0 to 20 nm on a single NCD sample, allowing us to test all thickness combinations of Pd and Cr. The thermal boundary conductance is measured using a non-destructive pump-probe optical technique, frequency domain thermoreflectance (FDTR). By scanning the FDTR across the sample surface, a 2D map of thermal boundary conductance is created for all Pd/Cr thickness combinations. A local maximum in thermal boundary conductance is observed for a specific Cr/Pd thickness combination, providing evidence that our hypothesis is correct. Using Tunneling Electron Microscopy (TEM), we inspect a lift-out sample taken from our original NCD results, at the location of the TBC local maximum. Using image filtering, we identify the structure of this metal interface and determine the thickness of each metallic and reacted-carbide layers. The sample was then annealed and remeasured multiple times. Changes in the 2D thermal boundary conductance map following each heating cycle is used to quantify the ability for thin Pd layers to improve the thermal stability of metal contacts like Cr. Since large temperature rises will alloy and chemically react metal films and interfaces, it is crucial that we evaluate the thermal performance of metal stacks throughout the entire device's lifetime, not just when it's first made.

4:40 PM NM08.09.03
Interplay of Interfacial Scattering and Internal Phonon Scattering for Thermal Interfacial Transport in a Si/Ge Interface Xun Li and Sangyeop Lee; University of Pittsburgh, United States

Interfacial resistance between solids has drawn great interest due to its importance for various applications such as thermal management in electronic devices and energy conversion. The simple Landauer formula, which had been widely used, fails in describing interfacial resistance because it neglects internal phonon scattering. Past studies have shown that the modified Landauer formula proposed by S. Simons could give a much smaller interfacial resistance by considering internal phonon scattering [S. Simons, Journal of Physics C: Solid State Physics, 1974]. However, it assumes that phonons near the interface follow the distribution of bulk phase (i.e., distribution in an infinitely large sample with homogeneous temperature gradient), neglecting the non-equilibrium phonon distribution due to the interface and the complex interplay between the interface scattering and internal phonon scattering. We study the phonon transport across an interface between silicon and germanium by solving the Peierls-Boltzmann transport equation with inputs from first-principles. The phonon distribution is solved in both real and reciprocal spaces, and the local effects can be well captured. The results

show that both the Landauer formula and its modified version fail for interfacial phonon transport due to their assumptions neglecting highly non-equilibrium phonon distribution near an interface. The highly non-equilibrium phonon distribution decays with a distance from the interface and finally recovers to the phonon distribution of bulk phase at the distance which we define as an effective interfacial region. We find that the internal phonon scattering within the interfacial region provides an important contribution to overall interfacial resistance. Our study can help to understand the large discrepancy between experimentally measured interfacial resistance and that from the Landauer formula that is often found in literature, providing a useful way to interpret experimental data.

Theoretical Analysis of Factors Affecting the Thermal Boundary Conductance Variability between a 2-Dimensional Layered Material and Its Substrate Zhun-Yong Ong, Gang Zhang and Yong-Wei Zhang; Institute of High Performance Computing, Singapore

Effective heat dissipation from a two-dimensional semiconducting transition metal dichalcogenide (TMD), such as MoS_2 or WS_2, to its substrate is constrained by the thermal boundary conductance (TBC) of their planar interface which can exhibit significant variability with: (1) the charge carrier density, (2) surface roughness, (3) substrate elastic property, and (4) TMD thickness. Hence, insights into the factors affecting the TBC variability can lead to superior thermally aware design and more effective thermal management of TMD-based nanoelectronic devices through the optimal use of materials. We probe the physical origins of the TBC variability by modeling the underlying electronic and phononic processes in the TBC.
We quantify the temperature-dependent electronic TBC G_{el} between a single-layer TMD (MoS_2 or WS_2) and different dielectric insulating substrates (SiO_2, HfO_2 or Al_2O_3) and find that it varies significantly with the dielectric material and electron density, indicating that G_{el} is strongly tunable with a metal gate especially with Al_2O_3 [1]. To account for the effect of surface roughness on the phononic TBC G_{ph}, we introduce a phenomenological theory for diffuse phonon scattering between the TMD and its substrate [2]. The G_{ph} from diffuse scattering is compared to and found to be substantially higher than the G_{ph} from coherent scattering as well as comparable to experimentally measured TBC values for the MoS_2-SiO_2 interface, suggesting that the TMD-SiO_2 interface is highly disordered. To understand the effects of anisotropic elasticity in the substrate, we formulate an elasticity theory-based model of stacked thin plates to model the phononic TBC between a TMD and h-BN, a layered substrate [3]. Good agreement between the model and experimental TBC data is obtained for the MoS_2-BN interface. Our results reveal that h-BN is substantially more effective for heat dissipation than SiO_2, especially when the number of layers in the MoS_2 is large, because of the effective coupling of flexural modes across the MoS_2-BN interface.

Nanoscale Thermal Transport at Bi_2Te_3 Interfaces Aoife K. Lucid[1], Javier Fernandez-Troncoso[2], Jorge Kohanoff[2], Stephen B. Fahy[1] and Ivana Savic[1]; [1]Tyndall National Institute, Ireland; [2]Queen's University Belfast, United Kingdom

Nanostructured thermoelectric materials are generally highly polycrystalline, meaning that defects such as interfaces are prevalent. Advancing beyond the current state-of-the-art nanostructured thermoelectric materials requires a detailed understanding of the impact of interfaces on their thermal properties. In addition to the

importance of nanoscale engineering, it is highly desirable to achieve high thermoelectric performance at room temperature for Internet of Things, energy harvesting, and active cooling applications. Bismuth telluride (Bi_2Te_3) is the best performing thermoelectric material at room temperature. One route to achieving highly efficient thermoelectrics at room temperature is to understand the impact of interfaces in materials such as Bi_2Te_3 on thermal transport at an atomistic level.

In this work, we utilise reverse non-equilibrium molecular dynamics (rNEMD) simulations, with a recently developed empirical interatomic potential [1], to elucidate the impact of specific twin boundary structures on thermal transport in Bi_2Te_3. Three basal plane twin boundaries terminated at different layers in Bi_2Te_3 and the 60° twin boundary [2] are investigated. The interfacial thermal resistance (Kapitza resistance) is calculated, along with an analysis of the structural changes observed at interfaces. We find that interfacial thermal resistance increases with decreasing stability of the interface, suggesting that the most effective interfaces may require more effort to fabricate. Despite large structural differences between the basal twin boundaries and the 60° twin boundary, we do not see significant variance in interfacial thermal resistance when comparing these interfaces. A comparison of the properties of these four twin boundaries is carried out, enabling us to identify those that may be the most impactful in terms of suppressing lattice thermal conductivity at room temperature.

Peak Thermal Conductivity Measurements of Bulk Boron Arsenide Crystals and Individual Carbon Nanotubes Yuanyuan Zhou[1], Qianru Jia[1], Chunhua Li[2], Geethal Amila Gamage[3], Zhifeng Ren[3], David Broido[2] and Li Shi[1]; [1]The University of Texas at Austin, United States; [2]Boston College, United States; [3]University of Houston, United States

The ultrahigh lattice thermal conductivities reported near the room temperature for boron arsenide (BAs) and carbon nanotubes (CNTs) make them useful for both thermal management applications and fundamental studies of phonon transport. The peak thermal conductivity of a single crystal usually appears at a low temperature and provides insight into the competition between extrinsic phonon-defect scattering with intrinsic phonon-phonon processes. However, existing measurements have yet to obtain the peak thermal conductivity of BAs and reported a much higher peak temperature for CNTs than for high-quality graphite. Here we report highly sensitive electro-thermal bridge measurements of the peak thermal conductivities of both bulk BAs crystals and individual CNTs. Theoretical calculations are used to correlate the thermal transport measurement results with the structure and chemical composition characterization data.

Transport Properties of Chalcogenide Systems—The Effects of Atomic Re-Arrangement and Doping Lilia Woods; University of South Florida, United States

Multinary chalcogenides are diverse systems, which can be derived from simpler binary compositions by cation substitution and preserving the octet rule. One can achieve different classes of materials with more complicated compositions, which share some common features and yet have distinct properties. By using first principles simulations we study the electronic and vibrational properties of quaternary chalcogenides from the I_2-II-IV-VI_4, I-II_2-III-VI_4, and I-IV-V-VI_3 families. These systems have inherently low thermal conductivity, which is directly related to the lattice structures and underlying anharmonic phonon scattering mechanisms. Our first principles simulations help us understand from a microscopic perspective the phonon conduction processes in these classes of materials. We also find that there are various possibilities for different atomic arrangements which can lead to distinct structural phases. Also, various types of doping are possible, which can further be used for electronic property optimization. The inherently low thermal conductivity and the available earth-abundant chemical compositions make these materials attractive for applications in thermoelectricity and solar cells among others.

Improvement of Thermoelectric Efficiency of Si-Based Clathrate Masato Ohnishi[1], Koji Fujimura[2], Takahiro Yamamoto[2], Hiroshi Shimizu[2], Kiyoshi Yamamoto[2] and Junichiro Shiomi[1]; [1]The University of Tokyo, Japan; [2]Furukawa Electric, Japan

Clathrate compounds are promising candidates for thermoelectric materials in terms of the “electron-crystal phonon-glass” concept. Clathrate compounds are composed of guest atoms encapsulated in cagelike structures. It is expected that electrons can smoothly transport in the frame work while phonons are scattered by guest atoms. Particularly, in type-I clathrate compounds, guest atoms vibrate in a strong anharmonic potential because they are composed of a Weaire-Phelan structure, which divides a space with the maximum volume with the same cross-sectional area. While off-center clathrates such as type-I $Ba_8Ga_{16}Sn_{30}$, in which guest atoms vibrate in a double-well anharmonic potential, have low thermal conductivity, silicon-based clathrates are preferable for actual use in terms of the material cost.
In this study, we show that aluminum substitutions can enhance thermoelectric performance of silicon-based clathrates, type-I $Ba_8Ga_{16}Si_{30}$. Comparing calculated thermoelectric figure of merits (ZT) with those obtained in experiment, we concluded that (a) aluminum additive enhances ZT with lowering doping level and (b) further suppression of doping level can enhance ZT significantly. To investigate thermoelectric properties, we obtained possible structures at finite temperature with using a cluster expansion and Monte Carlo method [M. Ångqvist, P. Erhart et al., Chem. Mater. 29, 7554 (2017) and 28, 6877 (2016)] and thermoelectric properties were averaged for different possible structures. Phonon properties of the clathrates were calculated with using a self-consistent phonon (SCP) theory based on first-principles calculations [Tadano *et al*. Phys. Rev. Lett 120, 105901 (2018)]. Our state-of-the-art analysis method shows a good agreement with experimental data.

Nonequilibrium Energy Dynamics in Nanoscale Metal Multilayers After Femtosecond Heating Richard B. Wilson[1,2], Ramya Mohan[2], Kexin Liu[1], Xinping Shi[1] and Michael Gomez[2]; [1]University of California, Riverside, United States; [2]University of California, RIverside, United States

Understanding the ultrafast energy dynamics in a metal after laser heating is critical for many engineering applications, including nanoscale thermal engineering, photocatalysis, and spintronics. Despite the topic’s importance, and decades of study, fundamental questions about the topic remain unanswered. In this talk, I discuss my group’s experimental work to answer two such questions. (i) Do photoexcited electrons transport energy ballistically, super-diffusively, or diffusively before thermalizing with phonons? (ii) Can we control the energy dynamics in metal alloys by using the effect of alloy composition on electronic band structure to control the strength of quasi-particle interactions? To answer the first question, we combine wavelength-dependent time-domain thermoreflectance experiments and time-resolved magneto-optic Kerr effect experiments to study

nanoscale heat-transfer in Au/Co multilayers. We perform measurements on a series of samples with varied Au thickness. Our experiments show that, while the energy dynamics in Au after photoexcitation are nonthermal, heat is still transported diffusively. To answer the second question, we perform pump/probe experiments on $Au_{1-x}Al_x$ and $Co_{1-x}Fe_x$ alloys. We find the ultrafast energy dynamics in these alloys depends strongly on composition. In $Au_{1-x}Al_x$ alloys, we credit the observed relationship between alloy composition and electron-phonon energy relaxation time to changes in the strength of electron-phonon interactions. In $Co_{1-x}Fe_x$ alloys, we credit the observed composition dependence of the electron-magnon energy relaxation time to changes in the strength of electron-magnon interactions. I conclude my talk by discussing the implications of our findings to the plasmonics and spintronics communities.

9:15 PM NM08.10.05
Long-Lived Modulation of Plasmonic Absorption by Ballistic Thermal Injection John A. Tomko[1], Evan Runnerstrom[2], Yi-siang Wang[3], Weibin Chu[3], Joshua R. Nolen[4], David Olson[1], Kyle Kelley[5], Angela Cleri[6], Josh Nordlander[6], Oleg Prezhdo[3], Jon-Paul Maria[6] and Patrick Hopkins[1]; [1]University of Virginia, United States; [2]CCDC US Army Research Laboratory, United States; [3]University of Southern California, United States; [4]Vanderbilt University, United States; [5]Oak Ridge National Laboratory, United States; [6]The Pennsylvania State University, United States

Light–matter interactions that induce charge and energy transfer across interfaces form the foundation for photocatalysis, energy harvesting and photodetection, among other technologies. One of the most common mechanisms associated with these processes relies on carrier injection. However, the exact role of the energy transport associated with this hot-electron injection remains unclear. Plasmon-assisted photocatalytic efficiencies can improve when intermediate insulation layers are used to inhibit the charge transfer or when off-resonance excitation is used, which suggests that additional energy transport and thermal effects could play an explicit role even if the charge transfer is inhibited. This provides an additional interfacial mechanism for the catalytic and plasmonic enhancement at interfaces that moves beyond the traditionally assumed physical charge injection. In this work, we report on a series of ultrafast plasmonic measurements that provide a direct measure of electronic distributions, both spatially and temporally, after the optical excitation of a metal/semiconductor heterostructure. We explicitly demonstrate that in cases of strong non-equilibrium, a novel energy transduction mechanism arises at the metal/semiconductor interface. We found that hot electrons in the metal contact transfer their energy to pre-existing free electrons in the semiconductor, without an equivalent spatiotemporal transfer of charge. Further, we demonstrate that this ballistic thermal injection mechanism can be utilized as a unique means to modulate plasmonic interactions. These experimental results are well-supported by both rigorous multilayer optical modelling and first-principle ab initio calculations.

9:30 PM NM08.10.06
Dependence of Electron-Phonon Energy Relaxation Times on Electron-Electron and Electron-Phonon Interactions Strengths Xinping Shi, Kexin Liu and Richard B. Wilson; University of California, Riverside, United States

Photoexcitation of a metal results in hot electrons that cool on femto to picosecond time-scales because of electron-phonon interactions. The energy relaxation times of hot electrons can vary a lot depending on the metal. For example, the electron-phonon energy relaxation time in Pt is less than 200 fs [1]. Alternatively, in Au experiments suggest the energy relaxation is between 1 and 3 ps [2-5]. In this work, we experimentally study how energy relaxation times in metals are determined by the interplay of electron-electron (e-e) interaction and electron-phonon (e-p) interaction strengths. We report on pump/probe measurements of picosecond acoustic signals in Au, Al, and their alloys. We perform these measurements on wedge samples with varied thicknesses. These metals have a wide range of e-e and e-p interaction strengths, and therefore provide a rigorous test on existing theories for hot electron dynamics. The picosecond acoustic signals we measure are caused by the rapid change in lattice temperature as a function of depth that occurs following laser excitation. Therefore, our experimental signals are a sensitive probe of electron-phonon energy relaxation times. Our results provide insight into how quasi-particle interactions govern nanoscale heat transfer in metal systems, which is important

to many disciplines, including nanophotonics, plasmonics, and ultrafast magnetism.

Microscopic Insulating Spacers for Thermionic Energy Conversion Mohsen Azadi[1], Zhipeng Lu[1], Matthew F. Campbell[1], Wujoon Cha[1], Josue Leon[1], Kyana Van Houten[2], Felix Schmitt[2], Jared W. Schwede[2] and Igor Bargatin[1]; [1]University of Pennsylvania, United States; [2]Spark Thermionics, United States

We introduce thermally insulating corrugated spacers that establish micron-scale electrode gaps without electrical shorting in thermionic energy converters, allowing temperature differences of hundreds of kelvins to be achieved with only a few watts of conductive heat transfer per square centimeter. These films' microscale corrugation serves both structural and thermodynamic functions, namely, to increase their robustness[1,2] and to increase their overall thermal resistivity to limit heat transfer between the electrodes[3,4]. Our thermomechanical testing reveals that these films have thermal resistance values high enough to reduce parasitic conduction to levels below that of thermionic heat transfer even at moderate (~1300 K) emitter temperatures, resulting in great enhancements in output current density and thermionic conversion efficiency while minimizing heat loss. These results represent a significant step toward high power density, mass producible, commercially viable direct heat-to-electricity energy conversion.

Thermionic energy converters are solid-state heat engines in which electrons are produced by a hot cathode, cross a vacuum gap, and impinge on a cold anode, delivering electric current. Maximizing efficiency and power density in these devices requires minimizing their vacuum gap thicknesses to roughly 2 μm. Establishing gaps of this scale by intricate external positioning mechanisms is impractical for mass-produced devices, thereby necessitating intra-gap spacers to internally maintain spacings. Previous methods of establishing these gaps have had limited success for reasons related to their high conductive losses or other manufacturing difficulties[5,6].

Therefore, we have developed spacers made through alumina atomic layer deposition with micron-scale thicknesses and square centimeter-scale areas that can be mass-produced using standard microfabrication techniques and subsequently transferred to thermionic energy converter electrodes. These films include hexagonal apertures to allow high electron currents (several A/cm^2), can tolerate compressive pressures of several atmospheres to ensure electrode parallelism, and have high thermal resistances (hundreds of cm^2K/mW) to minimize conductive losses. Our films' low conductance values stem from the high contact resistance they exhibit where they touch the electrodes[3] and their carefully architected nanoscale corrugation, which reduces the area through which conduction can occur[4].

We fabricate our spacer films by (1) constructing a silicon mold *via* sequential cycles of photolithography and deep reactive ion etching, (2) conformally coating the mold with insulating materials such as alumina using atomic layer deposition, (3) cutting hexagonal apertures in the insulating layer using inductively coupled plasma etching, and (4) releasing the film using XeF_2 etching. In addition, we have developed an ultra-high vacuum testing apparatus to probe the interactions between the mechanical and thermal properties of our films and in addition are conducting extensive electrical testing of these spacers in thermionic devices.

10:00 PM NM08.10.08
Comprehensive Modeling of Thermionic Energy Conversion with Micro/Nanoscale Vacuum Gaps with Constant Heat Flux Input Moh'd-Eslam Dahdolan and Mohammad Ghashami; University of Nebraska–Lincoln, United States

Thermionic energy conversion is the direct conversion of heat into electricity by the spontaneous emission of high-energy electrons from a surface. Although the physical mechanism of thermionic emission has been suggested to be used for energy conversion applications for over century now, thermionic energy converters (TEC) have not been widely implemented due to low conversion efficiency even at high temperatures. Recently, it has been suggested that by reducing the inter-electrode gap distance in a thermionic converter, electron emission can increase remarkably mainly due to the mitigation of excessive potential barriers (i.e., negative space charge). However, by shrinking the inter-electrode dimensions, other physical phenomena now need to be considered including near-field thermal radiation and image-charge effects. Therefore, significant knowledge gaps remain in the comprehensive modeling and analysis of thermionically induced electron and photon emission, particularly across nanometer distances. In this study, we present a comprehensive model describing the performance of a tungsten-based TEC by developing an energy balance with various heat flux inputs to the emitter and considering the effects of negative space charge, image charge, and near-field thermal radiation between the two electrodes. The steady-state temperatures of the emitter and collector are found to satisfy the energy balance of the TEC and the effects of inter-electrode gap distance, operating voltage, and work functions of the electrodes on the operating performance are further investigated for different heat input scenarios. The dependence of work output and efficiency on gap distance is highlighted to show the maximum efficiency and maximum power points, which are helpful in selecting gap distance for optimum performance. By clear illustration of the trade-off between the aforementioned physical phenomena at the nanoscale regime using this comprehensive model, our results prove that the power output and the conversion efficiency of a nanoscale TEC system can surpass those of conventional TECs and other competitive solid-state converters.

Phonon Transport Physics in Well-Controlled Various Nanomaterials Yoshiaki Nakamura and Takafumi Ishibe; Osaka University, Japan

With miniaturizing electronic devices, thermal management has attracted great interest for overcoming various heat issues in nanoscale world: dissipating heat, energy harvesting from the wasted heat, and so on. Therefore, much effort has been made to reveal the phonon transport physics in nanoscale leading to tailoring heat conduction. Nowadays, some studies experimentally demonstrated the interesting coherence property of phonon using superlattice structures [1, 2]. On the other hand, in the thermoelectric research field, phonon transport in nanostructured materials has also drawn much attention because of the thermal conductivity reduction. However, in general, the materials including nanostructures have unintentional defective structures:

uncontrolled crystal orientation, composition deviation, strains and crystal defects. It needs the atomically-controlled nanostructured materials to elucidate the phonon transport physics in the material system containing nanostructures.
We have developed various kinds of unique well-controlled nanostructures: IV group element-based nanodot structures, etc [3-6]. This talk will discuss the phonon transport physics in the unique nanomaterial films containing atomically-controlled nanocrystals where the thermal conductivity is drastically reduced. One example of our nanostructures is Si-based films including ultrasmall Ge nanodots with sharp interfaces and without strain unlike the conventional Stranski Krastanov nanodots. When Ge nanodots get smaller than 10 nm, the thermal resistance of Ge nanodot layers in Si films decreases, while that of Ge nanodot layers in SiGe films does not depend on Ge nanodot size. The tendency can be explained by phonon scattering theory. In this talk, we will introduce phonon transport in some kinds of well-controlled nanostructured materials. These findings will give a new insight for thermal management.

Phonon Mean Free Path Spectroscopy in Semiconductor Membranes Roman Anufriev[1], Jose Ordonez-Miranda[2] and Masahiro Nomura[1]; [1]The University of Tokyo, Japan; [2]Institute Pprime, France

Distributions of the phonon mean free path (MFP) in materials and nanostructures are important for understanding and engineering their thermal properties. In the past years, the phonon MFP in bulk semiconductors has been extensively studied both theoretically and experimentally. However, modern MEMS devices often rely on thin membranes rather than bulk material, yet the MFP spectra in thin membranes have not been measured experimentally.
In this work, we demonstrate an experimental method to probe the phonon MFP spectra in suspended semiconductor membranes. The method consists in measuring the thermal conductivity of membranes with arrays of slits and extracting the accumulated thermal conductivity as a function of the MFP through a fully analytical approach based on the semi-analytical procedure proposed by Hao et al. [1]. In silicon, we find that the phonon MFP in 145-nm-thick membranes is much shorter than that in bulk due to the scattering at the membrane boundaries [2]. At room temperature, the phonon MFP spans from 10 nm up to only 400 nm. Yet, at 4 K, the MFP becomes longer, and most phonons can travel ballistically for more than 100 nm. These results thus shed light on the long-lasting question of the range of ballistic and coherent phonon transport at different temperatures in nanostructures based on semiconductor membranes.

Artefacts in Scanning Thermal Microscopy—Nanometre-Scale Roughness and Oxide Films Down to Native Thickness Eloise Guen[1], Pierre-Olivier Chapuis[1], NJ Kaur[2], Petr Klapetek[2], Ravish Rajkumar[3], Gordon Mills[3], Philipp S. Dobson[4], Jonathan M. Weaver[4] and Severine Gomes[1]; [1]CNRS-CETHIL, France; [2]CMI, Czechia; [3]Kelvin NanoTechnology, United Kingdom; [4]University of Glasgow, United Kingdom

Scanning Thermal Microscopy (SThM) allows the thermal characterization of materials with a sub-micrometric spatial resolution [1]. While obtaining qualitative trends, e.g. by means of images, is straightforward, determining reliable quantitative thermal data from the experiments is challenging because the probe-sample heat exchange depends strongly on parameters such as the size, geometry and surface states of probe and sample. In this work, we study first the impact of sample roughness on the thermal conductance at the probe/sample contact and then the impact of thin fims of oxide on the surface.
Rough samples consisting of several sets of silicon surfaces with out-of-plane Sq roughness parameters of ~0, 0.5, 4, 7 and 12 nm were prepared by anodic oxidation [2] and measured with three types of probe (Wollaston, palladium and doped Si probes) in vacuum conditions. Sample roughness is clearly shown to reduce the thermal conductance very significantly compared to a flat Si sample, up to 40-95% depending on the probe. SThM sensitivity is low for highly conductive materials, so erroneous thermal conductivity can be deduced from a calibration curve performed for flat samples [3].
In a second step, we analyze the impact of thin oxide films on the determined thermal conductivity. It was shown that heat conduction in the cross-plane direction is strongly affected by native oxide in nanometre-thin suspended silicon membranes [4]. Here we extend the study to supported films of thickness varying between few nanometres and one micrometre. We find a logarithmic dependence on thickness for the apparent thermal conductivity and show that arbitrarily-small thicknesses may be detected. Nanoprobes are found to be less sensitive to the oxide thickness, as they probe only at the very surface [5]. We discuss the impact of thermal boundary resistances and ballistic dissipation in the samples.
All these results allow to envisage precise calibration of nanometre-scale thermal studies.

Heat Trapping and Thermal Conductivity Reduction Due to Specular Scattering in Nanoporous Si Laura de Sousa Oliveira[1], Seyed Aria Hosseini[2], Alex Greaney[2] and Neophytos Neophytou[3]; [1]University of Wyoming, United States; [2]University of California, Riverside, United States; [3]University of Warwick, United Kingdom

Nanostructuring has been successfully used to improve thermal transport performance across a wide range of materials, whether a high or low thermal conductivity is desired. This includes applications ranging from latent heat storage to thermoelectrics and phononic crystals. Nanoscale porosity has been shown to substantially decrease the thermal conductivity of semiconducting materials — thereby improving their thermoelectric efficiency — and, in some cases, even enhance transport. In this work [1], we identify an unusual anticorrelated specular phonon scattering effect which yields an additional ~ 80% decrease (at maximum efficiency) in the thermal conductivity of specific nanoporous geometries and which lends itself to a high degree of control by manipulating pore size and distribution.

Large-scale equilibrium molecular dynamics (MD) simulations show the presence of negatively correlated (or anticorrelated) heat flux for specific nanoporous geometries. Wave-packet MD simulations show how the heat becomes trapped between large pores with narrow necks due to specular scattering. We further reproduce the behavior observed in the MD simulations and demonstrate how specular scattering can give rise to negatively correlated heat flux using a heuristic ray-tracing analytical model. While specular scattering does not necessarily indicate the presence of coherence effects it is a necessary requirement for coherent interference, and our simulations support the notion that coherence effects could in principle be present at room temperature. We show with MD how the pore size/neck ratio and pore periodicity can be manipulated to control the strength

and duration of the correlated reflections and thus the reduction in thermal conductivity. In addition to thermoelectrics, we believe this work could have a broader application in phononics.

Thermal Rectification in Asymmetric Core/Shell Nanowires Paul Desmarchelier[1,2], Konstantinos Termentzidis[1] and Anne Tanguy[2,3]; [1]CETHIL-INSA de Lyon, France; [2]LaMCoS, France; [3]ONERA, France

Thermal rectification is one of the next steps for a better thermal management. In this study, this effect has been assessed, in an original nanostructuration, thanks to non equilibrium molecular dynamics and wave packets propagation simulations. The direction dependent thermal conductivity results from the use of asymmetric crystalline-core/amorphous-conical-shell nanowires that induces variable axial and radial phonon propagation/confinement. This effect is linked to the combination of a crystalline/amorphous interfaces parallel to the heat flux, and with the variable amount of amorphous coating due to the conical shell of the nanowire. Rectification is analyzed terms of mean free path of phonons, axial and radial energy transfer, energy diffusivity, and vibrational density of states restricted to different constitutive elements of the nanowire.

Interplay Between Thermal Boundary Resistance and Ballistic Transport in In-Plane Phonon Heat Conduction Ali Alkurdi and Pierre-Olivier Chapuis; CNRS-CETHIL, France

When the characteristic size becomes comparable to the mean free path of phonons, the quasi-ballistic heat conduction regime arises while interactions with boundaries become significant. Both thermal boundary resistance and ballistic transport flatten the temperature profile and induce temperature jumps in comparison to macroscopic heat conduction: it is therefore difficult to disentangle the two effects by simply observing a temperature profile. We solve the phonon Boltzmann Transport Equation using the Discrete Ordinate Method, which accounts for the directional and non-local aspects of the energy flux, in order to analyze independently the effects and observe their interplay in a system of two contacted thin films. In particular, we find that the effective thermal conductivity for in-plane heat conduction is a function on the nondimensional figure Kn_T/tau, where Kn_T is the mean Knudsen number (ratio of average mean free path to sum of the thicknesses of the two films) and tau the mean transmissivity at their interface. The impact of the specularity of the film boundaries and interface is also evidenced, especially on the angular distribution of phonons.
These results shed light on the relation between local energy non-equilibrium and transport properties.

Coherent Phonon Transport in Ultra-Low Thermal Conductivity Two-Dimensional Ruddlesden-Popper Phase Perovskites Alexander D. Christodoulides[1], Peijun Guo[2], Lingyun Dai[1], Justin M. Hoffman[3], Xiaotong Li[3], Xiaobing Zuo[4], Daniel Rosenmann[4], Alexandra Brumberg[3], Mercouri G. Kanatzidis[3], Richard Schaller[4] and Jonathan Malen[1]; [1]Carnegie Mellon University, United States; [2]Yale University, United States; [3]Northwestern University, United States; [4]Argonne National Laboratory, United States

An emerging class of methylammonium lead iodide ($MAPbI_3$) based Ruddlesden-Popper (RP) phase perovskites, $BA_2MA_{n-1}Pb_nI_{3n+1}$ (n = 1 – 7), exhibit enhanced stability to environmental conditions relative to $MAPbI_3$, yet still degrade at elevated temperatures. We use Frequency-Domain Thermoreflectance (FDTR) to experimentally determine the thermal conductivities of these layered RP phases for n = 1 – 4 thin films and n = 3 – 6 single crystals. We find that the initially decreasing trend of thermal conductivity in similarly oriented perovskites with increasing n results from the transport properties of coherent phonons, emergent from the

superstructure, that do not scatter at the interfaces of organic butylammonium (BA) chains and perovskite octahedra. With the exception of $n = 1$, the perovskites' thermal conductivities are lower than the range of 0.34 – 0.50 W/m/K reported for single crystal $MAPbI_3$. Reduced-order lattice dynamics modeling suggests that reduced group velocity of coherent phonons in $n = 3 – 6$, a consequence of band flattening in the phonon dispersion, is primarily responsible for their ultralow thermal conductivities. Similar effects on thermal conductivity have been experimentally demonstrated in deposited superlattices, but never in naturally defined materials like RP phases. GIWAXS measurements reveal that higher *n* RP phase thin films are less orientationally controlled, and therefore possess apparently elevated thermal conductivities relative to single crystals of the same *n*.

Late News: Modeling the Quasiballistic Phonon Thermal Resistance During Electron Beam Heating of Thin Films Geoffrey Wehmeyer; Rice University, United States

Electron beams with sub-10 nm diameters can be used as nanoscale heaters or thermometers, enabling new techniques to probe heat transfer in nanostructures. However, since the electron beam diameter is often smaller than the energy carrier mean free path, using Fourier's law will underpredict the (quasi-)temperature rise due to electron-beam induced heating. Here, we solve the Boltzmann transport equation (BTE) under the relaxation time approximation to quantify electron-beam induced heating in thin dielectric samples. In both thin and thick samples, the full BTE solution is in agreement with a simple "resistors in series model" that sums the ballistic resistance and the typical Fourier conduction resistance (considering the thin-film classical size effect). For nanoscale thermometry applications, the temperature rise under typical imaging conditions is predicted to remain negligibly small (<1 K), even when considering the dominant ballistic thermal resistance. Therefore, this BTE modeling indicates that nanoscale thermometry methods are not expected to display notable electron beam heating artifacts, even though the ballistic resistance is the dominant contibutor to the total thermal resistance in experiments using nanoscale heat sources.

Thermal Transport and Fullerene Dynamics in Superatomic Crystals Alan McGaughey[1], Qi Liang[1,2], Wee Liat Ong[1,3,4], Matthew Bartnof[1], Ya-Ling He[2], Xavier Roy[4] and Jonathan Malen[1]; [1]Carnegie Mellon University, United States; [2]Xi'an Jiaotong University, China; [3]Zhejiang University, China; [4]Columbia University, United States

Superatoms are atomically-precise and chemically-stable clusters that can emulate atoms, but at the nanometer scale. Ordered arrangements of superatoms are called superatomic crystals (SACs), which have potential use as electronic, thermoelectric, and phononic materials. In this talk, I will describe experiments and molecular dynamics (MD) simulations performed on SACs built from C_{60} fullerene, $Co_6Se_8(PEt_3)_6$, and $Co_6Te_8(PEt_3)_6$ superatoms to characterize their thermal transport properties.

Thermal conductivity measurements on the $[C_{60}]$ and $[Co_6Se_8(PEt_3)_6][C_{60}]_2$ SACs show a decreasing thermal conductivity with increasing temperature, as it typical for a crystal. The thermal conductivity of the

$[Co_6Te_8(PEt_3)_6][C_{60}]_2$ SAC, on the other hand, is lower and temperature-independent, as is typical for an amorphous solid. X-ray diffraction measurements suggest that the temperature dependencies result from the C_{60}s being either locked-in-place (crystalline behavior) or freely-rotating (amorphous behavior).

The MD-predicted thermal conductivities agree with the experimental trends and offer additional insight into the underlying mechanisms. The C_{60} rotational dynamics and orientation are quantified using the root mean square displacements of the carbon atoms and the relative orientations of the C_{60}s. At low temperatures, the C_{60}s exhibit small rotations around equilibrium positions (i.e., librations). When the librating C60s are orientationally-ordered, as in the $[C_{60}]$ and $[Co_6Se_8(PEt_3)_6][C_{60}]2$ SACs, thermal conductivity decreases with increasing temperature. When the librating C_{60}s are orientationally-disordered, however, as in the $[Co_6Te_8(PEt_3)_6][C_{60}]2$ SAC, thermal conductivity is temperature independent. At higher temperatures, where the C_{60}s in all three SACs freely-rotate and are thus dynamically disordered, thermal conductivity is temperature independent. The abrupt changes driven by the C_{60} dynamics suggest that fullerene-based SACs can be designed to be thermal conductivity switches based on a variety of external stimuli.

Impact of Dimensional Crossover on Phonon Transport in van der Waals Materials—A Case Study of Graphite and Graphene Patrick Strongman and Jesse Maassen; Dalhousie University, Canada

Low-dimensional materials are the focus of intense research due to their unusual and tailorable properties, including their thermal transport characteristics. Examples of distinctive features include flexural acoustic phonons with quadratic dispersions and, in the case of graphene, selection rules that prohibit certain 3-phonon scattering processes. Often the bulk counterparts to these 2D materials are layered van der Waals materials, with the only difference between bulk and monolayer originating from weak inter-layer coupling. Thus, 2D materials can be expected to retain much of the bulk character, and vice versa. In this talk, I will present our work investigating how phonon transport evolves in van der Waals materials when going from 3D to 2D, using graphite/graphene as a case study. Focus is placed on identifying the features impacting thermal conductivity that may be shared with other layered materials. Our calculations are carried out using density functional theory in combination with a self-consistent solution of the phonon Boltzmann transport equation.

Unlike previous studies that compare the thermal properties of mono- and few-layer to bulk, in this work the transition from 3D to 2D is investigated by gradually increasing the inter-layer distance in graphite to form graphene. This approach provides a different perspective on how the phonon and scattering characteristics continuously evolve from bulk to monolayer. We find that changes in the phonon dispersion play a significant role in the lower thermal conductivity of graphite, versus graphene. Specifically, as the graphene sheets are brought closer together, the acoustic flexural phonons form low-energy optical phonons with lower velocities, density-of-states, and phonon occupation, which reduce thermal conductivity. Interestingly, our findings on the 3-phonon scattering properties indicate that the selection rules are mostly upheld as the atomic layers are brought together to form graphite. While the selection rules only strictly apply to graphene, in practice similar scattering behavior is displayed due to the weak inter-layer coupling. Lastly, we attempt to identify key features in the 3D-to-2D transition, that impact thermal conductivity, which may be shared with a broader class of van der Waals materials.

12:25 PM NM08.12.03
Evolution of Microstructure and Thermal Conductivity of Multifunctional Environmental Barrier Coating Systems David Olson, Jeroen Deijkers, Kathleen Kate-Quiambao, John Gaskins, Bradley Richards, Elizabeth Opila, Patrick Hopkins and Haydn Wadley; University of Virginia, United States

Environmental barrier coating (EBC) systems are applied to the surface of silicon-based composites exposed to high temperature combustion gas flow paths in gas turbine engines. They reduce the rate of composite oxidation, its volatilization by reactions with water vapor, and the temperature of the composite as their thermal conductivity decreases. Current EBC systems consist of a silicon bond coat covered by an ytter- bium disilicate

(Yb_2O_3●$2SiO_2$: YbDS) permeation resistant and low silica activity barrier. When applied by atmospheric-plasma spray deposition, this outer layer contains 10–15% of a secondary ytterbium monosilicate (Yb_2O_3●SiO_2: YbMS) phase. YbDS has a coefficient of thermal expansion (CTE) of 4–5×10−6 $°C^{-1}$, similar to those of the silicon and the silicon-based composite, but a relatively high thermal conductivity of 5–7 W m^{-1} K^{-1}. YbMS has a higher steam volatility resistance than YbDS, and it has a much lower thermal con- ductivity (∼2–2.5 W m^{-1} K^{-1}) at ambient temperature compared to YbDS, but its higher, highly anisotropic CTE (3–11×10−6 $°C^{-1}$) results in channel cracking which reduces environmental protection. Here, we use a combination of scanning electron beam and laser-based thermoreflectance methods to spatially map the distribution of the silicate phases and thermal conductivity at ambient temperature in a Si-ytterbium disilicate EBC system exposed to thermal cycling in water vapor. We show that during thermal cycling, diffusion of silica from the thermally grown oxide on the Si bond coat surface to nearby YbMS regions transforms this phase to YbDS, thereby reducing the risk of thermomechanical coating failure but decreasing its effective thermal resistance. We also show that as silica is volatilized at the water vapor–ytterbium silicate interface, YbDS is transformed to YbMS, restoring some of the thermal protection of the coating system lost by its reduction in thickness and the YbMS to YbDS transformation near the bond coat.

Predicting Phonon Properties and Thermal Conductivity of Crystals with Rigid Molecules Using Rotational Lattice Dynamics Hyun-Young Kim and Alan McGaughey; Carnegie Mellon University, United States

Phonons are the primary heat carriers in semiconducting and insulating crystals. By calculating their harmonic (i.e., frequency) and anharmonic (i.e., lifetime) properties, it is possible to predict thermal conductivity. These calculations can be performed using a technique called lattice dynamics, which uses the force constants between individual atoms as inputs to solve the Boltzmann transport equation. Some crystals, however, include molecules with strong internal bonds. For such materials, the atomic degrees of freedom can be restricted in order to model the system as rigid molecules rather than as individual atoms. This choice allows for an examination of the effect of small rotations about equilibrium (i.e., librations) on the thermal properties, as well as the impact of removing the intra-molecular vibrations. For example, this approach was used in molecular dynamics simulations of the C60 molecular crystal to explain how its thermal conductivity varies with respect to temperature.
A formulation exists to perform harmonic lattice dynamics calculations in the presence of rigid molecules. Here, we extend this rigid molecule formulation to anharmonic lattice dynamics calculations, allowing us to examine the impact on full thermal transport properties. The ability to perform these calculations allows us to examine the phonon scattering caused by librations, as well as the effect of removing intra-molecular vibrations on the associated scattering phase space.
We used an in-house lattice dynamics code for our calculations and modeled a modified toy Lennard-Jones argon system. Bonds were placed between the basis atoms to form diatomic molecules. Green Kubo calculations were performed in molecular dynamics simulations to provide a thermal conductivity benchmark for the lattice dynamics results. The predicted thermal conductivities are in reasonable agreement, with values of 5.50 W/m-K and 4.33 W/m-K from lattice dynamics along the two non-isotropic directions at 5 K, compared against 5.45±0.52 W/m-K and 4.55±0.68 W/m-K from molecular dynamics. The phonon properties and scattering rates were then examined in order to identify the cause behind the decrease in thermal conductivity compared to a full degree of freedom system. With the success of the modified lattice dynamics code in calculating the thermal conductivity of this toy system, it can now be extended to real materials such as sodium superoxide and organic-inorganic perovskites.

Thermal Conductivity of Phonon-Engineered Hygroscopic Nanocellulose-Based Foams Varvara Apostolopoulou Kalkavoura, Pierre Munier and Lennart Bergström; Stockholm University, Sweden

Cellulose and cellulose nanomaterials (CNMs) can be used to produce light-weight foams and aerogels with

heat transport properties that can be phonon-engineered for thermal management and thermal insulation applications[1].
Cellulose possesses an intrinsic anisotropy of the thermal conductivity, which has been utilized to produce foams made with aligned CNM particles that exhibit highly anisotropic thermal conductivities. Anisotropic foams based on cellulose nanofibrils (CNF) made by ice-templating exhibit very low radial – perpendicular to the fibrils – thermal conductivity[2,3], which suggests that CNM-based foams could reduce both the carbon footprint and the energy consumption in buildings.
Cellulose is a hygroscopic material, and it is thus essential to understand how the heat transfer mechanisms are influenced by water uptake and the relative humidity in air. We have investigated how the thermal conductivity of anisotropic CNM-based foams depends on moisture uptake and temperature, together with the diameter and degree of alignment of the fibrils, and the density and nanoporosity of the foams. Combining molecular simulations, thermal conductivity measurements, and moisture uptake experiments we have identified the importance of swelling in reducing the radial thermal conductivity. Tuning the surface properties of cellulose nanomaterials or increasing their degree of crystallinity and temperature has a significant effect on the moisture uptake which plays important role in governing the heat transfer within CNM foams at humid conditions. Furthermore, here we show potential routes to achieve very low thermal conductivity by tuning the gaseous and solid conduction contributions. Apart from the degree of the alignment and the sizes of pores, the CNM entanglement and the plethora of solid/solid and solid/air interfaces are crucial parameters to consider. To this end, enhancing the diffuse phonon scattering by tuning the length and number of interfaces seems to be the most efficient way to reduce the thermal conductivity below the superinsulating level in highly porous (>95%) CNM foams.

Dual Crystal- and Glass-Like Heat Transport in Silicon Thin-Films with Nanscale Surface Substructures
Sanghamitra Neogi; University of Colorado Boulder, United States

Resonance hybridization (RH) can be described as the coupling between wavenumber-independent vibrons in a substructure and wavenumber-dependent modes (phonons) of the host medium. This mechanism showed remarkable consequences for thermoelectric applications such as the ~40-fold reduction of thermal conductivity (TC) of silicon (Si) membranes due to resonances induced by native oxide at membrane surfaces [1]. In particular, nanopillar resonators on silicon thin-films have been illustrated to exhibit unique subwavelength phonon properties at the nanoscale, resulting in strong TC reduction. Our recent study reported the first remarkable observation that the RH mechanism can enforce directional mode propagation, and therefore anisotropic TC at room temperature, in otherwise isotropic single-crystal thin films of materials with isotropic bond symmetries (e.g. cubic or hexagonal. In Si membranes with surface nanofins, TC is ~100% greater in the direction parallel to the fins than in the perpendicular direction [2]. Anisotropic in-plane TC has been observed or predicted in 2D and 3D materials due to direction-dependent bonding environments and anisotropic pore spacing, and in two to four monolayer thick silicene due to surface reconstruction, the effect decreasing with thickness. However, anisotropic in-plane TC in the Si membranes beneath nanofins is remarkable as it is the first time such an effect has been observed in isotropic semiconductors at room temperature. This method of inducing anisotropy is particularly valuable, since modern fabrication techniques allow for more precise control over the addition of surface resonators than embedding Bragg scattering mechanisms within the material. This study further suggested that hybridized modes within the base material of such structures, deemed nanophononic metamaterials (NPMs), may not retain their full crystalline character. In fact, RH potentially induces ``glass-like" phonon transport, rendering the host membrane or film a disordered "phonon-glass" for low frequency modes. Heat conduction mechanisms in crystals and glasses are fundamentally different. The

structural periodicity of crystals allows propagating phonons (propagons) to become excited and carry heat. In glasses, a lack of periodicity breaks the quasi-particle nature of heat carriers so that heat is transported mainly by the coupling of vibrational modes (diffusons) as described by the Allen and Feldman (AF) model. In NPMs, some hybridized modes retain a propagating character while others become localized with ~0 group velocity and display glassy heat transport behavior. The presence of both types of modes within `simple' crystalline materials has not been adequately probed, and therefore further research is essential to describe the phenomenon. In this work, we use a combination of classical molecular dynamics, harmonic and anharmonic lattice dyanmics and the newly proposed lattice dynamics based quasi-harmonic Green-Kubo approach to provide a complete microscopic description of the transport processes of the hybridized modes. We aim to establish the extent to which established phonon physics models remain valid for these systems.

Nanoscale Thermal Transport in PVDF-Al Nanocomposites Ramya Mohan[1], Dylan Kline[2,1], Victor Ortiz[1], Michael Zachariah[2,1] and Richard B. Wilson[1,1]; [1]University of California, Riverside, United States; [2]University of Maryland, United States

Fluorine-rich polymers incorporated with aluminum particles are of interest to the energetics community due to their enhanced flame propagation characteristics. Recent investigations have shown that PVDF-Al demonstrates better ignition and sustained combustion when compared to similar fluoropolymer-metal composites such as Viton-Al and THV-Al [1]. Enhanced thermal conduction in PVDF-Al nanocomposites due to the Al nanoparticles is speculated to contribute to their superior energetic properties. My talk will focus on nanoscale thermal transport in PVDF-Al films and their influence on flame propagation. Using time-domain thermo-reflectance (TDTR), I present high resolution 2-dimensional thermal conductivity maps of thin PVDF-Al films. The PVDF-Al composite samples have varying volume fractions of Al. The TDTR maps provide spatially correlated thermal conductivity and heat capacity measurements across the polymer, metal particles, and heterogenous metal-polymer interfaces. I also report the results of TDTR measurements as a function of heating frequency. Heating frequency dependent measurements allow us to study how homogenous the transport properties of the composites are as a function of thermal penetration depth. My investigation provides important insights into the nanoscale thermal transport in Al/PVDF nanocomposite systems, which could be used to predict their flame propagation and combustion characteristics.

High Temperature Formalism of Phonon Transport Keivan Esfarjani; University of Virginia, United States

In this talk we report on recent progress in modeling phonon transport in bulk and across interfaces at high temperatures beyond the harmonic approximation. In bulk crystalline materials the self-consistent phonon theory has been extended within a variational formalism to include thermal strain and phase transitions. The anharmonic hamiltonian parameters of the high-symmetry phase are first extracted from a set of total-energy

and force calculations (from first-principles DFT calculations) in a supercell. Then a variational free energy is constructed which when minimized, produces the equilibrium structure and its lattice dynamical properties at any temperature, beyond the quasi harmonic approximation.
As for the interfacial thermal conductance, within the Landauer formalism, an expression is derived for the non-equilibrium thermal current of the anharmonic system based on the Green's function formalism. This non-perturbative expression is made to satisfy the detailed balance and current conservation constraints. Examples illustrating both methodologies will be shown.

Effect of Four-Phonon Scattering on the Phonon Lineshapes in Weakly-Bonded Solids from First Principles Navaneetha Krishnan Ravichandran; Indian Institute of Science, India

Recently, it has been shown computationally and experimentally that the inclusion of higher-order scattering among four phonons is crucial to accurately represent the phonon thermal conductivities of several strongly-bonded materials like boron arsenide and indium phosphide [1-3], as well as weakly-bonded solids like sodium chloride (NaCl) [4]. Here we show, from rigorous first-principles calculations, that four phonon scattering also critically affects the phonon lineshapes of NaCl and other weakly-bonded solids typically observed in inelastic neutron/x-ray scattering and Raman scattering experiments. These calculations are performed by building on the unified first-principles framework [4], which already includes the effects of the lowest-order three-phonon and higher-order four-phonon scattering processes on the thermal conductivity of materials, a many-body self-consistent anharmonic phonon renormalization step to address the possible ill-defined nature of certain phonon quasiparticles in weakly-bonded solids, and the determination of the stable lattice constants at finite temperatures, by explicitly evaluating and minimizing the fourth-order accurate free energy of the crystal. By performing these calculations over a broad range of temperatures, we show that the four-phonon scattering processes significantly broaden the phonon lineshapes compared to their three-phonon counterparts - particularly at high temperatures, and their inclusion into the calculations are pivotal to explain the experimental data.

This work has been supported by a start-up fund from the Indian Institute of Science, Bangalore, India.

Uncertainty Quantification in First-Principles Predictions of Phonon Properties and Lattice Thermal Conductivity Holden Parks, Hyun Kim, Venkatasubramanian Viswanathan and Alan McGaughey; Carnegie Mellon University, United States

Density functional theory (DFT) is an ab-initio method that has been successfully used to predict the phonon dispersion and thermal conductivity of a variety of insulating and semiconducting materials. DFT-based calculations are attractive because, unlike calculations based on empirical potentials, they are free from fitting parameters. A DFT calculation is made computationally tractable by describing the complicated exchange-correlation (XC) electron interactions with an effective potential, called an XC functional. There is no a priori method of choosing an XC functional for a given material, so that choosing any single XC functional introduces uncertainty in any quantity derived from that calculation.

We present a framework for quantifying the uncertainty that results from the choice of XC functional in predictions of phonon properties and thermal conductivity that use DFT to calculate the atomic force constants. The framework uses the energy ensemble capabilities of the BEEF-vdW XC functional to predict ensembles of interatomic force constants, which are then used as inputs to lattice dynamics calculations and a solution of the

Boltzmann transport equation. We apply the framework to isotopically-pure silicon and find that the ensembles bound property predictions (e.g., phonon dispersion, specific heat, thermal conductivity) from other XC functionals and experiments. We distinguish between properties in silicon that are correlated with the predicted thermal conductivity [e.g., the transverse acoustic branch sound speed (Pearson correlation coefficient, R2, of 0.89) and average Gruneisen parameter (R2 = 0.85)] and those that are not [e.g., longitudinal acoustic branch soundspeed (R2 = 0.23) and specific heat (R2 = 0.00)]. We find that differences in ensemble predictions of thermal conductivity are correlated with the behavior of transverse acoustic phonons with mean free paths between 100 and 300 nm. This framework systematically accounts for XC uncertainty in phonon calculations and should be used whenever it is suspected that the choice of XC functional is influencing physical interpretations.

Monte Carlo and DFT Calculations Coupling; Application to Heat Transfer in Nanostructures David Lacroix and Laurent Chaput; Université de Lorraine, France

Models and tools devoted to the theoretical modeling of heat transport in new materials and nanostructures are of very different natures. Strong interest for DFT based methods has raised to compute thermal properties of bulk material from scratch, just knowing the atom organization in a supercell. In this field, tools such as those provided by the Phonopy [1] environment developed by A. Togo have paved the way to the discovery of new compounds with optimal thermal properties. The main strength of such an approach is its intrinsic reliability that usually matches very well with the available experimental data [2]. Yet, such an approach also has drawbacks, the most prominent is related to computing resources needed to carry out calculations. In addition, this approach basically addresses bulk materials. Dealing directly with nanostructures is currently impossible with such methods, as they remain too large for the actual computing facilities and probably even for the next generation ones. Nevertheless, we can circumvent this limitation by the coupling of ab-initio outputs with mesoscale modelling tools such as Monte Carlo solution of the Boltzmann transport equation (BTE) for phonons. For the latter technique, MC simulation of BTE is often limited by the knowledge of phonon dispersion properties and lifetimes of any kind of material.
However, what is a weakness for one method is a force for the other. Thus, coupling both techniques make sense and should allow to overcome intrinsic limitations of DFT and MC approaches. Within the group, but also in collaboration with the “Centre de Nanosciences et Nanotechnologies” (Université Paris-Saclay), we work on this coupling. As a first challenge, we investigate how to combine full band modelling approach in K-space, given by DFT calculations. Furthermore, for MC model the scattering term of the BTE was treated in the frame of the relaxation time approximation, considering the Matthiessen rule and statistics on phonon populations to define relevant lifetimes. Considering DFT coupling, a direct access to the mode lifetime with respect to the K-grid discretization is now possible.
On this basis, we have modified our existing MC tool for phonon transport in order to take into account full band phonon properties and lifetimes given by the DFT calculations. Among the main improvements of this new ab-inito/MC model, there is the resolution of BTE along characteristic lines. With this method there is a rigorous balance between energy and momentum as we follow each phonon bundle sampled on the K-grid. This new technique is much more rigorous as this is no longer necessary to compute scattering probability of phonon to restore equilibrium. Results concerning those calculations have been recently published in Applied Physics Letters [3], demonstrating the ability of the method to handle phonon lifetimes extracted from DFT calculations. In addition, for the first time, we extend the methodology to the coupling of phonon-phonon and electron-phonon interactions in doped Si, Ge and C compounds using DFT simulations that provide the relevant lifetimes. Application to such coupling are numerous, especially for materials where electron transport can hindered/increase heat transfer.

Phonons and Thermal Transport Near Lattice Instabilities—From Soft-Mode Transitions to Phonon Breakdown in Superionics Olivier Delaire; Duke University, United States

Using detailed measurements of inelastic scattering of neutrons and x-rays, complemented with first-principles simulations of atomic dynamics, we investigate strongly anharmonic effects on phonons near or across phase transitions, and their impact on thermal transport. This presentation will focus on transitions ranging from soft-mode condensation to sublattice melting in the case of superionic compounds. In particular, we will highlight systems undergoing ferroelectric transitions or related Jahn-Teller distortions (e.g. SnS and SnSe across their high-temperature structural transition [1]), which strongly renormalize group velocities and scattering phase-space, as well as “phonon-liquid electron-crystal” systems, in which selective phonon modes collapse to relaxational dynamics, as in Cu or Ag-based superionics [2,3].

Local Study of the Evaporation Mass Flux in a Thin Liquid Film Using Thermoreflectance Experiments and Numerical Methods Xiaoman Wang, S. Arman Ghaffarizadeh, Alan McGaughey and Jonathan Malen; Carnegie Mellon University, United States

Thin film evaporation is important in the design of heat pipes, desalination, lubrication, air conditioning, and medical devices. Existing theories suggest that with smaller film thickness, the local evaporation mass flux will increase due in part to an increased interfacial temperature that results from lower conduction resistance in the liquid. However, this mass flux will sharply decrease to zero as the film gets even thinner due to the increased interface forces that inhibit the escape of interfacial vapor molecules.
In this project, we present the first experimental effort to locally measure the evaporation mass flux in a liquid meniscus. The microscale lateral extent of the meniscus and sub-Kelvin liquid-vapor temperature differences (superheats) challenge conventional thermometry. Here, Frequency domain thermoreflectance (FDTR), a non-contact laser-based method with a lateral resolution of micrometers, is used. A non-monotonic experimental signal change is observed as a function of position in the thin film portion of the meniscus, where a high evaporation heat flux is expected. This experimental technique has been hitherto widely employed with micron-scale lateral resolution in thin solid films, but not when evaporation is present. To extract the evaporation heat transfer coefficient in the meniscus region from the obtained signal, we modify the analytical solution to the heat diffusion equation to account for the phase change. This modification provides a new paradigm for investigating heat flux discontinuity in thermal models. Furthermore, to account for the thickness variation in the meniscus we also analyze the data using a finite element simulation performed with ANSYS. The ANSYS simulations are first validated against the modified FDTR equation for uniform liquid thicknesses. The ANSYS model is also able to capture account for the variation in evaporative heat transfer coefficient that occurs within the region interrogated by the 3 μm laser spot. A machine learning framework that uses neural networks is then used to find the optimal combination of meniscus thickness and evaporative heat transfer coefficient distribution to match the ANSYS model to the experimental data.

Near-Field Thermophotovoltaic Conversion with High Electrical Power Density and Efficiency Above 14% Christophe Lucchesi[1], Dilek Cakiroglu[2], Jean-Philippe Perez[2], Thierry Taliercio[2], Eric Tournié[2], Pierre-Olivier Chapuis[1] and Rodolphe Vaillon[2]; [1]CNRS-CETHIL, France; [2]IES Montpellier, France

A thermophotovoltaic (TPV) device converts infrared radiation from hot sources into electrical power via a specifically designed photovoltaic cell. In order to increase the generated electrical power, the cell can be coupled with an infrared emitter brought in its near field (< 4 µm at 700 K), where the emitter-cell radiative heat exchange can be enhanced by several orders of magnitude. This enhancement is well described theoretically but near-field TPV devices have been demonstrated experimentally only recently [1-3], unfortunately with very low electrical output power densities (<10 $W.m^{-2}$) and conversion efficiencies (<1 %).
In this work, we first characterize experimentally fully-functional InSb TPV cells [4] that operate below room temperature (77 K). Indium antimonide (InSb) is an attractive material for TPV cells since its very low energy band gap (~5 µm at 77 K) matches well the blackbody spectrum of infrared emitters. We then demonstrate strong electrical power photogeneration by placing a graphite spherical emitter in the near field of the InSb TPV cells. In order to maximize the electrical power, large temperature differences are investigated: the emitter can be heated up to temperatures higher than 1000 °C. Impacts of emitter material and cell design on the near-field radiative heat transfer and near-field TPV conversion are investigated as a function of emitter-cell distance down to a few tens of nanometers. We measure a 7-fold enhancement of the generated electrical power when bringing the emitter in the near field, leading to an electrical power as high as 7500 $W.m^{-2}$, three orders of magnitude higher than previous works [1-3], and near-field conversion efficiency larger than 14 % [5].

5:30 PM NM08.14.03
Late News: Thermal Transport Across Nanoscale Gaps and Across Single-Molecule Junctions Merabia Samy[1], Ali Alkurdi[2], Christophe Adessi[1], Fatemeh Tabatabaei[1], Manuel Cobian[3], Konstantinos Termentzidis[2], Pierre-Olivier Chapuis[2] and Thomas Niehaus[1]; [1]Universite de Lyon, CNRS, UCBL, ILM, UMR5306, France; [2]Institut National des Sciences Appliquées, France; [3]Ecole Centrale de Lyon, France

Heat transfer in the extreme near field has shown recently an increased interest driven by the development of scanning probe techniques allowing to measure thermal transport across a nanoscale gap and across single molecule junctions. On the one hand, recent experimental studies reported giant heat flux transfer between gold surfaces separated by nanometer distances [1]. These results showed discrepancies with the conventional theory which are attributed to phonon tunneling neglected.in the standard picture. On the other hand, the thermal conductance of single molecule junctions has been recently determined experimentally [2,3] opening the door to confirm the high thermoelectric efficiency displayed by these junctions. All these experiments call for models capable of describing accurately phonon tunneling and phonon thermal transport across molecules.

In this contribution, we model heat transfer across nanometer gaps and across single-molecule junctions using a combination of molecular dynamics and ab-initio simulations. First; we demonstrate, using a combination of ab-

initio lattice dynamics [4] and molecular dynamics simulations, that phonons dominate heat transport at nanometer distances, even in the presence of molecules in the gap [5]. This conclusion is shown to hold for nanogaps separating different types of materials. The computed thermal conductance turn out to be several orders of magnitude higher than the predictions of acoustic continuous models. We show that these discrepancies originate from the contribution of intermediate phonon frequencies which are not accurately described by acoustic models. Moreover, we highlight the leading role played by phonon scattering as compared with electron tunneling and electron/phonon processes at interfaces [6].
The second issue to be be discussed concerns thermal transfer across molecular junctions [7]. We consider junctions made of OPE3 derivatives, as these molecules are commonly synthesized by experimentalists and already extensively studied for electronic transport.
The phonon thermal conductance of the corresponding gold-molecule-gold junctions are computed here using a combination of molecular dynamics and ab-initio calculations. In particular, we parametrize the interaction between the gold surface and the OPE3 derivative using an ab-initio adiabatic connection scheme [8]. For Au-OPE3-Au junctions, the computed thermal conductance obtained is in good agreement with the experimental value [3]. Next, we characterize the phonon thermal conductance of cross-linked molecules junctions, as a function of their length and the nature of the cross-linker. In particular, we show that constrained cross-linked molecules display relatively low thermal conductance, which makes them promising for thermoelectric applications. These low conductance levels are interpreted based on phonon transmission calculations.

Energy Transfer and Conversion in Nanoscale Gaps Pramod Sangi Reddy; University of Michigan–Ann Arbor, United States

Understanding radiative heat transfer in nanoscale gaps and devices is of considerable interest for creating novel energy conversion devices. In this talk, I will first describe ongoing efforts in our group to experimentally elucidate nanoscale radiative heat transfer. Specifically, I will present our recent experimental work where we have addressed the following questions: Can existing theories accurately describe radiative heat transfer in single nanometer sized gaps? Can radiative thermal conductances that are orders of magnitude larger than those between blackbodies be achieved? In order to address these questions we have developed a variety of instrumentation including novel nanopositioning platforms and microdevices, which will also be described. Further, I will discuss possible applications of near-field thermal radiation for energy conversion and photonic cooling. Finally, I will briefly outline how these technical advances can be leveraged for future investigations of nanoscale heat transport and near-field thermophotovoltaic energy conversion.

Thermophotovoltaic (TPV) systems are based on solid-state energy conversion technique and involve a hot emitter to radiate photons that excite electron hole pairs in a photovoltaic (PV) cell. Recent TPV studies in the far-field demonstrated impressively high efficiencies, but at low power densities. Several theoretical proposals have shown that dramatic enhancement in power density can be achieved by reducing the gap to tens of nanometers. However, such demonstrations have been elusive due to the challenge of maintaining such nano-separations between a hot emitter (~1000 K) and a cold cell (~300 K). Here, we will describe how high resolution calorimetry and a custom-built nano-positioning platform have made possible the first demonstration of ~40-fold increase in the power output, compared to far field, when the gap between the PV cell and thermal emitter at 650 K is reduced from ~10 μm to 60 nm. Further, we will discuss our recent work aimed at achieving larger power densities and efficiencies by developing thermal emitters that can operate at high temperatures (~1300 K) that may lead to power densities exceeding 1 W/cm^2.

6:25 PM NM08.14.06
Late News: Near-Filed Heat Transfer in High-Tc Superconductors. Bulk and Thin Films Raul Esquivel-Sirvent, Giuseppe Pirruccio, Shunashi Castillo-López and Carlos Villarreal; Universidad Nacional Autonoma de Mexico, Mexico

We investigate the near field radiative heat transfer between two slabs made of high temperature superconductors, namely, YBCO. We find a three orders of magnitude decrease in the total heat flux when the temperature of at least one of the slabs is below the critical temperature. We interpret this suppression as a consequence of the detailed balance of the charge carrier density: the increased density of the condensed electron pairs is accompanied by the simultaneous decrease of the density of the unpaired electrons. This effectively increases the conductivity of the superconductor by suddenly suppressing the electron damping mechanisms. Consequently, we observe a reduction of the contribution of the p-polarized waves compared to the s-polarized ones to the spectral heat flux.
The difference between using free-standing films and bulk meda is also discussed. Thin-films allow for more modes that modify the radiative heat transfer making it larger than the case of bulk-materials.

Atomistic to Continuum Modeling of Two-Phase Cooling Processes Anirban Chandra[1], Assad Oberai[2], Zhi Liang[3] and Pawel Keblinski[1]; [1]Rensselaer Polytechnic Institute, United States; [2]University of Southern California, United States; [3]California State University, Fresno, United States

Two-phase cooling is one of the most powerful approaches for removal of large amounts of thermal energy, which is required in a number of applications ranging from high power electronics to nuclear reactor safety. The analysis of the two-phase cooling processes is typically based on continuum modeling of heat and mass transport equations. While the constitutive laws for these transport processes in the bulk are well established, the quantitative, physics-based description of the transport processes at the liquid-vapor interface is still a challenge. A typical assumption here is that the interface is in a local thermal equilibrium. While such assumption might be appropriate for modeling systems with large feature sizes, is might lead to inaccurate predictions for micro/nanoscale systems, particularly for highly driven systems.

In our presentation I will describe an approach that enables high fidelity, predictive modeling of the two-phase flow systems based a continuum modeling framework informed via physics-based and molecular dynamics simulations verified “interfacial constitutive laws”. These interfacial laws provide quantitatively the rate of phase change in terms of local thermodynamic variables, such as temperature and pressure, and allow for non-equilibrium vapor pressure and temperature discontinuity at the interface. We demonstrated the fidelity of this approach in the case of planar heat pipe geometry, even in the limit of nanoscale systems and highly transient heating processes. We will discuss avenues and challenges for the development of this approach for more complex systems and processes.

9:25 PM *NM08.15.02
Heat Transfer Across van-der-Waals Interfaces and Au/thiol Heterojunctions Through Remote Coupling of Charge Carriers and Polar Vibration Modes Yee Kan Koh; National University of Singapore, Singapore

Most previous studies of interfacial heat transport focus on transmission of vibration modes across the interfaces. It is generally believed that heat is predominantly carried by vibration modes, even for metal/dielectric interfaces in which electrons in metals could be coupled remotely to the polar vibration modes in dielectrics due to the long-range nature of Coulomb force. In this talk, we will discuss our recent attempts to experimentally measure the interfacial heat transfer due to this remote coupling. In the first work, we measured the heat transport across van-der-Waals graphene interfaces, due to remote coupling of induced charge couriers in graphene and polar phonons in oxide substrate, by a newly developed technique called voltage-modulated thermoreflectance (VMTR). We find that the thermal conductance of SiO_2/graphene/SiO_2 interfaces increases by up to ≈1.5 MW m^{-2} K^{-1} under electrostatic fields of <0.2 V nm^{-1}, and hence establish an upper limit for direct heat transfer from graphene to SiO_2 substrates via remote interfacial phonon (RIP) scattering. In the second work, we integrate two pump-probe techniques, the picosecond transient absorption and time-resolved Raman spectroscopy, to concurrently monitor heating and cooling of gold nanorods and bonds in the conjugated ligands, with a sub-picosecond time resolution and an atomic spatial resolution. We find that bonds in the conjugated ligands are heated almost instantaneously and reach a peak temperature within ~1 ps after the nanorods were heated by the laser pulse. We attribute this fast heating to direct heating of bond by the non-equilibrium electrons in gold nanorods, due to the remote coupling across the Au-thiol heterojunction. Our analysis suggests that the remote coupling could contribute substantially to heat transport across Au-thiol heterojunctions. Our work could provide a new pathway to enhance and control heat transport across interfaces and heterojunctions, through remote coupling of charge carriers and polar vibration modes.

9:50 PM NM08.15.04
Thermal Conductance of Nitride/Diamond Interfaces Samreen Khan and Richard B. Wilson; University of California, Riverside, United States

The interface conductance between two strongly bonded materials is determined by the vibrational stiffness of the constituent materials. In theory, because diamond is very vibrationally stiff, interfaces between diamond and other materials should have a high interface conductance. In practice however, the interface conductance values observed in diamond systems are small. Observed conductance values in diamond systems range from 30-60 MW/m^2-K for Pb and Au on diamond to ≈ 150 MW/m^2-K for Al or Pt on diamond [1]. Low thermal boundary conductance in diamond systems is an obstacle to efforts to improve thermal performance in nitride electronic devices by using diamond substrates. In this work, we report time-domain thermoreflectance (TDTR) measurements of the interface conductance between nitride metals and diamond. Nitride metals are amongst the most acoustically stiff metals and are therefore good candidates for investigating the upper limits to the conductance of metal/diamond interfaces. We find TiN/diamond has a large interface conductance of ≈ 400 MW/m^2-K, much larger than typical in diamond systems.

10:05 PM NM08.15.05
Modeling of Phonon Transport Across Defected and Atomically Precise Interfaces Zexi Lu, Anne Chaka, Nathaniel P. Smith and Raymond Bunker; Pacific Northwest National Laboratory, United States

Phonons play important roles in quantum information science (QIS) devices through heat dissipation and transduction of signals. To better engineer such devices, it is critical to understand the phonon transport mechanism, especially how they interact with the interfaces. While defects, including vacancies, impurities, oxidations etc., naturally appear in all materials and their interfaces, recent developments in techniques such as molecular beam epitaxy also make possible the formation of atomically perfect interfaces between metals and semiconductors. Therefore, considering interfaces from both perspectives is necessary towards a deeper understanding of phonon transport in realistic devices. However, so far the detailed phonon scattering mechanism at such interfaces is not well understood.

In this study, we applied two complementary classical molecular dynamics (MD) techniques to elucidate an understanding of interfacial phonon transport mechanisms: 1) non-equilibrium MD to identify the overall transport mechanism of the entire phonon spectrum, and 2) wave packet formalism to reveal the individual scattering behavior of a single phonon at an interface. With NEMD we identified the effects of atomic vacancies at a Cu(100)/Si(100) interface, finding that interfacial phonon conductance can be increased by up to 76% with just a 3% concentration of vacancies. Further analysis based on phonon normal modes and density of states showed that the increase is primarily due to high-frequency phonons through enhanced inelastic scattering. On the other end, we revealed how individual phonons interact with atomically perfect Si(111)/Al(111) interfaces using wave packet simulations, considering 1×1, sqrt(3)×sqrt(3) and 7×7 Si surface reconstructions. It was found that interfacial scatterings differ depending on the interfacial bonding, phonon mode and frequency. Our study provides insights on manipulating interfacial phonon transport through defect and atomically precise engineering, and interpreting measurements involving phonon signals in QIS.

10:20 PM NM08.15.06
Anisotropic Transient Disordering of Colloidal, Two-Dimensional CdSe Nanoplatelets Following High-Fluence Photoexcitation Alexandra Brumberg[1], Matthew Kirschner[1], Benjamin Diroll[2], Xiaoyi Zhang[2] and Richard Schaller[2,1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Colloidal, two-dimensional nanocrystals (NCs) known as nanoplatelets (NPLs) exhibit many advantages over more traditional spherical NCs while maintaining the benefits of colloidal processability and bandgap tunability. Namely, the lack of size dispersion in the single quantum-confined dimension bestows NPLs with exceptionally narrow emission linewidths that bolster their use in optoelectronic applications such as light-emitting diodes and lasers. However, these applications operate under high-fluence conditions that raise a fundamental concern regarding NC stability and the effect of such excitation conditions on desired properties such as optical bandgap. NPLs in particular may exhibit reduced thermodynamic stability even beyond that of other NCs, owing to the presence of high surface energy corners and edges. While some movement toward understanding impacts of heat on electronic properties of NCs is underway, the influence of NC morphology, and especially dimensionality, to the material stability remain largely unexplored.

To this end, here we employ time-resolved x-ray diffraction at the Advanced Photon Source to study the effect of heating on anisotropic NCs. NPLs are excited using a picosecond pulsed laser and then probed using synchrotron x-rays, which reveals both thermal expansion and transient disordering following photoexcitation. Photoexcitation induces greater out-of-plane than in-plane disordering, with thicker NPLs producing more anisotropic responses. Recovery dynamics suggest that out-of-plane cooling slightly outpaces in-plane cooling, with recrystallization occurring on indistinguishable time scales. This response to high-fluence excitation differs significantly from the response of spherical NCs, which both respond and recover isotropically to photoexcitation and recover on faster timescales. These findings offer significant implications for optoelectronic devices, where the ability to operate at high excitation densities without loss of efficiency is advantageous. Our results suggest that both the composition and structure of the NC must be taken into account when considering

crystal lattice stability and optical performance, and that NPLs are likely to exhibit superior performance over traditional, zero-dimensional nanocrystals.

SESSION NM08.16: On-demand
Wednesday Morning, April 14, 2021
NM08

8:00 AM NM08.15.03
Late News: Grain-Boundary Thermal Resistance—An Important Factor in Thermal Conductivity Reduction Observed in Micro-Grained Bismuth Telluride Sien Wang[1], Xiaowei Lu[2], Ankit Negi[3], Jixiong He[3], Kyunghoon Kim[3], Hezhu Shao[4], Peng Jiang[2], Jun Liu[3] and Qing Hao[1]; [1]University of Arizona, United States; [2]Dalian Institute of Chemical Physics, Chinese Academy of Sciences, China; [3]North Carolina State University, United States; [4]Wenzhou University, China

As the dominant thermoelectric material around the room temperature, Bi_2Te_3-based alloys have been intensively studied for its applications in power generation and refrigeration. Nanograined bulk Bi_2Te_3 can be synthesized by grinding down bulk Bi_2Te_3 or mixed element ingot into nanopowder and then hot pressing the nanopowder into a bulk disc. The obtained nanostructured bulk material has even better thermoelectric performance due to the largely suppressed lattice thermal conductivity by high-density grain boundaries (GBs) inside the material. In kinetic theory, lattice thermal conductivity reduction is attributed to the effective phonon mean free path (MFP) reduced from the bulk value due to the restriction of grain sizes. In this aspect, atomistic simulations suggest bulk phonon MFPs in Bi_2Te_3 are below 100 nm along major axis directions. Therefore, a reduced effective phonon MFP cannot explain the lattice thermal conductivity reduction observed in micro-grained Bi_2Te_3. To better understand thermal transportation in crystalline Bi_2Te_3, high-quality single crystals for accurate thermal measurements and modeling is needed.
In this work, high-quality Bi_2Te_3 nanoflakes are synthesized using chemical vapor deposition on a SiO_2/Si substrate. Thickness-dependent thermal conductivity has been measured along the cross-plane direction using the time-domain thermoreflectance (TDTR) method at room temperature. The film thickness ranges from 20 nm to 300 nm, as confirmed using the atomic force microscopy.
To explain the experimental data, first-principles calculations are carried out to extract both in-plane and cross-plane phonon MFP distributions for bulk Bi_2Te_3. Calculations based on the computed cross-plane phonon MFPs and measurement data agree well with each other.
These validated bulk phonon MFPs are then used to explain the reported lattice thermal conductivities of various polycrystalline Bi_2Te_3 and its alloys. It is found that the observed lattice thermal conductivity reduction is mainly attributed to the GB thermal resistance that results from the GB reflection and transmission of phonons. Particularly, optical phonons are largely filtered out by GBs to explain the data for micro-grained samples. This result could provide important guidance for thermal studies of general polycrystalline materials.

8:00 AM *
Nanogenerators and Piezotronics—History and Fundamental Principles Zhong Lin Wang; Georgia Institute of Technology, United States

Prof. Wang will first introduce the fundamental science, engineering approach and technological applications of nanogenerator as a sustainable, self-sufficient power source for micro-/nanosystems by harvesting energy from our body and living environment. Prof. Wang will then introduce the fundamentals of piezotronics and piezo-phototronics and to give an updated progress about their applications in energy science, electronics and sensors.

9:00 AM BREAK

9:15 AM *
Piezotronics and Piezo-Phototronics—From Fundamental Science to Applications Caofeng Pan; Chinese Academy of Sciences, China

Piezotronics concerns the devices fabricated using the piezopotential as a “gate” voltage to tube/control charge carrier transport at a contact or junction. The piezo-phototronic effect is to use the piezopotential to control the carrier generation, separation, transport, and/or recombination for improving the performance of optoelectronic devices, such as photon detector, solar cell, and LED. In this tutorial, Prof. Pan will first give an in-depth introduction of the mechanisms and applications of nanowire-based piezotronics and piezo-phototronics

10:15 AM BREAK

10:30 AM *
Theory of Piezotronics Yan Zhang; University of Electronic Science and Technology of China, China

Prof. Zhang will introduce fundamental piezotronic theory established, piezotronic p-n junction and metal-semiconductor contact models. The class of materials includes wurtzite and two-dimentional piezoelectric semiconductors, such as ZnO, GaN, InN, CdS and monolayer MoS2.

11:30 AM BREAK

11:45 AM *
Modeling and Conditioning Triboelectric Nanogenerators Philippe Basset; ESIEE Paris, France

For TENG, a power management circuit is needed to generate a low DC voltage for the load, while implementing a high voltage interface at the transducer's side, so to maximize the converted power. Prof. Basset will present an overview of the main architectures for power management systems proposed to date for triboelectric nanogenerators, and the various circuits will be compared based on electrical simulations.

Tutorial NM09: Nanogenerators and Piezotronics—Fundamentals and Applications II
Session Chairs: Sang-Woo Kim, Yong Qin, Sihong Wang and Yunlong Zi
Saturday Afternoon, April 17, 2021
NM09

5:00 PM *
Human-Compatible Designs of Nanogenerators for Harvesting Energy from Human Bodies Sihong Wang; University of Chicago, United States

Prof. Sihong Wang will first introduce the overall needs and technological challenges for harvesting mechanical energy from human bodies, towards realizing sustainable power sources for human-integrated electronics. Then Prof. Wang will introduce the major approaches in material and device designs for achieving both high power output and multi-aspect biocompatibility, based on the requirements from different body locations.

6:00 PM BREAK

6:15 PM *
Standardized Evaluation of Nanogenerators Yunlong Zi; Chinese University of Hong Kong, Hong Kong

Prof. Zi will systematically introduce the evaluation standards and standardized evaluation methods for nanogenerators. Starting from cycles of maximized energy output, the figures-of-merit will be proposed. And then, considering the breakdown effect, the maximized energy output should be modified by reducing the breakdown areas. Finally the experimental characterization methods will be introduced and the output energy density will be introduced and compared between different nanogenerators.

7:15 PM BREAK

7:30 PM *
Triboelectric Nanogenerator as a New Platform for Energy Harvesting and Wireless Energy Transfer Technologies Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

As main topics, Prof. Kim will introduce recent global achievements regarding highly robust and efficient TENGs with multifunctional materials, which provides new insights to an innovative energy solution for various wearable electronics, IoT sensors, bio/healthcare applications. In addition, he will share with audiences about a new wireless energy transfer technology based on ultrasound-driven TENG in a body.

8:30 PM BREAK

8:45 PM *
Flexotronics in Centrosymmetric Semiconductors Yong Qin; Lanzhou University, China

Prof. Yong Qin will first elaborate on the fundamental science of flexotronic effect in centrosymmetric semiconductors, which serve as the basis for understanding and utilizing the interfacial polarization engineering in the new area of flexotronics. Then he will provide an overview of the development of flexotronics, and

discuss the relationship between the piezotronics and the flexotronics. Finally, he gave a perspective about their further development and potential applications in emerging fields of enhanced solar technology, active electronics/optoelectronics, hybrid-spintronics etc.

8:00 AM *NM09.01.01
The Physics of Contact-Electrification and the Theory of Triboelectric Nanogenerators Zhong Lin Wang[1,2] and Aurelia Chi Wang[2]; [1]Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, China; [2]Georgia Institute of Technology, United States

Contact electrification (CE) (or usually called "triboelectrification") effect, the most fundamental effect for electricity, has been known for over 2600 years since ancient Greek time, but its scientific mechanism remains unclear. The study of triboelectrification is recently revived due to the invention of the triboelectric nanogenerators (TENGs) by using the coupling of triboelectrification and electrostatic induction effects. In this talk, we first present the physics mechanism of triboelectrification for general materials. Our model is extended to liquid-solid contact electrification, reviving the classical understanding about the formation of electric double layers. Secondly, the fundamental theory of the TENGs is explored based on a group of reformulated Maxwell equations. In the Maxwell's displacement current proposed in 1861, the term $\boldsymbol{dE/dt}$ gives the birth of electromagnetic wave, which is the foundation of wireless communication, radar and later the information technology. Our study indicates that, owing to the presence of surface polarization charges present on the surfaces of the dielectric media in TENG, an additional term $\boldsymbol{dP_s/dt}$ that is due to non-electric field induced polarization should be added in the Maxwell's displacement current, which is the output electric current of the TENG. Therefore, our TENGs are the applications of Maxwell's displacement current in energy and sensors.

Self-Powered Flexible Electronics Beyond Thermal Limits Keon Jae Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

This seminar introduces three recent progresses of self-powered flexible electronic systems beyond thermal limits. The first part will introduce self-powered systems for IoT sensors and flexible energy source. Flexible nanogenerator converts external bio-mechanical movement into electrical energy for self-powered IoT and biomedical devices such as pacemaker and transportation. In addition, flexible piezoelectric materials detects the minute vibration of membrane or human skin that expands the application of self-powered acoustic sensor and healthcare monitor. The second part will introduce laser material interaction for flexible applications. Laser technology of ultra-short pulse duration becomes important for future flexible electronics since high temperature process can be adopted on plastic substrates, which is essential for high performance electronics. Exciting results of flexible laser material interaction will be explored from both material and device

perspectives including nanomaterial synthesis, inorganic laser liftoff and plasmonic material reaction. The third part will discuss flexible large scale integration (f-LSI) for flexible CPU and high density memory. Flexible LSI is an essential part of future electronics for data processing, storage, and radio frequency (RF) communication. To fabricate f-LSI, we integrated 0.18 CMOS process of single crystal silicon nano-transistors with flexible electronics. Simultaneous roll transfer and interconnection of flexible NAND Flash memory was achieved using anisotropic conductive film (ACF). Finally, we introduce the highly efficient and long-term stable flexible vertical micro LED (f-VLED) for full color displays, wearable and biomedical applications. Using optogenetic mouse models, f-VLED stimulated motor neurons deep below layer III from the brain surface and induced mouse behavior changes. These f-VLED can be also used as tools of skin research and phototherapy.

Sustainable Output Power Generation Based on Triboelectric Nanogenerator Jeong Min Baik;
Sungkyunkwan University, Korea (the Republic of)

Contact electrification (CE) is a well-known phenomenon in physics, in which opposite charges are created at surfaces due to continuous contact and separation processes occurring between two materials, followed by the generation of electric potentials between them. To date, CE has been exploited in a vast range of ways to affect our lives and industry, it has been used in fields such as photocopying, laser printing, and electrostatic separation. Recently, during the COVID-19 pandemic, many kinds of face masks have included filters with electrostatic charges that were created using the CE, these masks have been employed as public and personal health measures against the spread of coronavirus. Here, we will present the strategies for the sustainable output power generation of the triboelectric nanogenerator (TENG) based on the CE in terms of materials aspect by synthesizing a new dielectric, a C_{60}-containing block polyimide (PI–*b*–C_{60}). Two non-contact mode applications, a keyless electronic door lock system and a speed sensor with a tone wheel for a car, will be demonstrated. A new facile approach to increasing the output voltage of a thermoelectric generator that does not involve material modification will be also reported.

9:00 AM *NM09.01.04
Strategies for Maximizing Output Charge Density of Triboelectric Nanogenerator Chenguo Hu;

Chongqing University, China

Triboelectric nanogenerator (TENG) is one of the most important technology to solve the problem of distributed energy supply of wireless sensor networks. However, the low charge density constrains TENG output performance and application field. Poor contact with the tribo-material interface, air breakdown effect and insufficient charge generation capability are the main factors affecting TENG charge density. In this talk, I will introduce the strategies for maximizing output charge density of triboelectric nanogenerator in our group, including the material modification, structure design and energy management, specifically, establishing criteria to quantitatively evaluate the contact status and inhibition of the interface air breakdown effect for contact/separation TENG, and the enhancement of charge generation capacity by shielding layer and device structural design of the sliding TENG.

Achieving Ultrahigh Output Energy Density of Triboelectric Nanogenerator in High-Pressure Gas Environment Jingjing Fu; The Chinese University of Hong Kong, Hong Kong

Through years of development, the triboelectric nanogenerator (TENG) has been demonstrated as a burgeoning efficient energy harvester. Plenty of efforts have been devoted to further improving the electric output performance through material/surface optimization, ion implantation or the external electric circuit. However, all these methods cannot break through the fundamental limitation brought by the inevitable electrical breakdown effect, and thus the output energy density is restricted. Here we proposed a method for enhancing the threshold output energy density of TENGs by suppressing the breakdown effects in the high-pressure gas environment. With that, the output energy density of the contact-separation mode TENG can be increased by over 25 times in 10 atm than that in the atmosphere, and that of the freestanding sliding TENG can also achieve over 5 times increase in 6 atm. Our research demonstrated the excellent suppression effect of the electric breakdown brought by the high-pressure gas environment, which may provide a practical and effective technological route to promote the output performance of TENGs.

Piezoelectric Nanotransducers—What's Next? Christian Falconi; University of Rome Tor Vergata, Italy

Nanoscale piezoelectric transducers can outperform conventional piezoelectric devices for energy harvesting (nanogenerators), sensing (e.g. piezotronics), implantable systems, wireless piezoelectric nanotransducers, and more. In fact, the properties of transducers greatly depend on dimensions due to both classic scaling laws and, at nanoscale, quantum effects. Consistently, a systematic analysis allowed to identify up to 16 possibly significant advantage of nanoscale piezoelectricity [1]. For instance, nanoscale materials can withstand larger deformations (which translate into higher piezopotentials, more robust and flexible devices and extended measurement ranges), have higher piezoelectric coefficients, offer superior mechanical force-to-displacement sensitivities and operate at higher speed. Moreover, several materials which are not piezoelectric in their bulk form due to the opposite orientations of adjacent atomic layers, are piezoelectric as single layer [1,2]. Besides, some working mechanisms are only possible at nanoscale [1,2]. Additionally, nanoscale results in more degrees of freedom for structures [3], types of mechanical input, positions of contacts, dimensionalities, and shapes [3,4]. Downscaling also uniquely offers the opportunity to fabricate piezoelectric transducers which can be used *in vivo* for a variety of tasks [5,6].
Despite such an impressive potential, practical applications can be complicated by many difficulties, with special reference to synthesis, characterization, modeling and device implementation. In this talk, also taking advantage of our last results, I will discuss some of the most important open challenges and possible strategies to address them, namely rational design of synthesis procedures [7], real time monitoring [8], dynamic synthesis procedures [8], 3D geometrical characterizations of quasi-1D single crystal nanostructures from conventional SEM images [9] and recent results for both modeling and synthesis.

High-resolution 3D Printing of Piezoelectric Structures Using Micro-CLIP Process Siying Liu, Luyang Liu, Wenbo Wang and Xiangfan Chen; Arizona State University, United States

Piezoelectric materials and composites enable a wide range of energy harvesting and sensing applications owning to their intrinsic capability of converting mechanical energy to electrical energy and vice versa. Additive manufacturing (AM), also known as 3D printing, is thriving as a category of effective and robust techniques in manufacturing three-dimensionally (3D) architected piezoelectric composites comprising of inorganic/organic piezoelectric materials, and these architected structures possess the potential of delivering

anisotropic piezoelectric responses upon specific structural designs. Nonetheless, the serial nature of the additive building processes results in the inherent speed-accuracy trade-off, which seriously limits the scalability and efficiency of manufacturing functional devices that require precise control of fine features. As a result, the reported progress in this field either limit themselves to macroscale devices due to relatively low printing resolution, e.g, fused deposition modeling (FDM), or require extensive amount of fabrication time, e.g., projection micro- stereolithography (PμSL). On the contrary, micro continuous liquid interface production (μCLIP), a recently developed 3D printing technology, has been shown to create 3D geometries at very high speeds, with good surface finish, and uniform mechanical properties.
Herein, we report rapid 3D printing of architected barium titanate (BTO) composite structures with high resolution by using mCLIP. The BTO nanoparticles were surface functionalized prior to mixing to enable stable dispersion in poly(ethylene glycol) diacrylate (PEGDA). Resins with up to 25 wt% of functionalized-BTO (f-BTO) nanoparticles were prepared and printed continuously to yield a variety of architected structures with unprecedented longitudinal printing speeds of up to ~ 25 μm/s. The architected structures were tested with a customized piezoelectric characterization setup and demonstrate effective piezoelectric constant d_{33} of 37.9 pC/N, and piezoelectric voltage constant g_{33} of 0.92 Vm N^{-1}, which is comparable to other reported work. This work not only enables the rapid 3D printing of architected piezoelectric structures with tailorable properties via compositional and structural modifications, but also intrinsically enlightens its potential capability for eco-friendly and biocompatible applications.

11:00 AM NM09.02.04
High-Performance Polyvinylidene Difluoride/Dopamine Core/Shell Piezoelectric Nanofiber and Its Application for Biomedical Sensors Tong Li, Long Gu, Corey Carlos and Xudong Wang; University of Wisconsin-Madison, United States

Soft piezoelectric materials are an important group of functional material for state-of-the-art energy harvesting, energy conversion and sensing technologies. Driven by the rapid evolution of internet of things and biomedical engineering, current energy and senor technologies, particularly those interfacing with human beings, are placing tremendous emphasizes on the flexibility, processability, conformality and biocompatibility to the piezoelectric components, in addition to their high performance. While polyvinylidene difluoride (PVDF) has been a well-known and broadly used piezoelectric polymer material over years, their mechanical property, piezoelectric performance and processability still cannot meet the high requirements of wearable devices. Recent years see a surge of research efforts on PVDF-based nanostructures to interface with biological systems for energy or sensing applications. However, unlike ceramic-based piezoelectric materials, to reach desired high piezoelectric property and long-term stability in biological environment still stand as a big challenge in PVDF soft nanomaterial development.
In this work, we report a one-step strategy for fabricating core/shell polyvinylidene difluoride (PVDF)/dopamine (DA) nanofibers (NFs) with a very high β-phase content and self-aligned polarization. The self-assembled core/shell structure is believed essential for the formation and alignment of β-phase PVDF, where strong intermolecular interaction between the $-NH_2$ groups on DA and $-CF_2$ groups on PVDF is responsible for aligning the PVDF chains and promoting β-phase nucleation. As-received PVDF/DA NFs exhibit significantly enhanced piezoelectric performance and excellent stability and biocompatibility. An all-fiber-based soft sensor is fabricated and tested on human skin and in vivo in mice. The devices show a high sensitivity and accuracy for detecting weak physiological mechanical stimulation from diaphragm motions and blood pulsation. This sensing capability offers great diagnostic potential for the early assessment and prevention of cardiovascular diseases and respiratory disorders.

11:10 AM *NM09.02.05
Closed-Loop Electrostimulation Enabled by Nanogenerator Technology Xudong Wang; University of Wisconsin-Madison, United States

Electrostimulation (ES) has long been utilized as a versatile therapeutic strategy for treating human diseases. The nanogenerator technology stands at a unique position for connecting biological ES to body motions by

converting biomechanical energy to electric pulses. This process forms a closed-loop ES in both energy flow and function feedback. This talk will first elaborate how the closed-loop ES operates as a close analogue to how the body controls its own functions. The most recent progresses of flexible and complex piezoelectric material innovations in our group will be viewed for implantable nanogenerator development, including 3D printing techniques and degradable piezoelectric biomaterials. These materials exhibited tissue-matching mechanical property as well as excellent electromechanical coupling properties, ideal for in situ electrostimulation generation. In our recent research, we also successfully implemented the closed-loop electrostimulation concept for skin wound healing, hair growth, bone healing and vagus nerve stimulation for obesity control with superb performance. An electrical stimulation bandage was developed that could accelerate skin wounds recovery to within 3 days as compared to 12 days of usual contraction-based healing processes in rodents. Via a similar design, the electrical pulses were applied to stimulate hair growth. In another work, an implanted vagus nerve stimulation system was developed in responsive to the peristalsis of stomach. The electric signals generated by this device stimulates the vagal afferent fibers to reduce food intake and achieve weight control. With the advanced electromechanical material and device design and engineering, the closed-loop electostimulation concept will quickly grow into a very impactful application direction of nanogenerator technology for human wellbeing.

11:30 AM NM09.02.06
Quantifying and Understanding the Triboelectric Series of Inorganic Non-Metallic Materials Haiyang Zou and Zhong Lin Wang; Georgia Institute of Technology, United States

Contact-electrification is a universal effect for all existing materials, but it still lacks a quantitative materials database to systematically understand its scientific mechanisms. Using an established measurement method, this study quantifies the triboelectric charge densities of nearly 30 inorganic nonmetallic materials. From the matrix of their triboelectric charge densities and band structures, it is found that the triboelectric output is strongly related to the work functions of the materials. Our study verifies that contact-electrification is an electronic quantum transition effect under ambient conditions. The basic driving force for contact-electrification is that electrons seek to fill the lowest available states once two materials are forced to reach atomically close distance so that electron transitions are possible through strongly overlapping electron wave functions. We hope that the quantified series could serve as a textbook standard and a fundamental database for scientific research, practical manufacturing, and engineering.

11:40 AM *NM09.02.07
Conformable Facial Code Extrapolation Sensor (cFaCES) for Non-Verbal Communication Canan Dagdeviren; Massachusetts Institute of Technology, United States

Devices that facilitate nonverbal communication typically require high computational loads or have rigid and bulky form factors unsuitable for use on the face or on other curvilinear body surfaces. Here, we report the design and pilot testing of an integrated system for the decoding of facial strains and for predicting facial kinematics. The system consists of mass-manufacturable, conformable piezoelectric thin films for strain mapping, multiphysics modelling for the analysis of the nonlinear mechanical interactions between the conformable device and the epidermis, and three-dimensional digital image correlation for the reconstruction of soft-tissue surfaces under dynamic deformations and for informing device design and placement. In healthy subjects and in subjects with amyotrophic lateral sclerosis, we show that the piezoelectric thin films, coupled with algorithms for the real-time detection and classification of distinct skin-deformation signatures, enable the reliable decoding of facial movements. The integrated system could be adapted for use in clinical settings as a nonverbal communication technology or for use in the monitoring of neuromuscular conditions.

SESSION NM09.03: Nanogenerator III
Session Chairs: Christian Falconi and Jun Liu

1:00 PM *NM09.03.01
Turn the Triboelectric Charges on the Body into Energy and Signals Renyun Zhang; Mid Sweden University, Sweden

The triboelectric charges on the human body are generated by the contact electrification of the human skin and other surfaces. The mechanism behind this is that the human skin has a very positive charge affinity due to its surface biological composition. Such a high positive charge affinity leads to electron transfer between the skin and other materials when the physical contact-separation process is happening.

Utilizing such unique properties of the human skin, we have constructed different types of triboelectric nanogenerators (TENGs) including human body based TENGs (H-TENGs) for harvesting energy from body motions with maximum output power density above 30 W/m^2. Moreover, due to the unique charge generating process of the body, we have developed new types of body motion sensors that can sense the movements of the human body. Such sensors have great applications in healthcare and security areas. Beyond these, one can also create human-machine interactions based on the charges generated on the human body.

Our studies have discovered the fundamentals of the triboelectricity of the human body, as well as future applications in different areas. New types of human-machine interaction prototype are expecting to be developed in the future.

1:20 PM DISCUSSION

1:40 PM *NM09.03.03
Zinc Oxide Nanowires Based Nanogenerator: Design, Manufacture, Modelling and Characterization
Guylaine Poulin-Vittrant[1,2], Taoufik Slimani Tlemcani[1], Kevin Nadaud[1], Emmanuel Dumons[2], Louis P. Tran-Huu-Hue[2] and Daniel Alquier[1]; [1]CNRS, Université de Tours, France; [2]CNRS, INSA-CVL, Université de Tours, France

Piezoelectric composites based on PZT ceramic rods or fibers have emerged long time ago for ultrasonic applications [1]. With the progress in nanotechnologies, similar composites incorporating piezoelectric nanowires have been manufactured for mechanical energy harvesting, generally called nanogenerators [2]. These devices have attracted increasing research interest, as possible micro-power supplies for wireless and mobile electronics, with the growing importance of the Internet of Things (IoT) [2,3].

Here, we will present an original design as well as a modelling strategy of nanogenerator devices. The flexible nanogenerator is manufactured on a polydimethylsiloxane (PDMS) substrate. It consists in a multilayer device with a Ti/Au bottom electrode, a nucleation layer, a zinc oxyde (ZnO)/parylene C composite layer, a Ti/Al top electrode, and a final PDMS encapsulation [4]. ZnO nanowires are synthesized using a low temperature Chemical Bath Deposition (CBD) process (85°C), compatible with various substrates and transferable to industrial processes.
Some of the key properties of the nanogenerator constitutive elements have been studied and optimized: the flexible substrate [4], the bottom electrode layer and the nucleation layer – which may be the same layer and, indeed, the ZnO crystalline quality. The ZnO nanowires properties have been adjusted through the CBD growth conditions (temperature, duration, reactants) [5,6] and the nucleation layer type and thickness (Au, ZnO or Al-doped ZnO) [7,8].
A dedicated test bench has been designed in order to measure the electrical power or energy delivered to an external circuit. Average electrical power and RMS voltage are measured thanks to a double buffer amplifier [9]. The nanogenerator produces a 0.4 $\mu W/ cm^2$ average power (or 2 $\mu W/ cm^2$ peak power) for a 6N force applied at 5Hz [10]. The force sensitivity of the device is 2 V/N at 5Hz. In order to determine the doping properties of the ZnO nanowires, single nanowire – Field Effect Transistors (FETs) were manufactured and characterized [5]. A 10^{18} cm^{-3} doping level is estimated for pristine nanowires, decreasing by two orders of magnitude thanks to thermal annealing of the nanowires in air. This intrinsic doping, resulting from native defects, is increasing with HMTA (hexamethylenetetramine) concentration used for CBD growth. The ZnO doping values estimated thanks to single nanowire FETs have been correlated to photoluminescence spectroscopy results [6].
In terms of modelling, an analytical model and a Finite Element (FE) model have been developed depending on the simulation purpose. In particular, the analytical model takes into account the possible wide frequency band of the mechanical excitation and allows the prediction of the harvested power for a mechanical force with an arbitrary time-domain form [11]. The FE model of a single cell – with appropriate symmetry conditions – containing a piezoelectric and semiconducting material embedded into a dielectric polymer matrix, on a given rigid or flexible substrate, provides a better understanding of the electromechanical behavior of the transducer. Based on this model, energetic considerations are discussed, like conversion rate or electromechanical coupling factor.

2:00 PM NM09.03.04
Photoinduced Strain in Ferroelectric-Based Cantilevers Stéphane Gable, Komalika Rani, Thomas Maroutian, Guillaume Agnus, Philippe Lecoeur and Sylvia Matzen; Université Paris-Saclay, France

Due to their large number of properties, such as switchable polarization, piezoelectricity or optical absorption, ferroelectrics are particularly promising in order to develop the next generation of electronic microdevices. Among these ferroelectrics, lead zirconium titanate (PZT) has been widely investigated for its high electromechanical properties and more recently for its light-induced deformation[1], commonly named photostriction, combining simultaneously bulk photovoltaic and converse piezoelectric effects[2]. Although this

phenomenon was discovered in multiple ferroelectrics materials these last decades[3], the photostriction is not fully understood and thus requires further studies in order to promote the future electronic microdevices.
In this work, the interplay between the electric polarization and the photoinduced strain is investigated in PZT epitaxial-based cantilevers. For this purpose, the resonance frequencies of the cantilevers and their deflection were studied under UV illumination, through electrical measurements and optical profilometry respectively. The recent results have shown that the sign of both the photoinduced shift of resonance frequency and photoinduced deflection strongly depend on the polarization state in the ferroelectric thin film.

Revealing Fundamental Multi-Scale, Multi-Physics Interaction in Contact Electrification Jun Liu; University at Buffalo, The State University of New York, United States

Understanding the fundamental mechanism of contact electrification has been the Holy Grail for physicists for centuries. The direct-current generation in semiconductor-based dynamic contacts is a newly discovered triboelectric phenomenon, where multi-scale interaction and multi-physics coupling of contact interfaces under non-equilibrium condition are involved. At microscopic level, mechanical modulation is exerted at local single asperities due to surface roughness. Lattice distortion of a dynamic contact could be extremely large considering a high local pressure at GPa level at the single asperity. As a result, one would expect an ultrahigh 'local' temperature as high as 1000 K given rise by the rigorously perturbed surface atoms. In an effort to elucidate the physical picture of the energy conversion process, we investigate the long-existing problem from different scales and different angles: At microscopic level, the contribution of flexoelectric effect due to strain gradient on the interfacial electric field; At atomic level, the contribution of surface dipole formation due to perturbation of surface to the interfacial electric field; At quantum level, the contribution of non-adiabatic electron-phonon interaction on the electronic excitation. It is proposed that those factors should be considered comprehensively, in addition to the simple charge transfer theory based on thermodynamic fermi-level alignment, in order to understand the fundamental mechanism of contact electrification.

Holistic Engineering of Biocompatible and Biodegradable Polymers as Wearable Triboelectric Devices for Self-Powered Cardiovascular Monitoring Ruoxing Wang and Wenzhuo Wu; Purdue University, United States

Personalized real-time health monitoring in non-clinical environments can significantly improve the life quality by regularly evaluating health status, immediate warning of abnormality, and remote diagnosis. The continuous detection of various vital signals such as respiration, perspiration, and temperature have been realized by wearable sensors. Heart rate is another critical parameter which is closely related to cardiovascular health.

Cardiovascular disease is one of the leading causes of death globally, which costs more than $219 billion each year in healthcare service, medicine, and loss of productivity. The precise continuous monitoring of pluse waveform is critical for assessing overall cardiovascular health and the state of the autonomic nervous system (ANS) responsible for regulating cardiac activity.
The emerging frontiers in real-time cardiovascular health monitoring demand that the corresponding sensors be biocompatible, wearable, and self-sustainable. The capability of sensor systems to efficiently scavenge the stray, weak environmental energies through sustainable pathways would enable self-powered bioelectronic systems. Triboelectric nanogenerators (TENG) can effectively transform the otherwise wasted environmental, mechanical energy into electrical power. Recent advances in TENGs witness a significant boost in the output performance. However, obstacles hindering the development of efficient triboelectric devices based on biocompatible materials continue to prevail. Being naturally degradable, biocompatible, low-cost, and lacking in cytotoxicity, chitosan and polyvinyl alcohol (PVA) are two materials with great potential being functional constituents in biomedical devices.
Here, we present for the first time the holistic engineering of chitosan and PVA with tunable mechanical properties, biodegradable rates, and electrical outputs for wearable TENGs, through revealing and understanding the interactions between the constituent materials and the structure-property-performance relations.[1, 2] The feasibility of laser processing of biopolymers was explored for the first time to improve the TENG performances. Leveraging the high mechanical deformability and biocompatibility of the constituent materials, the optimized triboelectric devices built with PVA composite films and chitosan composite films exhibit stable and robust triboelectricity outputs. Such wearable devices are capable of detecting the imperceptible degree of skin deformation induced by human pulse and capture the cardiovascular information encoded in the pulse signals with high fidelity for self-powered cardiovascular health monitoring. The gained fundamental understanding and demonstrated capabilities are expected to enable the rational design and holistic engineering of novel materials for more capable biocompatible triboelectric devices that can continuously monitor vital physiological signals for self-powered health diagnostic and therapeutic systems.

4:10 PM NM09.04.02
Plasma Nanoengineering for the Development of Hybrid Piezo and Tribonanogenerators Xabier García-Casas[1], Nicolas Filippin[1], Javier Castillo-Seoane[2], Francisco J. Aparicio[1], Ali Ghafarinejad[1], Jorge Budagoski[1], Carmen Lopez-Santos[2], Angel Barranco[1], Juan R. Sanchez-Valencia[2] and Ana Borras[1]; [1]Spanish National Research Council (CSIC), Spain; [2]Universidad de Sevilla, Spain

In this communication, we show an innovative approach to the production of piezoelectric nanogenerators by combining polycrystalline and texturized ZnO layers fabricated at room temperature by plasma enhanced chemical vapor deposition with flexible small-molecule organic nanowires (ONWs) acting as 1D and 3D soft-template. We address the one-wire / one-device concept by developing a core-multishell piezoelectric nanogenerator including gold and silver shells acting as inner nanoscopic electrodes.[1] Besides, this nanoarchitecture is integrated in high density in a contact-separation mode triboelectric nanogenerator. We aim to demonstrate the advantages of the application of plasma assisted deposition and plasma nanoengineering to optimize the output power of the hybrid nanogenerator at two levels, namely, the nanoengineering of the piezoelectric nanowires and the plasma treatment and functionalization of the triboelectric surfaces. On the one hand, we discuss the role of the piezoelectric shell microstructure, texture, and hierarchical formation of nanotrees. On the other hand, the plasma assisted fluorinated functionalization of PDMS is evaluated as a sustainable approach to increase the electronegativity and hydrophobicity of the negative friction layer. For the optimized vertical separation-contact TENG on ITO/PET, the measured output on manual pressing stimulation reached values higher than 75 V of open-circuit voltage and 0.5 μA of short-circuit current. A setup for the generation of reproducible mechanical stimuli either in frequency or amplitude was developed and applied, which allowed us to obtain a characteristic frequency for the maximal output of the device. Finally, the wetting properties of TENGs surfaces have been tuned by controlling the surface micro and nanoroughness and superhydrophobic hierarchical structures ranging from Petal to Lotus mechanisms. The liquid-solid

electrification and its application for fabricating a single electrode TENG have been exploited to harvest energy from microdroplets' impacts and sliding.

4:20 PM NM09.04.04
Towards Flexible and Scaled-up Schottky Direct Current Generator Ruizhe Yang, Matthew Benner and Jun Liu; University at Buffalo, The State University of New York, United States

High-current density dynamic Schottky junctions hold great promise for ambient energy harvesting, which overcome the transient and limited current output as faced by traditional piezoelectric/triboelectric nanogenerators. However, self-powered applications for wearable/implantable electronics call for excellent flexibility for the device, whereas the materials of dynamic Schottky junction being used hitherto are inorganic bulk materials with poor flexibility. In addition, the low open-circuit voltage and high-cost scaling up have hampered its further implement for practical applications in self-powered electronic devices. Here, we design and optimize the scalable DC generators with high power output as well as excellent flexibility. The flexible DC power generator exhibits a robust mechanical stability and durability under ambient temperature. The design of flexibility in such DC energy generator is inherited from the long chain polymer concept. The Schottky DC power generation nature provides such flexible generator with high current density performance without rectification. The demonstration of scalable and flexible of high current density DC energy generator opens up energy conversion applications with remarkable power output performance (approaching mA level of short-circuit current, and 1 volt open-circuit voltage for single unit) enabled by low frequency movement, high flexibility, and excellent durability performances.

4:30 PM *NM09.04.05
Nylon-11 Nanowires for Triboelectric Energy Harvesting Yeon Sik Choi[1] and Sohini Kar-Narayan[2]; [1]Northwestern University, United States; [2]University of Cambridge, United Kingdom

Triboelectric energy harvesting from ambient mechanical sources relies on motion-generated surface charge transfer between materials with different electron affinities. In order to achieve highly efficient energy harvesting performance, choosing materials with a high surface charge density is crucial, and odd-numbered polyamides (Nylons), such as Nylon-11, are particularly promising due to their strong electron-donating characteristics and the possibility to achieve dipolar alignment leading to high surface potential. The use of Nylon-11 as a material for triboelectric energy harvesting has been rather limited due to the extreme processing conditions required for film fabrication, and the high-voltage poling process required for dipole alignment. However, several methods to achieve “self-poled” Nylon-11 nanowires via facile nanoconfinement techniques have been demonstrated recently, leading to highly efficient Nylon-11 nanowire-based triboelectric nanogenerators. In this talk, I will discuss the most recent advances in the fabrication of Nylon-11 nanowires, with a focus on how nanoconfinement-based fabrication methods can be used to control phase and crystallinity. These growth methods lead to self-poled nanowires without the requirement for subsequent electrical poling, facilitating their integration into triboelectric energy harvesting devices. Strategies to fabricate Nylon-11 nanowires for applications in triboelectric devices can be extended to other polymeric families as well, giving rise to improvements in energy harvesting performance.

[1] "Unprecedented dipole alignment in α-phase nylon-11 nanowires for high-performance energy-harvesting applications" Y. S. Choi, S. K. Kim, M. Smith, F. Williams, M. E. Vickers, J. A. Elliott and S. Kar-Narayan*, Science Advances 6, eaay5065 (2020), DOI: 10.1126/sciadv.aay5065

4:50 PM NM09.04.07
Two-Stage Conditioning System for Triboelectric Nanogenerators Using a High-Voltage MEMS Plasma Switch Hemin Zhang[1,2], Frédéric Marty[1], Dimitri Galayko[3], Naida Hodzic[1] and Philippe Basset[1]; [1]ESYCOM, Univ Gustave Eiffel, CNRS, CNAM, ESIEE Paris, France; [2]University of Cambridge, Cambridge, United Kingdom; [3]Sorbonne Université, France

Adding a switch at the output of a TENG or in its conditioning circuit largely promotes the energy harvesting efficiency. However, the switch has to be self-activated with a minimum consumption, so electronic switches are not suitable. We propose to apply MEMS technologies to develop a self-sustained, high-voltage and well-controlled narrow-hysteresis switch for high-efficiency energy transfer.
Our plasma switch is made of bulk silicon. It is part of a 2-stage conditioning system with a first stage including a ~35cm^2 flexible TENG and a Bennet doubler circuit, plus a second stage including the MEMS switch and a buck converter. The switch includes a movable anode connected to the Bennet output, a fixed cathode connected to the buck input, and a ground reference. At start, the switch is OFF and the voltage progressively increases across the rectifier capacitance C_{buf}, while an electrostatic force pulls the anode close to the cathode. According to Paschen's Law, if the plasma breakdown voltage is higher than the physical-contact voltage, a contact occurs between the electrodes and a full-hysteresis ON-OFF loop appears because the contact current is high enough to release all the energy from C_{buf}. If the breakdown voltage is lower than the physical-contact voltage, micro-plasma occurs before contact, leading to a narrow-hysteresis ON-OFF loop because the low plasma current cannot fully release the energy stored in C_{buf} due to the end of the plasma.
We used a 2-stage circuits with a Bennet doubler and a MEMS switch having an initial gap of 6µm and 9µm to charge a larger capacitor C_{store}, or using only a full-wave rectifier. Defining the charging efficiency as the energy per cycle in C_{store} at 4.5V (the regulator's operation voltage) divided by the charging time to this voltage, we can conclude that using the 2-stage conditioning circuit with a 6µm-gap MEMS switch improves the energy transfer efficiency by 145 times compared to only a full-wave rectifier. With the 6µm-switch, contact occurs with a full hysteresis, while with the 9µm-switch a µ-plasma is obtained with a very narrow hysteresis. Despite its full-hysteresis, the 6-µm switch has a better energy conversion per mechanical cycle without any load because of its much higher ON voltage. However, in a practical implementation with a commercial regulator and a 660kW load, the circuit with the 6µm-switch has many glitches at the regulated output, on the contrary to the one with the 9µm-switch. This is explained by the longer time for recharging C_{buf} induced by the full-hysteresis that drastically decreases the mean value of the voltage across C_{buff} Therefore, the switch can be further improved by designing a 6µm-switch with plasma discharge and no contact.

5:00 PM NM09.04.08
Slide Electrification to Supply Power for Smart Contact Lenses Erfan Pourshaban, Aishwaryadev Banerjee, Mohit Karkhanis, Chayanjit Ghosh, Adwait Deshpande, Hanseup Kim and Carlos Mastrangelo; The University of Utah, United States

One of the essential components for practical realization of the smart wearables, is an efficient and standalone power scavenging system. Photovoltaics and wireless power transfer are widely used for such purposes. However, these techniques depend on the presence of an external energy source which poses certain limitations on their practical deployment. Alternatively, conversion of mechanical motion to electrical energy can be considered as a practical and standalone method to generate power for wearable electronics systems such as smart contact lenses. Due to its high output power density, triboelectric power generators are an attractive choice for such purposes. Here, we have investigated a slide triboelectric power generation of liquid-solid movements with respect to each other. Our results confirm the feasibility of supplying power for biomedical electronics just by natural human muscle motions. In this talk we present a triboelectric generator driven by eye blinks suitable for powering up smart contact lenses. A human's average eye blinking speed is approximately 200 mm/s[1]. Furthermore, an adult blinks about 12 times per minute[2].
One of the main shortcomings of the common solid-solid triboelectric power generators is the materials' surface properties. Micro and nanoscale surface roughness, together with surface destruction by the friction effect, deteriorate the performance of the solid-solid triboelectric devices. However, in the present study, we have used the liquid as one side of our slide electrification system. Having liquid as one side of the mechanical to electrical power generators, not only benefits from touching all possible surface area of the solid's surface but also offers a higher lifetime to the triboelectric power generation devices. The solid plate of our device is made up of a grating aluminum (Al) with a surface area and spacing of 1×5 mm2 and 5 mm, respectively. 300 nm of silicon dioxide (SiO2) was sputtered, followed by coating 800 nm of polytetrafluoroethylene (PTFE). SiO2 prevents any leakage current from the slide electrification process. In addition, thin layer of PTFE is used to

make the solid's surface hydrophobic and prevent the wetting of the surface by the motion of the liquid. The liquid side is composed of a simple Al electrode and different types of liquids. Results confirm that the motion of the liquid with respect to the solid plate generates an alternative voltage which is due to the capacitor behavior. Furthermore, the liquid's ion concentration and the movement speed determine the output generated voltage of the liquid-solid triboelectric system.
A noise-free, battery operated digital oscilloscope (Yeapock ADS1013D) with the input impedance of 1 MΩ was used for the output voltage measurements. In addition, an operational amplifier (ST Microelectronics LM358D) was configured as a unity-gain voltage follower which buffered our device to detect the open-circuit voltage of the triboelectric power generators, properly. We have used different NaCl concentrations (0, 0.01, 0.1, and 1M) as the liquid part of our triboelectric power generator. Higher NaCl concentration results in higher output voltage. At the movement speed of 30 mm/s, deionized (DI) water without NaCl shows no output voltage
while the same value is outstandingly rising to 3.7 V by adding 1 M NaCl to the DI water. Using the commercially available moisturizing eye drop as the liquid part of the slide electrification device at the movement speed of 30 mm/s results in an output voltage of 3.7 V and 4.7V at of 200 mm/s. The calculated effective power density was ~ 0.4 Wm-2.

Smart Textiles for Personalized Health Care Jun Chen; University of California, Los Angeles, United States

There is nothing more personal than healthcare. Health care must move from its current reactive and disease-centric system to a personalized, predictive, preventative and participatory model with a focus on disease prevention and health promotion. As the world marches into the era of Internet of Things (IoT) and 5G wireless, technology renovation enables industry to offer a more individually tailored approach to healthcare with more successful health outcomes, higher quality and lower costs. However, empowering the utility of IoT enabled technology in personalized health care is still significantly challenged by the shortage of cost-effective and wearable biomedical devices to continuously provide real-time, patient-generated health data. Textiles have been concomitant and playing a vital role in the long history of human civilization. In this talk, I will introduce our current research on smart textiles for biomedical monitoring and personalized diagnosis, textile for therapy, and textile power generation as an energy solution for the future wearable medical devices.

6:30 PM NM09.05.01
A Flexible Piezoelectret Actuator/Sensor for Mechanical Human-Machine Interfaces Junwen Zhong; University of Macau, China

Flexible and wearable devices with the capabilities of both detecting and generating mechanical stimulations are critical for applications in human-machine interfaces, such as augmented reality (AR) and virtual reality (VR). Herein, a flexible patch based on a sandwiched piezoelectret structure is demonstrated to have a high equivalent piezoelectric coefficient of d_{33} to selectively perform either the actuating or sensing function. As an actuator, mechanical vibrations with peak output force of more than hundreds of mN have been produced, similar to

those from the vibration mode of a modern cell phone and can be easily sensed by human skin. As a sensor, both high sensitivity of 1.84 Pa for sensing resolution and excellent stability of less than 1% variations in thousands of cycles have been achieved. The design principle together with the sensing and driving characteristics can be further developed and extended to other soft matters and flexible devices.

Polymer-Based Multifunctional Self-Powered Systems for Energy Harvesting and Active Sensing Ruiyuan Liu; Soochow University, China

Functional polymers provide unique advantages in flexible electronics to improve their electrical performance, flexibility and functions. An integration of flexible energy harvesting and storage components enables a self–powered system that can simultaneously harvest solar/mechanical energy and store electricity for soft robotics, the internet of things and portable electronics. The introduction of functional polymers into a self-powered system pave a new direction for the multifunctional applications in energy harvesting, storage and mechanosensing.

A Constant Direct-Current Triboelectric Nanogenerator Arising from Electrostatic Breakdown Jie Wang; Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, China

In-situ converting mechanical energy to electricity is a feasible solution to satisfy the increasing power demand of wearable electronics and Internet of Things (IoTs). Triboelectric nanogenerator (TENG) is considered as a potential solution via building self-powered systems. With its pulsed alternating-current (AC) output characteristics, a conventional TENG, based on triboelectrification effect and electrostatic induction, always needs rectification and energy storage units to obtain a constant direct-current (DC) output to drive electronic devices. Here we report a next-generation TENG, which realizes constant current (crest factor ~ 1) output for the first time by coupling triboelectrification effect and electrostatic breakdown, which has similar essence of lightning. Meanwhile, its output charge density can be improved by nanostructure design, working temperature and atmosphere control. Until now, its charge density is reach ~5.4 mC m^{-2}, which is over 2-fold the state-of-art of TENGs. The novel direct-current triboelectric nanogenerator (DC-TENG) is demonstrated to power electronics directly without any rectifier or energy storage units. Our findings not only promote the miniaturization trend of the self-powered system used in wearable electronics and IoTs, but also provide a paradigm shifting technique to harvest mechanical energy efficiently.

7:00 PM *NM09.05.05
Tribotronics for Active Mechanosensation and Self-Powered Microsystems Chi Zhang and Tianzhao Bu; Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, China

Tribotronics has attracted great attentions as a new research field about the control and tuning of semiconductor transport by triboelectricity. Here, the tribotronics is firstly reviewed for active mechanosensation and human-machine interfacing. As the fundamental component, contact electrification field-effect transistor is analyzed, in which the triboelectric potential could be used to control the electrical transport in semiconductors. On the basis, several tribotronic functional devices have been developed including tribotronic smart skin, tactile

sensing array and tuning diode, which has demonstrated triboelectricity-controlled electronics and established the active mechanosensation for external environment. In addition, the triboelectric power management strategy is also reviewed, in which the triboelectricity can be managed by electronics in reverse action. With the implantation of triboelectric power management module, the harvested triboelectricity by various kinds of human kinetic and environmental mechanical energy could be effectively managed as a power source for self-powered microsystems. By the research prospects for interactions between triboelectricity and semiconductor, tribotronics is expected for significant impacts and potential applications in MEMS/NEMS, flexible electronics, robotics, wireless sensor network, and Internet of Things.

7:20 PM *NM09.05.06
Stand-Alone Printed Flexible DC TENGs with Ion-Gel Supercapacitor Ju Hyun Lee, Sungjune Jung and Unyong Jeong; Pohang University of Science and Technology, Korea (the Republic of)

The voltage output of TENG without a rectifier and a capacitor intrinsically displays in sharp AC spikes of several hundred volts. However, numerous functional devices demand continuous DC voltage from the triboelectric power source. Two components are needed for TENG generating a DC voltage (DC-TENG): a rectifier, and a capacitor. Many researches on TENG have employed the conventional silicon diodes to obtain unipolar peaks. Utilizing typical silicon diodes and commercially available aluminum oxide capacitors has been a common way of converting AC voltage to constant voltage, but the integrated triboelectric system based on the hard materials restricts flexibility and patterning. Direct application of the energy harvester as wearable device necessitates a standalone DC-TENG system with flexibility as well as printability. This talk presents the conversion of the spike voltage to continuous DC voltage with the integrated triboelectric system by printing all components of TENG, rectifier, and capacitor on the flexible substrate. And also it demonstrates the self-powered electrochromic display on a single flexible substrate and show the change in color due to the charge accumulation in the ion gel capacitor unit. It holds potential to realize completely wireless and wearable self-power in the future.

7:40 PM NM09.05.09
Dynamic Mechanical Stimuli Communication via Switchable Ionic Polarization Dong-Min Lee, Hong-Joon Yoon and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

Awareness of diverse tactile experiences has been a challenge toward greater human-machine interaction, which requires its full comprehension for both static and dynamic stimuli. Recent advances in triboelectricity-based touch sensors take great advantages in regard of cost, simplicity of design, and use of a wider range of materials. Due to their reliance on the level of contact electrification at the interface of materials, they encounter major difficulties to measure the extent of deformation of materials under a given mechanical force. Here, we describe an ion-doped gelatin hydrogel-based touch sensor, identifying not only contact with an object but also deformation under a certain level of force. Switchable ionic polarization plays an essential role to allow different sensing mechanisms when the touch sensor is contacted and deformed. We successfully demonstrate that this sensor provides dynamic deformation-responsive signals that can be used to control the motion of a miniature car, thereby broadening the potential applications in a human-machine communication system.

Piezoelectric Response of In_2Se_3 Layered Nanosheet Based Heterostructures for Diverse Devices Jianhua

Hao; The Hong Kong Polytechnic University, Hong Kong

Currently, technological progress has pushed increasingly miniaturized devices and systems, stimulating a search for nanoscale piezoelectric materials. Taking the mechanical property with large elastic strain limits, excellent flexibility and the observed piezoelectricity into account, it is expected to develop diverse devices based on the 2D layered nanosheets and their heterostructures, giving rise to ultrathin device technologies towards piezoelectric nanogenerators, actuators, piezo-phototronics, active human-machine smart sensors and self-powered stretchable/wearable devices. Noted that the out-of-plane and in-plane piezoelectricity found in mono- and multilayered α-In_2Se_3 nanosheets offers an opportunity to enable a variety of piezoelectric devices. In my group, we design several kinds of In_2Se_3 layered nanosheet based heterostructures. We have demonstrated the high tunability of In_2Se_3 Raman spectra and PL characteristics under compressive biaxial strain induced by the piezoelectric substrate. The controllable biaxial strain is experimentally imposed on α-In_2Se_3 nanosheets by an electromechanical device. By precisely *in situ* modulating bias voltage on the substrate, the biaxial strain can be generated and delivered to In_2Se_3 nanosheets, resulting in the prominent shift in Raman and PL spectra. The vibrational behavior of In_2Se_3 is examined based on the Grüneisen parameter. On the other hand, we have demonstrated superior out-of-plane piezoelectric coefficient d_{33} for In_2Se_3/MoS_2 vdW heterostructure. By combining the experimental studies and density functional theory calculations, the enhanced piezoelectric properties of In_2Se_3/MoS_2 are ascribed to a larger interfacial dipole moment result from the type II band alignment. The high-precision piezoelectric actuators in 2D atomic scale are conceived based on the out-of-plane piezoelectricity of In_2Se_3 based heterostructure. Lastly, we present enhanced performance in the photodetectors based on In_2Se_3 van der Waals heterostructure according to the piezo-phototronic effect. Consequently, our design and strategies enable us not only to achieve enhanced piezoelectric response in the In_2Se_3 nanosheets, but also to offer the possibility for realizing various high-performance devices. The works are supported by the grants from RGC GRF (PolyU153025/19P), CRF (C7036-17W) and NSFC (No. 51972279).

9:20 PM NM09.06.04
Self-Powered Microbial Disinfection System Using the Nanowire-Enhanced Localized Electric Field Young Jun Kim, Zheng-Yang Huo and Sang-Woo Kim; Sungkyunkwan University(SKKU), Korea (the Republic of)

Air-transfer pathogens can cause severe epidemics (e.g., COVID-19), which shows a substantial public health threat. Inactivation of the pathogenic microbes in the air is an essential process, whereas the feasibility of existing air disinfection technologies has encountered obstacles including only achieving physical separation but no inactivation, noticeable pressure drops, and energy intensiveness. Here we report a rapid disinfection method for inactivating air-transfer bacteria and viruses using the nanowire-enhanced localized electric field to damage microbes' outer structures. This air disinfection system is driven by a triboelectric nanogenerator that effectively converts mechanical vibration to electricity and achieves self-powered. Assisted by a rational design for accelerated microbes' accelerated charging and trapping, this self-powered air disinfection system promotes microbial transport. It achieves high performance: >99.99% microbial inactivation within 0.025s in a fast airflow (2 m/s) while only causing low pressure drops (<24 Pa). This rapid, self-powered air disinfection method may fill the urgent need for the air-transmitted microbial inactivation to protect public health.

9:30 PM NM09.06.05
Fully Biodegradable Triboelectric Nanogenerator Based on Nature-Derived Polysaccharide with Tunable Lifetime and Tunable Output Performance Minki Kang, Muhammad Syafiq Bin Mohammed Khusrin and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

Development of biocompatible, biodegradable polymer with tunable properties is essential for multifunctioning implantable electronic devices (IEDs). To address this issue, we propose nature-derived polysaccharide, Kappa Carrageenan-Agar composite (kC-Agar composite) based fully biodegradable triboelectric nanogenerator (TENG). We found that triboelectric property of kC-Agar composite can be largely enhanced because of

electron-donating oxygen-rich functional groups and abundant presence of Ca^{2+} cations via ionic crosslinking. Through the evaluation of surface potential and triboelectric output, we demonstrate 80 wt% kC-Agar composite is the most highly triboelectric positive as well as surface potential is largely increased by at most 58 % compared to kC and Agar. In addition, to reveal the potential of kC-Agar composite for fully biodegradable triboelectric and encapsulation materials, we demonstrate tunable output performance and lifetime of fully biodegradable triboelectric nanogenerator (BDTENG) based on kC-Agar composite by simply varying the concentration. We believe that our findings would provide multiple options for researchers and engineers in the field of IEDs and biodegradable materials.

9:40 PM NM09.06.06
Long-Lifetime Triboelectric Nanogenerator Operated in Conjunction Modes and Low Crest Factor
Xinyuan Li, Jie Wang and Zhong Lin Wang; Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, China

The high-output triboelectric nanogenerator (TENG) is indispensable for its practical applications toward industrial products. However, the electricity loss in simple parallel connection among all units and the typically high crest factor output seriously hamper the practical applications of TENG. Here, a rectified TENG is reported in parallel structure to solve the problem of electricity loss in simple parallel connection. The rotational contact-separation structure with phase difference between rectified TENGs addresses high crest factor output and extends service life of rotational TENG simultaneously. The current crest factor is dramatically decreased to 1.31 in multiple rectifier multiple TENG in parallel (MRM-TENG), while that of TENG in simple parallel is higher than 6. A theory based on simulation results was also proposed to reduce the high crest factor and avoid energy loss of traditional TENG in parallel, and its feasibility was confirmed by the experiment. Meanwhile, the current output can retain up to ~93% of its initial performance after 7 200 000 rotations under 2.00 r s^{-1} of 1000 h. Furthermore, the equivalent current can be in linear growth with low crest factor by making MRM-TENG in parallel for distributed energy supply without electricity loss. This work may provide a new strategy for TENG in parallel to achieve a low crest factor output and long-term cycling stability power generation in distributed energy harvesting for large-scale power application.

Microscopic Models of Contact Electrification Morten Willatzen[1,2] and Zhong Lin Wang[1,3]; [1]Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, China; [2]Technical University of Denmark, Denmark; [3]Georgia Institute of Technology, United States

Quantum-mechanical models for contact electrification are presented by virtue of tunneling and light-assisted electron transfer between dissimilar solids. Firstly, a description of electronic states in solids (either metal/semiconductor/dielectric) is presented using the one-band effective-mass approach. Then, based on continuity of the wavefunction and its derivative (multiplied by the inverse effective mass), computation of the transmission probability through a barrier potential of vacuum (air) is carried out and weighted by the Fermi functions of the solids to the left and right of the vacuum barrier and the electron density of states. The model captures details of the Fermi levels of the two solids in contact, their temperatures, and the vacuum (air) layer thickness. We investigate the strength of the electron transfer as a function of the effective mass, Fermi levels, temperatures, and the vacuum barrier thickness using the Landauer-Boettiker equation in a one-dimensional formulation. Secondly, we take into account the Coulomb repulsion effect that is gradually established as electrons transfer from one material to the other. This is done by solving for the electric field as a function of the temporal build up of surface charges (positive on the material from which electrons are emitted and equally negative on the other material). The resulting electric potential is a linear function of distance in the vacuum region and the envelope of the electron wavefunction becomes a linear combination of Airy functions. Due to the linearly increasing barrier potential, the electron transfer rate is increasingly reduced as the surface charge build up takes place. This leads to a saturation effect such that the Fermi levels do not become equal as time goes. On the other hand, if the electron transfer is small at all times, the two Fermi levels eventually become equal. In the second part of the talk, light-assisted electron transfer models (spontaneous emission, stimulated

emission or absorption) are described using Einstein rate equations and the Fermi Golden Rule. This is first done for a system of coupled atoms separated by a barrier potential and later generalized to arbitrary solids described by Fermi levels.

Stretchable Nanogenerators for Wearables and Human-Machine Interface Pooi See Lee; Nanyang Technological University, Singapore

Development of mechanical energy harvesting devices that are compliant to curvilinear surfaces or mountable onto human body or skin are attractive for human-machine interface and wearable applications. Fabric based or textile based wearable triboelectric nanogenerators (TENGs) have attracted attention since it is conformable and feasible for users to generate electricity from simple biomechanical motions. We develop a conformable textile nanogenerator utilizing black phosphorus as charge trapping layer. The conformable textile nanogenerator was found to deliver considerably high output with a small force (~5 N) and low frequency (~4 Hz), which can be used to power small electronic gadgets. Fabric based TENGs with self-cleaning and antifouling properties are important attributes. Through the preparation of hydrophobic cellulose oleoyl ester nanoparticles, a low-cost and nontoxic coating material can be realized to harvest mechanical energy from water flow. The all-fabric-based dual-mode device harvests both the electrostatic energy and mechanical energy of water, achieving the maximum instantaneous output power density of 0.30 W m^{-2}. Recently, with the aim of attaining stretchability, breathability and waterproofness simultaneously for wearable applications, we fabricated mechanical interlocked stretchable nanofibers using electrospinning and electrospraying, delivering breathable TENG for tactile interactive sensing and energy harvesting. Designing thermoplastic elastomer that can be 3D printable attains the function of stretchable triboelectric active layer and simultaneously a stretchable current collector. In addition, we have synthesized self-healable elastomers based on porous supramolecular polyurethane which exhibited gas-solid interacted triboelectric behaviour, with high stretchability and adhesion properties.

Innovations at Interfaces for Water Energy Harvesting Zuankai Wang; City University of Hong Kong, Hong Kong

Water covers about 70% of the earth's surface and contains tremendous renewable and clean energy. Despite success in the harvesting hydrodynamic energy based on heavy-weight and bulky electromagnetic generators, a great deal of water energies stored in the low-frequency flow of water, such as in the form of raindrop, river/ocean wave, tide, remain largely untapped. In recent years, numerous promising techniques that allow for the efficient harvesting of water/liquid energy have emerged [1-3].

In this talk, I will discuss our recent progress in taking advantage of the fusion of slippery surfaces and transistor-inspired architecture on efficient water energy [4]. On the research line of liquid/liquid-interface based energy harvesting, we developed a novel slippery lubricant-impregnated porous surface (SLIPS) based

TENG, termed as SLIPS-TENG, that exhibits distinctive advantages including optical transparency, self-cleaning, impact tolerance, flexibility, and enhanced power generation stability even under harsh environments [5]. On the research line of solid/liquid-interface based energy harvesting, we report an original droplet-based energy generator (DEG) with field-effect transistor (FET)-like architecture that fundamentally overcomes the physical limitation inherent in the traditional approaches which are imposed by the undesirable interfacial effect and achieves the highest energy conversion efficiency [6]. Such a unique design allows for the reversible and efficient transfer of charges between the source and drain, resulting in the enhancement of power density by several orders of magnitude over its counterparts.

Self-Polarized PVDF Based Thin-Film Nanogenerator—An Approach Towards Developing Self-Powered Devices Vaibhav Khurana and Dipti Gupta; Indian Institute of Technology Bombay, India

Over the years, self-powered devices (SPDs) have been investigated to reduce the dependency of various electronic components on externally connected power sources. These components not only range from biomedical sensors but also basic building blocks of modern electronics-thin film transistors. SPDs are capable of not only powering and storing the energy but also provide the required driving potential to the sensors, which run at minimal input energy. In general, mechanically powered SPDs work on the principle of piezoelectricity; as human motion-powered devices can be considered as the mechanical power source of energy, these self-powered devices can be produced using the same principle. With this motivation, we have fabricated a piezoelectric nanogenerator (PNG) using poly-vinylidene fluoride (PVDF) as an active material spin-coated on a polyethylene terephthalate (PET) coated aluminum substrate. The adopted approach takes care of the device flexibility along with the extrication of mechanical energy via several degrees of motion owing to the involvement of polymeric components. Piezoelectricity in PVDF matrix is due to an electroactive all-trans β phase (re-orientation of H-F dipoles across C-C chain along one direction). To create a self-polarized PVDF film, we have made use of the quenching process, which has not been much explored in fabricating PNGs. The quenching based polarization solely depends on nucleation and growth concept, specifically nucleation of β crystallites under lower temperature. The employed organic solvents during the fabrication process contributed to the appearance of the β phase, which is confirmed by X-ray diffraction and Fourier transform infrared spectroscopy. These films were then incorporated into a PNG device that had a single active layer providing a thin device that is self-polarized and paves the way towards a small area, robust energy harvester. A two-step approach fabrication of the PVDF device showed exceptional performance, resulting in an open-circuit peak-to-peak voltage of 19.2 V upon human hand pressing and short-circuit current >0.7 μA. The average d_{33} value for the quenched PVDF film is observed to be −15.16 ± 5.81 pm/V. Further, charging of a capacitor and powering the liquid crystal displays (LCDs) are realized through the nanogenerator, thus validating mechanical energy conversion, storage, and powering applications.

8:30 AM NM09.07.03
Poly(vinyl alcohol)/Polyethyleneimine Composite for Energy Harvesting and Self-Powered Sensing Applications Lingyun Wang[1,2], Yunlong Zi[2] and Walid A. Daoud[1]; [1]City University of Hong Kong, China; [2]The Chinese University of Hong Kong, China

The advances of wearable electronics and the Internet of things has triggered tremendous demands for wearable power sources as well as sensors, with multifunctionalities, such as transparency and flexibility/stretchability. Since 2012, triboelectric nanogenerators (TENG) have demonstrated themselves as promising power sources as well as self-powered sensors for various applications. Scientists are devoted to enhancing the output performance of TENG through materials exploration, structural design, and circuit management. From a material point of view, developing tribo-materials with a strong affinity to gain/lose electrons, good mechanical, dielectric, surface properties, and other functionalities is one of the key factors to maximize the output power of TENG.
Herein, we explore a poly(vinyl alcohol)/polyethyleneimine composite, featuring high transparency, ionic conductivity, flexibility, good mechanical property, and plenty of functional groups. These features enable the polymer composite capable of serving as both a tribo-material and a current collector for TENG applications. Through embedding conductive nanofillers with surface capping ligands, the dielectric constant of the composite can be fine-tuned, where the higher power output of the resultant TENG can be achieved. In addition, the ionic conductivity of the composite can be enhanced by tuning the weight ratio of polyethyleneimine in the composite, facilitating its charge collection as a current collector. In this regard, a metal-electrode-free transparent wearable power source and a fully integrated self-powered triboelectric sensor array for self-powered tactile sensing are developed. Furthermore, the interfacial interactions between the functional groups of the composite and the carbon dots enable the composite with enhanced transmittance, resulting in a dual-functional layer for both solar energy and raindrop energy harvesting.

8:40 AM DISCUSSION

8:50 AM NM09.07.06
Triboelectrification Behaviors and Photoinduced Enhancement of All-Inorganic Perovskite Triboelectric Nanogenerators Yudi Wang, Xiya Yang, Jialong Duan and Qunwei Tang; Institute of New Energy Technology, College of Information Science and Technology, Jinan University, China

The in-depth understanding on the electrification behavior of dielectric materials is a prerequisite to improve the surface triboelectric charge density for triboelectric nanogenerators (TENGs). Dielectric property is favorable for triboelectric materials due to its high charge sustaining capability and dielectrics are commonly utilized for TENG devices. However, the inherent large impedance of dielectric materials undoubtedly causes limited current and power density outputs, alternatively, semiconductors with higher charge mobility can facilitate the charge transfer thus enhancing the electrical output performances.

Halide perovskites, as one of the most promising semiconductors, have gained tremendous attentions in the past decade given its fascinating optical and electronic properties in solar cells, light emitting diodes and

electrochemical sensors. Herein, triboelectric charging affinities and polarities of all-inorganic cesium lead tri-bromine ($CsPbBr_3$) and ions doped (alkaline earth / alkali metal ions) perovskites are systematically investigated by assembling into vertical contact-separation TENGs. An enriched triboelectric series supplemented with inorganic perovskites and quantified triboelectric charging polarities is delivered through analyzing their dielectric properties, electrical output performances, figure-of-merits (FOM), work function, bond energy and electron binding energy. Moreover, the photoinduced charges play significant role in enhancing the triboelectrification charges and altering charging polarity of perovskite based TENGs under illumination. This work not only supplements inorganic perovskites to triboelectric series and also provides new insights of inorganic perovskite in the foundation of tribo-photovoltaic theory and hybrid devices.

9:00 AM DISCUSSION

9:10 AM NM09.07.10
Micro Triboelectric Ultrasonic Device for Acoustic Energy Transfer and Signal Communication Chen Chen, Xuhui Sun and Zhen Wen; Soochow University, China

As a promising energy converter, the requirements for miniaturization and high-accuracy of triboelectric nanogenerator (TENG) always keep urgent. In this presentation, a micro triboelectric ultrasonic device will be introduced by integrating TENG and micro-electro-mechanical systems (MEMS) technology. To date, it sets a world record of smallest TENG with a 50 μm-sized diaphragm, and enables to bring the working frequency to Mega Hertz. This dramatically improves the miniaturization and chip integration of triboelectric nanogenerator. With 63 kPa@1 MHz ultrasound input, the micro triboelectric ultrasonic device can generate the voltage signal of 16.8 mV and 12.7 mV through oil and sound-attenuation medium, respectively. It also achieved the signal-to-ratio of 20.54 dB and exhibited the practical potential for signal communication by modulating the incident ultrasound. Finally, the detailed optimization approaches have also been proposed to further improve the output power of the micro triboelectric ultrasonic device.

Implanted Battery-Free Direct-Current Micro-Power Supply from *In Vivo* Breath Energy Harvesting Jun Li and Xudong Wang; University of Wisconsin–Madison, United States

Majority of current IMDs are powered by conventional primary or secondary batteries that contribute up to 90% weight and volume of the entire device. [1.2] While replacement of or recharging the batteries requires substantial surgical or technical efforts, introducing additional suffering and complexity to the patients, other batteries potential issues such as overheat and leakage of toxic electrolyte further prohibit the advancement and miniaturization of IMDs. Therefore, increasing efforts are now being focused on the innovation of designated IMD power sources. Implantable nanogenerators (i-NGs) have been designed to convert biomechanical energy into electricity. [3,4] In spite of their numerous merits, the outputs of state-of-the-art i-NGs are always in a form of largely discrete pulses. Although their theoretical output power could be sufficient for IMDs, battery component is still needed in the i-NG design to produce a steady and useable direct current (DC) output.

Moreover, most i-NGs are non-stretchable with incompatible mechanical properties compared to soft biological tissues, which further challenges their practical applications.
In this work, we reported an ultra-soft stretchable i-NG system that could function as a battery-free DC micro-power supply. The i-NG consisted of ultrafine micro-scale interdigital electrodes (IDEs) and multi tribo-active layers with a small working area (approximately 2 cm^2), packaged with biocompatible silicone elastomer. While the micro IDEs support the output of high frequency electricity (1 μA at 70 Hz) driven by slow mechanical stimulation, the silicone elastomer and an embedded cavity design enable i-NGs with extremely low Young's Modulus (46 kPa), exactly matching the mechanical property range of most soft biological tissues. By implanted inside the abdominal cavity of Sprague Dawley (SD) adult rats, the i-NG could convert slow diaphragm movement during normal breath into stable high-frequency electrical spikes, which were readily transmitted into a continuous ~2.2 V DC output on a LED load after being integrated with a basic electrical circuit (rectifier and capacitor) for a relatively long period of time.
This electric output could continuously power the LED without any observable power decay, successfully demonstrating a constant operation of small electronics DC power free of the battery component.This solely biomechanical-energy driven DC micro power supply offers a very promising solution for the development of self-powered IMDs in the near future.

Self-Activated Omnidirectional Electrostimulator for Effective Hair Regeneration Guang Yao, Xiaoyi Mo, Jingyi Yan, Qian Wang, Chenhui Yin and Yuan Lin; University of Electronic Science and Technology of China, China

Hair loss is classified as a dermatological disorder due to growth factors deficiency and/or hair cycle disorder, which is a common disease for both men and women throughout the world and the number of hair loss cases in 2011 has exceeded 30% of the global population.[1,2] Major current treatments for hair loss including topical treatments, oral medicine and hair transplant to re-establish healthy hair growth cycles, where topical treatments are the most common choice by patients due to the non-invasive nature and high absorbability. Minoxidil (MNX) and oral finasteride are the two FDA-approved drugs to treat hair loss, but they may still induce severe side effects. Hair transplant is invasive and associated with high cost, discomfortness and time commitment.[3] Recent study showed electric stimulation can induce a non-invasive biological effect named electrotrichogenesis (ETG), which could enhance the influx of calcium ions into the dermal papilla cells via voltage-gated transmembrane ion channels, facilitate ATP synthesis in mitochondria, activate protein kinases, and stimulate protein synthesis and cell division.[4,5] As a result, the ETG effect is believed to be able to regulate secretion of multiple hair growth factors, promote hair follicles (HFs) proliferation, prolong the anagen stage, and ultimately promote hair regeneration. However, the electrical stimulation is typically complicated for implementation and not quite suitable for everyday treatment.
Here, a universal motion-activated and wearable electric stimulation device (*m*-ESD) that can effectively promote hair regeneration via random body motions was designed.[6] Significantly facilitated hair regeneration results were obtained from Sprague-Dawley (SD) rats and nude mice. On shaved SD rats, compared to the other conventional pharmacological MNX and vitamin D_3 treatments, the hair growth rate in *m*-ESD region is 0.73 mm per day, and the final hair shaft length under *m*-ESD was 1.8 times and 2.2 times longer than those treated by MNS and vitamin D_3, respectively. Meanwhile, the HF density from *m*-ESD stimulating was 141% of the MNX and vitamin D_3 regions. We also showed that *m*-ESD can promote HFs proliferation and improve the secretion of vascular endothelial growth factor and keratinocyte growth factor, and thereby alleviate hair keratin disorder, increase the number of HFs and promote hair regeneration on genetically defective nude mice. In general, our work provided an effective hair regeneration strategy in the context of non-pharmacological self-

powered wearable electronic device, and possessed a great value in reshape modern pharmacological physical approaches in biomedical treatments. It is expected to be able to quickly evolve into a practical and facile solution to address the hair loss problem suffered by billions of people over the world.

Flexible Symbiotic Non-Pharmacological Biomedical Therapy Systems Guang Yao, Xiaoyi Mo, Jingyi Yan, Maowen Xie, Tianyao Zhang and Yuan Lin; University of Electronic Science and Technology of China, China

Flexible bioelectronics, integrated into a variety of accessories, seamlessly fitting to the skin, or even implanted in the living body, have been extensively researched and have made great progress in biomedical fields such as electronic skin, intelligent monitoring and human-machine interface.[1,2] In particular, a significant interest of flexible bioelectronics lies in monitoring physiological signals, revealing timely information on the state of our body and further providing actionable feedback for disease treatment to sustain a healthy lifestyle.[3,4] In addition, non-pharmacological neuromodulation can manipulate influencing neurophysiological signals or body functions by stimulating through the neural networks to achieve therapeutic purpose, which is a non-destructive and reversible therapeutic strategy.[5,6] However, the device power source still faces the limitation of large size, rigidity and short working life.[7] If wearable electronic devices can be attached to a living body to collect energy generated by low-frequency motion and directly drive a flexible smart biomedical device, the nonnegligible problem of the size, rigidity and working life can be solved.
Here, we present a novel symbiotic non-pharmacological therapy system through low-invasive electrical intervention methods, including a wearable hair regeneration device, an implantable weight loss device and a biodegradable tissue repair device, emphasizing their role in biomedical applications in vivo and problems in practical applications. The work of weight loss provides an efficient and low-invasive strategy, and the weight of the device-implanted rat group was reduced by ~40% compared with the control group. A closed-loop feedback regulation system through food intake, gastric motion, electrical neuromodulation and brain control was established. Meanwhile, in the experiments of hair regeneration and tissue repair, the non-pharmacological electrical stimulation can regulate secretion of multiple growth factors, promote cell proliferation, and ultimately achieve the efficient repair effect. In general, due to the non-pharmacological and low-invasive nature, the widespread application of symbiotic bioelectronics will effectively treat more diseases or symptoms.

Energy Harvesting and Ultra-Low Power Electronics for Implantable Biosensors and Sustainable Iot

Tharun R. Kandukuri[1], Pelumi Oluwasanya[1], Ioannis Prattis[1], Vincenzo Pecunia[2] and Luigi G. Occhipinti[1]; [1]University of Cambridge, United Kingdom; [2]Soochow University, China

Energy-autonomous smart sensor systems have been the subject of intense research and innovation activities for applications in multiple and diverse sectors, from wearable wireless sensor patches in sport, wellness and healthcare to battery-assisted distributed sensor nodes for the Internet of Things [1]. Selecting and combining energy harvesting from multiple sources, including from mechanical displacements, thermal gradients and electromagnetic radiations, from radiofrequencies to visible and infrared light, provides a unique opportunity to extend the battery life throughout the entire lifetime of the device [2]. This is particularly important in applications where physical access to the system once in operation is not convenient, such as in distributed environmental sensors for air quality monitoring in metropolitan or rural areas, and indoor [3], as well as in implantable medical devices, such as those operating low voltage (<1V) biosensors in contact with organs and tissues in order to avoid water electrolysis and faradaic reactions [4].
Both fields are critically affected by the appropriate choice of materials in terms of environmental sustainability at the end of life, such as the battery component materials. In recent work we have demonstrated the possibility to operate the front-end and digital electronics via printable thin-film transistors with a carbon nanotube-based channel and hybrid nanodielectrics operating in the deep-subthreshold ambipolar regime, achieving ultralow voltage (<0.5V) and record-low power consumption of 10^{-15}-10^{-12}W/μm per gate [5].
Hence our research focuses on combining smart sensor technologies with energy harvesting and ultra-low power electronics to achieve long-lifetime and battery-less biosensor systems and sustainable IoT nodes for "place and forget" applications.
Different types and forms of piezoelectric materials such as thin films, bulk or nanowires have been subject of intense research as a route towards mechanical energy harvesting and triboelectric nanogenerators with both environmental sustainability and biocompatibility. Piezoelectricity has been theoretically predicted first [6] and then reported in low dimensional materials, such as hexagonal boron nitride (hBN), transition metal dichalcogenides (TMDs), including MoS_2, $MoSe_2$, WS_2, WSe_2, $MoTe_2$ WTe_2, and graphene engineered by atom adsorption (with e.g. Li, K, F, H) or by incorporating non-centrosymmetric in-plane defects [7], with coefficients of piezoelectric strain (d_{11}) and piezoelectric stress (e_{11}) of the 2H-TMD monolayers comparable to, sometimes even better than, those of the conventional bulk piezoelectric materials, such as AlN and GaN. Additionally, it has been discovered that ultrathin MoS_2 with odd-layers could produce oscillating piezoelectric voltage and current outputs with highest values of the piezoelectric coefficient recorded in the case of a monolayer of MoS_2, whereas no piezoelectric output was observed for the MoS_2 with even-layers [8]. More recent works have reported enhanced values of the piezoelectric effect induced in butterfly-shaped monolayers of MoS_2 with grain boundaries (GB-MoS_2) achieving current densities 50% higher than those measured in MoS2 monolayers without grain boundaries [9] paving the way towards practical energy harvesting applications for self-powered printed electronic devices.

11:20 AM NM09.08.05

Comparison Between a Selection of Stable and Unstable Charge-Pumps for TENG Conditioning

Ahmad Delbani[1], Naida Hodzic[1], Armine Karami[1], Dimitri Galyko[2] and Philippe Basset[1]; [1]ESYCOM, Université Gustave Eiffel, France; [2]LIP6, Sorbonne Université, France

Triboelectric energy generators (TENGs) are characterized by their high electric field and relatively high output

power. They usually generate high AC open-circuit voltage around hundreds of volts peak-to-peak, with relatively low short-circuit current around tens of micro ampere (μA) peak-to-peak. However, most applications require DC voltages around a few volts, with DC current of at least a few hundreds of μA, and a conditioning circuit for the TENG is needed to rectify the high AC voltage. Moreover, for a better kinetic-to-electrical energy conversion, TENGs need to maximize their bias voltage, which can be improved with dedicated conditioning circuits (CC). CC can be separated in two categories: Stable Charge Pumps (SCP) and Unstable Charge Pumps (UCP). SCPs reach constant saturation voltage after a few mechanical cycles, whereas the UCPs can generate an exponential increase of the output voltage until the components' limitation, even with a basic TENG. Although the unstable charge pumps can show biasing advantages over the stable charge pumps, UCP must have a minimum TENG's capacitance variation for an adequate operation, characterized by the max-to-min ratio η. This constraint may differ from one UCP architecture to another.
In this presentation, we will compare several stable charge pumps (half/full-wave bridge rectifiers and Cockroft Walton multipliers) with different architectures of unstable charge pumps such as Bennet's doubler and its variations from Lefeuvre and Karami. A series of simulations are conducted for all the conditioning circuits under the same parameters for the TENG and the same simulation conditions. The transducer used in simulations has a surface area S=9 cm^2, and a surface charge density σ = -50μC/m^2.
It is not simple to make a valid comparison between the UCPs and SCPs. SCPs reach a saturation voltage so the optimal power and the energy conversion is achieved during a specific mechanical cycle. On the other hand, UCPs' rectified voltage is always increasing thus the energy, and there is no specific optimal power. Due to such discrepancy between the two, the comparison will be done by choosing a certain mechanical cycle at a given maximal voltage and calculating its QV-cycle area. We show that there is a tradeoff between the time needed to reach the high energy conversion state and the amount of the converted energy. SCPs are more convenient if we need to reach a significant energy conversion rate very quickly. On the contrary, if we want much higher energy conversion, UCPs need to be chosen, but it requires more time, thus average power cannot be that good, unless a 2-stage power management system is used.

11:30 AM NM09.08.06
Study of the Bennet Doubler Conditioning a TENG with a Double Anti-Phase Variable Capacitance
Naida Hodzic[1], Ahmad Delbani[1], Minki Kang[2], Armine Karami[1], Sang-Woo Kim[2], Dimitri Galayko[3] and Philippe Basset[1]; [1]ESYCOM, Université Gustave Eiffel, CNRS, CNAM, France; [2]Sungkyunkwan University (SKKU), Korea (the Republic of); [3]Sorbonne Université, LIP6, France

Kinetic energy harvesters (KEHs) are typically not considered as stand-alone devices having very high voltage and low current at the output. Given that the direct converted energy cannot be sufficient for powering a system, and at minimum need to be rectified, conditioning circuits are necessary. Traditionally, stable charge pumps such as half- full-wave rectifier, or unstable charge pumps such as Bennet's doubler are used. It has been previously shown that unstable charge pumps can be significantly more efficient due to no limitations or saturation points in charge multiplication. Keeping the high energy conversion in mind, Bennet's charge doubler has been studied in detail and applied to different architectures and types of electrostatic KEHs, such as triboelectret nanogenerators (TENGs). Several variations of this circuit have also shown the expected exponential increase with various optimum for specific TENG configurations.
By adding a third electrode to a classical 2-electrode TENG, we can obtain a device with three terminals and two variable capacitors having a 180° phase-shift. Converted energy of such device is higher than of a similar TENG with one variable capacitor, but specific conditioning is needed. In this work, we demonstrate that replacing the fixed capacitor in Bennet's charge doubler by the 2nd variable capacitor of the 3-electrode TENG leads to higher converted energy. While this new combination gives promising results, its behavior and details about each phase that occurs during one conversion cycle have not been fully analyzed yet.
To obtain the most information about the circuit's behavior during the energy conversion process, the best is to observe the change of voltage and charge over the two TENG's variable capacitors. Taking each of them and examining their behavior through variation of the two mentioned parameters gives the converted energy in each mechanical cycle. This study discussed critical points occurring during one conversion cycle that are a combination of mechanical and electrical variations occurring at the same time. Constraints are set for the

TENG, particularly the physical parameters defining $\eta = C_{max}/C_{min}$ ratio conditioning the start of the circuit. Furthermore, we broke down and analytically expressed each significant moment within one mechanical cycle of double variable TENG. Each crucial point is defined by relevant parameters such as local capacitance, voltage and charge over the capacitor, leading to the full definition of such a system.
The analytical study of double variable TENGs is corroborated with simulation models with Bennet's charge doubler circuit operating in steady state, or in other words, when exponential output is guaranteed. Theoretical study and simulation results have been completed by experimental test through practical implementation of a gap-closing double variable TENG and the charge doubler circuit, leading to the conclusion that, indeed, realistic systems convert expected higher amounts of energy.
Even though this study has been conducted on double variable gap-closing TENG, it can be universally applied to any three-terminal KEH with a phase shift of 180° between its output signals, ensuring steady exponential output.

Late News: Combined Design of Wind Tunnel and Triboelectric Structure for Optimized Power Conversion Elias Kharbouche, Cyril Calmes, Marc Ramuz, Roger Delattre and Sylvain Blayac; Mines Saint-Etienne, France

The last decade highlighted Triboelectric Nanogenerators (TENGs) as a very promising technology for the conversion of mechanical energy into reliable electrical power sources. This technique takes advantage of the triboelectrification effect. Nowadays, lithium batteries supply the biggest part of Internet of Things (IoT) nodes since their energy storage density is significant. However, considering the limits in terms of maintenance cost, resources consumption and environmental dissemination, it is highly desirable to develop alternative self-powering solutions. In the context of the fourth industry era, the wind energy extraction from ventilation systems or areas with permanent airflows can supply enough power for the operation of numerous sensors deployed in the facilities. Ambient energy harvesting is then to be considered as an attractive solution to provide sustainable power sources.

Our initial investigation of an Insulator-Metal-Insulator (IMI) composite thin-film reported an attractive way to obtain compact devices with high power density. The presented work highlighted the great potential of this multilayer structure in a high-performance Wind Actuated Triboelectric Nanogenerator (WATENG). For this study, the collecting wind tunnel is improved. This solution converts wind power to lateral oscillations in a symmetric triboelectric structure using mobile flexible electrodes. This innovative architecture optimizes the triboelectric charges accumulation into metal islands to boost the output power of the WATENG. Different customized stacks and materials are investigated to overcome the localized charge density saturation into the triboelectric harvesting layers.

This study demonstrates the great potential of an IMI structure coupled to a pioneering WATENG architecture in the same device, to greatly enhance the potential airflow-powered connected objects.

Late News: Ultraflexible and High-Durable Ferroelectric Transducers and Organic Circuits for Energy-Efficient Wireless Health Patches Andreas Petritz[1,2], Esther Karner-Petritz[1,2], Takafumi Uemura[2], Philipp Schäffner[1], Teppei Araki[2], Barbara Stadlober[1] and Tsuyoshi Sekitani[2]; [1]Joanneum Research

Forschungsgesellschaft mbH, Austria; [2]Osaka University, Japan

Health is a very precious commodity, as we experience every day and especially in these times shaken by a pandemic. Continuous recording of health status through diagnostic techniques that combine high wearing comfort with high reliability, accuracy and cost-effectiveness is therefore very desirable. In this context, we present an ultraflexible solution for the power supply of wireless medical patches for monitoring of heart rate and blood pressure. The ultraflexibility is due to the very low overall thickness (only 2.5 µm in total) of the ferroelectric polymer transducers, organic rectifiers and capacitor components manufactured on a substrate only 1 µm thick, and it guarantees high sensitivity (15 nC N^{-1}), superior component reliability (over 6000 cyclic loading) and a very high peak power density (1 mW cm^{-3} at 2 Hz excitation). Our health patch solution not only includes this radically reduced layer thickness, but also new material combinations (ferroelectric polymers on parylene), novel device concepts (organic thin-film transistor-based diodes) and new integration principles (multi-stack transducers on 3D curved surfaces).[1]

1:10 PM NM09.09.03
Late News: Fully Spray Coated Flexible Triboelectric Devices for Self-Powered Wearable and Ubiquitous Sensors Shujia Xu[1,2] and Wenzhuo Wu[1,2,3]; [1]Purdue University, United States; [2]Flex Laboratory, United States; [3]Birck Nanotechnology Center, United States

Triboelectric nanogenerator (TENG) has been widely used as self-powered wearable sensor, and progresses on novel material for high output TENG have attracted tremendous attention. However, simultaneous consideration on materials system design and manufacture process receives limited attention. Manufacture and encapsulation techniques feasible for large scale fabrication compile with functional materials systems need to be developed. Spray coating is an attractive method due to its potential for large scale deposition of ink-based materials. Here, we demonstrate fully sprayed TENG using ink-based functional materials. Several functional inks compatible with spray coating are formulated to fabricate flexible TENG for human pulse monitoring and human-machine interaction. All functional materials are solution processable and can be sprayed layer-by-layer to form the triboelectric sensor. Such flexible sensors could also be sprayed and integrated on arbitrary surfaces for ubiquitous electronics and sensors.

1:20 PM *NM09.09.04
Bio-Derived Materials Based Wearable Triboelectric Sensors for Human-Integrated Technologies
Wenzhuo Wu; Purdue University, United States

The capability of sensor systems to efficiently scavenge their operational power from stray, weak environmental energies through sustainable pathways could enable viable schemes for self-powered health diagnostics and therapeutics. Triboelectric nanogenerators (TENG) can effectively transform the otherwise wasted environmental, mechanical energy into electrical power. However, obstacles hindering the development of efficient triboelectric devices based on biocompatible materials continue to prevail. I will discuss our recent progress in the design and engineering of bio-derived materials for biocompatible, wearable triboelectric devices.

Such wearable devices are conformable to human skins and can sustainably perform non-invasive functions, e.g., gesture recognition, by harvesting the operation power from the human body. These devices can also detect the imperceptible skin deformation induced by the human pulse and capture the cardiovascular information encoded in the pulse signals with high fidelity. The gained fundamental understanding and demonstrated capabilities enable the rational design and holistic engineering of novel materials for more capable biocompatible triboelectric devices that can continuously monitor vital physiological signals for self-powered health diagnostics and therapeutics.

1:40 PM NM09.09.05
High-Performance Tactile Graphene-Based TENG Devices Based on Simple Laser-Assisted Fabrication Method Kapil K. Bhorkar[1,2], Nikolaos Samartzis[1,3] and Spyros N. Yannopoulos[1]; [1]FORTH, Greece; [2]Univ Rennes, France; [3]University of Patras, Greece

Strong research efforts have been dedicated towards the miniaturization of energy conversion devices to support the development of self-powered sensors and relevant devices. The harvesting of ambient energy, predominantly vibrational motion, has been demonstrated to convert into the electrical energy by employing various mechanisms, such as electrostatic, electromagnetic, and piezoelectric. These devices face a number of unachievable targets related to the proper output power demanding by specific applications, durability to withstand long life time and flexibility to conform to requirements of wearable electronics. Triboelectric nanogenerators have emerged as an alternative technology to confront with the above challenges. The first TENG devices have been envisaged and fabricated by Wang and co-workers [1]. The working principle is based upon the coupling between electrostatic induction and triboelectric effect. In the current work, we apply a novel method which entails the simultaneous growth and deposition of graphene on any substrate with the use of laser-assisted decomposition of organic compounds. The method allows the deposition of hybrid nanomaterials with a single laser processing step. Employing this method, a single-electrode TENG device architecture was implemented by the direct laser-assisted forward transfer of graphene and graphene/SiO_x hybrids on PDMS substrate acting as one of the tribo-materials. A fairly low sheet resistance of the graphene film and its ability to withstand several cycles of operation are key factors towards replacing the precious metals deposited on the back side of the contact material. The electrical features and the output power of the flexible single-electrode TENG devices were evaluated against various external loads. A remarkable finding of this work is that the current external resistance value providing maximum output of the TENG, is much lower than values reported in the literature. Given the high impedance of other TENGs, this is a significant advantage of the current device, considering that the reduction of the internal impedance is highly desirable in a number of applications requiring low impedance loads for many practical applications.

1:50 PM NM09.09.06
Understanding the Fundamental Role Played by Electrodes Design for Increasing Triboelectric Nanogenerators Power Output Giuseppina Pace[1], Michele Serri[2], Alberto Ansaldo[2], Antonio Esau Del Rio Castillo[3] and Francesco Bonaccorso[3]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]BeDimensional S.p.A., Italy

The operation of wearable and portable electronics requires only few tens of microwatts of power supply. These new low power devices, such as the one largely developed for the internet of Things technologies (IoT), have fostered the development of low power energy sources which harvest the environmental green energy. In particular, the fast-growing demand for new sustainable energy, and the ubiquitous and abundant environmental mechanical energy, has raised the interest in energy harvesters able to convert such energy into electrical power. Triboelectric nanogenerators (TENGs) can provide such green power supply. Recent developments in TENGs technology show that they can be used in different applications ranging from wearable self-powered sensors to wind and sea wave energy harvesting (blue energy). Despite the wide number of TENGs developed so far, an in depth understanding of their working mechanism operating at the sub-microscale is still missing. In this work, we highlight the fundamental role played by the interface between the triboelectric material and the electrode collector in contributing to the TENG's power generation. In particular, we will show the fundamental role played by the electrodes work function and capacitance in boosting triboelectric nanogenerators power outputs. We will describe the guidelines for the combination of electrode and triboelectric materials to optimize the mechanical energy conversion efficiency in TENGs. The outcomes of our studies provide essential insights for the proper design of new TENGs to the aim of further enhancing their performances.

2:00 PM NM09.09.07

Strain-Induced Piezoelectric Polarization of Zinc-Oxide Nanosheets Studied via Piezo Force Microscopy
Corey Carlos, Kevin J. Berg and Xudong Wang; University of Wisconsin–Madison, United States

Flexible, wearable, and human-compatible electronics are helping shape a future of integrated nanotechnologies. As such, piezoelectric and semiconducting materials have drawn intense interest by many research groups for the excellent potential to advance the field of wearable devices. Moreover, two-dimensional (2D) nanomaterials, valued for their enhanced mechanical, electronic, and structural properties, have moved to the forefront of compliant electronic devices. Therefore, a thorough understanding of the interfacial charge distribution is required when utilizing flexible piezoelectric semiconductors, such as zinc-oxide (ZnO). We present a method for monitoring the piezoelectric response of nanometer-thick 2D ZNO nanosheets (NS) grown via Ionic Layer Epitaxy (ILE). The direct piezoelectric effect, and the coupling of electronic dipole polarization to lattice strain within ZnO-NSs, is monitored *in situ* via piezo force microscopy (PFM). Using PFM, we illustrate the effects of modulating strain in piezoelectric nanomaterials and its role in the polarization charge distribution across the surface of the 2D ZnO-NS. Our results illustrate the critical need for understanding the interdependent roles of static piezoelectric charges, semiconducting properties, and strain, for future flexible devices.

NM09.10.01
Self-Powered Electronic Paper with Energy Supplies and Information Inputs Solely from Mechanical Motions Tingting Hou[1,2], Bo-ru Yang[3], Xiong Pu[1,2] and Zhong Lin Wang[1,2]; [1]Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, China; [2]University of Chinese Academy of Sciences, China; [3]Sun Yat-sen University, China

The electronic paper (E-paper) display features flexibility, sunlight visibility and low power consumption, which makes it ideal for Internet of Things (IoT) applications where maintenance of bulky power modules is better to be eliminated. In electrophoretic E-papers, the most successfully commercialized E-paper technology, there are generally different color particles, and these particles are usually surface-modified and charged by charge control agents (CCAs) for good stability in nonpolar solvent. The color of a pixel is updated by changing the distribution of charged pigment particles of different colors between two electrodes with an external electric field. With the specific driving waveforms, different distributions of pigment particles are formed to provide various colors according to Grassmann's laws, which indicates the possibility of full-color E-paper.
Currently, smart sensor networks of the emerging Internet of Things (IoT) have to be self-powered by the energy *in-situ* harvested from the working environment, so as to avoid the impossible maintenance of numerous smart devices. This trend bring E-papers new opportunities, especially if a low-power E-paper can be integrated with an energy-generating device for self-powered displays.
Therefore, we report a unique self-powered E-paper (SPEP), where information inputs and energy supplies are all converted from mechanical motions by a sliding-mode triboelectric nanogenerator (TENG). The operation of an electrophoretic E-paper is firstly investigated, identifying the current density as a determinative parameter for driving pigment particles motion and color change. Electrical and optical responses of the E-paper driven by a sliding-mode TENG are then found to be consistent with that under a current source mode. All-in-one monochromic and chromatic SPEPs integrated with a flexible transparent TENG are finally demonstrated. The sliding-driven mechanism of SPEP allows potential handwriting function, is free of extra power supply and promises certainly a wide range of future applications.

NM09.10.02

Acoustic Sensor Based on Two-Dimensional Piezoelectric MoS_2 Hyoung Taek Kim, Ahrum Sohn, Jae-Hwan Jung and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

Experimental studies on the physical properties of two-dimensional (2D) materials have grown exponentially since 2D materials offer unique advantages for use in such next-generation devices. Various semiconducting 2D materials have been studied, including transition metal dichalcogenides (TMDs) such as molybdenum disulfide (MoS_2), molybdenum diselenide ($MoSe_2$), tungsten diselenide (WSe_2), which are likely to bring breakthroughs in future electronic and optoelectronic devices. The physical properties of 2D MoS_2 nanosheets have been actively explored particularly as a result of their possible integration in both nano/microelectromechanical devices and energy harvesting devices. Monolayer MoS_2 has a direct band gap and high mobility and has been used to successfully fabricate field-effect transistors so it has emerged as an interesting complement to graphene in various semiconducting applications. In additions it is expected that piezoelectric properties of 2D layered materials are very useful to realize highly sensitive, high impact resistive, self-powered sensor. However, studies on the suspended model of 2D MoS_2 have been done mainly on studies on the measurement method or photosensitivity, and studies using the piezoelectric characteristics of suspended MoS_2 have not been actively done. Here we demonstrate a new way to use 2D MoS_2 for highly sensitive 2D piezoelectric acoustic sensor. The acoustic sensor fabricated by using suspended structure of MoS_2 that generate piezoelectric output potential due to vibration transmitted by sound. We have achieved high sensitivity and high impact resistance by using single layer or several layers of MoS_2, and by using piezoelectric properties of MoS_2, we have produced an acoustic sensor that does not require standby power. This study demonstrates a new way of studying 2D MoS_2 research and acoustic sensors by developing a high-sensitivity and high-durability acoustic sensor using suspended MoS_2.

NM09.10.05

Anisotropic Structural Index for Ferroelectric Properties of Strained $KNbO_3$ Perovskite Polymorphs Woohyun Hwang, Seungjae Yoon, Jihwan Lee and Aloysius Soon; Yonsei University, Korea (the Republic of)

Despite many attempts to harness a strain-driven control of ferroelectric properties in thin films, there remains a technical hurdle to understand the delicate relationship between crystal structure, spontaneous polarization (P_s), and the electronic band gap (ε_{gap}) modulation under the anisotropic strain. To further our understanding of how these complex anisotropic structure-property relationships may be rationalized by their local atomic arrangements in ferroelectric materials, we perform first-principles density-functional (perturbation) theory calculations to understand how applied epitaxial strain may influence their structural, thermodynamic, electronic, and (anisotropic) polarization properties in polar $KNbO_3$ polymorphs – a potential contender for Pb-free piezoelectric applications. Specifically, we examine the displacement of the center metal cation (niobium, Nb) as a key descriptor for its polar behavior and find that it exhibits an anisotropic nonlinear relationship between εgap and the commonly-used isotropic scalar quadratic elongation ($<\lambda>$). To overcome the inadequacy of the simple $<\lambda>$, we propound a revised definition of this key structural descriptor – the new bond elongation index (λ_i), that contains vectorial structural information. Using λ_i, we successfully rationalize the linear dependency of direction-dependent P_s on λ_i for strained $KNbO_3$ polymorphs with a R^2 value of 0.998. We further demonstrate and verify that this newfound linear relationship can be used to predict direction-dependent P_s in $BaTiO_3$ polymorphs without further expensive calculations under strain, and thus allows for the fast and consistent determination of direction-dependent P_s in strained perovskite polymorphs in the course of high-throughput polar materials design.

NM09.10.07

Auxetic Structure Enabling the Bending Energy Harvesting Mode of Piezoelectric Nanogenerator Xinran Zhou[1,2], Shlomo Magdassi[3,2] and Pooi See Lee[1,2]; [1]Nanyang Technological University, Singapore; [2]Campus for Research Excellence and Technological Enterprise (CREATE), Singapore; [3]The Hebrew University of Jerusalem, Israel

Piezoelectric nanogenerator (PENG) is a kind of mechanical energy harvester, which utilizes the dipole moment in piezoelectric material to convert mechanical energy to electrical energy. Among all piezoelectric materials, PVDF-based piezoelectric polymer is one of the best materials for PENG due to its high piezoelectricity, light weight, simple fabrication, and high toughness and flexibility comparing with the ceramics. However, since the elasticity of PVDF-based polymers is low, the piezoelectricity in the 31 and 32 directions are underutilized. In this work, auxetic structure is 3D printed onto the drop casted piezoelectric film, of which the synclastic effect enables the bending mode energy harvesting of piezoelectric films by slightly stretching the film in 1 and 2 directions during bending, activating the 31 and 32 direction piezoelectric effect, at the same time the tensile strain of the film can be controlled to avoid over-stretching the device. The structure design and strain distribution are evaluated by finite element analysis. The piezoelectric composites made of P(VDF-TrFE) copolymer and surface modified barium titanate nanoparticles effectively improves the piezoelectricity. With the auxetic structure, the PENG can generate voltage over six times of that without the auxetic structure. Under slight bending, it generates 350 nW/cm^2 power density. The PENG is also demonstrated as a sensor to detect the motion at various positions on human body.

NM09.10.08

Self-Powered Flexible Fiber-Based Triboelectric Sensors Toward Traffic Monitoring System Guangqing Liu, Xiya Yang, Jialong Duan and Qunwei Tang; Institute of New Energy Technology, College of Information Science and Technology, Jinan University, China

With the rapid development of 5G network and internet of things (IoT), there are incredibly increasing sensors and corresponding applications emerging to benefit our daily lives. However, the power supplies for the countless sensors become an issue to suppress the IoT further expansion. In this work, we present a strategy which applies triboelectric nanogenerator (TENG) as self-powered sensor in traffic control system. Flexible and reliable polyvinylidene fluoride (PVDF) embedded with multi-wall carbon nanotubes (MWCNTs) fiber-based composite membrane is synthesized by electrospinning to act as triboelectric layers. Vertical contact-separation mode is adopted to design the fiber-based triboelectric sensor toward detecting the incoming vehicles signals on roads. Through systematically investigating the impacts of MWCNT concentration and controlling the electrospinning parameters, the electrical output performances of the fiber-based triboelectric sensors are optimized and an ultra-sensitivity can be achieved for detecting the vehicles signals. Based on the sensors' electrical charges outputs and the advanced cloud IoT services, a traffic control system including traffic flow management, offending vehicle such as overlapping and overspeed capture, and plate number recognition is developed to facilitate the potential application scenarios of the fiber-based triboelectric sensors. This engineered self-powered triboelectric sensors not only open a new potential area for TENG in traffic monitoring, but also significantly popularized the application of TENG in IoT industry.

NM09.10.09

Honeycomb Structured Triboelectric Nanogenerator for High-Efficiency Particulate Matter Filtration Toward Vehicle Exhaust Scavenging Dahao Chen[1,2], Xiya Yang[1], Chuanyong Xu[1,2], Xiaozhen Du[2] and Qunwei Tang[1]; [1]Institute of New Energy Technology, College of Information Science and Technology, Jinan University, China; [2]College of Mechanical and Electronic Engineering, Shandong University of Science and Technology, China

Air pollution has become a major environmental concern due to the large amount of air pollutants emitted from human activities such as traffic, industry, and power plants. Particulate matter (PM) serious impacts the living environment in terms of air quality, visibility, climate effects and ecosystems. Haze is mainly formed by PM2.5 (PM with diameter of 2.5um or less), which results in serious health issues such as cardiovascular and respiratory diseases and even lung cancer, increasing the morbidity and mortality. Based on the coupling of the triboelectric effect and electrostatic induction effect, the typical characteristic of triboelectric nanogenerator (TENG) is its high voltage output of hundreds to thousand volts, which is promising for capturing the PMs using electrostatic effect without external power supply. Herein, a honeycomb ceramic based triboelectric PM

vehicle exhaust filter (HTPMF) filled with fluorinated ethylene propylene (FEP) particles is introduced to efficiently capture the PMs from vehicle exhaust. Finite element analysis software (COMSOL) is applied to simulate the dynamic behaviors of the triboelectrification process of the PMs in the HTPMF. An open-circuit voltage of 63V can be achieved in one single hole of the HTPMF. Through well controlling the number of FEP particles, the achieved filtration efficiency for PM1.0, PM2.5, PM4.0, PM10 are all over 90% with the highest filtration efficiency of 93.49% for PM2.5. This honeycomb triboelectric PM filter presents promising potential in the application for industrial dust emission and vehicle emission removal.

Fusion of Slippery Interfaces and Transistor-Inspired Architecture for Water Kinetic Energy Harvesting
Wanghuai Xu and Zuankai Wang; City University of Hong Kong, Hong Kong

Water and energy, as two fundamental components of our 21st-century life, cannot be considered separately. Solving this water-energy nexus becomes a promising strategy to relieve the global energy and water crisis facing humanity today. In this regard, the diversiform water-related energies, such as tidal energy, wave kinetic energy, and thermal differential energy, are being explored to generate electricity. Recently, interfacial energy harvesting, relying on the interfacial charges and relative motion between two different materials, is drawing significant attention, as it provides new pathways for collecting the low-frequency water energy. In spite of the extensive progress, the state of the art low-frequency water energy harvesting devices are generally limited by low energy density, poor durability, and hence it remains challenging for multiscale practical implementations. In this talk, I will focus on high-performance water kinetic energy harvesting by designing novel slippery materials and novel electrode architecture. First, I will report an original droplet-based energy generator (DEG) with transistor-inspired architecture that fundamentally overcomes the physical limitation inherent in the traditional approaches, which are imposed by the undesirable interfacial effect, and achieves the highest energy conversion efficiency and power density. Second, inspired by hierarchical structures on the peristome of the Nepenthes pitcher, we will also report a novel slippery lubricant-impregnated porous surface (SLIPS)-based TENG, termed as SLIPS-TENG, that exhibits distinctive advantages including optical transparency, self-cleaning, impact tolerance, flexibility, and enhanced power generation stability even under harsh environments. In the future, we envision fusing the advantages inherent in slippery interfaces and transistor-inspired architecture will provide a paradigm shift in the design of efficient energy harvesting devices, and trigger a new wave in the research of the water energy harvesting, including basic fundamental understanding, material design, as well as the multiscale practical applications.

8:10 AM NM09.11.05
A Highly Efficient Triboelectric Negative Air Ion Generator Hengyu Guo; Chongqing University, China

Negative air ions (NAIs) have been widely harnessed in recent technologies for air pollutant removal and their beneficial effects on human health, including allergy relief and neurotransmitter modulation. Herein, we report a corona-type, mechanically stimulated triboelectric NAI generator. Using the high output voltage from a triboelectric nanogenerator, air molecules can be locally ionized from carbon fibre electrodes through various movements, with the electron–ion transformation efficiency reaching up to 97%. Using a palm-sized device, 1 × 1013 NAIs (theoretically 1 × 105 ions cm−3 in 100 m3 space) are produced in one sliding motion, and particulate matter (PM 2.5) can be rapidly reduced from 999 to 0 μg m−3 in 80 s (in a 5,086 cm3 glass chamber) under an operation frequency of 0.25 Hz. This triboelectric NAI generator is simple, safe and

effective, providing an appealing alternative, sustainable avenue to improving health and contributing to a cleaner environment.

8:20 AM NM09.11.06
Effect of Surface Modification on the Electromechanical Properties of Lead-Free (Na,K)(Nb,Sb)O_3-$BaZrO_3$-(Bi,K)ZrO_3) Nanoparticle-Embedded Piezoelectric Composite Nanofiber for Flexible Nanogenerators Seung-Rok Kim, Ju-Hyun Yoo, Ji Ho Kim, Yong Soo Cho and Jin-Woo Park; Yonsei University, Korea (the Republic of)

Emerging deformable energy harvesting systems gain a significant interest as power sources for wearable and implantable electronics because they acquire and convert readily available mechanical, ambient light, biochemical, and thermal energies from the human body and surroundings into electrical energy. Among deformable energy harvesting systems, piezoelectric nanogenerators (PNGs) are the most promising because they harvest the mechanical energy provided by the evermoving and deforming human body to empower wearable electronics. Although PZT is one of the most extensively exploited ceramic piezoelectric materials because of their high piezoelectric coefficient, high Curie temperature, and low cost, the inherent toxicity and rigidity of Pb-based PZT restrict its application to wearable electronics. Hence, tremendous efforts have been made to develop Pb-free perovskite-structured ceramic alternatives to solve the safety issues of PZTs, while the hybrid composite of Pb-free perovskite-structured ceramics with organic polymers ensures the deformability of f-PNGs as the power sources of wearable electronics. However, the excellent mechanical energy harvesting performance of flexible PNGs made of perovskite ceramic nanoparticles (PCNPs) embedded in piezoelectric polymer NFs is challenging to achieve because of the poor adhesion between the ceramic and polymer materials. Because of the weak interaction of the ceramics and polymers together with the very high surface-to-volume ratio of the nanoparticles, the PCNPs easily form agglomerates within the polymer NFs. In this work, we investigated the mechanical and piezoelectric properties of Pb-free NKNS-BZ-BKZ PCNPs uniformly embedded in c-NFs for f-PNGs. A significant reduction in the agglomerate size of the PCNPs and their enhanced interfacial adhesion with the P(VDF-TrFE) matrix were achieved through a tetradecylphosphonic acid (TDPA) surface treatment of the PCNPs. The surfaces of the NKNS-BZ-BKZ PCNPs were modified with TDPA to enhance the interfacial interaction of the PCNPs with the P(VDF-TrFE) matrices. We used the electrospinning method for fabricating the c-NFs of NKNS-BZ-BKZ PCNPs and P(VDF-TrFE) piezoelectric polymers. Particle size distribution analysis, transmission electron microscopy (TEM), and in situ tensile testing in a scanning electron microscope chamber were used to evaluate the effect of the TDPA surface treatment of the PCNPs on the mechanical properties of the c-NFs. The piezoelectric properties of the c-NFs were characterized through Kelvin probe force microscopy (KPFM) and PNG cell performance evaluation. The uniform distribution of the embedded PCNPs made the web of c-NFs highly negative relative surface potential and a high effective modulus of approximately 170 MPa. Consequently, the f-PNG with the TDPA surface-treated PCNPs maintained an open-circuit voltage, a high maximum generated power, and an output voltage of approximately 12.2 V, 33.2 nW, and 1.25 V, respectively, despite being bent for 10,000 cycles at a bending radius (r) of 15 mm.

Tactile Electronic Skin to Simultaneously Detect and Distinguish Between Temperature and Pressure Based on a Triboelectric Nanogenerator Fang Yi; Sun Yat-sen University, China

Tactile electronic skin (e-skin) aims to mimic the functions of skin, which could have profound implications for areas including medical care, prosthetics and robotics. However, it faces a great challenge to simultaneously detect and distinguish between multiple stimuli by a single device. Here, a tactile e-skin that can simultaneously detect and distinguish between temperature and pressure in real time is developed, based on a single-electrode-mode triboelectric nanogenerator (TENG) with a specially prepared thermoresistive electrode combining BiTO and rGO. The TENG based tactile e-skin outputs voltage in response to pressure and its electrode resistance changes in response to temperature (thermal sensitivity $\beta_{25/100}$: 1024 K, temperature coefficient of resistance: -1.15 %/K at 25 °C, range: 25~100 °C). The pressure sensing performance maintains stable with varying

temperatures and the temperature sensing performance is undisturbed under pressure. The tactile e-skin also demonstrates excellent sensing reproducibility and durability. When the e-skin is mounted on the human body, it can monitor and distinguish between temperature and pressure with the two signals imposing no interference on each other. This work provides new routes for wearable sensing and sheds new light on the development of electronic skin.

8:50 AM NM09.11.10
Fabrication of Piezoelectric Biomaterials for Energy Applications Rusen Yang; Xidian University, China

Multifunctional materials have received increasing attention in recent years. Owing to their inherent biological nature as well as piezoelectric properties, piezoelectric biomaterials are considered as promising candidates for application in fields ranging from electrochemical energy storage to biological systems. Rational material design is important to enhance their piezoelectric and biological activity. Herein, recent advancements to piezoelectric biomaterials like peptide-based micro/nanostructures are provided. Synthetic methods, morphological features, and piezoelectric performance of piezoelectric biomaterials are presented. The effect of growth direction, phase and structure of piezoelectric biomaterials on their piezoelectric activity are discussed. The applications of piezoelectric biomaterials in the field of nanogenerators are provided at the end.

9:00 AM NM09.11.12
Electrostatic Interaction Assembled Transparent Piezoelectret Zisheng Xu, Jun Zhou and Bin Hu; Huazhong University of Science & Technology, China

Piezoelectric polymers hold physical properties, such as high mechanical flexibility and smaller acoustical impedance, that ceramics do not. Nevertheless, owing to the lack of dipoles, most non-crystalline polymers are hard to generate a high piezoelectric response. Here, we developed a class of hybrid electret films with high piezoelectric performance via electrostatic self-assembly. Their piezoelectric effect stems from an out-plane electric-dipole structure in the inner dielectric polymer constructed by two electret films. The piezoelectret exhibits direct and converse piezoelectric effect (d_{33} of 77 pC/N, g_{33} of 4 V m/N), pyroelectric effect, and high mechanical flexibility. Additionally, we also developed different hybrid piezoelectric films and applied them to wearable electronics, such as ultrathin strain sensors and acoustic transducers, based on the ultrathin characteristic (~25 μm thickness), providing a different class of polymer piezoelectric film.

Late News: *In Vivo* Self-Powered Wireless Transmission Using Biocompatible Flexible Energy Harvester Min SeongWook and Dong Hyun Kim; KAIST, United States

The practical use of biomechanical energy is demonstrated with flexible single crystal PMN-PZT energy harvesters. A flexible PMN-PZT piezoelectric energy harvester is used to demonstrate powered, wireless data transmission activated by biomechanical energy in vivo derived from the movement of the heart in a large animal model. In the contraction and relaxation of the pig's heart, the single crystal flexible energy harvester produced an open circuit voltage of 17.8V and short circuit currents 1.74μA, 4.45 and 17.4 times higher. To

demonstrate the biocompatibility of the piezoelectric energy harvesting PMN-PZT flexible energy harvester, various cell viability tests and histological methods were conducted, but no signs of biological damage and inflammatory reactions were shown. Finally, an automated driving system was used to collect the pig's heart energy and transmit communication data wirelessly. It is also visually proven to repeat the light bulb on and off at a distance of about 5 meters without using another power source. This successful automated driving data transfer demonstrates potential applications in implantable biomedical devices that use direct biomechanical energy.

NM09.12.02
Late News: Decentralized Triboelectric Electronic Health Monitoring Flexible Microdevice Ulises G. Vidaurri Romero; University of Texas Rio Grande Valley, United States

In recent years, triboelectric nanogenerators (TENGs) have been the center of attention for research due to its wide range of applications as a microsystem component. This environmentally friendly energy framework can be implemented in advanced healthcare monitoring as a wearable electronic for sensory applications. Unfortunately, the production cost of TENGs are high and lead to loss of accessibility and production. Our research focuses on a triboelectric universal health monitoring device (TUHMD) that is biocompatible, highly sensible, self powered andeconomically advantageous simple structured, multifunctional, and wearable. The fabrication of the device shows the combination of cellulose paper and polydimethylsiloxane (PDMS) / polytetrafluoroethylene (PTFE) copolymer electrodes. The addition of this gadget into a wearable hardware provides real-time data of physiological movements and vibrations. The TUHMD shows promise as it can potentially be used for personalized medicine, rehabilitation, and remote monitoring of patients. The TUHMD reported a response as a triboelectric nanogenerator with a range of 12 V with negligible charge accumulation, along with a maximum capacitive performance of 11 F. The smart device demonstrated the capability of maintaining full health care monitoring applications.

Late News: Spray Printed Triboelectric Tactile Sensors Powered by Artificial Intelligence Shengjie Gao and Wenzhuo Wu; Purdue University, United States

The seamless and adaptive interactions between functional devices and their environment are critical for advancing emerging technologies. The state-of-the-art technologies, however, require a complex integration of heterogeneous components to interface the environmental mechanical stimulus, which is ubiquitous and abundant in the above applications. Here we report a convenient layer-by-layer spray printing method to fabricate Triboelectric Nanogenerator (TENG) sensing unit for tactile sensing. In addition to the general optimization of fabrication process, we also carry out learning-based quantitative study between TENG signals and external factors to extract more in-depth relationship. This research is expected to help construct a smarter sensing system with potential application in biomedical monitoring, consumer electronics, and intelligent robotics.

NM09.12.04
Remote Plasma Assisted Vacuum Deposition of Functional Organic and Polymeric Layers for the Development of thin Film Piezoelectric Nanogenerators and UV Piezotronic Detectors Xabier García-Casas[1], Francisco J. Aparicio[1], Jose M. Obrero[1], Jorge Budagoski[1], Angel Barranco[1], Juan R. Sanchez-Valencia[2] and Ana Borras[1]; [1]Spanish National Research Council (CSIC), Spain; [2]Universidad de Sevilla, Spain

In this communication, we present the advantages of the application of the remote plasma assisted vacuum

deposition method for the development of nanocomposite layers of organic functional molecules as adamantane and Spiro-OMETAD and polymers as PVDF. The synthesis is carried out at room temperature and under a low power plasma activation in an ERC-MW reactor to avoid energetic species or UV radiation of the plasma to reach the substrate surface. This methodology has been previously applied for the fabrication of photonics films based on organic dyes and small functional molecules working as optical sensors, optical filters, tunable photoluminescence emitters and lasing gain media. We present for the first time the exploitation of this approach to develop PENGs and UV photodetectors in combination with texturized ZnO thin films fabricated by plasma enhanced chemical vapour deposition.

Triboelectric Human Machine Interfaces Chengkuo Lee; National University of Singapore, Singapore

Triboelectric nanogenerator (TENG), since its first invention in 2012, has been proved as a promising energy harvesting technology and widely adopted in energy generation, self-powered sensing, actuation, and self-sustained systems, etc. In recent decades, advances in the Human Machine Interface (HMI) have improved from tactile sensors, such as touchpads and joysticks, to now include the accurate detection of dexterous body movements in more diversified and sophisticated devices. In this talk, we discuss a few triboelectric based human-machine interfaces with unique design of electrode patterns aiming for the gaming control. In addition, artificial intelligence (AI) as an effective data analytics tool has been integrated with various triboelectric sensors to achieve intelligent monitoring and recognition system. The AI-enabled triboelectric glove-based HMIs are investigated for gaming and VR/AR applications. On the other hand, the AI-enabled soft robotic manipulator is demonstrated with object recognition capability. Lastly, a smart floor monitoring system is reported with the merits of low cost, high scalability, and self-powered sensing capability, based on the integration of triboelectric sensors and deep learning-based data analytics.

9:20 PM *NM09.13.02
Integrated High Resolution Imaging Based on Micro-/Nanomaterials Qing Yang[1,2,3]; [1]Zhejiang University,Joint International Research Laboratory of Photonics, China; [2]Zhejiang Lab, Res Ctr Smart Sensing, China; [3]Shanxi University, China

High resolution imaging is a key technology for physics, biology, medicine and material development. Most high resolution imaging relies on cost, large volume and complex equipment. It is desired to have integrated high resolution imaging for invasive internal diagnosis and low cost drug discovery. Here we report our recent results on integrated high resolution imaging based on micro-/nanomaterials: chip-based super-resolution imaging [1-4] and multimode fiber based high resolution endoscope [5,6].

A majority of developed super-resolution techniques rely on nonlinear response to achieve nanoscale resolutions, while their low throughput could limit their practical applications. To achieve fast imaging with a large field-of-view (FOV), linear super-resolution microscopy via synthesis aperture approach is an alternative way that can be used. However, current linear super-resolution imaging is limited in resolution because a missing spatial-frequency band occurs when trying to use a shift magnitude surpassing the cutoff frequency of the detection system beyond a factor of two. In the presentation, we will show our recent results in wide-field far-field super-resolution imaging based on tunable frequency shifting. The missing of spatial-frequency can be effectively solved by developing a spatial-frequency-shift actively tuning approach through wave vector

manipulation and operation of optical modes propagating along multiple azimuthal directions on a waveguide chip to interfere.
Multimode fiber, as a potential minimally invasive endoscope, possesses larger mode capacity, higher efficiency of light collection, and much lower cost than fiber bundle. The main challenge in multimode fiber imaging is the complex light propagation process inside multimode fibers: light suffers from modal scrambling caused by environmental fluctuation, meaning that an image injected from one end of a fiber will become scrambled as very little fluctuation of environments. In this presentation, we propose some potential methods to increase the contrast-to-noise ratio (CNR) and stability of multimode fiber imaging. Wavelength modulation is introduced to suppress the background without increasing the number of controllable modes. Bending effect was investigated carefully and used to improve the imaging stability. We combine exhaustive bending and Convolutional Neural Networks to find the bending status precisely and compensate it fast. The results will improve the flexibility of multimode fiber imaging system, paving the way for deep and volumetric tissue endoscope imaging based on multimode fiber.

Wireless Passive Pressure Sensor for Wound Repair by Electrical Stimulation Qian Wang, Guang Yao and Yuan Lin; University of Electronic Science and Technology of China, China

Flexible intelligent sensor-stimulation integrated devices can dynamically capture the physiological signals of human tissues and organs, sensing real-time health information, and provide timely and accurate stimulation or treatment for injuries and diseases, which plays a key role in the next generation of intelligent healthcare systems.[1] However, almost all of the wearable electronic devices rely on some form of power supply and battery, and still face the problems of large volume and short working life. If the wearable electronic devices can be attached to the organism to collect the energy generated by low-frequency motion and directly applied to the flexible intelligent sensor-excitation device, it can get rid of the traditional battery and realize the infinite power supply of symbiosis in a sense.[2-4] Piezoelectric materials are the core part of piezoelectric electronic devices and the decisive component to realize the conversion of mechanical energy to electrical energy. Therefore, the research and development of high energy density piezoelectric materials is of great significance for the practical application of miniaturization and high sensing excitation performance flexible electronic devices. However, under the condition of large deformation and extensibility, rigid piezoelectric components are seriously limited due to the relaxation of human-machine interface coupling, low electromechanical coupling conversion/ wearing comfort and brittleness, resulting in short working life. It is not appropriate to directly use hard materials as functional components of wearable devices.
Here, a flexible wireless passive piezoelectric polymer polyvinyldiene fluoride (PVDF) film stimulation device is designed for effective wound healing and repair. Firstly, compared with the traditional inorganic piezoelectric materials, organic piezoelectric polymer PVDF has the advantages of excellent stability, flexibility and low density.[5] Secondly, we designed the flexible PVDF film into grids, at the same time, the pyramid microstructure is introduced. The introduction of the microstructure plays an important role in improving the comprehensive performance of the flexible pressure sensor. Compared with the flexible device that is not combined with the pyramid structure, the piezoelectric output of this device has been increased from the original (3.43 V) to the current (4.61 V), and it can continue to work stably for at least 60 minutes. This provides the possibility for effective wound treatment. In summary, flexible piezoelectric film devices can not only prepare flexible wearable devices for disease treatment, but also the passive devices can get rid of the traditional batteries, which makes the devices further develop towards lightweight, miniaturization and integration. Therefore, the application of piezoelectric passive devices in wound treatment is an important research direction in the field of wearable devices.

Multifunctional Self-Powered Switch toward Delay-Characteristic Sensors Haoyu Wang and Yunlong Zi; The Chinese University of Hong Kong, China

With the development of smart city which has been considered as a new lifestyle in the future, the Internet of Things (IoT) technology becomes more and more mature and important. According to a recent report there will be 20 billion devices connected by 2020. Nowadays, with a great progress in communication and embedded technology, emerging technologies such as the big data transfer and microprocessor distributed computing are being rapidly developed. Therefore, research on sensors requires sensing systems to be accurate, stable and small. However, in traditional sensing systems, the power supply circuits are usually complex and may cause environmental issues. In this case, self-powered devices which could work without external power source provide a more sustainable solution to meet the power requirement of such a big sensor network. Triboelectric nanogenerators (TENGs) which work based on the triboelectric effect and electrostatic induction have a list of great advantages, such as high sensitivity to detect motions, significant output voltage, flexibility, light weight, low cost, environmentally friendliness. With that, TENG plays an important role in detecting movement, direction, force, speed, and acceleration signal. However, the extremely-high-voltage output from TENG makes it difficult to directly power most electronics. By using the output electrical signals from TENGs to trigger the traditional electronic control devices, the extremely-high-voltage output from TENGs could break down these electronic devices. Furthermore, the TENG's output current is too low to meet the power requirement of some switches. Alternatively, TENG's output signal could be transferred to other kinds of signals which are easily detected and processed, such as transferring to optical signal to realize free-space optical communication. The switching devices which can directly transfer the high-voltage TENG output signal to other types of signals that can be easily processed are highly preferred. On the other hand, the delay characteristic plays an important role in fields of control and signal transmission. It brings convenience and energy-saving features to daily life, for example the delay light control system and the delay air conditioner control system. It can maintain safe operation of systems, such as the alternating current (AC) motor control and the time-limit current quick-break protection. It is also used in controlling the time delay of signals to improve the system's bandwidth, a.k.a. delay line. A wide kinds of delay characteristic switches have been designed with different mechanical structures or electrical circuits. However, current devices are usually complex and need external power source. It is demanded to achieve delay characteristic switching function in a simple but self-powered way, enabling smart systems. With the principle of dielectric polarization and electrostatic force, an electrostatic force based self-powered switch (EFS) which can work as an electrostatic force optical switch (EFOS) or a controlled electrostatic force electrical switch (CEFES) has been developed. It could be used to detect slight motions through TENG, or work as a high-threshold-voltage (over 1000 V) switch with a high sensitivity and delay characteristic. Upon applying a voltage on the EFOS, the nitrile butadiene rubber (NBR) film in EFOS will be attracted by the electrostatic force to block the light beam with a certain delay time, converting high-voltage electrical signal to optical signal. CEFES could conduct a controlled circuit when the control voltage reaches the threshold value with the delay characteristic. The self-powered EFS is achieved by using a freestanding sliding mode TENG (FS-TENG) as the power and controlling unit to realize the function of delay-characteristic self-powered sensing, which can be applied in various fields such as coding communication, human-machine interface, architecture auto-monitor, etc.

Water-Based Electricity Generator and Applications Hao Wu[1,2]; [1]City University of Hong Kong, Hong Kong; [2]The Chinese University of Hong Kong, Hong Kong

Water is ubiquitously existing on the earth. Natural water sources including rainfall, river water, and ocean waves always contain a certain amount of mechanical energy. When water contacts a specific solid surface, it will either generate a static surface tribo-charge or lead to electrostatic induction. In some circumstances, these both occur. By properly using the static charges generated by water/solid contact and the electrostatic induction process, the mechanical energy contained in the water movements can be converted into electrical energy. In this presentation, I will first introduce the mechanism of electricity generated from water/solid contact and then demonstrate some related application cases.

10:10 PM NM09.13.06
Deformable, Green, and Self-Healable Triboelectric Nanogenerators and Their Applications in Flexible Electronics and Self-Powered Sensing Uses Ying-Chih Lai; National Chung Hsing University, Taiwan

Deformable and wearable soft devices have attracted great interest because they cannot only extend the scope of smart systems but also provide compliant user experience. Operating those devices inevitably need power sources. However, traditional batteries suffer from heavy weight, bulky volume, and limited capacity and lifetime, hindering the progress and practical uses of those emerging devices. Toward the soft future, it is necessary to explore new energy technology. In this talk, deformable, mechanically-durable, green, and even self-healable energy-collecting triboelectric nanogenerators will be demonstrated for not only serving as new energy providers but also self-powered sensing uses. First, super-stretchable triboelectric nanogenerators will be presented for generating electricity by contacting with other materials regardless of various extreme deformation required from uses, such as extreme stretching, multiple twists and folds. Particularly, even experiencing severe tearing damages, the device can retain its functionality to act as a power source for other components. Such technology can also be introduced into fabric materials for wearable energy and fabric-based self-powered sensing uses. Then, we will discuss the use in self-powered and deformable electronic skins that can actively sense proximity, contact, and pressure to external stimuli via self-generating electricity. Further, the perfect integration of the tribo-skins and soft actuators enables soft robots to perform various actively sensing and interactive tasks including actively perceiving their muscle motions and working states, checking baby diaper conditions, and even detecting subtle human physiological signals. The self-generating signals can even drive optoelectronic devices for visual communication and be processed for diverse sophisticated uses. Then, a self-healing, highly-transparent, and super-stretchable triboelectric nanogenerator with energy-extracting and activity-sensing abilities will be demonstrated in the use of self-powered electronic skin, human-interactive interfaces, and so forth. Last, a triboelectric nanogenerator based on recycled coffee waste is presented for future low-cost and green energy devices. These works may open the crucial doors for the tremendous potentials of wearable/stretchable/deformable electronics, and energy devices.

Modulus Controllable HEMA-Based Hydrogel for Ultrasound-Driven Implantable Triboelectric Nanogenerator Bosung Kim, Hong-Joon Yoon and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

Recently. the demand for implantable medical devices has steadily increased as the number of the adult patients is on the rise with westernized diet and aging population. Implantable medical devices normally use batteries, which have a limitation in the lifetime and a need for replacement surgery at the end of life. To overcome these limitations of the batteries, various studies have been conducted and a paper using triboelectric nanogenerator which is capable of transmitting vibration energy using ultrasonic waves from the outside of the body, has been published. The implantable energy harvesting devices for medical devices need to be packaged with titanium plate when they are implanted in the body to avoid unintended immune response or inflammatory reaction from toxic material. However, there is a major disadvantage that large amount of energy is reflected and lost from the titanium surface because titanium has large acoustic impedance compared to the human body tissues. Therefore, we produced an ultrasound implantable triboelectric nanogenerator with bio-implantable and modulus controllable HEMA-based hydrogel which does not require titanium packaging. The voltage and current generated in-vivo by ultrasonic energy transmission reached 3.42 volts and 130 microamps under rat's tissue which can charge the 100 μF capacitor at the rate of 23.9 μC/s. This HEMA-based US TENG shows higher output than the titanium packaged US TENG device and it generates sufficient energy level to charge the batteries of implantable medical devices.

10:30 PM NM09.13.08
Continuous, Low-Level Pressure Sensor Enabled by a Convolution of Electrostatic Induction in Triboelectric Nanogenerator Soyeon Lee and Jin-Woo Park; Yonsei University, Korea (the Republic of)

A pressure sensor is one of the essential electronic devices for human-machine interfaces that enables monitoring from low-level pressure such as vibration and acoustic signals to moderate-level pressure such as physical body signals, including heart rate and blood pressure. Capacitive, resistive, piezoelectric, and triboelectric pressure sensors are commonly used as an electrical signal modifier or transducer responding to mechanical stimuli. Among those sensors, piezoelectric and triboelectric based pressure sensors have been established as self-powered active sensor as they do not consume electrical energy during sensing. Recently, triboelectric-based active sensors are exponentially used, having many advantages such as abundant materials candidate, fast response, and broad dynamic sensing range with linearity. Furthermore, many studies employed hierarchical nano/microstructure in the friction surface of the triboelectric pressure sensor since the micropattern structure improves deformability and contact area variation and enhances the frication surface and charge density. However, the effect of deformation and contact area variation is not significant in a small pressure range (<1kPa), which results in incorrect information in the low-level pressure signal. Herein, a highly sensitive and amplified electrical signal upon low-level pressure input can be achieved by using the convolution of electrostatic induction in a micropatterned triboelectric nanogenerator. By defining electrostatic induction in individual micro-ridge of the microstructure, distance variation between the two separate films can be continuously encoded. The microstructure was fabricated by mold casting of PVDF-TrFE using a commercial 3D printer (Formlabs), and electrodes were prepared by spray coating of AgNW. Face centered cubic (FCC) structure induced-hemisphere micro-ridge patterns were fabricated with diameter varied from 100 to 1000 micro-meter—of which scale pattern cannot be achieved in etched Si mold, and FCC interlocked structure of two separate films enabled spacer-free paired triboelectric system. To identify the electrostatic induction in microstructure, electrodes were embedded at a different distance from the friction surface, and PVDF-TrFE/AgNW/PVDF-TrFE layered structures were formed. Here, spray coating of AgNW on the micro-structured PVDF-TrFE films enabled the conformal distribution of electrode along every micro-ridge morphology, which was confirmed by FE-SEM images and EDS mapping of the respective film layers. As the electrode distance from the friction surface decreased, the open-circuit voltage and short circuit current are exponentially increased. Here, to exclude the capacitance increase effect due to the thinner dielectric layer in a closer distance electrode system, flat samples are also prepared alike the micropattern PVDF-TrFE/AgNW/PVDF-TrFE layered structure. Compared to the linear increase of electrical output when varying the distance between friction surface and electrode in the flat samples, an exponential increase of output signal in micropatterned samples with varying electrode distance can be explained by the convolution of electrostatic induction term from every near micro-ridge. The electric field applied on every surface of the micro-ridge can

participate in the triboelectric charge generation and, finally, sensitively respond to every distance variation from individual micro-ridge patterns. This enhancement is typically helpful for detecting pressure levels under 1kPa.

10:40 PM NM09.13.09
Stretchable and Mechanically-Durable Triboelectric Nanogenerator Based on Recycled Coffee Waste as Flexible Power Sources and Self-Powered Smart Sensors Ying-Chih Lai; National Chung Hsing University, Taiwan

Maximizing resource recycling and finding renewable energy sources are important for a sustainable environment considering the development and consumption of electronic products with the advancement of the internet of things and artificial intelligence technologies. Herein, an economic and environment-friendly triboelectric nanogenerator derived from the discarded coffee ground waste (CG-TENG) is developed to serve as a light-weight and shape-adaptive energy source and self-powered sensitive sensor (CG-TENG sensor). The coffee ground, embedded into the silicone rubber elastomer, is first used as the metal-free electrode feedstock to minimize waste generation. Based on the triboelectrification and electrostatic induction, the shape-adaptive CG-TENG, as wearable power, is capable of harvesting surrounding energy from human motions and extreme deformations, exhibiting excellent stretchability and mechanical durability. The generated electricity can be stored in the conductive coffee ground-derived capacitors to drive portable electronics, which is beneficial for building completely green power systems using coffee waste. Furthermore, the self-powered CG-TENG sensor with optimized structure endows its ultra-high sensitivity for sensing human physiological signals, monitoring motions, emulating gestures, as well as for developing smart tactile epidermal controller and intelligent vending coaster, paving the way for building large-scale energy-efficient artificial sensors and eco-environmental wearable electronics towards humanoid robotics and human-machine interfaces.

10:50 PM NM09.13.10
Triboelectric Nanogenerator as Highly Sensitive Sensors for Human Machine Interface Xianjie Pu; Chongqing University, China

Human-machine interface (HMI) has become an indispensable part of our lives. From the original keyboards to the virtual reality today, the goal of HMI is to make life more convenient and fascinating. In certain scenarios, for example, when a user's two hands are fully occupied, or the disabled expect to achieve necessary self-care, a hands-free operation via eye movement or voice is most definitely the approach of choice for human-machine interfacing. Based on the unique advantages of high sensitivity, low cost, light weight, applicability of structure design, prominent stability, robustness, etc. of triboelectric nanogenerator (TENG), we design a mechnosensational TENG (msTENG) and a triboelectric auditory sensor (TAS) for controlling the equipment via eye-blink and interacting with the robotic via voice, respectively. While in the scenarios of manufacturing industry, deep-sea exploration, telesurgery and disaster salvation etc., gesture control can help bringing about an intuitive interface instead of operation based on amount of learning and training. From this point, we design a joint motion triboelectric quantization sensor (jmTQS) for constructing a robotic hand synchronous control system. Then, keeping on investigating into intuitive interface and coming down to the universal experience in daily life, some traditional interactive modes such as mouse and keyboards, still have a strong vitality and practical value. Thus, we develop a 3D triboelectric touch pad (3D-TTP) for an effective and efficient touch-screen graphical user interface. These studies cover the control modes of eye-movement, voice, gesture, and touch of HMI nowadays. While in the feedback phase of HMI, TENG as a highly sensitive sensor transform mechanic movements into electric signals can also do benefits as in visual, auditory, and tactile modes. Take the TAS study above for example, this resonant frequency-tunable auditory sensor is also a hearing aid for people with impaired hearing in the feedback stage between robotics and them. Further, the 3D-TTP can be another kind of electronic skin of the robotics. With above successful attempts, we may foresee more potentials of TENG-based sensors in the control-feedback loop of HMIs.

Mechanobiology of Epithelial Folding and Migration in Intestinal Organoids Xavier Trepat; Institute For Bioengineering Of Catalonia, Spain

Intestinal organoids capture essential features of the intestinal epithelium such as folding of the crypt, spatial compartmentalization of different cell types, and cellular movements from crypt to villus-like domains. Each of these processes and their coordination in time and space requires patterned physical forces that are currently unknown. In this study, we map the three-dimensional cell-ECM and cell-cell forces in mouse intestinal organoids grown on soft hydrogels. We show that these organoids exhibit a non-monotonic stress distribution that defines mechanical and functional compartments. The stem cell compartment pushes the ECM and folds through apical constriction, whereas the transit amplifying zone pulls the ECM and elongates through basal constriction. Tension measurements establish that the transit amplifying zone isolates mechanically the stem cell compartment and the villus-like domain. A 3D vertex model shows that the shape and force distribution of the crypt can be largely explained by cell surface tensions following the measured apical and basal actomyosin density. Finally, we show that cells are pulled out of the crypt along a gradient of increasing tension, rather than pushed by a compressive stress downstream of mitotic pressure as previously assumed. Our study unveils how patterned forces enable folding and collective migration in the intestinal crypt.

8:25 AM *SM01.01.02
Force-FAK Signaling Coupling at Individual Focal Adhesions Coordinates Mechanosensing and Microtissue Repair Andrés J. García; Georgia Institute of Technology, United States

How adhesive forces are transduced and integrated into biochemical signals at focal adhesions (FAs) is poorly understood. Using cells adhering to deformable micropillar arrays, we demonstrate that traction force and FAK localization and traction force and Y397-FAK phosphorylation are linearly coupled at individual FAs on stiff, but not soft, substrates. Similarly, FAK phosphorylation increases linearly with external forces applied to FAs using magnetic beads. This mechanosignaling coupling requires actomyosin contractility, talin-FAK binding, and full-length vinculin that binds talin and actin. Using an in vitro 3D biomimetic wound healing model, we show that force-FAK coupling coordinates cell migration and tissue-scale forces to promote microtissue repair.

A simple kinetic binding model of talin-FAK binding interactions under force can recapitulate the experimental observations. This study provides insights on how talin and vinculin convert forces into FAK signaling events regulating cell migration and tissue repair.

The Response of Human Induced Pluripotent Stem Cells to Cyclic Cold Shock Yan Nie[1,2], Weiwei Wang[1,3], Xun Xu[1,3], Nan Ma[1,3] and Andreas Lendlein[1,2,3]; [1]Institute of Biomaterial Research and Berlin-Brandenburg Center for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany; [2]Institute of Biochemistry and Biology, University of Potsdam, Germany; [3]Helmholtz Virtual Institute − Multifunctional Biomaterials for Medicine, Germany

Human induced pluripotent stem cells (hiPSCs) attract interest to develop patient-specific therapeutic tools for their clinical applications [1]. The *in vitro* culture of hiPSCs with high quality is dependent on the signals from their extracellular environments [2, 3]. In this study, we explore the effect of cyclic cold shock on hiPSCs behavior. A computer-controlled thermochamber was employed to exert cyclic cold stress on hiPSCs, in which temperature was alternately varied between 10 °C and 37 °C, whereby each temperature was kept for 30 min. The expression of pluripotent markers was evaluated 24 h after culture either under constant temperature at 37 °C or under cyclic temperature changes (ΔT). An atomic force microscope (AFM) was used to detect changes in cellular mechanics and the decellularized extracellular matrix (ECM). Immunofluorescence analysis showed that the expression of pluripotent markers, NANOG and SOX2, was maintained within 24 h of culture. A slight change in Young's modulus of hiPSCs cultured under different conditions was observed. This observation might be a result of an alteration in the arrangement of the actin cytoskeleton revealed by the immunofluorescence analysis. Notably, the topography of decellularized ECM showed an increase in surface roughness in the ΔT group. The average surface roughness (Ra) and roughness mean square (Rms) of decellularized surfaces under the ΔT condition were 31.56 ± 2.82 nm and 38.07 ± 3.58 nm, while under the constant temperature were 39.52 ± 2.83 nm and 49.14 ± 4.23 nm. This result suggested that the component and/or the arrangement of ECM protein was altered by the cold stress. This was supported by the enzyme-linked immunosorbent assay (ELISA), which showed the cyclic cold shock promoted the secretion of laminin. The presented findings provide an insight into the interactions between hiPSCs and factors of their microenvironment, which would contribute to a better understanding of the interactions between hiPSCs and their local microenvironment.

The Spatial Self-Organization within Pluripotent Stem Cell Colonies is Continued in Detaching Aggregates Mohamed H. Elsafi Mabrouk[1,1], Roman Goetzke[1,1], Giulio Abagnale[2], Burcu Yesilyurt[1], Lucia Salz[1,1], Kira Zeevaert[1,1], Zhiyao Ma[1], Marcello A. Toledo[3], Ronghui Li[1], Ivan G. Costa[1], Vivek Pachauri[3], Uwe Schnakenberg[3], Martin Zenke[1,1] and Wolfgang Wagner[1]; [1]RWTH Aachen University Medical School, Germany; [2]St. Anna Children's Cancer Research Institute (CCRI), Austria; [3]RWTH Aachen University, Germany

Colonies of induced pluripotent stem cells (iPSCs) reveal aspects of self-organization even under culture conditions that maintain pluripotency. To investigate the dynamics of this process under spatial confinement, we used either polydimethylsiloxane (PDMS) pillars or micro-contact printing of vitronectin. There was a

progressive upregulation of OCT4, E-cadherin, and NANOG within 70 μm from the outer rim of iPSC colonies. Single-cell RNA-sequencing demonstrated that *OCT4*^{high} subsets have pronounced up-regulation of the TGF-β pathway, particularly of NODAL and its inhibitor LEFTY, at the rim of the colonies. Furthermore, calcium-dependent cell-cell interactions were found to be relevant for the self-organization. Interestingly, after 5 to 7 days, the iPSC colonies detached spontaneously from micro-contact printed substrates to form 3D aggregates. This new method allowed generation of embryoid bodies (EBs) of controlled size, without any enzymatic or mechanical treatment. Within the early 3D aggregates, the radial organization and differential gene expression continued in analogy to the changes observed during self-organization of iPSC colonies. Our results provide further insight into the gradual self-organization within iPSC colonies and at their transition into EBs.

Enzymatically Crosslinked Hydrogels for the Encapsulation of Living Cells and Enzymes Changzhu Wu; University of Southern Denmark, Denmark

Hydrogels are the ubiquitous three-dimensional networks that can store a great amount of water in their porous scaffolds, holding great potential for bio-related applications.[1] In particular, their biophysical similarity to living tissues and extracellular matrix has made them valuable for tissue engineering, drug/gene delivery, biocatalysis, and regenerative medicine. However, the preparation of robust hydrogels in a mild fashion remains a technical challenge. Typically, hydrogels are prepared by physical interactions or chemical reactions. However, physically crosslinked hydrogels are generally limited by the instability due to their weak interactions, while chemical approaches are often associated with the problems of involving toxic reagents and harsh reaction conditions. Therefore, there has been a quest to establish a reliable and efficient methodology to construct stable hydrogels under physiological conditions.

Here, we demonstrate an enzymatic approach to creating hydrogels to encapsulate living cells and biocatalytically active enzymes for regenerative therapy, catalysis, and antibacterial study, respectively.[2-4] In the first study, the hydrogels were prepared using horseradish peroxidase (HRP) to enzymatically crosslink phenolic derivatized dendritic polyglycerol polymer into hydrogels in a buffer.[2] Our results showed that the resultant gels were not only biocompatible to fibroblast murine cells but also allowed for their encapsulation with high viability over 48 hours. This successful demonstration suggests the potential of our hydrogels for future use in regenerative medicine. Furthermore, we used the same enzymatic crosslinking method and materials to prepare nanogels for the encapsulation of HRP and *Candida antarctica* lipase B, respectively.[3] The advantage of this method is the mild condition that maintains the good enzyme activity, and more importantly, the process doesn’t require any quench steps, thus substantially simplifying purifications. Therefore, this study proves a new concept of “enzymatic nanogelations” for biocatalysis. Lastly, the enzymatically crosslinked hydrogels were explored for antibacterial applications.[4] Similar to the previous,

hydrogels were crosslinked on glass slides by HRP, but differently, a second enzyme, glucose oxidase (GOD), was co-encapsulated. The existence of GOD could generate toxic H2O2 when supplying glucose, and kill *Pseudomonas putida* (Gram-negative) by 100% and *Staphylococcus aureus* (Gram-positive) by ≥40%, respectively.

Overall, we show a facile method to prepare hydrogels using enzymatic crosslinking for diverse applications. The success of this method suggests its great potential in future biomedicine and biotechnology.

Engineering Liquid Interfaces with Viscoelastic 2D Protein Networks—Microdroplet Design for Stem Cell Technologies Julien Gautrot, Dexu Kong, Lihui Peng and Minerva Bosch; Queen Mary, University of London, United Kingdom

Adherent cell production is hindered by the use of solid substrates or hydrogels for culture and expansion. Such materials and platforms are difficult to scale up and parallelise. In contrast, liquid-liquid technologies and microdroplet platforms have been applied very successfully in the field of Chemical Engineering for the scale up of synthesis and purification of fine chemicals, therapeutics, polymers and nanomaterials. Yet, their use in the field of biotechnologies is restricted to the high throughput screening of single planktonic cells. However, we recently reported that the culture of adherent cells at the surface of liquids [1, 2], previously observed with fibroblasts, was mediated by the self-assembly of protein nanosheets forming mechanically strong interfaces [3, 4]. This enabled the adhesion of stem cells such as keratinocytes and mesenchymal stem cells and the regulation of their spreading via the classic integrin and acto-myosin machinery, allowing the retention of stem cell phenotypes despite the extreme compliance of liquid substrates [5]. We now examine the chemical design of protein nanosheets systematically and identify groups of pro-surfactant molecules effectively supporting stem cell expansion at liquid interfaces. Surprisingly, the shear moduli of associated interfaces does not correlate with cell expansion. Instead, we observe that the viscoelastic behaviour of protein nanosheets correlates with stem cell proliferation. We identify that particularly stiff nanosheets that display poor elasticity do not support stem cell expansion and that this phenomenon is associated with the formation of brittle domains that can relax and dissipate energy in response to cell mediated forces. Hence the multi-scale viscoelasticity of liquid-liquid interfaces, rather than shear moduli, is the primary physical determinant of stem cell proliferation. Based on neutron reflectometry, TEM and polarised optical microscopy, we report that this behaviour is controlled by the nanoscale organisation of prosurfactant-mediated rigid domains. To demonstrate the capacity to expand stem

cells at liquid interfaces whilst retaining their phenotype, and the relevance of these systems for stem cell manufacturing, we characterised the expansion of mesenchymal stem cells over multiple passages, their retention of stem cell markers and ability to differentiate into multiple lineages. Cells cultured on nanosheet-stabilised emulsions displayed comparable phenotype in long-term expansion compared to stem cells cultured on 2D plastic and solid microcarriers. Overall, our results pave the way to the use of microdroplet technologies and liquid-liquid interfaces in the field of tissue engineering and for stem cell technologies.

1:25 PM SM01.03.02
An Innovative Approach to Study Cell Mechanics—A Skin-Over-Liquid Platform with Compliant Microbumps Actuated by pyro-EHD Pressure Martina Mugnano[1], Romina Rega[1], Emilia Oleandro[1,2], Vito Pagliarulo[1], Pietro Ferraro[1] and Simonetta Grilli[1]; [1]Institute of Applied Sciences and Intelligent Systems of the National Research Council (CNR-ISASI), Italy; [2]Department of Mathematics and Physics, University of Campania "L. Vanvitelli", Italy

Investigating the mechanical crosstalk between cells and their surrounding environment is fundamental to understand the influence of forces on cell functions and responses. In attempt to better elucidate the material – cell interaction *in-vitro* during adhesion process, here we report a new concept for a reliable and dynamic skin-over-liquid system for studying mechanobiology. It is made of a periodic array of highly compliant microbumps actuated through electrode-free electrohydrodynamic (EHD) pressure. These structures are highly repeatable and capable of swelling and deflating easily under a simple thermal stimulation driven by the pyroelectric effect, thus providing an innovative and easy tool that can be actively controlled at the microscale. To confirm the formation of the cytoskeleton structures after the stimulation, a fluorescence imaging system was used as a control to visualize actin filaments. The strategy here proposed portends broad applicability to investigate the correlation between the mechanical stress applied to cells by swelling these microbumps and their cytoskeleton assembly process. Moreover, the preliminary results are promising and permit us to consider skin-over-liquid platform as an easy assay for cell nanomechanic investigations in the future.

Late News: Intranasal Vaccination with Polycation/HA/CpG Nanoparticles Confers Cross-Protection Against Influenza Viruses Chunhong Dong and Baozhong Wang; Georgia State University, United States

Influenza remains one of the most severe threats to public health. Influenza mucosal immunity could confer broad cross-protection against influenza viruses. Intranasal (*i.n.*) vaccination with recombinant protein/peptide vaccines is a safe and promising strategy in the prevention of influenza virus infection due to the capability of generating both systemic immunity and local mucosal immunity. However, the intranasally administrated protein/peptide vaccines are poorly immunogenic due to the harsh and tolerogenic mucosal environment.

Adjuvants could program the dimension and magnitude of antigen-specific immune responses and are helpful boosters to promote rapid and strong immune responses with a dose sparing effect. Nevertheless, few mucosal adjuvants are currently licensed for human use.
Nanoparticles are a special and promising class of vaccine adjuvants as it could not only serve as effective delivery carriers for antigen and/or molecular adjuvants but also synergistically work with molecular adjuvants like TLR agonists in a whole system. Polyethyleneimine (PEI) is a kind of organic polycations that could form nanoscale complexes with viral glycoprotein antigens. In our study, we prepared PEI-hemagglutinin (HA) nanocomplexes with or without CpG ODN molecules, and comprehensively studied the humoral and cellular immune responses after *i.n.* vaccination with the nanocomplexes. Our results showed that the PEI-HA nanocomplexes induced significantly enhanced mucosal and systematic antibody responses than soluble HA antigens. The combination of PEI and CpG in PEI-HA/CpG further boosted the responses. Furthermore, we would investigate the induced cellular responses and study the cross-protection efficacy of these nanocomplexes against different influenza strains in mice. The role of PEI, CpG and the nanoparticulate feature in regulating the immune responses would be further discussed. Our study will provide perspectives to guide the development of effective mucosal adjuvants for influenza vaccines.

1:45 PM SM01.03.04
Late News: One-Step Synthesis of Water-Soluble Fullerene Derivative with Myogenic Activity and Pronounced Antiviral Properties Olga A. Kraevaya[1], Alexander Shestakov[1,2], Dominique Schols[3], Svetlana Kostyuk[4] and Pavel Troshin[1]; [1]IPCP RAS, Russian Federation; [2]Department of Physical and Chemical Engineering, Lomonosov Moscow State University, Russian Federation; [3]Rega Institute for Medical Research, Belgium; [4]Research Centre for Medical Genetics RAMS, Russian Federation

We will discuss a straightforward method for the synthesis of a water-soluble C_{60} fullerene derivative (F1) with five attached residues of phosphonic acid. Self-assembly of the synthesized compound in an aqueous solution leads to the formation of various nanostructures, as observed by AFM and DLS methods.
Antiviral screening of the synthesized compound *in vitro* demonstrated its activity against ten different viruses such as Feline coronavirus, Influenza A virus (H3N2 and H1N1), Influenza B virus, Varicella zoster virus, Cytomegalovirus, Herpes simplex virus (HSV-1, HSV-2), Cowpox virus, Feline herpes virus, and Human immunodeficiency virus (HIV-1, HIV-2).
The most unexpected effect of the water-soluble fullerene derivative F1 was its ability to promote myogenic differentiation of human mesenchymal stem cells (MSCs). In the absence of the fullerene derivative, stem cells from adipose tissue partially differentiate into adipocytes in the non-differentiating culture medium. During prolonged cultivation of MSCs in the presence of F1, the morphology of the cells changes spectacularly: fragments of stem cells with an ordered structure, which express markers of myogenic differentiation, appear. This kind of activity is unknown for all other reported water-soluble fullerene derivatives.
The obtained results open new horizons for the development of fullerene-based drugs for the regeneration of damaged muscle tissue and the treatment of severe muscle atrophy.
This work was supported by the Russian Science Foundation (project 19-13-00411).

1:50 PM SM01.03.05
Late News: *In Vitro* Assessment of Polymer Thrombogenicity—The Effect of Endothelial Culture Conditions on Platelet Responses Skadi Lau[1], Anna Maier[1], Steffen Braune[1], Manfred Gossen[1], Andreas Lendlein[1,2] and Yue Liu[1]; [1]Institute of Active Polymers and Berlin-Brandenburg Center for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany; [2]Institute of Chemistry, University of Potsdam, Germany

The establishment of near-physiological in vitro thrombogenicity test systems for the evaluation of blood-contacting biomaterials requires co-cultivation of endothelialized materials and platelets (PLT) under blood flow-like conditions. Commercial perfusion systems for this purpose are equipped with gas plasma-treated cyclic olefin copolymer (COC)-based standard slides for endothelialization. Here, COC was characterized for physicochemical properties prior to co-culture studies. Moreover, endothelial culture conditions were systematically analyzed regarding PLT responses considering their sensitivity to external influences, both of

their handling and their environment, and their central role in hemostasis and innate immunity.
A basic chemical characterization of COC and of its physical surface properties was performed. Human platelet rich plasma (PRP) was mixed with EGM-2 basal medium (BM) or with BM separately containing each of nine supplements or with BM containing all supplements together. PLT adherence analysis was carried out on COC and poly(tetrafluoro ethylene) (PTFE) as a control. PLT activation and aggregation were analyzed using light transmission aggregometry and flow cytometry (CD62P). COC endothelialized with human umbilical vein endothelial cells was co-cultivated with 150.000 PLT/µL for 1 h under static conditions and laminar flow (10 dyn/cm^2).
The physical and chemical characteristics as determined were in line with COC's cell adhesive properties. Medium supplements had no effect on PLT activation and aggregation. Regarding PLT adherence, supplements differentially affected PLT number, size and PLT covered area on COC and PTFE. EC count was significantly higher under laminar flow than under static conditions. PLT count and PLT covered area increased under static culture conditions compared to flow both on endothelialized and non-endothelialized surfaces.
Gas plasma-treated COC is suitable for the establishment of an in vitro thrombogenicity test system. Systematical medium analysis showed that according to the readouts employed here, the use of standard endothelial growth medium maintains functionality of PLT under EC compatible conditions without masking the differences of PLT adherence on different polymeric substrates. Moreover, improved EC attachment and reduced PLT adhesion under flow underlines the importance of blood flow-like conditions. These findings are important prerequisites for the assessment of polymer-based cardiovascular implant materials in contact with EC, PLT and, in the future, possibly also with further immune cells to grasp the complex role of blood homeostasis in contributing to thrombogenic events.

2:05 PM SM01.03.06
Covalent Cell Surface Conjugation of Nanoparticles by a Combination of Metabolic Labeling and Click Chemistry Alexander Lamoot, Annemiek Uvyn and Bruno G. De Geest; Ghent University, Belgium

Modification of the cell surface with nanoparticles (NP) can be of interest for a wide variety of biomedical applications. An attractive therapeutic strategy involving conjugation of NP to living cells is to exploit the tissue homing properties of specific cell types for targeted delivery of drugs loaded into NP (e.g. *ex vivo* engineering of tumor infiltrating T lymphocytes and CAR T cells). Cell surface conjugation requires either a covalent or non-covalent reaction. Non-covalent conjugation with ligand decorated NP is challenging and involve a dynamic equilibrium between the bound and unbound state. By contrast, covalent NP conjugation where reactive groups on the NP surface react with a complementary reaction partners in the cellular glycocalyx, results in a permanently bound state of NP. Current routes for cell surface conjugation predominantly make use of natural occurring lysines and cysteines on the cell surface and respectively activated esters and maleimides on the surface of NP. However also these routes tend to be challenging due to slow reaction kinetics, random conjugation to proteins in the glycocalyx etc. Therefore, there is strong need for new strategies that allow for efficient covalent cell surface conjugation. In particular, bio-orthogonal click reactions are an attractive alternative and in this context, introducing azides on the cells surface through metabolic labelling with azido sugars is attractive to introduce unnatural functional groups on the cell surface that can be addressed further on using biorthogonal strain promoted azide-alkyne cycloaddition (SPAAC) click chemistry. To explore this strategy, we used dibenzyl cyclooctyne (DBCO) functionalized lipid nanoparticles (LNP) formed by electrostatic complexation of an ionizable lipid and a double stranded RNA synthetic analogue, polyinosinic: polycytidylic acid (polyIC).Interestingly, we found that, whereas the reaction between small molecule dye-labeled DBCO and azido-labeled cells is extremely fast and efficient, reaction between DBCO-LNP and azide-labelled cells is rather inefficient, leading to a low degree of functionalization and high unspecific background adsorption of LNP to cells when attempting at optimizing conjugation conditions. We attribute this to a combination of sterical hindrance and the low concentration and slow Brownian motion of the reaction partners. This issue could be circumvented by designing LNP that contain a diisopropylamino-functionalized lipid that has a pKa below physiological pH. A short co-incubation time at pH 7.4 shows almost no association between DBCO-LNP and azido-labelled cells, but at pH 5, where the diisopropylamino moieties bear a cationic charge, strong LNP adsorption takes place due to electrostatic interaction. Due to the close contact between DBCO-

LNP and azide-labelled cells, SPAAC takes place and LNP remain permanently bound to the cell surface. However, this route leads to an extremely high non-specific background adsorption of control non-SPAAC-reactive LNP and on control cells, despite multiple washing steps with neutral buffer. To tackle the issue of low reactivity and high non-specific binding, we explored the ultra-fast bio-orthogonal inverse electron demand Diels–Alder (IEDDA) reaction between tetrazines (Tz) and trans-cyclooctene (TCO). We developed a 2-step conjugation sequence in which metabolically azide labelled cells first react with sulfo-6-methyl-*tetrazine-DBCO* (Tz-DBCO), followed by co-incubation with TCO-LNP. Eventually, this strategy gives a highly specific cell surface conjugation of LNP, with very low non-specific background fluorescence for controls cells and for control LNP lacking TCO, as evidenced by flow cytometry and confocal microscopy. Hence, we believe that this last strategy holds a general applicability for cell surface modification in view of adoptive cell transfer therapy with NP-backpacked cells.

2:20 PM *SM01.03.07
Multifunctional Biomaterials for Directing and Orchestrating Behavior and Functions of Stem Cells via Mechanical Cues Weiwei Wang[1], Zijun Deng[1,2], Xun Xu[1], Nan Ma[1,2] and Andreas Lendlein[1,2,3]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]Free University of Berlin, Germany; [3]University of Potsdam, Germany

Stem cells are highly relevant in tissue regeneration due to their self-renewal capacity and differentiation potential. Given the capacity of stem cells to sense the environmental cues and to convert the perceived information to intracellular signaling cascades, the use of external stimulation through biomaterials to regulate stem cells has become a safe and effective approach to guide them towards a desired function and lineage commitment. We designed and fabricated polymer based cell culture substrates with well-defined geometric micro-wells (size, shape) to exhibit static mechanical cues or thermally controlled artificial muscles as dynamic substrates. We investigated how the stem cells respond to these mechanical stimuli provided by the biomaterial and elucidated the underlying mechanism.
The micro-topography of the differently structured substrates exerted highly distinct effects on the major cellular process of mesenchymal stem cells (MSCs), including cell morphology, cytoskeleton organization, focal adhesion distribution, migration, gene expression, proliferation, and differentiation. Taking advantage of an AB copolymer network with a thermally controlled shape-memory actuation capability, we studied MSC response to the thermal (environmental temperature change) and mechanical (substrate shape change) stimuli. The combinational and synergetic effect of the dual stimuli as well as the activated signaling cascades were explored. The Ca^{2+} dynamics was shown to regulate the intercellular connection of mechano- and thermosensing components, promoting the osteogenic differentiation of MSCs.
These results provide a fundamental principle for design and application of advanced multifunctional biomaterials in regenerative medicine.

2:45 PM SM01.03.08
Late News: Gradient Granular Microgels for Spatial Differentiation of Mesenchymal Stem Cells Thomas G. Molley, Gagan Jalandhra, Tzong-tyng Hung and Kristopher Kilian; University of New South Wales, Australia

During tissue development, progenitor stem cells form functional tissue with high cellular diversity and intricate micro and macro architecture. Current approaches have attempted to replicate this process with materials cues or through spontaneous cell self-organization. However, it has become increasingly clear that cell-directed and material-directed organization are both required to achieve native structure and function. Here, I will present a biomanufacturing method to deposit stem cells in freeform within a granular matrix while spatially guiding their differentiation. The directed combination of varied microgels establish a 3D bioprinting support medium with gradients of mechanical stiffness and growth factor release. The packed suspension of gelatin methacrylate microgels crosslink together under near UV light, locking the cells and gradients in place. And controlled deposition of mesenchymal stem cells across these gradients within the gel enables guided differentiation to osteogenic, adipogenic, or chondrogenic phenotypes. As a demonstration of this method, we combine a gradient of stiffness and growth factor release with a gradient of hyaluronic acid to create a model meniscus. We

anticipate this material platform will open new avenues for regenerative medicine and fundamental studies on the role matrix cues play in stem cell differentiation.

Metabonegenetic Citrate-Based Biomaterials for Orthopedic Applications Jian Yang; The Pennsylvania State University, United States

Citrate-based biodegradable polymer has recently joined in a handful of biodegradable synthetic polymers used in Food and Drug Administration (FDA) approved implantable medical devices such as orthopedic fixation devices. Citrate, historically known as an intermediate in the Krebs cycle, is a multifunctional, nontoxic, readily available, and inexpensive cornerstone monomer used in the design of citrate-based biomaterials. We have recently identified citrate as an osteo-promotive factor and revealed a key link between citrate metabolism and its downstream effects on osteogenic differentiation of human mesenchymal stem cells (hMSCs), named metabonegenic regulation. Our studies show that extracellular citrate uptake through solute carrier family 13, member 5 (SLC13a5) supported osteogenic differentiation via regulation of energy-producing metabolic pathways, which led to elevated cell energy status to fuel osteo-differentiation of hMSCs with high metabolic demands. We have also identified other factors such as phosphoserine (PSer) that can synergize with citrate to exhibit concerted action not only in metabonegenic potential for orthopedic regeneration, but also in functionalizing materials with imaging capability for materials tracking and monitoring. This unique citrate metabonegenic regulation has allowed us to design new citrate-based platform biomaterials to meet the dynamic biological, biochemical, and biophysical needs in tissue regeneration. The recent regulatory success of citate-based biomaterials makes them promising candidate materials for technology translation and commercialization. In this presentation, a methodology for the design of citrate-based biomaterials in various regenerative engineering applications with a focus on orthopedic applications will be discussed.

4:25 PM SM01.04.02
Integrating Transferrable Chemically Modified Graphene with Materials and Biological Substrates Keith E. Whitener[1], Dhanya Haridas[1], Woo-Kyung Lee[1], Saron Yoseph[2] and Christopher So[1]; [1]U.S. Naval Research Laboratory, United States; [2]Howard University, United States

Developing interfaces between active materials and biological structures is becoming increasingly important for manipulating and interrogating living systems for use in advanced biological engineering. We have developed techniques for transferring graphene-based thin film materials from one substrate to another without needing to use harsh chemicals to detach the films from their initial substrates. This allows us to interface a number of materials directly with biological substrates including live stem cells without sacrificing viability. We found that partially reduced graphene oxide can be used as a transferrable surface for printing a number of materials, including metallic structures, fluorescent cell dyes, and phase-separated block copolymers. The mild transfer techniques we have developed allow us to easily probe biological systems at the scale of individual cells, and we can also use our transferrable block copolymer technology to lithographically pattern novel hierarchical structures on arbitrary substrates. These capabilities offer a cheap and easy way to exert spatiotemporal control over single cells and cell-cell interactions.

4:40 PM SM01.04.03
Mechanical Characterization of Collagen Hydrogels by Quasi-Static Uniaxial Tension Jieung Kim[1],

Sangmin Lee[1], Taek-soo Kim[1], Hyunjoon Kong[2] and Dongchan Jang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]University of Illinois at Urbana-Champaign, United States

Collagen is one of the most abundant extracellular matrix of animal tissues and also serves as the main structural material by providing mechanical environments for cells. Especially, collagen hydrogels are widely used as scaffold materials in vitro since the chemo-mechanical environments they give the cells are almost identical to those in vivo. Thus, providing physical reliability of the collagen hydrogel presents significant challenges for tissue engineering applications, and it is essential to understand its mechanical behavior and deformation mechanisms. In this study, we aim to investigate the mechanical behavior of collagen hydrogels under quasi-static uniaxial tensile strain to present the complex tempo-mechanical response of biomaterials apart from the rheometric response. A combination of tensile testing in a hydrogel-friendly hydrated environment and microstructure analysis including structural parameters and strain evolution demonstrates the mechanism of tensile properties, complementarily. When the tensile strain is applied, the stress-strain relationship of collagen hydrogels shows a non-linear response with strain-stiffening. This non-linearity of the physical properties of collagen hydrogel comes from the shift of deformation mechanism and the unfolding dominated deformation of the collagen fiber network is completed as the very first stage, the mechanical response gradually turns to the stretching dominated deformation of the collagen fibers by aligning their microstructure. These results illustrate that collagen hydrogels respond to tensile strain with two main different deformation mechanisms, unfolding and stretching of collagen fibers, which shows the non-linear stress-strain relationship, and the topology of collagen hydrogels can control the mechanical response. Furthermore, it is a new approach to physical behavior for soft and hydrated materials that can be applied throughout the bioengineering field.

Late News: Mesenchymal Stem Cells Derived Exosomes Promote the Expansion of Bregs and Alleviate the Collagen-Induced Arthritis Qiugang Zhu, Ke Rui, Shengjun Wang and Jie Tian; Jiangsu University, China

Olfactory ecto-mesenchymal stem cells (OE-MSCs) exert protective effects in some autoimmune diseases, partly through the regulation of activation, proliferation and differentiation of lymphocytes. Extracellular vesicles (EVs), including exosomes, released by MSCs contain bioactive factors, such as microRNAs, proteins, lipids, and some studies have confirmed that the immunoregulatory function of MSCs was mediated by exosomes. However, it is unclear whether OE-MSC-derived exosomes (OE-MSC-Exos) influence regulatory B cells in collagen-induced arthritis (CIA). In this study, we found that OE-MSC-Exos could promote the expansion of interleukin-10-producing B cells (B10 cells) with regulatory function in an Epstein-Barr virus-induced gene 3 (EBI3)-dependent pathway. In vivo, intravenous injection of OE-MSC-Exos into CIA mice significantly inhibited the disease progression and reduced the severity of both clinical score and joint damage. Taken together, our findings identified that OE-MSC-Exos might become a new cell-free therapy for the treatment of RA and other inflammatory diseases.

5:00 PM SM01.04.09
Thermomechanical Modulation of Toll-Like Receptor Internalization and Expression Profile in Mesenchymal Stromal Cells Xun Xu[1], Weiwei Wang[1], Yan Nie[1,2], Nan Ma[1,3] and Andreas Lendlein[1,2,3]; [1]Institute of Biomaterial Science and Berlin-Brandenburg Center for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany; [2]Institute of Biochemistry and Biology, University of Potsdam, Germany; [3]Institute of Chemistry and Biochemistry, Freie Universität Berlin, Germany

During the current SARS-CoV-2 pandemic, intravenous infusion of mesenchymal stromal cells (MSCs) is emerging as one of the promising therapeutic tools for treating the severe respiratory syndrome in COVID-19, which mainly relies on the regenerative capacity and superior immunomodulatory function of MSCs [1, 2]. The transplanted MSCs were found to be recruited at the interface of alveoli and surrounding capillaries, where respiratory airway structures are exposed to periodic heat exchange and mechanical stresses with respiratory

cycles [2, 3]. Toll-like receptor (TLR) triggers innate immune response against virus including SARS-CoV-2 [4, 5]. TLR also plays a key role in regulation of differentiation and immune polarization of MSCs, which highly associated with the MSC therapeutic efficacy. However, TLR expression profiles and distributions are varying in MSCs not only depending on the cell sources but also the culture conditions [6]. To date, little is known about the influence of the thermomechanical cues on regulating the TLRs in MSCs. Here, thermally-controlled polymer sheets with programmable actuation capacity (cPCLBA) were created to autonomously synchronize and transfer the thermomechanical signal to MSCs. With the periodic temperature change between 10 °C and 37 °C, 14 ± 1% elongation of programmed sheets can be achieved at both macro- and micro-scales. As a result, in response to thermomechanical stimuli, the proportion of cells expressing SARS-CoV-2 responsive TLRs (TLR4+TLR7+) were significantly increased from 69 ± 5% to 81 ± 3%, while the TLR3+TLR9+ cells that sensing double-stranded RNA and unmethylated DNA virus was decreased from 41 ± 5% to 26 ± 4%. Moreover, the internalization of cell surface expressed TLR4 was promoted and the intracellular TLR4 was co-localized with TLR7, and retained closely to the endoplasmic reticula where viral entry, replication and assembly takes place [7]. In summary, the programmed cPCLBA sheet provided a simple, cost effective and efficient respiratory cycle model, which synchronized and transduced the thermomechanical stimuli into MSCs. Such stimuli were able to accumulate TLR4 and TLR7 at endoplasmic reticula and selectively amplified the TLR4+TLR7+ MSCs, which can specifically react to single-stranded RNA virus including SARS-CoV-2. These results highlight the potential application of boosting the anti-viral immunity via preconditioning of MSCs with thermomechanical cues prior to cell infusion.

The Mechanical Responses of Tension-Transmission Supramolecular Linkages Jie Yan; National University of Singapore, Singapore

The task of mechanosensing of cells involves dynamic assembly of various tension-transmission supramolecular linkages, which enable the cells to properly sense and respond to the level of tension in the linkages. A tension-transmission linkage typically consists of a few non-covalently linked proteins, in which the domains and protein-protein interfaces are subject to dynamic fluctuation of intracellular tensions. This leads to highly complex tension-dependent connectivity of the supramolecular linkages, conformational changes of the domains and the resulting tension-dependent interactions of binding sites in the linkage with signalling proteins. Increasing evidence has suggested that protein-protein interfaces and protein domains in various mechanosensing tension-transmission supramolecular linkages have been evolved with special structural and topological features that impart them with special mechanical properties. In this talk, I will introduce our recent single-molecule and theoretical investigations of the effects of the structural-topological features shared by many tension bearing protein-protein interfaces and protein domains on the mechanical stability and

mechanosensing function of tension-transmission supramolecular linkages.

Poly(I:C) Delivery Strategies to Selectively Activate TLR3 and MDA-5 Pathways for Immunotherapy
Apoorv Shanker[1], Imane Bouzit[1], Sandeep Koshy[2], Janelle Velez[2], Stephanie Schwartz[2] and Paula Hammond[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Novartis Institutes for BioMedical Research, United States

Agonists of toll-like receptors (TLRs) form an important class of adjuvants employed in cancer immunotherapies and prophylactic vaccines. Among the various TLR agonists, polyriboinosinic acid:polyribocytidylic acid (poly(I:C)), a synthetic mimic of viral dsRNA, has been shown to activate and boost antigen cross-presentation by dendritic cell (DCs), promote NK cell cytotoxicity as well as effect direct tumor-killing to generate tumor-associated antigens for DC presentation. Poly(I:C) is recognized by the endosomal receptor TLR3 as well as cytosolic receptors such as RIG-I and MDA-5. Poly(I:C) binding to its receptor initiates a cascade of signaling pathways resulting in the activation of NF-κB and production of pro-inflammatory cytokines (TLR3), or IRF and production of type-I interferons (MDA-5). Despite its potent immunogenic properties, safety concerns including inadvertent immune over-stimulation, induction of autoimmune diseases, and short half-life *in vivo* have limited the scope of poly(I:C). Several strategies including liposomal and polymeric encapsulation, polycationic complexes or polyplexes, and surface-assembly on nanoparticles (NPs) or microparticles (MPs) have been explored to overcome these issues.

Here, we present a comparative study of poly(I:C) polyplexes and layer-by-layer (LbL)-assembled NPs/MPs carrying poly(I:C) to selectively activate the TLR3 and MDA-5 receptors. Poly(I:C) delivery platforms were fabricated using three classes of polycations: polypeptides, polysaccharides, and synthetic polymers. Dynamic light scattering, zeta potential measurements, gel electrophoresis, fluorophore exclusion titration assay, circular dichroism, and isothermal titration calorimetry were utilized to characterize the polyplexes and assess the structural integrity of poly(I:C) complexed with different polycations. LbL particles were built on a negatively-charged core using the polycations to electrostatically assemble poly(I:C) on the particle surface. HEK-Blue mTLR3 reporter cell line was used to assess the ability of polyplexes and LbL particles to activate the endosomal TLR3 receptors. For the polyplexes with varying poly(I:C):polycation ratios, TLR3 activation was found to be roughly inversely correlated with the poly(I:C) binding strength of the polycations. While poly(I:C)-loaded LbL particles were as effective as free poly(I:C) in activating TLR3 when in direct contact with the cells, significant loss of bioactivity was observed when the cells and the particles were separated using a trans-well. This was likely due to enhanced cellular uptake of the LbL particles or degradation of poly(I:C) released from the LbL particles in the latter case. The selectivity of polyplexes and LbL particles toward TLR3 and MDA-5 receptors was assessed in A549 dual NF-κB-SEAP and IRF-luciferase reporter cell line. Activation of the two pathways was further correlated with cellular uptake and trafficking of the polyplexes and LbL particles. We elucidate the role of the delivery mechanism and polycationic carriers in stabilizing poly(I:C) against serum nucleases, reducing cellular toxicity and selectivity toward endosomal or cytosolic receptors. The presented biophysical studies provide critical insight into the design of poly(I:C) delivery platforms toward more potent adjuvants.

Immunomodulating Nano-Adaptors Potentiate Antibody-Based Cancer Immunotherapy Cheng-Tao

Jiang[1], Kai-Ge Chen[1], Song Shen[1,2] and Jun Wang[1,2,2]; [1]South China University of Technology, Guangzhou International Campus, China; [2]South China University of Technology, China

Modulating effector immune cells via monoclonal antibodies (mAbs) and facilitating co-engagement of T cells and tumor cells via CAR T cells or bispecific T cell-engaging antibodies are two typical cancer immunotherapy approaches[1-3]. We speculated that immobilizing two types of mAbs against effector cells and tumor cells onto single nanoparticle could integrate the functions of these two approaches, as the engineered formulation (immunomodulating nano-adaptor, imNA) could potentially associate with both cells and bridge them together like an ‘adaptor’ while maintaining the immunomodulatory properties of parental mAbs. However, existing mAbs immobilization strategies mainly rely on chemical reaction, a process that is rough and difficult to control. Here, we built up a versatile antibody immobilization platform by conjugating anti-IgG (Fc specific) antibody (αFc) onto nanoparticle surface (αFc-NP), and confirmed that αFc-NP could conveniently and efficiently immobilize two types of mAbs through Fc-specific noncovalent interactions to form imNAs. The superiority of imNAs over the mixture of parental mAbs were validated in T cell-, natural killer cell- and macrophage-mediated antitumor immune responses in multiple murine tumor models.

8:00 AM *SM02.01.01
Antibacterial Cationic Molecular Umbrellas Edmund F. Palermo and Ao Chen; Rensselaer Polytechnic Institute, United States

We synthesized "cationic molecular umbrellas", which are dendrons of multivalent cationic charge attached to a

hydrophobic alkyl chain. The generation number and alkyl chain length are key determinants of activity against bacteria and red blood cells. In the best case, we identified a very promising composition that exerts potent, broad-spectrum antibacterial activity (MIC = 4–8 μg/mL) while remaining non-hemolytic (HC_{50} ~ 5000 μg/mL) even at concentrations 1000x higher than the effective antibacterial dose. Although these compounds do self-assemble into stable micelles in aqueous solutions, the antibacterial activity is observed at concentrations far lower than the CMC, suggestioning that the active species is the individually solvated dendron. Mechanistic studies strongly point to a mechanism involving membrane disruption.

8:15 AM *SM02.01.02
Development of Nanoantibiotics to Fight Drug-Resistant Bacterial Infections Hongjun Liang; Texas Tech University Health Sciences Center, United States

Antibacterial nanomaterials, or nanoantibiotics, are emerging contenders to fend off drug-resistant bacteria when conventional antibiotics fail. Nanostructure itself is widely and sometimes blithely speculated to instigate added benefits in killing bacteria, but whether it plays any role on defining the encounter between nanoantibiotics with bacteria that seals the dour fate of the microbes is not clear. In order for nanoantibiotics to stay relevant in the clinical battlegrounds against bacterial infections, it is imperative to dissect the antibacterial role of nanostructures from the inherent and external chemical moieties associated with the nanoantibiotics that are detrimental to both bacteria and mammalian cells. In this talk, I will discuss our effort to elucidate the antibiotic role of nanostructures using model spherical and rod-like polymer molecular brushes (PMBs) that mimic the two basic structural motifs of bacteriophages. While the individual linear-chain polymer branch that makes up the PMBs is hydrophilic and a weak antimicrobial, amphiphilicity is not a required antibiotic trait once nanostructures come into play. The phage-mimicking PMBs induce an unusual topological transition of bacterial but not mammalian membranes to form pores. The sizes and shapes of the nanostructured PMBs further help define their antibiotic activity and selectivity against different families of bacteria. This nanostructure-induced transformation of antibacterial activities further suggests that nanoantibiotics have the potential to serve as a generic platform for the design of "smart" antibiotics with in-demand activity and selectivity in response to external stimuli by assembly or disassembly of their nanostructures. To exploit this concept for the design of environmentally benign antibiotics that remain fully active in clinical services but become deactivated rapidly once released into the environment, I will discuss an example of antibiotic PMB design that epitomizes the concept of carrying a built-in "OFF" switch responsive to natural stimuli. In their nanostructured forms in services, these PMBs are potent killers for both Gram-positive and Gram-negative bacteria, including clinical multidrug-resistant strains; after services and being discharged into the environment, they are shredded into antimicrobially inactive pieces by bioorthogonal chemistry that does not exist in human body but occurs abundantly in natural habitats.

8:40 AM DISCUSSION

9:05 AM SM02.01.04
Broad-Spectrum Polyimidazolium Against Pan-Resistant Bacteria Wenbin Zhong and Mary Chan-Park; Nanyang Technological University, Singapore

Antimicrobial resistance (AMR) has become a global severe problem and is aggravated by the slow pace of antibiotic development. Antimicrobial peptides and its mimics have emerged as alternative therapeutic agents but most failed in clinical trials due to varied reasons like limited antimicrobial spectrum, reduced activity in physiological condition, toxicity issue etc. Here we applied one-pot multicomponent polymerization and prepared a series of main-chain cationic polyimidazoliums (PIMs). The lead compound, PIM1, demonstrated good biocompatibility and potent broad-spectrum antimicrobial efficacy against both multi-drug resistant Gram-positive and Gram-negative bacteria even including colistin-resistant *burkholderia*, and it's an anti-mycobacterial agent. Unlike classic antimicrobial peptides, PIM1 does not permeabilize bacterial cell membrane but accumulates into cells with assistance of membrane potential, and ultimately leads to cell death. PIM1 does not develop resistance in Gram-negative *P. aeruginosa* cells while has menaquinone mutation in

Gram-positive *S. aureus*. In murine wound model, PIM1 demonstrated good potency in preventing topical skin infection, but systemic toxicity in mice was found via intraperitoneal injection of PIM1. We further developed PIM1 derivative, PIM1D, which has amide bond and become less hydrophobic. Experiments showed that PIM1D does not cause systemic toxicity to mice even with 7-days repetitive dosing but maintained good antimicrobial potency and demonstrated the ability to rescue mice suffering sepsis infection. Overall, we successfully showed a potential drug candidate in fighting against pan-resistant bacterial infections.

9:20 AM SM02.01.05
Cost-Effective Hybrid Membranes with Antimicrobial Efficacy for Burn Treatments Kausik Mukhopadhyay, Suvash Ghimire, Kasey Rigby and Kaitlyn E. Crawford; University of Central Florida, United States

There are about 1.1 million burn injuries that receive medical attention every year in the United States, of which majority are related to first- and second-degree burns. Burns are among the most painful and debilitating wounds and often turn deadly when infection sets in. Approximately 50,000 of these require hospitalization; around 20,000 suffer from major third degree burns, and an estimated 4,500 die from burn wounds. Patients who are admitted to the hospital after sustaining a large burn injury are at high risk for developing hospital-associated infections. If patients survive the initial three days after a burn injury, infections are the most common cause of death. The risk of infections caused by multidrug-resistant bacteria increases as the patients stays longer time in the hospitals. While susceptible gram-positive organisms predominate in the initial days, the more resistant gram-negative organisms are found later. These findings affect the choice of empiric antibiotics in critically ill burn patients.

To combat such infections only a handful of FDA-approved products are available in the market to treat second and third degree burns, and hardly a handful treat scars associated with such burns. Topical agents in treating wounds such as chlorhexidine, proflavine, iodine, hydrogen peroxide, silver etc. have been used to combat wound infections. However, the relentless emergence of antibiotic resistant strains of pathogens, often with multiple antibiotic resistances, together with the discovery of novel antibiotics has led to the need to find alternative treatments.

We have developed a series of hybrid membranes engineered using material modification through intercalation and exfoliation of silicate-based materials and metal ions to prevent infections from ESKAPE pathogens sans the expensive or environmentally toxic ions or nanoparticles while promoting rapid wound and scar healing. Further, we will also display a metal-less hybrid organic-inorganic system that shows huge promise in antimicrobial efficacy against gram-negative and gram-positive bacteria. Complete characterization including physico-chemical, spectroscopic and mechanical analyses corroborates our hypothesis for the structures, properties, mechanisms, mechanical durability and microbial activity of such membranes. The membranes also exhibit optimal water vapor transport through the pores and skin - an important feature that helps with the healing and quick recovery. Cost-effective, near-zero toxicity, biodegradable and durability features, together with easy application on the wound areas, make these hybrid membranes unique for burn treatments.

9:35 AM SM02.01.06
What Nanozymes Preferentially Kill Bacteria Over Mammalian Cells and Bio-Compatibly Inhibit Biofilm Formation (Those Generating Surface-Bound Reactive Oxygen Species) Feng Gao, Tianyi Shao, Yunpeng Yu, Yujie Xiong and Lihua Yang; University of Science and Technology of China, China

Nanozymes kill bacteria with reactive oxygen species (ROS) they produce *in situ.* Because ROS can simultaneously oxidize diverse substances crucial for proper cell functions, nanozymes are recognized as a class of novel antimicrobial agents that are promising for tackling antimicrobial resistance. However, the intrinsic inability of ROS to distinguish bacteria from mammalian cells deprives nanozymes of the selectivity necessary for an ideal antimicrobial. Note that mammalian cells, but not bacteria, actively internalize nanoparticles via endocytosis and that reactive ROS have extremely short lifetimes. We hypothesize that nanozymes that generate

surface-bound ROS may selectively kill bacteria over mammalian cells, thereby offering disinfection and biofilm inhibition in a biocompatible manner. To prove this hypothesis, we identified AgPd, a silver-palladium bimetallic alloy nanoparticle, to be an oxidase-like nanozyme that generates surface-bound ROS and, using AgPd as a model for surface-bound ROS-generating nanozymes, carried out antibacterial assays and mammalian cell cytotoxicity tests both in vitro and in animal models. We further excluded the possibility that our hypothesis applies only to AgPd, by examining the performances of another two nanozymes that are distinct in materials from AgPd but generate surface-stabilized ROS in oxidase-like way as well. To examine whether or not the surface-bound nature of ROS on AgPd impacts its potential in eliminating antibiotic-resistant bacteria or delaying the onset of bacterial resistance emergence, we performed serial antibacterial assays in vitro. Moreover, to evaluate the potential of AgPd as antibacterial additive for surface coating, we coated AgPd onto an inert substrate and tested the potency of the resulting surface in thwarting biofilm formation both in vitro and in mouse models. Results from above in vitro assays and animal experiments will be reported.

SESSION SM02.02: Anti-Viral Materials

10:30 AM *SM02.02.04
Engineering Antimicrobial Biomaterials—The Fight Against Bacteria, Fungi and Viruses Jayanta Haldar; Jawaharlal Nehru Centre for Advanced Scientific Research (JNCASR), India

Emergence of antimicrobial resistance (AMR) caused by superbugs, has threatened the global public health thereby constituting a major share of the annual mortality, worldwide. On top of that, COVID-19 pandemic in the recent times has further worsened the prevailing scenario. In this context, the global community has been realizing the significant role of surfaces in infection transmission and necessity for the development of effective preventive measures and therapeutics. Towards this goal of mitigating the spread of pathogens through fomites, our group has engineered numerous polymeric antimicrobial paints.[1-2] Recently, we have developed a one-step curable, covalent antimicrobial coating, which can be applied to various surfaces such as cotton, plastic, polyurethane, surgical mask, apron, gloves.[3] The coating displays excellent activity against drug resistant bacteria, and pathogenic fungi. Remarkably, this coating shows complete killing of human influenza viruses and is also being investigated for ability to inactivate SARS-CoV-2. Our interest into biomaterial researched has also led to antimicrobial hydrogels and injectable antimicrobial sealant with superior adhesive strength and haemostatic ability and potent therapeutic effect against corneal infections.[4-6] Alongside, we have contributed significantly in the development of synthetic peptidomimetic antimicrobial polymers.[7-9] These membrane-active macromolecules demonstrate excellent activity against multidrug resistant pathogenic bacteria and fungi in *in-vitro* as well as *in-vivo*, without any detectable resistance development. Overall, the aforementioned inventions hold promise leading to be developed as smart technologies in future to combat microbial infections and antimicrobial resistance.

10:55 AM SM02.02.02

On-Mask Chemical Modulation of Respiratory Droplets Haiyue Huang, Hun Park, Yihan Liu and Jiaxing Huang; Northwestern University, United States

Mask-wearing has become a new normal in many parts of the world in the COVID-19 pandemic. There has been much interest in enhanced masks that can better protect the wearers. However, a mask or face covering is much more effective in protecting others, because it can block and reroute a large portion of the virus-laden respiratory droplets from symptomatic or asymptomatic infected wearers during coughing and sneezing. Here we report an on-mask chemical modulation strategy, where droplets escaping a masking layer are chemically contaminated with antipathogen molecules (*e.g.*, mineral acids or copper salts) pre-loaded on polyaniline-coated fabrics. Colorimetric method based on the color change of polyaniline and fluorometric method utilizing fluorescence quenching microscopy are developed for visualizing the degree of modification of the escaped droplets by H^+ and Cu^{2+}, respectively. It is found that even fabrics with low fiber packing densities (*e.g.*, 19%) can readily modify 49% of the escaped droplets by number, which accounts for about 82% by volume. The chemical modulation strategy could offer additional public health benefits to the use of face covering to make the sources less infectious, helping to strengthen the response to the current pandemic or future outbreaks of infectious respiratory diseases.

11:10 AM SM02.02.03
A FAST Platform to Counter Antimicrobial Resistance and Pandemics Anushree Chatterjee[1,2]; [1]University of Colorado Boulder, United States; [2]Sachi Bioworks Inc, United States

The rapid rise of multidrug-resistant (MDR) superbugs and the declining antibiotic pipeline are serious challenges to global health. Rational design and synthesis of therapeutics can accelerate development of effective therapies against MDR bacteria. In this talk, I will describe multi-pronged systems, synthetic biology, and nano-biotechnology based approaches being devised in our lab to rationally engineer therapeutics that can overcome antimicrobial resistance. We have developed a synthetic biology and materials-engineering based platform called Facile Accelerated Specific Therapeutic (FAST) for developing accelerated therapeutics in less than a week. This approach relies on designing, building and testing engineered antisense therapeutics that can block translation or increase transcription of any desired gene in a species-specific manner. We have used this approach to uncover and target novel genes to re-sensitize MDR clinical isolates of bacteria to antibiotics, develop new classes of antibiotics, as well as develop therapeutics effective against SARS-CoV2 in very short periods of time. I will also present a nano-biotechnology based approach involving development of a unique semiconductor material-based quantum dot-antibiotic (QD ABx) which, when activated by stimuli, release reactive oxygen species to eliminate a broad range of MDR bacterial clinical isolates. This approach has been shown to eliminate MDR clinical isolates under both planktonic and biofilm conditions. Pre-clinical animal studies evaluating the FAST and QD Abx platform demonstrate low toxicity and high efficacy, and thus promise for further translation. The FAST and QD Abx platforms and inter-disciplinary approaches presented in this talk offer novel methods for rationally engineering new therapeutics to combat disease challenges.

11:35 AM *SM02.02.01
Viral Inhibition with DNA Star Strategy Xing Wang; University of Illinois at Urbana-Champaign, United States

Many infectious diseases including viruses, bacteria, and toxins, present unique spatial patterns of antigens on their surfaces [1-3]. These specific patterns facilitate multivalent binding to host cells, resulting in enhanced pathogenic infectivity. Based on this naturally occurring multivalent binding mechanism, synthetic multivalent entry blockers were previously introduced by linking epitopes-binding ligands to a scaffold to improve multivalent binding avidity [4-7]. Recently, the anti-influenza assays by Kwon *et al*. has suggested that matching ligand spacing with the distance of viral epitopes is a critical factor in inhibiting viral infection, while higher ligand densities have resulted in null or much weaker inhibition of influenza infection [8]. However, existing scaffolds, which include polymers, dendrimers, nanofibers, inorganic nanoparticles and lipid nanoemulsions, have shown toxicity [9,10]. Furthermore, the complex geometric patterns of viral epitopes

cannot be matched by existing scaffolds because they are not as precise in ligand spacing or provide limited control over the scaffold shape and ligand valency.

A customizable molecular scaffold strategy capable of incorporating pathogen-specific ligands and patterns may address these issues on both therapeutic and diagnostic fronts. DNA, when folded into nanostructures with a specific shape, is capable of spacing and arranging binding sites into a complex geometric pattern with nanometer-precision. Here we demonstrate designer DNA nanostructures (DDNs) that can act as templates to display multiple binding motifs with precise spatial pattern-recognition properties, and that this approach has been shown to confer exceptional potent viral inhibitory capabilities against dengue virus (DENV) and SARS-CoV-2.

As a proof-of-concept, we designed and synthesized a star-shaped DNA architecture to display 10 DENV envelope domain III (ED3)-targeting aptamers into a two-dimensional pattern precisely matching the spatial arrangement of ED3 clusters on the viral surface [11]. DENV was chosen as a representative target because its epitopes represent the most complex spatial pattern among all known viruses. The binding strength of monovalent ligand to proteins on a viral or cell surface is often relatively weak [8,11]. However, the "DNA star" allows for polyvalent and spatial pattern-matching interactions, affording dramatic improvement in DENV-binding avidity and providing highly potent DENV inhibitor in human blood with an EC_{50} of 2 nM (~7,500-fold more effective than the monovalent aptamer). Live confocal imaging confirmed that dengue virions lost their cell internalization ability after binding by the DNA stars in blood. Our molecular-platform design strategy could be adapted to combat other disease-causing pathogens by generating the requisite ligand patterns on customized DNA nanoarchitectures. The design and characterization of our SARS-CoV-2 inhibitors will be also discussed.

SESSION SM02.03: Anti-Biofilm Materials I
Session Chair: Haitao Liu
Monday Afternoon, April 19, 2021
SM02

1:00 PM *SM02.03.01

Nanogenerator-Enabled Electrical Strategy for Suppressing Biofouling Xudong Wang and Yin Long; University of Wisconsin-Madison, United States

The attachment and accumulation of organic substances and subsequent microbe attaching on submerged solid surfaces can cause substantial energy waste and severe damage. In addition to conventional antifouling coatings, alternating strong electric fields have also been investigated as a promising anti-biofouling strategy via

the effects of killing microbes by irreversible electroporation of cell membranes or to repel microbes via the dielectrophoresis effect. We recently investigated nanogenerator technology as an effective approach to generate alternative electric fields by harvesting mechanical energy from ambient environment. With appropriate design, the electric potential generated directly from water agitation can be utilized as a self-sustainable energy source to effectively to prevent microbe adhesion by changing surface charge distribution on microbes. We demonstrated an efficient and eco-friendly anti-biofouling system using an alternating low-intensity and discrete electric field generated by a water-driven nanogenerator. The anti-biofouling mechanism was attributed to the electric field-induced disturbance to the double layer, which impairs the stable adsorption of organic substances and the subsequent microbe attachments. The anti-biofouling efficacy was directly related to the strength of the electric field but less dependent to the alternating frequency. A long-time on-site demonstration in lake demonstrated superior performance compared to copper based surfaces and commercial coatings. This development brings a novel, effective and eco-friendly solution for protecting a broad range of surfaces against biofouling, including underwater surface and maybe even for implanted medical devices.

1:25 PM *SM02.03.03
Entrapment of Commensal Skin Bacteria in Polymer Materials: An Approach to Treat Skin Disorders due to Pathogens? Karine Glinel, Wanlin Xu, Sophie Demoustier-Champagne and Alain M. Jonas; Université Catholique de Louvain, Belgium

Usual approaches to treat skin infections are based on the use of antimicrobial products such as disinfectants or antibiotics. However, these compounds are rarely fully selective so that they act not only on pathogens responsible for the skin infection but also against commensal bacteria living on the human skin and which are now recognized as a part of the host defense system. Indeed, some bacteria involved in the skin microbiota play a major role against proliferation of pathogens by secreting active substances such as antimicrobial peptides, quorum sensing molecules, etc. These microorganisms produce also substances which stimulate the wound repair and limit the inflammation related to the infection.
As a consequence, treatments impacting this community can give rise to serious skin disorders leading to pathologies even more serious than the initial infection to be treated. Therefore, it is now well-admitted that skin treatments need to be targeted to preserve the bacterial community composing the skin microbiota. In this context, recent approaches explored the use of commensal bacteria known for their beneficial activity against pathogens to treat skin diseases. However, applying directly such bacteria on the patient's skin is not without risk considering their tremendous ability to mute or to become pathogenic in certain conditions. Therefore, an approach allowing to manipulate such bacteria to treat skin disorders while avoiding their uncontrolled proliferation could be a promising approach for topical applications.
In this presentation, we present different approaches to entrap *Staphylococcus epidermidis*, a predominant commensal skin bacterium known for its active role in the host defense system but also reputed to be an opportunistic agent being a major source of hospital-acquired infections, mostly associated with the use of invasive medical devices. The objective is to develop polymer envelops which preserve the viability and the activity of bacteria and allow the diffusion of secreted molecules but also avoid the release of cells to prevent their uncontrolled growth on human skin. Different strategies based on encapsulation of individual cells in a polymer shell, entrapment of cells in mats of polymer nanotubes, in polymer microtubes and in pores of polymer membranes will be presented. The advantages and the limitations of these different approaches towards the final application, i.e., the development of new therapeutic strategies to treat skin disorders, will be discussed.

1:50 PM SM02.03.04
DNA-Based Nanofabrication for Antifouling Applications Liwei Hui and Haitao Liu; University of Pittsburgh, United States

This talk will present our recent work on the fabrication of antifouling surface using DNA-based nanofabrication. We used DNA triangle nanostructures as templates to produce triangular-shaped trenches *ca.* 100 nm in size on a SiO_2 surface. Using *B.subtilis* as a bacterial model, we found that such nanopatterned

surface showed a 75% reduction in bacterial adhesion and 74% reduction in biofilm density at only 35% surface coverage of the nanoscale triangle trenches. Our work demonstrates the potential of DNA-based nanofabrication in antifouling and other surface engineering applications.

2:05 PM SM02.03.05
Antimicrobially Active Polymer Materials for Interfaces and Applications Karen Lienkamp[1,2]; [1]Albert-Ludwigs-Universität Freiburg, Germany; [2]Universty of Saarland, Germany

Bacterial infections of patients often initiate at the surface of medical devices. In consequence, biofilms form, often with life-threatening consequences. It is estimated that by 2050, up to 10 million people will die every year due to bacterial infections if the current trends cannot be reverted. Thus, antimicrobial polymers are currently experiencing a renaissance both as drugs and materials. Polycationic materials have long been known for their antimicrobial activity; however, they fail once they are fully covered by bacterial debris. To overcome this problem, we followed different strategies. First, we designed micro- and nanostructured polymer surfaces from a protein-repellent and an antimicrobial poly(oxanorbornene) by colloidal lithography and microcontact printing. By varying the polymer patch sizes, we obtained structure-property relationships for the interaction of these patterned polymer surfaces with proteins, bacteria, and human cells, and found that they were simultaneously protein-repellent, antimicrobial, and cell-compatible at a spacing of 1-2 μm, a size matching bacterial dimensions. We also serendipitously found a stimulus-responsive poly(oxanorbornenes) that was protein-repellent and cell adhesive, yet antimicrobial when in contact with bacteria, and thus makes ideal material for implant coatings. Finally, we investigated interfaces that can shed their functional skin when contaminated, like a reptile, and thereby regenerate their original surface functionality.

SESSION SM02.04: Hybrids Against Bacteria

Monday Afternoon, April 19, 2021
SM02

4:00 PM SM02.04.01
Late News: Synergistic Antimicrobial Activity of Nanopillars Combined with an Inherently Antimicrobial Hydrogel Sara Heedy[1], Michaela Marshall[2], Juviarelli Pineda[2], Eric Pearlman[2] and Albert Yee[1]; [1]University of California, Irvine, United States; [2]University of California Irvine, United States

Microbial keratitis has ~1 million new cases annually worldwide and is the principal cause of blindness in Asia. The most frequent cases occur in Nepal and South India, which have an incidence rate of 799 and 113 per 100,000 individuals, respectively. One study in India found up to 44% of these infections were caused by fungi. These fungal infections are usually caused by injuries contaminated by soil, allowing invasive molds into the wound area. In humid regions across the world, keratitis is often caused by the invasive mold *Fusarium oxysporum*, while in the United States, keratitis is often caused by the opportunistic bacteria *Pseudomonas aeruginosa.*

The current method to prevent microbial infection is overused chemical solutions that lead to antimicrobial resistance. This leads to the development of antimicrobial surfaces which aim to limit the spread of microbes in the first place. The two main methods of antimicrobial surfaces are inherently antimicrobial materials, and physical nanopattern topography. Inherently antimicrobial materials include cationic polymers and chemical tethering of antimicrobial agents. These are simple, effective, but may suffer from leaching. Natural, nanotextured surfaces such as those on cicada wings cause bacterial and fungal cell rupture and death. These textures are promising as a long term solution, but many times the fabrication steps use harsh chemicals. This leads to our work that harnesses the synergistic antimicrobial activity of the inherently antimicrobial biopolymer

chitosan and a nanopillar coating. We examined the growth of pathogenic fungi and bacteria on these hydrogel surfaces. After 24 hours, we found fewer viable fungi on all of the hydrogel films compared to a control. While dense biofilm was observed on the control surface, the surface without nanopillars inhibited biofilm development due to the antimicrobial activity of the chitosan material. The addition of nanopillars onto the chitosan surfaces appear to stunt the germination and germ tube development even further compared to the film without nanotextures. Additionally, there was a decrease in viable bacteria on the hydrogel surfaces compared to a control. We conclude that the nanopillars act synergistically with the inherently antimicrobial chitosan material to inhibit disease causing microbial growth. This study may inspire the design of future antimicrobial systems that harness multiple antimicrobial effects.

4:15 PM SM02.04.02

Late News: Development of Antibiofilm Surfaces' Coating -Pickering Emulsion Based Mor Maayan[1,2], Karthik Ananth[1,2], Michal Natan[3], Ehud Banin[3] and Guy Mechrez[2]; [1]The Hebrew University of Jerusalem, Israel; [2]Volcani Institute, ARO, Israel; [3]Bar-Ilan University, Israel

This research presents bio-friendly and cost-effective antibiofilm coating formulations based on Pickering emulsion templating. The coating does not contain any active material, where its antibiofilm function is based on passive mechanisms, laying solely on the superhydrophobic nature of the coating, and thus highly suitable for food and medical applications.
The coating formulation is based on water in toluene or xylene emulsions that are stabilized by commercial hydrophobic silica, with Polydimethylsiloxane (PDMS) that is dissolved in the organic phase. The stability of the emulsions and their structure were studied by microscopy methods. The most stable emulsions were applied on polypropylene surfaces and dried in an oven to form PDMS/silica rough coatings. The surface morphology of the coatings shows a honeycomb-like structure that exhibits a combination of micron-scale and nano-scale roughness resulting in a Superhydrophobic property.
The superhydrophobicity of the resulting coatings has been tuned to meet the demands of highly efficient antibiofilm passive activity. The obtained coatings have shown a decrease of one order of magnitude in the *E-coli* accumulation on the surface, that is a significant value for coating with a passive based antibiofilm coating.

4:30 PM SM02.04.03

Late News: Encapsulation of Bacteria in Membrane-Based Patches with Antibacterial Surface Wanlin Xu, Karine Glinel, Sophie Demoustier-Champagne and Alain M. Jonas; Uniersity Catholique Louvain, Belgium

Bacteria communities are essential components of the skin ecosystem, whose disbalance can be related to several skin disorders, such as acne, eczema or psoriasis. Therefore, exogenously supplying skin-beneficial bacteria to dysbiotic skin is increasingly considered as a way to restore immune response, inhibit infection and treat skin inflammation. This requires encapsulation to control the dispersion and proliferation of bacteria while keeping their benefits. Encapsulation of bacteria was previously studied in spherical particles, microcapsules, gels and electrospun fibers; here, we investigate the encapsulation and growth of bacteria in the micropores of track-etched membranes, aiming at checking the role of channel confinement on bacteria proliferation and at producing soft patches for direct topical application.
Well-defined cylindrical micropores of polycarbonate (PC) membranes were modified by a biocompatible coating based on chitosan and alginate. *Staphylococcus epidermidis* (*S. epidermidis*), a Gram-positive commensal skin bacterium that is known to have potential benefits to human hosts, was then introduced in the modified micropores. The metabolic activity of *S. epidermidis* was then tested, showing the proliferation of encapsulated bacteria in the microchannels. However, the release of *S. epidermidis* from the microchannels is not desirable for practical skincare applications, since *S. epidermidis* proves to be a dangerous pathogen when it passes the skin barrier. Therefore, to prevent the free growth of *S. epidermidis* and maintain its metabolic activity, the modified PC membrane was coated with a layer of agarose gel, followed by coating of this gel with layer-by-layer assembled multilayers, either based on alginate/chitosan, or on polyethylenimine/poly(styrenesulfonate) (PEI/PSS). These barrier layers were demonstrated to efficiently delay the leaking of bacteria from the membrane-in-gel patch, with the lag time depending on bilayer number (coating

thickness). In this respect, PEI/PSS is more efficient than alginate/chitosan multilayer in controlling the release of bacteria, with only four bilayers sufficient to effectively prevent bacterial escape over long times. The polyelectrolyte multilayers coatings act as barriers preventing bacteria from escaping, while the agarose gel protects them from direct contact with this antibacterial coating and keeps them alive. The resulting soft patches are thus ideally suited to topical applications of *S. epidermidis*.

4:45 PM SM02.04.04
Late News: Synthesis and Characterization of Silver Chloride Nanocolloids in Aqueous Medium for Antimicrobial Application Syed I. Hossain[1,2], Maria C. Sportelli[1], Rosaria Anna Picca[1,2], Nicoletta Ditaranto[1,2] and Nicola Cioffi[1,2]; [1]Dipartimento di Chimica, Università degli Studi di Bari "Aldo Moro", Italy; [2]CSGI (Center for Colloid and Surface Science) Bari Unit, Università degli Studi di Bari "Aldo Moro", Italy

Synthesis and characterization of silver halides (AgX) have drawn much attention due to its specific properties and promising application [1,2]. Particularly, AgX have the potential to be nanoantimicrobials (NAMs) by providing a constant concentration of biocidal Ag^+ ions in aqueous medium and tailoring control release of Ag^+ ions into the surrounding environment. Nonetheless, it is known that AgX salts in pure crystalline form are unstable [3], whereas AgX salts in a dispersed state are considered stable [4]. Therefore, it is worth pursuing to study the convenient ways to prepare a stable dispersion of AgX with intrinsic antimicrobial activity. In the present study, nano colloidal dispersion of silver chloride (AgCl) in aqueous medium is prepared by using $AgNO_3$ as precursor and quaternary ammonium chlorides (QAC) as both source of chloride, and stabilizer. Tetra-octyl-ammonium chloride (TOAC) and Benzyl-hexadecyl-dimetyl-ammonium chloride (BAC) were chosen as model QAC systems, holding a symmetric or asymmetric molecular structure. The synthetic approach resulted to be scalable and green. Morphology and stability of AgCl nanocolloids were investigated as a function of different molar fractions of the reagents. Size distribution and kinetics of the particle growth were monitored by dynamic light scattering, which predicted the formation of QAC bilayered structures associated with the AgCl nanoparticles (NPs). Nanocolloids were further characterized by transmission electron microscopy, X-ray photoelectron and infrared spectroscopies. Zeta potential measurements revealed a highly positive potential value at every stage of synthesis. Experimental evidences support the morphological stability of the nanocolloids, along with their antimicrobial property. Application of the antimicrobial NPs is being investigated as slow-releasing active phases in the Food Packaging industry, mainly aiming at bacteriostatic, long term effects.

5:00 PM SM02.04.05
Late News: Electrosynthesized ZnO Nanoantimicrobials for Cultural Heritage Applications Margherita Izzi[1], Maria C. Sportelli[1], Roberto Gristina[2], Rosaria Anna Picca[1] and Nicola Cioffi[1]; [1]University of Bari Aldo Moro, Italy; [2]Institute of Nanotechnology, National Research Council of Italy (CNR-NANOTEC), c/o Department of Chemistry, Italy

The employment of bioactive nanomaterials is one of the most strategical approach to fight antimicrobial resistance and biofilm formation. In particular, metal and metal oxide nanoparticles with controlled ion release can show a noteworthy antimicrobial activity [1]. The use of zinc oxide (ZnO) nanostructures for these purposes is continuously expanding, due to its biocompatibility and low toxicity. In our research group we are exploring

electrochemical strategies for the preparation of ZnO nanostructures based on the use of a sacrificial Zn anode in an aqueous electrolytic bath [2] as alternative approach to conventional methods. By tuning the synthesis parameters and selecting the proper stabilizer, spheroidal and flower-like ZnO nanostructures are synthesized. Particularly, poly-sodium-4-styrenesulfonate (PSS), cetyltrimethylammonium bromide (CTAB), benzyl-hexadecyl-dimethylammonium chloride (BAC) and poly-diallyl-(dimethylammonium) chloride (PDDA) have been tested as capping agents [3–5]. Novel hybrid coatings were developed by dispersing the as-synthesized ZnO into commercially-available consolidating agents. The nanostructured coatings were deposited on stone monuments as multifunctional films, providing antimicrobial and consolidating properties [6,7]. More recently, flower-like nanostructures have been successfully tested against *Bacillus subtilis* as a Gram-positive model microorganism [5]. Morphological analyses carried out on the ZnO-based nanomaterials will be presented. The combination of UV–Vis, FTIR and XPS spectroscopies afforded for the univocal assessment of the material composition as a function of different processing and deposition conditions. A critical comparison of the different materials will be presented, outlining the effects of the stabilizer.

5:15 PM SM02.04.06

Late News: Cu-Based Hybrid Nanoantimicrobials (Nams)—Electrochemical Synthesis And Characterization Ekaterina Kukushkina, Maria C. Sportelli, Rosaria Anna Picca, Nicoletta Ditaranto and Nicola Cioffi; University of Bari, Italy

Copper is one of the most promising agents to fight antimicrobial resistance (AMR) and growth of biofilms: it is commonly incorporated as part of the novel composite systems with synergistic effects [1]. In this study, organic/inorganic Cu-based nanohybrids were prepared by Sacrificial Anode Electrolysis (SAE) technique in organic medium. Several quaternary ammonium compounds (QAC) were used as cationic stabilizers and supplementary organic components with intrinsic antimicrobial properties [2]. These organic species, carrying positive charge, are well-known for their ability to bind to a negatively-charged outer surface of majority of pathogens. In particular, Benzyl-hexadecyl-dimethyl-ammonium chloride (BAC) and Tetra-butyl-ammonium perchlorate (TBAP) were used as a “shell” for comprising a hybrid composite: these organic compounds are widely used as disinfectants with ability to prevent formation of biofilms [3].
Morphological and spectroscopic characterization of these nanocomposites was performed: UV-vis spectroscopy, transmission electron microscopy (TEM), X-ray photoelectron spectroscopy (XPS), and Fourier Transform infrared spectroscopy (FTIR) were used. Stability and kinetics were studied at different conditions: organic to inorganic component ratio, time and applied potential to the working electrode among other

parameters. Stability of the colloids and surface potential were studied by dynamic light scattering (DLS) and Zeta potential measurements. These hybrid nanoantimicrobials (NAMs) are subjects for further microbiological and toxicological tests as potential materials for controlling and inhibiting biofilm and pathogen growth. Inclusion of the NAMs in biodegradable polymers and their use as active coatings for Food Packaging applications are being investigated, as well.

Computational Modeling of Antimicrobial Materials using Zinc Oxide Nanoparticles Roxanne Esparza and Sungwook Hong; California State University, Bakersfield, United States

The use of zinc oxide nanoparticles (ZnO NPs), biologically safe and compatible, has gained a great amount of attention in a wide range of biotechnological applications due to their ability to act as antimicrobial materials. That is, ZnO NPs could interact with a small cluster of bacteria like Escherichia coli (*E. coli*) preventing a growth of *E. coli* molecules. While many studies showed the antimicrobial behavior of the ZnO NPs, bioactivities of the ZnO NPs with E. Coli have not been clearly understood at a molecular level. Here, we perform reactive molecular dynamics (RMD) simulations based on ReaxFF to investigate effects of the addition of ZnO NPs on the growth of *E. coli* molecules. We found that the addition of ZnO NPs could successfully delay the growth of *E. coli* clusters. We also identified key reaction pathways for the antibacterial behaviors of ZnO NPs. As such, our work will help guide experimental design of Antimicrobial materials using ZnO NPs for a wide range of medical solutions like lotions and ointments.

SM02.05.02
A Study of the Interaction Between BSA Conjugated Silver Nanoparticles and Hyaluronic Acid-PEG Based Hydrogel for the Design of an Antimicrobial Hydrogel Nanocomposite Olufolasade F. Atoyebi[1], Berhanu Zewde[1], Ayele Gugsa[1], Karen Gaskell[2] and Dharmaraj Raghavan[1]; [1]Howard University, United States; [2]University of Maryland, United States

Significant interest has been directed to synthesizing topical gel formulations capable of encapsulating silver nanoparticles where the nanoparticles released can be effective against antibiotic resistant bacterial strains. The release of nanoparticles from the hydrogel nanocomposite is dictated by the interaction between nanoparticles

and the crosslinked hydrogel. The objective of this study is to develop an understanding of the interactions that exist within the nanocomposite hydrogel between the bovine serum albumin stabilized silver nanoparticles (Ag/BSA) and the hydrogel (hyaluronic acid-PEG based hydrogel) using XPS and FTIR, as well as AAS to quantify the release of Ag/BSA nanoparticles from the hydrogel nanocomposite. Characteristic IR peaks in the nanocomposite were found to have broadened and/or red shifted compared to the neat hydrogel; suggesting possible hydrogen bonding or weak interactions between the nanoparticles and the hydrogel in the nanocomposite. A striking difference in the C1s XPS spectrum of the neat hydrogel and the nanocomposite suggested structural rearrangement of the hydrogel in the presence of the BSA coated nanoparticles. Specifically, a large increase in C-O bonding at the surface relative to hydrocarbon bonds in the composite was observed and is indicative of the hydrogel molecule rearranging such that PEG is pointing towards the surface while the ends of the hyaluronic acid are interacting with the BSA of nanoparticles. Additionally, only 50% and 20% of nanoparticles were desorbed from the lightly and highly crosslinked nanocomposite matrix, respectively, after a 14 day of desorption study. This suggests that the role of the nanostructure and the importance of nanoparticle-hydrogel interaction is in controlling the release of nanoparticles from the hydrogel matrix. Antimicrobial studies of the neat hydrogel against *E. coli 107*, *L. monocytogenes*, and *S. sonnei* showed poor antibacterial activity. All the while the nanocomposite showed excellent bactericidal activity against the three kinds of bacteria; indicating that the observed antimicrobial properties are a direct result of the nanoparticles released from the hydrogel. Future studies will explore the potential wound healing properties of the hydrogel nanocomposite when dosed with antibiotic resistant bacterial strains.

SM02.05.03

Impact of ZnO Microcrystal Morphology and Surface Chemistry on Growth Inhibition of *s. aureus* Bacteria John Reeks, Iman Ali, Jacob Tzoka, Dustin Johnson, Daniel Lopez, Shauna McGillivray and Yuri Strzhemechny; Texas Christian University, United States

Microscale ZnO particles are known to inhibit the growth of bacteria. The fundamental mechanisms driving this process, however, are not completely understood. While there are many contributing factors to consider, we hypothesize that the antimicrobial action is most fundamentally derived from the ZnO surface and its interaction with growth media and the bacteria's extracellular material. In this work, we implement minimum inhibition concentration and novel comparative assays to evaluate the antibacterial activity of ZnO microcrystals produced by us using a hydrothermal chemical growth method. The samples were synthesized in the range of sizes from 1μm to 5μm with varying abundances of surfaces with different polarities. This approach prevents the ZnO particles from being internalized by the bacterial cells with diameters ca. 500 nm, thus allowing one to study correlations between overall surface polarity and antibacterial action. These experiments were performed in conjunction with optoelectronic studies of ZnO crystals (photoluminescence, surface photovoltage) to characterize electronic structure and dominant charge transport mechanisms as fundamental phenomena, which could potentially govern the processes leading to an antibacterial behavior in our samples. We report on the results of these comparative studies relating antibacterial properties with surface morphology and electronic behavior.

SM02.05.05

Late News: Nanostructured Antibacterial Aluminum Foil Produced by Hot Water Treatment Against E. coli in Meat Quinshell Smith[1,1], Nawzat Saadi[1], Khulud Alotaibi[1], Khalidah Al-Mayalee[1], Atikur Rahman[1], Nawab Ali[1], Ashraf Khan[2] and Tansel Karabacak[1]; [1]University of Arkansas–Little Rock, United States; [2]National Center for Toxicological Research,, United States

Antibiotic resistance has been on the rise due to the overuse of antibiotics in the livestock and fishing industry. This has led to an increase in foodborne illnesses and a need for alternative modes of action to help mitigate bacterial growth. This study broaches the potential applications of hot water treated (HWT) aluminum foil for use in the food packaging industry. Through HWT, a layer of aluminum oxide nanostructures is formed on the surface of the foil, which conveys antibacterial properties. In this study, we analyze the efficacy of HWT aluminum foil in preventing bacterial growth of Escherichia coli on red meat. Aluminum foil samples were

treated in hot water at different temperatures including 75°C, 85°C, and 95°C. It was found that HWT foils were on average 80% more effective than untreated foil samples at preventing bacterial colony growth. This research shows promising alternative modes of action against foodborne illnesses by offering a green and cost-effective means of curbing bacterial growth.

SM02.05.06
Late News: The Antibacterial Efficacy of Aluminum Oxide Nanostructures for HVAC Systems Quinshell Smith, Kenneth Burnnett, Ashley Esparza, John Bush and Tansel Karabacak; University of Arkansas–Little Rock, United States

Air quality is the most important factor in heating, ventilating, and air conditioning (HVAC) systems. This is even more important in an environment where the population is composed of an already immunocompromised segment. Nowhere is this more apparent than in hospitals and health facilities. A review of the current literature suggest that these HVAC systems increase the risk of nosocomial infections if not properly maintained and frequently scrutinized via quality checks. Bacteria, viruses, and fungi find entry into health facilities via equipment, people, and air flow. It is the latter which this research has as its focus. This airflow, once inside the health care center, recirculates throughout the facility, carrying with it the microorganisms it has within it. We utilized a novel hot water treatment (HWT) to produce aluminum oxide nanostructures on the surface of aluminum sheets which are used as ductwork for heating, ventilating, and air conditioning (HVAC) systems. We hypothesized that our HWT duct would greatly reduce the bacterial activity in the air circulating through the HVAC system as well as on the surface of the HWT duct. Air and surface analysis were done with an untreated ventilation system and compared to a ventilation system which had received the hot water treatment to produce Aluminum oxide nanostructures. This research was carried out at temperatures of 20–22 °C. Our results show the extreme effectiveness of using this novel, inexpensive, chemical-free method of producing aluminum oxide nanostructures to decrease bacteria growth in HVAC systems, and in turn significantly improving the air quality.

High-Performance 3D Printing and Coatings with Graphene Oxide Anti-Pathogenic Properties Rigoberto C. Advincula[1,2,3]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]Case Western Reserve University, United States

Optimized polymer and nanocomposite materials for additive manufacturing (3D printing) and smart coatings play an important role in improving thermo-mechanical properties, preventing corrosion, influencing the wetting properties of surfaces. And improving any process industry. Graphene nanomaterials and their unique processing methods have been reported and be optimum with a minimum percolation threshold and optimum performance peak. They have been demonstrated to have anti-microbial, anti-fungal, and anti-viral properties, including preventing biofilm formation. Nanostructuring of these materials is important to understand its efficacy. In this talk, we will describe nanostructured graphene composite materials' use to demonstrate and distinguish this anti-pathogenic effect in 3D printed materials and coatings and applications even with high-temperature environments. The use and characterization of these nanocomposite materials coatings are described. Graphene oxide (GO) additives also enhance their surface chemistry ability, having acid, hydroxy, and other oxidized species sufficient for interaction with silanes. The interest is in utilizing the capabilities of GO to form a hierarchical structure capable of anti-microbial properties, non-cytotoxicity, and preventing

biofilm formation. Important surface analytical and characterization methods will also be described.

9:30 PM SM02.06.02
Hydrogen Sulfide Slow Releasing Peptide as an Antimicrobial in Burn Wounds Nicole Levi[1], Afnan Altamimi[1], Yun Qian[2], Shaina A. Yates Alston[1], Mingjun Zhou[2], Santu Sarkar[1] and John Matson[2]; [1]Wake Forest School of Medicine, United States; [2]Virginia Tech, United States

Burn wounds are a devastating form of injury that leads to substantial morbidity, mortality, and costs. One of the critical complications of burn wounds is infections, especially with *Staphylococcus aureus*. Rising antimicrobial resistance is contributing to the complexity of wound management. Topical antimicrobial therapy, early wound debridement and grafting, and advances in trauma care and intensive management have all contributed to the decline in burn injury mortality. Management for these burns is challenging and is dependent on many factors including but not limited to patient age, total body surface area (TBSA) involved, the cause of the burn and other aspects that shape the treatment plan. *Staphylococcus aureus* and *Pseudomonas aeruginosa* are the most common pathogens isolated from wound infections including burn wounds. These microorganisms commonly attach to any surface and start producing extracellular polysaccharides, creating a film like a matrix. Biofilms are a serious problem for public health because of the protective effect of this matrix to the microorganisms they house, shielding them from antibiotics or immune cells, and set the path for deveoplment of chronic wounds, and failure of skin grafts. Hydrogen Sulfide (H_2S) is a novel gasotransmitter that has many physiological functions and acts as a signaling molecule, with pro-inflammatory effects. It also acts as a vasodilator allowing for more blood perfusion to the burn wound, We hypothesized that the a slow releasing H_2S peptide, based on the S-aroylthiooxime (SATO) functional group (S-FE), that self-assembles into nanofibers that form into a gel, could provide benefits in an infected burn wound model. Dipeptide gels were examined in vitro to evaluate the antimicrobial effects on S. aureus. Assays showed bactericidal and bacteriostatic properties of both S-FE and control (non-H_2S releasing) hydrogels. We next evaluated the H_2S dipetides in an ex vivo burn model using porcine skin and established *S. aureus* biofilm. These results aligned with the i*n vitro* results showing a decrease in bacterial burden with both S-FE and control gels compared to the bacteria only group. Building on the behavior of bacterial populations after S-FE and control treatments *in vitro* and *ex vivo* experiments the dipeptides were further in vivo on a well-established infected porcine burn model. The S-FE dipeptide hydrogels resuislted in reduced bacterial burden, improved blood perfusion to the burn area and better wound healing compared to the control hydrogels.

9:45 PM SM02.06.03
Tailoring Surface Physicochemical Properties of SU-8 to Modulate Bacterial Motility, Adhesion and Biofilm Formation of *Xylella fastidiosa*. Silambarasan Anbumani[1], Aldeliane M. da Silva[1], Mariana de Souza de S. Silva[2], Hernandes F. Carvalho[1], Alessandra A. de Souza[2] and Monica A. Cotta[1]; [1]University of Campinas, Brazil; [2]Agronomic Institute of Campinas, Brazil

SU-8 is an epoxy-based photo resist which has been used as a novel platform for biomedical applications due to its chemically tunable and biocompatible surface in addition to its relatively high stiffness, chemical resistance, optical transparency and ease of processing properties. Such properties can have a deep impact on the adhesion of single prokaryote cells and subsequent biofilm formation. In this work, we tailor SU-8 surface properties to investigate single cell motility and adhesion of the bacteria *Xylella fastidiosa*.

Different SU-8 samples have been prepared using UV illumination, thermal processing and oxygen plasma treatment. In addition, flat InP substrates were used for reference control since adhesion on InP surfaces has been well studied in our group. Atomic Force Microscopy and X-Ray Photoelectron Spectroscopy were used to determine nanoscale surface properties; ex-vivo studies at the level from single cell to biofilm formation were carried out with Confocal Laser Scanning Microscopy (CLSM) for different bacterial growth times. The mean velocity and displacement of single cells have been extracted from CLSM tracking information data and the size and quantity of biofilms are compared for different samples. We observed a significant difference in bacterial cell motility, adhesion and biofilm architecture on SU-8 as nanoscale surface property changes. Larger density

of carboxyl groups in treated SU-8 surfaces provide enhanced cell motility, while denser biofilms are found in pristine SU-8. Our results can improve understanding of the role of nanoscale properties on bacteria-surface interaction and thereby create strategies to prevent microbial adhesion and consequently, biofilm development of pathogenic species.

10:00 PM SM02.06.04
Investigation of Organic Polymer Nanoparticle Photothermal Ablation and Combination Antibiotic Treatment Against *S. aureus* Biofilms Shaina A. Yates Alston[1,2], Santu Sarkar[2], Matthew Cochran[2], Scott Northrup[2] and Nicole Levi[2,1]; [1]Wake Forest School of Medicine, United States; [2]Wake Forest Baptist Medical Center, United States

Biofilm infections are suggested to be associated with over 99,000 deaths annually and are thought to be responsible for over 80% of bacterial infections. It has been reported that over 90% of chronic wounds become colonized by biofilm, like that caused by *Staphylococcus aureus*. These ubiquitous biofilms are also a well-known cause of medical device implant infections and are thought to be responsible for 80% of limb amputations. These biofilms consist of an extracellular matrix (ECM) of extracellular polymeric substances (EPS), composed of polysaccharides, various proteins and glycoproteins, extracellular DNA (eDNA), and other host-derived factors and substances. These aspects of the biofilm help to confer resistance to the host immune response and antimicrobial resistance, as well as tolerance to other stressors like heat. Research demonstrates that antibiotic efficacy can be increased against biofilms after exposure to both mildly hyperthermic ($T < 45°C$) and ablative ($T > 45°C$) temperatures. Studies indicate that hyperthermia alone can alter biofilm structural integrity and viability, but the lack of localization of hyperthermia upon the biofilm matrix creates a challenge for clinical application. This study investigates the impact of near-infrared photothermal ablation (NIR-PTA), via polymer nanoparticles and combined antibiotic treatment, on *S. aureus* biofilms.

We have synthesized biocompatible polymer dynamic organic theranostic spheres (PolyDOTS) composed of two polymers: Poly[4,4-bis(2-ethylhexyl)-cyclopenta[2,1-b;3,4-b']dithiophene-2,6-diyl-alt−2,1,3-benzoselenadiazole-4,7-diyl] (PCPDTBSe) for heat generation and Poly(3-hexylthiophene-2,5-diyl) (P3HT) for fluorescence. PolyDOTS are capable of repeated photothermal generation under NIR irradiation and exhibit no photobleaching. They absorb in the NIR range, peaking at 760 nm. Thermocouple measurements determined the photothermal generating capacity of PolyDOTS at different concentrations, under 5 W, 60 secs 800 nm irradiation. They exhibited increasing heat generation at increasing concentrations, with an approximate plateau of 80°C.

Biofilms were challenged with a one-log (90%) effective minimal bacterial eradication concentration (MBEC-90) of clindamycin and a similarly effective dose (100 μg/mL) of PolyDOTS NIR-PTA. Clindamycin was administered either simultaneously with, 24-hours before or immediately after PolyDOTS NIR-PTA. Results showed that simultaneous administration was the most effective, up to a clinically significant three-log (99.9%) reduction in biofilm viability, compared to controls. The least efficacy occurred when clindamycin was added after NIR-PTA, suggesting that the observed ECM changes can inhibit antibiotic efficacy. Confocal microscopy using LIVE/DEAD stain surprisingly showed no confirmation of viability reduction, which is suggestive of a hyperthermia-induced loss of the biofilm layers. Biofilm biomass and structural changes were analyzed via an ECM confocal stain, scanning electron microscopy, and crystal violet assay. *S. aureus* biofilms showed increasingly pronounced aggregation on SEM and uncharacteristic coalescence, suggestive of compaction of the ECM. The crystal violet assay and spectrophotometry seemed to support the suspected ECM compaction of the PolyDOTS NIR-PTA-treated *S. aureus* biofilms. The results of this study provide evidence that PolyDOTS NIR-PTA alone, and in combination with an antibiotic, can significantly mitigate biofilm viability. While further investigation into the ECM structural changes resulting from localized biofilm hyperthermia would be merited, this study suggests that the combination treatment may improve existing biofilm infection therapy by enhancing antimicrobial efficacy.

8:00 AM SM02.03.02
The Pyro-Electrification of Polymer Sheets as a New Platform for the Evaluation of Biofilm Formation
Emilia Oleandro[1,2], Romina Rega[1], Martina Mugnano[1], Vito Pagliarulo[1], Filomena Nazzaro[3], Pietro Ferraro[1] and Simonetta Grilli[1]; [1]Institute of Applied Sciences and Intelligent Systems of the National Research Council (CNR-ISASI), Italy; [2]Department of Mathematics and Physics, University of Campania "L. Vanvitelli", Italy; [3]Institute of Food Sciences, National Research Council of Italy (CNR-ISA), Italy

The availability of surface-charged polymer-based materials opens up new perspectives for many industrial applications. In recent years, we developed a new technique for achieving such kind of surfaces through a chemical-free procedure that what we call pyro-electrification (PE). It exploits the electrostatic fields spontaneously generated on the surface of pyroelectric lithium niobate (LN) crystals. We present here how this technique can be used in various applications ranging from live cell patterning to biofilm formation for bacteria. In fact, the bacteria intrinsically become more resistant to environmental stresses under biofilm configuration, and may be a serious problem in different industrial sectors. Therefore, the possibility of monitoring the adhesion and the biofilm formation of bacteria is a very important issue, and has numerous advantages, since a fast detection of the presence of bacteria can significantly reduce the risk of contamination. In particular, we show the characterization of biofilm formation through qualitative and quantitative procedures in order to demonstrate the reliability of technique even for different bacterial strains.

SM03

8:00 AM *SM03.01.01
PEDOT:PSS-Based Neural Devices George Malliaras; University of Cambridge, United Kingdom

Neural devices are important for understanding how the brain works and for treating neurological disorders. The commercially available conducting polymer PEDOT:PSS has emerged as a state-of-the-art material for neural devices due to its mixed conductivity, biocompatibility, and convenient deposition. I will present examples of implantable and cutaneous neural devices for bidirectional neural interfaces, explaining the advantages of this material over commonly used metal electrodes. I will discuss the relationship between materials properties and device performance, elaborate on device fabrication techniques, and discuss lessons learned in the design of competitive materials.

8:20 AM *SM03.01.02
Soft Electronic and Ionic Materials and Devices for Neural Interfaces Klas Tybrandt; Linköping University, Sweden

Two-way communication between electronics and neural tissue is key for advancing diagnosis and therapies for neurological diseases and disorders in both the central and peripheral nervous systems. Establishing such neural interfaces is a major challenge, as the tissue response to implants can have a detrimental effect on the signal quality and functionality of the implant. Also, electrical stimulation is inherently limited in its stimulation of neural tissue, in comparison to the sophisticated chemical signaling processes within biological tissue. Here, I present our efforts in addressing two critical material and device aspects for the creation of versatile neural interfaces: the matching of mechanical properties of tissues and electronics, and the development of fast and low-leakage chemical interfaces. Soft electronic biomedical implants have a demanding set of requirements, including biocompatibility, desirable mechanical and electromechanical properties, long-term stability and good electrode performance. To meet these requirements, we have developed a high-performance, long-term stable soft and stretchable conducting nanowire composite. Several fabrication strategies have been developed around this composite to enable the fabrication of soft neural electrodes of different dimensions and geometries. Based on this technology, we have developed devices for both the central and peripheral nervous systems. Next, I will outline our strategy for creating high-speed low-leakage chemical neural interfaces by first discussing the relationship between delivery delay and leakage, and then present an iontronic approach to achieve low leakage and small delivery delay simultaneously.

Late News: Diamond-Based Multielectrode Sensors for *In Vitro* Detection of Excitable Cells Activity
Veronica Varzi[1], Pietro Aprà[1], Giulia Tomagra[1], Andrea Marcantoni[1], Alberto Pasquarelli[2], Paolo Olivero[1], Valentina Carabelli[1] and Federico Picollo[1]; [1]University of Torino, Italy; [2]Ulm University, Germany

To better understand neuronal signalling behind brain activity, a proper detection of both electrical and chemical signals is essential. Indeed, action potentials (APs) generation and synaptic quantal release of neurotransmitters play a fundamental role in the cellular mechanisms underlying brain functions, being at the basis of information transmission and signal communication in neuronal microcircuits.

In the present work, we present the employment of diamond-based micro-patterned graphitic biosensors to extracellularly record the activity of excitable cells, to resolve APs waveforms and neurotransmitter release [1-2]. The multi-electrode-array sensors were fabricated using a three-dimensional patterning process by means of MeV He ion-beam-based lithography on an artificial-type-IIa single-crystal monocrystalline diamond sample ($4.5\times4.5\times0.5$ mm^3), thus creating 16 independent graphitic electrodes embedded in its matrix. Being electrically conductive, the micro-channels of the sensors were used to investigate the in-vitro neuron activity both in terms of electrical signals generation (APs firing) and neurotransmitter secretion (quantal exocytic events).
The diamond biocompatibility allowed neuronal cells to be plated directly over the diamond device. Potentiometric measurements of APs generation were recorded from cultured hippocampal neurons, while quantal secretory events were amperometrically recorded from plated mouse dopaminergic neurons [3]. The electrical activity of an intact mouse sinoatrial node directly placed on the sensor was also recorded.
These results demonstrated the usability of diamond-based biosensors as promising devices for the simultaneous multi-parametric in-vitro detection of both electrical and chemical signals, representing in perspective a further step for a better understanding of brain functioning.

8:55 AM SM03.01.04
Flexible ITO-Based Electrolyte Gated FETs for Bioelectronic Applications Mary J. Donahue, Ludovico Migliaccio, Mehmet Say, Gaurav Pathak and Eric Glowacki; Linköping University, Sweden

Electrochemical and electrolyte-gated transistor architectures have emerged as powerful components for bioelectronic sensors and biopotential recording devices. For amplification of weak electrophysiological signals, maximum transconductance, high cutoff frequencies, and large on/off ratios are key desired parameters. Organic conducting polymer devices have recently dominated the field, especially where flexible and conformable *in vivo* electronics are necessary. Herein we report ultrathin, flexible indium tin oxide (ITO) electrolyte-gated field-effect transistors (EGFETs). These accumulation-mode devices combine high transconductance ($g_m > 30$ mS), excellent on/off ratio (10^5), and fast modulation with excellent stability and the possibility of optically transparent layouts. While oxides are normally considered brittle, we obtain mechanically flexible and robust ITO layers by room temperature deposition of ultrathin (30 nm) amorphous layers onto parylene substrates. This approach results in low strain and the devices survive bending and deformation tests over hundreds of cycles. In addition to favorable material properties, these transistors offer low power consumption, as a result of the normally off state and low off currents. Furthermore, a wide variety of biosensor applications can be envisioned since the material is an oxide with active oxygen surface chemistry (hydroxyl groups) and facile chemical functionalization approaches may be employed. Based on the demonstrated stability and performance, as well as the future possibilities using these transistors, indium tin oxide EGFETs represent a promising avenue for bioelectronic devices.

9:10 AM SM03.01.05
High Performance Conducting Polymer Nanofiber Actuators Operate in Liquid and Gel-Polymer Electrolytes Mohammadjavad Eslamian, Fereshtehsadat Mirab, Vijay Krishna Raghunathan, Sheereen Majd and Mohammad Reza Abidian; University of Houston, United States

Electrochemical actuators that transform electrical energy to mechanical energy through electrochemical reactions have numerous applications for biomedical devices, soft robotics, and bioelectronics. However, the design of high performance and durable electrochemical actuators that efficiently operate in biological environment remains a challenge yet. To address this challenge, here we developed and characterized a flexible organic electronic actuator based on poly(pyrrole) nanofibers (PPy NFs) that reversibly operates in liquid and gel polymer electrolytes under electrical stimulation. PPy is a versatile biocompatible CP which has been widely employed for bioactuators due to its low weight, fracture tolerance, and relatively large actuation strain.

To fabricate the PPy NFs actuator, we electrodeposited an electroactive layer of PPy doped with polystyrene sulfonate (PSS) around template poly-L-lactide (PLLA) nanofibers that were previously electrospun onto a thin layer of gold coated poly(propylene) (PP) film (20 mm × 1 mm × 30 μm). The average diameter of template nanofibers and the resultant PPy NFs were 140 ± 4 nm and 626 ± 16 nm, respectively. The PPy NFs were subjected to cyclic voltammetry (CV) in an aqueous solution and 0.2 wt.% agarose hydrogel both containing 0.1 M poly(sodium 4-styrenesulfonate) (NaPSS) at various scan rates of 10, 50, 100, and 200 mV/s with the potential window of -0.8 V to +0.4 V. We demonstrated that the actuator kinematics (i.e. displacement and speed) can be tuned by adjusting the CV parameters (voltage and scan rate). Remarkably, the PPy NFs actuator demonstrated excellent properties, including low power consumption/strain (as low as 1 $mW/cm^2/\%$), relatively high actuation strain (up to 1.85%) a controlled cycling response, and excellent cycling stability (>96.5 % bending stability over 15000 actuations equivalent to 25 hr continuous operation). Overall, this study presents a new strategy for development of flexible, mechanically durable and dynamically tunable organic electronic actuators for variety of applications ranging from soft robotics to biomedical devices.

9:13 AM SM03.01.06
Late News: Patterning PEDOT:PSS Microgel Based Electrodes to Interface Cell Culture Models
Sebastian Buchmann, Liangqi Ouyang, Mahiar Hamedi and Anna Herland; KTH Royal Institute of Technology, Sweden

Conjugated polymers such as PEDOT:PSS provide soft interfaces with cells and tissue. Their large surface area and innate ability to transport ions make them attractive, high-performance materials that work in ion-rich, wet conditions.[1]

We have developed a method of patterning PEDOT:PSS microgels into functional devices with heterogeneous structures. Using an out-of-shelf wax printer, we patterned filtrations membranes and have PEDOT:PSS microgels filtered through the membrane. PEDOT:PSS was retained on the hydrophilic region that was not covered by wax. We reached a resolution of ~100 um both at the patterned thickness and the gap distances between materials. Utilizing its microgel nature, we show that the patterns can be healed by water treatment. In its hydrated state, it can also be stretched by over 30% to 70%, depending on the stretching directions and the geometry of PEDOT.

By transferring PEDOT:PSS patterns onto adhesive substrates, followed by consecutive transferring of other colloidal materials, such as carbon nanotube (CNT), we demonstrate functional PEDOT:PSS electrodes and electrochemical transistors. We also developed methods to tune the water stability of the devices. This allowed us to perform ON/OFF switching cycles on the transistors in water for over 500 cycles.

Finally, we demonstrated biocompatibility of the materials by cultivating human tumor-derived U87 glioma cells as well as Lund Human Mesencephalic (LUHMES) neuronal cells on patterned PEDOT:PSS microgels electrodes, thus showing the possibility to use this method in both tumor-biology studies and more demanding neural models.

9:16 AM *SM03.01.07
CMOS Microelectronic Systems to Characterize Neurons and Networks at Subcellular Resolution
Andreas Hierlemann; ETH Zürich, Switzerland

Microelectrode arrays (MEAs) have been widely used in recent years for in-vitro investigation of neuronal cells and neural networks, as they enable long-term bi-directional interfacing with networks of living cells [1, 2]. Modern CMOS-based active MEA devices, especially high-density MEAs, provide the capability to

simultaneously perform electrophysiological recordings from thousands of electrodes at cellular/subcellular spatial resolution [3-6]. The high spatio-temporal resolution enables better separation and assignment of neural activities for closely spaced neurons as well as localized and specific stimulation of single individual neurons [7].

An exemplary CMOS high-density microelectrode system includes a large sensing area of 4.48 × 2.43 mm^2 comprising 59'760 (332 × 180) electrodes of 3 × 7.5 μm^2 size at a pitch of 13.5 μm [6]. The system incorporates several types of sensing units with the aim of extracting a wide spectrum of information from the same neuronal culture or brain slice: 16 dual-mode stimulation buffers, 2048 action-potential recording channels, 32 local-field-potential recording channels, 32 current recording units, 32 impedance measurement units and 28 neurotransmitter detection units [6].

By using such a system it was possible to record subcellular-resolution data in various preparations, ranging from organotypic and acute slices to cultures of dissociated neurons and stem-cell derived neurons. It was also possible to detect low-amplitude signals of action potentials traveling along thin axons (~100 nm diameter). Moreover, the stimulation features of CMOS microtransducer arrays and integrated microsystems offer the capability to bi-directionally interact, also in closed loop and real time, with potentially every single neuron in a given neuronal network. Applications include research in neural diseases and pharmacology.

Closing the Gap Between Organic Bioelectronics and Neuronal Systems Magnus Berggren; Linköping University, Sweden

Organic Bioelectronics operating in the electrochemical mode has been widely explored to record and stimulate signaling of neuronal systems. To make this technology successful in therapy and prosthesis applications as a future med-tech platform, included devices and materials should possess minimal invasiveness and must operate at a proximity, addressability and signal specificity to capture as much as possible of the signaling spectrum of the nervous system. Here, recent progress of the development of Organic Bioelectronics is presented that address these challenges, specifically targeting the development of devices integrated into capillaries and also self-organized neuro-bioelectronics.

3D Multifunctional Mesoscale Frameworks as Neural Interfaces to Cortical Spheroids John A. Rogers; Northwestern University, United States

Three-dimensional (3D), sub-millimeter-scale constructs of neural cells, known as cortical spheroids, are of rapidly growing importance in biological research because these systems reproduce complex features of brain architecture and organization in vitro, at levels qualitatively more sophisticated than those found in traditional two-dimensional (2D) cell cultures. Despite their great potential for studies of neurodevelopment, neurological disease modeling and evolution, detailed investigations of these miniature, 3D living objects cannot be accomplished easily using conventional approaches to neuromodulation, sensing and manipulation. This talk describes classes of microfabricated 3D frameworks as mechanically compliant, multifunctional neural interfaces to individual spheroids and to engineered, interconnected collections of them, known as assembloids. Electrical, optical, chemical and thermal interfaces to cortical spheroids derived from human induced pluripotent stem cells demonstrate some of the capabilities. Complex architectures and high-resolution features, in isolated or arrayed configurations, and in layouts that enable full surface coverage highlight the design versatility. Detailed studies of the spreading of coordinated bursting events across the 3D surface of an isolated cortical spheroid and of the cascade of processes associated with formation and regrowth of bridging tissues across a pair of such spheroids represent two of the many opportunities in basic neuroscience research and regenerative medicine uniquely enabled by these platforms.

2:35 PM *SM03.02.02
Materials and Bioactive Strategies Towards Better Neural Electronics-Tissue Interface Xinyan T. Cui; University of Pittsburgh, United States

Microelectronic devices placed in the nervous system present tremendous potentials for mapping neural circuits and treating neurological disorders. Currently, the performance of these devices is sub-optimum due to electrode material limitations and undesired host tissue responses. Quantitative histology and 2-photon imaging have revealed neuronal damage and degeneration, inflammatory gliosis, blood brain barrier leakage and oxidative stress at the site of implants which may compromise the intended recording/stimulation/neurochemical sensing function. We use several biomaterial strategies to minimize these responses in order to achieve seamless and stable device-tissue interface. Conducting polymer based nanocomposites have been investigated as electrode coatings and facilitate the signal transduction/charge transfer between the ionically conductive tissue and the electrical device. Nanostructuring is employed to improve the adhesion, stability and charge injection and drug delivery capability of the conducting polymers to meet the material challenges at the neural interface. As we continue to improve our understanding of the implant induced tissue response, bioactive approaches are being developed to modulate the cellular responses for seamless integration. Surface modification with bioactive molecules or anti-fouling materials have been found to significantly improve neuronal health and inhibit the inflammatory tissue response around the implants. Alternatively, therapeutics that control inflammation, neurodegeneration and oxidative stress can be delivered systemically or locally. These bioactive approaches demonstrated significant benefit in neural recording quality and longevity. The ultimate solution to a seamless device/tissue interface may be a combinatorial approach that takes advantage of multiple biomaterial strategies discussed above and beyond.

2:55 PM *SM03.02.03
NIH/NINDS Funding Opportunities for Technology Development and Translation Eric Hudak, Kari Ashmont, Brooks Gross and Nick Langhals; National Institutes of Health, United States

The mission of the NINDS Division of Translational Research (DTR) is to accelerate basic research findings

towards patient use for neurological disorders and stroke by providing funding, expertise, and resources to the research community. DTR provides funding and resources through grants, cooperative agreements, and contracts to academic and industry researchers to advance early-stage neurological technologies, devices, and therapeutic programs to industry adoption (i.e. investor funding and corporate partnerships). We have created a variety of programs that support the design, implementation, and management of research activities critical to translational challenges in the treatment of neurological disease. In addition, DTR plays an active role in the NIH BRAIN Initiative, the Blueprint for Neuroscience Research, the HEAL Initiative, and the SPARC Program. DTR is actively managing programs that support small molecule, biologic, and neural device therapeutics, biomarkers, and training through grants, contracts, and consultants. These programs cover all stages of translational research from early assay/biomaterial/device development and optimization to preclinical development and early clinical development. Funding opportunities and resources are actively supporting translational research in preclinical discovery and development of new therapeutic interventions for neurological disorders and stroke, as well as neuropsychiatric disorders and neurotraumatic injuries (BRAIN Initiative). An overview of NIH/NINDS translational programs and resources will be presented.

3:15 PM *SM03.02.04

Local Cytostatic Hypothermia to Control Glioblastoma Syed Faaiz Enam, Cem Y. Kilic, Jianxi Huang, Brian J. Kang, Reed Chen, Connor S. Tribble, Martha I. Betancur, Ekaterina Ilich, Stephanie J. Blocker, Steven Owen, Johnathan G. Lyon and Ravi Bellamkonda; Duke University, United States

As a cancer therapy, hypothermia has been used at sub-zero temperatures to cryosurgically ablate tumors. However, these temperatures indiscriminately damage both tumorous and healthy cells. Additionally, therapies targeting single molecules or pathways are highly susceptible to evolutionary escape. To address these limitations, we studied the use of hypothermia as a broad cytostatic tool against cancer and deployed it in rodent models of glioblastoma (GBM). To identify the minimal dosage of ‘cytostatic hypothermia’, we cultured at least 4 GBM lines at 4 continuous or intermittent degrees of hypothermia and evaluated their growth rates through a custom imaging-based assay. This revealed cell-specific sensitivities to hypothermia. Subsequently, we examined the effects of cytostatic hypothermia on these cells by a study of their cell-cycle, energy metabolism, and protein synthesis. To assess the efficacy of cytostatic hypothermia *in vivo*, we report the design of an implantable device to focally administer cytostatic hypothermia in rats bearing F98 and U87-MG GBMs. Hypothermia at supra-cytostatic temperatures significantly doubled the median survival of rats bearing F98. Cytostatic hypothermia delivered in rats bearing U87-MG resulted in no deaths during the study period. An absence of gross behavioral alterations was also observed and in concurrence with literature suggesting the brain is naturally resilient to focal hypothermia. We also investigated the use of cytostatic hypothermia as an adjuvant to chemotherapy and CAR T immunotherapy. Our studies demonstrated that cytostatic hypothermia did not interfere with Temozolomide *in vitro* and may have been synergistic against at least 1 GBM line. Interestingly, we also demonstrated that CAR T immunotherapy can function under cytostatic hypothermia. Based on these findings, we anticipate that focally administered cytostatic hypothermia alone has the potential to delay tumor recurrence or increase progression-free survival in patients. Additionally, it could also provide more time to evaluate concomitant, curative cytotoxic treatments.

3:35 PM *SM03.02.06

Cholesterol-Functionalized Poly(3,4-ethlenedioxythiophene) (PEDOT-cholesterol) Samadhan Nagane, Shrirang Chhatre, Yuhang Wu, Vivek Subramanian, Peter Sitarik, Quintin Baugh, Junghyun Lee and David C. Martin; The University of Delaware, United States

We continue to investigate the design, synthesis, and characterization of functionalized variants of poly(3,4-ethylenedioxythiophene) (PEDOT). PEDOT and its derivatives have proven to be of considerable interest for a variety of applications, particularly bioelectronic neural interfaces. Substituted variants of the 3,4-ethylenedioxthiophene (EDOT) monomer, including EDOT-carboxylic acid (EDOT-acid) and EDOT-maleimide (EDOT-MA) make it possible for us to create a variety of functionalized PEDOT copolymers. This allows us to optimize electronic and ionic transport, adhesion to surfaces and biological tissue, and mechanical

properties. Here, we will present results from our recent studies of PEDOT functionalized with cholesterol side groups, attached either via the EDOT-acid (PEDOT-cholesterol) or EDOT-MA (PEDOT-MA-cholesterol) chemistries. Cholesterol is the most abundant steroid in the animal kingdom, and provides flexibility and resilience to cell membranes. It is also known to promote the formation of chiral liquid crystalline mesophases. We will discuss the structure and properties of PEDOT-cholesterol using a variety of characterization techniques, and compare these results with previous studies of PEDOT and PEDOT copolymers.

Neural Interface via Iontronics and Synaptic Interface Taek Dong Chung, Min-Ah Oh, Seok Hee Han, Joohee Jeon, Sung Il Kim, Wonkyung Cho, Sun-heui Yoon, Ji Young Kim and Chang Il Shin; Seoul National University, Korea (the Republic of)

Ongoing interest in the interface between the manmade device and live neural system is at the heart of many researchers that develop new materials to facilitate the neural interface. The ultimate goal in the neural materials is to seamlessly integrate the neural system with the device so as to monitor and modulate signals from neurons. In this regard, there are two major technical hurdles in connecting electronic devices and neural systems. First, the neural signal transmits across synaptic cleft through elaborate secretion and recognition of neurotransmitters, which are tricky to mimic using artificial gadgets. Second, it is difficult to secure stable and intimate contact between the neural system and the electronic device because of dissimilar material properties such as flexibility and softness. In this talk, we suggest our two approaches to get over the challenges.
One is the gel-based iontronics to the neural interface. Iontronics is the field of ion-based information processing inspired by the neural system and various biological structures such as ion channels. Materials that allow an electric field to manage gradients of ions, such as polyelectrolyte gels (charged hydrogel), can be used as components of iontronics. Taking hints from it, we constructed microfluidic chips such as a bipolar ionic diode, transistor, and logic circuits through polyelectrolyte gels. Even a fully aqueous and ionic circuit can be created on a chip powered by reverse electrodialysis (RED), which is reminiscent of neurons that transduce signals just by the ion transport. PDMS, a transparent and flexible material, can be employed as a chip substrate to expand the libraries of materials available for iontronics. Recently, we invented a new form of iontronic tools, i.e. an ion current rectifying micropipette, to address the neural system for chemical stimulation with high spatial and temporal resolutions.
The other is a biologically spontaneous and steady conjugation between the neural systems and electrode through synaptic proteins. One of the key issues in functional neural materials is persistent stability to minimize inflammation and neuron cell loss. We materialized the neural interface harnessing the synaptic proteins, paying attention to the fact that neuron stably transmits signals through neurotransmitter secretion in the synapse. Engineered the Neuroligin1 (Nlg1) as known to induce the presynaptic differentiation is immobilized onto the substrate to call for its counterpart protein, Neurexin (Nrx), in the live neuron that contact with the modified electrode. Heterogeneous association of the two proteins belonging to natural and artificial surfaces facing each other comes to form a unique junction that is mechanically as well as biologically stable enough to be persistent for several days.

Late News: Customizable and Rapidly Manufacturable 3D-Printed Neural Probes for Wireless Optogenetics Juhyun Lee[1], Kyle E. Parker[2,3,4], Chinatsu Kawakami[5], Jenny R. Kim[2,3,4], Raza Qazi[1], Junwoo Yea[6], Shun Zhang[7], Choong Yeon Kim[1], John Bilbily[2,3,4], Jianliang Xiao[7], Kyung-In Jang[6], Jordan G.

McCall[2,3,4] and Jae-Woong Jeong[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Washington University in St. Louis, United States; [3]St. Louis College of Pharmacy, United States; [4]St. Louis College of Pharmacy and Washington University School of Medicine, United States; [5]Toyohashi University of Technology, Japan; [6]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [7]University of Colorado Boulder, United States

Optogenetics is a powerful neuromodulation technique that enables dissection of neural circuitry and treatment of neurodegenerative diseases based on its cell-type specificity and high temporal resolution in control. Implementing optogenetics traditionally relies on fiber optics or microfabricated optical probes. Although highly reliable and effective, however, these approaches do not support facile and rapid design adjustment to meet various needs for *in vivo* neuroscience. Specifically, optical fibers are hard to be transformed to 2D or 3D configurations to enable multisite neural interfacing. Microfabricated probes can address this limitation by providing design versatility. However, the fact that microfabrication requires special cleanroom facilities and complex processes makes this approach expensive and time-consuming, hampering easy optimization and rapid prototyping for targeted *in vivo* applications.
To address these issues, we have developed a 3D printing-based manufacturing technique for rapid and customizable fabrication of optogenetic probes. The 3D printed optogenetic probes (3D-POPs) consist of microscale inorganic light-emitting diodes, electrical interconnects made of silver paste, and thin 3D printed substrates (60 μm thick). The 3-D printed patterned substrate determines the overall framework of the probe and facilitates electrode formation using silver paste in its groove patterns. The design can be easily altered using a 3D computer-aided design (CAD) program, thus providing facile design customizability. This straightforward 3D printing scheme can not only enable low-cost ($0.54 per 5 mm-long probe) and mass production of probes (fabrication of 50 probes (printing area of 1800 mm^2) in 3 minutes), but also significantly reduce the time and cost needed for developing new devices optimized for specific applications. Successful experiments with live mice show biocompatibility as well as wireless functionality of 3D-POPs, verifying their practicality for *in vivo* optogenetics. We foresee that this 3D printing strategy can be applied to cost-effective production of diverse bioelectronics beyond neural probes.

9:35 PM *SM03.03.04
Dimensional Stability of Conductive Hydrogel Electrode Coatings for Deep Brain Stimulation Laura Poole-Warren; University of New South Wales, Australia

Background: Low charge transfer, mechanical mismatch and host response to the implant, can ultimately compromise the long-term performance of deep brain stimulation (DBS) devices. Conductive hydrogel (CH) electrode coatings are hybrid systems that address these limitations by combining the high electroactivity of conductive polymers with the soft mechanical properties of hydrogels. Successful use of CHs on DBS electrode arrays relies on their ability to withstand mechanical stress during electrode placement. A key challenge in use of CH electrode coatings is dimensional change due to swelling of the hydrogel component. This work aimed to control CH swelling via modifying hydrogel chemistry, and assessing the effect of insertion on electrode coating stability *in vitro* and *in vivo*.
Methods: Two CH formulations based on poly(vinyl alcohol) were fabricated with low or high crosslinking densities (CD). DBS arrays modified for use in rats were dip-coated in polymer solution, polymerised, electrodeposited with poly(ethylenedioxytiophene) (PEDOT), and ethylene oxide (ETO) sterilised. Electrode coating stability was assessed *in vitro* via insertion in 0.6% agarose gels before and after ETO sterilisation. Stability was evaluated by impedance spectroscopy (EIS), charge storage capacity (CSC), and charge injection limit (CIL). The higher-crosslinked, lower swelling formulation was tested in a rat animal model and compared to Pt DBS arrays over 8-weeks implantation.
Results: CH coated DBS arrays maintained superior electrochemical performance when compared to Pt model electrodes *in vitro*. Following insertion in agarose gels, there was no significant impact on electrical properties of DBS coated arrays. ETO sterilisation significantly affected CSC and CIL as well as the coat adhesion on Pt electrode substrates. Nonetheless CH coated electrodes electrically outperformed Pt counterparts *in vivo* allowing for high fidelity neuronal recordings following chronic implantation.

Conclusions: CH coat dimensional stability can be improved by tailoring hydrogel crosslinking density without affecting electrical performance. Further research is required to understand the effect of sterilisation techniques on coating stability.

9:55 PM SM03.03.05
Carbon Nanotubes Embedded Silk Film Enables the Photoacoustic Neural Stimulation and the Control of Neurite Outgrowth Nan Zheng and Chen Yang; Boston University, United States

Neural regeneration is important for repairing nerve injuries and treating neurological disease. Despite with improved understanding of pathophysiology, a critical problem of slow nerve regeneration remains unsolved and often leads to a delayed and incomplete functionality recovery. Current stimulation technologies, such as electrical, ultrasound stimulation and optogenetics were found to improve nerve regeneration often due to an enhanced production of neurotrophic factors. However, electrical stimulation is invasive. Ultrasound lacks spatial specificity. Optogenetics, as a genetics-based technique, has limitation in translation from bench to patients.
Photoacoustic (PA) neural modulation is an emerging light-mediated technique allows temporally and spatially precise control of neural activity. The photoacoustic process is initiated by shining a pulsed laser on the absorber, and then broadband acoustic waves will be generated by the transient heating and thermal expansion. In this study, we developed a composite film of silk fibroin and carbon nanotubes (CNT) as a novel neural interface with the function of PA stimulation upon near infrared (NIR) second window excitation. PA signals can be controlled by varying the laser power and the concentration of CNT. To investigate the neural stimulation function, we examined the response of cultured cortical neurons to PA stimulation under different stimulation conditions. By time-resolved calcium imaging, we demonstrated this PA stimulation can robustly generate neural activations. Furthermore, as a key messenger in nerve system, we found that the calcium influx triggered by the PA stimulation can also modulate the neurite outgrowth of cultured rat dorsal root ganglion (DRG).

10:10 PM SM03.03.06
Late News: Nanostructured Biohybrid Material Composed of Metalloprotein/DNA/Gold Nanoparticle/Electrically Controllable Complex for Electrical Control of Neural Differentiation Joungpyo Lim, Jinho Yoon and Jeong-Woo Choi; Sogang Univ., Korea (the Republic of)

Accurate control of cell differentiation has received lots of attention because of due to its high applicability in personalized medicine. For this reason, numerous researches for control of cell differentiation have been reported such as introduction of functionalized nanoparticles or surface modified electrodes. However, these methods are difficult to apply directly to cell-based therapy because it is hard to simultaneously control the time and region in which cells are induced to differentiate into desired lineages. In this study, nanostructured biohybrid material composed of metalloprotein, DNA, gold nanoparticle (GNP), and electrically controllable complex was developed to control the neural differentiation electrically. The electrically controllable complex composed of 5,5-Bis(mercaptomethyl)-2,2-bipyridine, cucurbit [8] uril, and retinoic acid modified WGG tripeptide (RA-WGG). The result indicates that the neural differentiation was successfully conducted due to the release of the RA-WGG from electrically controllable complex by applied electrical stimulation. Furthermore, by adjusting the time and location of applying electrical stimulation to nanostructured biohybrid material, it was possible to increase the efficiency of neural differentiation over a long period of time and various regions on substrate. Proposed nanostructured biohybrid material should be used for differentiation of various stem cells as an innovative method in cell therapy. **Acknowledgments**: This research was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. 2019R1A2C3002300) and by the Ministry of Education (No. 2016R1A6A1A03012845).

10:13 PM SM03.03.07
Stem Cell-Laden Gelatin-Based Microelectrode Arrays Applied for Nerve Tissue Engineering and Neuromodulation Shu-Han Li[1], Yue-Xian Lin[2], Huei-Min Stu[3] and Wei-Chen Huang[4]; [1]Undergraduate Honors

Program of Nano Science and Engineering, National Chiao Tung University, Taiwan; [2]Department of Materials Science And Engineering, National Chiao Tung University, Taiwan; [3]National Chiao Tung University, Taiwan; [4]Department of Electrical and Computer Engineering, National Chiao Tung University, Taiwan

Implanted neural prosthetics are electrical interfaces enabling neural recording and stimulation for the treatment of multiple neurological diseases. The typical neural prosthetic devices are designed for neuromodulation, while they cannot permit neuroreplacement or neuroregeneration which is a critical goal for rehabilitation in nervous injury. Herein, we developed tissuelike microelectrode arrays (MEAs) composed of bioresorbable materials to show the functions including neural recording, neural stimulation, and stem cell therapy. The electrode, PDGA, was synthesized with copolymerized poly(3,4-ethylenedioxythiophene) (PEDOT) and gelatin methacrylate (GelMA) to exhibit both nerve tissue-mimicked properties and hydroresponsive conductivity. Based on the thermal-responsive and photo-responsive sol-gel transition properties, PDGA can be directly micropatterned into a circuit in a resolution down to 30 μm, followed which an adhesive hydrogel substrate synthesized by gelatin and Transglutaminase (mTG) can directly transfer print the PDGA micropatterns. Applied with PLGA as the insulation layer, the integrated final MEAs demonstrated tissue-like mechanical and structural properties, adipose tissue-derived stem cell (ADSC) -laden capability, and electrical monitoring/neuromodulation. With the examination of physical, chemical, and biological properties, this device was expected as a revolutionary platform to promote nerve regeneration.

10:16 PM *SM03.03.08
Wirelessly-Controlled Implantable Drug Delivery Devices for Brain Diseases Dae-Hyeong Kim; Seoul National University, Korea (the Republic of)

Treatment of brain tumours, particularly maglinant one such as glioblastoma, is extremely challenging because the efficacy of the conventional chemotherapy is quite limited due to the blood-brain barrier. Meanwhile, the wireless integration of wearable devices with implantable drug delivery devices can present a new opportunity in the development of unconventional devices for the treatment of fatal seizures. In this talk, recent progresses in the wirelessly-controlled implantable drug delivery devices for brain diseases, such as brain tumour and fatal sezure, will be presented. In the first part, an implantable drug delivery device using a flexible, sticky, and bioresorbable drug reservoir integrated with the biodegradable wireless electronics for the treatmet of glioblastoma will be presented. In the second part, a device that consists of a soft implantable drug delivery device integrated wirelessly with a wearable electrophysiology sensor for the treatment of status epilepticus will be presented. Such novel wirelessly-controlled drug delivery devices are expected to present new opportunities for the treatment of brain diseases.

8:00 AM SM03.04.02
Multimodal Neural Probe for Simultaneous Optogenetics, Neuropharmacology and Neurochemical Sampling Guangfu Wu and Yi Zhang; University of Connecticut, United States

The multimodal neural probe for simultaneous monitoring and manipulation of neuronal circuits in small animal models during behavioral tasks has advanced the understanding of complex brain functions. Although sophisticated and powerful in the manipulation and analysis of neural circuits, these multimodal neural probes are constrained by their inability to monitor changes in neurochemicals, which leaves many of the molecular mechanisms underlying neurological and psychological disorders unresolved. This limitation can be overcome by using systems that combine independently controlled neuromodulation with neurochemical sampling within

a single platform. Conventional *in vivo* extracellular fluid sampling approaches such as microdialysis technology rely on rigid probes and semipermeable membranes, and therefore suffer from poor spatial resolution (~ 1 mm^2), low temporal resolution (several minutes), and limited capacity to collect large molecules, such as neuropeptides and neuroproteins. Here, we demonstrate a battery-free, wireless, "all-in-one" neural probe for simultaneous optogenetics, neuropharmacology and neurochemical sampling in awake, freely moving animals. *In vitro* studies demonstrate the programmable operation for efficiently sampling various neurochemicals (K^+, dopamine, and neuropeptide Y) with a small sampling area (10 × 10 μm^2) and fast dynamics (< 1 min). Open field test reveals that the device implantation does not impact the movement and spatial preferences of mice. The probe is implanted in the brain of freely moving mice and could successfully sample the pharmacologically evoked release of the large molecule neuropeptide Y. The soft mechanics and lightweight construction allow for applications in freely moving small animal models to uncover the basis of brain disorders.

8:10 AM SM03.04.03
High Density, Individually Addressable Silicon-Based Nanowire Arrays Record Native Intracellular Activity from Primary Rodent Neurons without Electroporation Jihwan Lee[1], Ren Liu[1,2], Youngbin Tchoe[1], Andrew Bourhis[1], Sang Heon Lee[1], Deborah Pre[3], Gaëlle Robin[3], Mary Elizabeth Phipps[4], Jennifer S. Martinez[4], Anne Bang[3] and Shadi Dayeh[1,1,1]; [1]University of California, San Diego, United States; [2]Harvard University, United States; [3]Sanford Burnham Prebys Medical Discovery Institute, United States; [4]Center for Integrated Nanotechnologies, United States

New technologies that can provide intracellular electrophysical access with high spatiotemporal resolution and minimal invasiveness could assist neurophysiological undertakings that aim to gain an in-depth understanding of how neurons regulate and orchestrate large network activity to coordinate cognition, disease, and function. Numerous nanoscale devices were invented in the last decade for probing intracellular potentials but such methods exhibit a compromise between stability and scalability. Of these, vertical nanowire arrays generally employ electroporation techniques which lead to a compromised stability of the nanowire-neuron interface and additionally suffer from low sensitivity. We address these challenges by innovating large scale vertical ultra-sharp nanowire arrays that are individually addressable and exhibit sub-10 nm tips. This silicon-based nanowire array interface system enables native recording of graded potentials proceeding high-amplitude intracellular action potentials without resorting to electroporation methods. Passive intracellular recording is performed stably with in vitro rat cortical neurons without attenuation of the amplitude for the duration of the experiment (several minutes). Systematic studies show chronically stable nanowire-neuron interfaces with somas naturally permeated by the nanowire, validated by FIB-SEM image of the cross-section at the nanowire-neuron interface. Pharmacological stimulation and inhibition of electrophysiological activities confirmed our results. By constructing a comprehensive small signal model used for modeling potential transients at nanowire-neuron interfaces, we demonstrate by simulation and experimental investigations the significant reduction of signal amplitude as we deliberately increased the number of nanowires per recording channel. Overall, our ultra-sharp nanowire array platform may pave the way to high-throughput and low-cost drug screening for neurological diseases and can enable future investigations of neuronal dynamics that coordinate function and of relevance to brain-machine interfaces.

8:20 AM SM03.04.04
Action Potential-Like Oscillations in Biomolecular Neuristors Sijie He[1], Ahmed S. Mohamed[1], Md Sakib Hasan[2] and Joseph S. Najem[1]; [1]The Pennsylvania State University, United States; [2]The University of Mississippi, United States

Biological neurons process signals and compute by integrating incoming stimuli and initiating action potentials to convey information within the nervous system without loss. The process from generation to propagation is regulated by membrane potential and voltage-activated sodium and potassium channels. These key features inspire the design of neuron-like materials and neuristors for applications in signal processing, computing, and lossless propagation of information. To date, despite success in emulating neural functionalities, the state-of-

the-art neuristors consisting of nanoscale memristors fall short in energy efficiency compared to biological neurons due to their electronic nature. Further, while suitable for neuromorphic computing applications, current neuristors lack biocompatibility and operate at non-biological timescales, which makes them incompatible with biological applications. In contrast, neuristors assembled from synthetic biomolecular elements are biocompatible, bear similarities in structure and dynamics to their biological counterpart, and can operate at biological timescales.

Here, we demonstrate a dynamic neuristor consisting of two biomolecular memristors in parallel operating according to the same principles as Hodgkin-Huxley. The biomolecular memristors consist of insulating biomembrane doped with voltage-driven, pore-forming peptide, *alamethicin*. To capture the switching dynamics of the sodium and potassium channels, we used DPhPC- and BTLE-based memristors, which can offer fast and slow-switching dynamics, respectively. The neuristor exhibits a firing behavior similar to a biological neuron as well as power efficiency that far exceeds metal oxide-based memristors. Further, we confirm that the addition of a lipid-based memcapacitor into the circuit embeds short-term synaptic plasticity dynamics within the neuristor—adding another layer of nonlinearity and complexity in signal processing. Our results demonstrate that the addition of a symmetrical memcapacitor resulted in a decreased firing rate (inhibition), while an asymmetrical memcapacitor resulted in an increased firing rate (facilitation). This novel neuristor composition can be implemented in an adaptive nonlinear control system, a brain-machine interface (BMI) device, as well as a wide range of applications in signal processing. Further, this neuristor can serve as a model to aid in fathoming the neuronal structure and functions.

8:30 AM SM03.04.05
Flexible Crossbar Arrays of Biomolecular Memristors for Brain-Inspired Computing Nicholas Armendarez and Joseph S. Najem; The Pennsylvania State University, United States

With the rise of Artificial Intelligence and the Internet of Things in biological domains, it is imperative to construct computing devices that are biocompatible, low-power, and preferably ionic. We believe an approach that takes inspiration from the brain can yield a computational system that mimics synaptic and neuronal functionalities with the scalability of semiconductor processors, all while maintaining the biocompatibility and mechanical flexibility of biological materials. To this end, we have recently demonstrated that lipid bilayer membranes formed between two lipid-encased water droplets in oil (i.e., droplet interface bilayers or DIBs) can exhibit memcapacitive and memristive properties. To leverage all the diverse functionalities exhibited by a single membrane, large networks of functional membrane-based elements need to be assembled to achieve vast interconnectivity and flexibility—similar to how individual synapses/neurons operate together to perform complex tasks and functions in the brain. However, previous efforts to incorporate such components at a scale that could be usefully comparable to modern solid-state processors have been blocked by the difficulty of organizing liquid state DIBs into a dense, digitally addressable material. To address these shortcomings, we propose a pressure-driven PDMS microfluidic device to form lipid-encased water droplets in the initially liquid oil phase, organize them into DIBs, and connect them to electrodes forming a crossbar array. Crossbar arrays have been used in solid-state computers as a method to densely pack two-terminal devices while maintaining individual addressability to each device. The microfluidic system operates on the principle of a shift register where droplets pumped into the device fill the first available empty register and subsequent droplets move past onto the next register. This allows for the exact positioning of droplets within a 2D geometry which, in this case, is an n-by-n arbitrary-sized array with equal spacing between each DIB. Electrodes run the length of the top and bottom of the device such that the top electrodes electrically connect each row of the array, and the bottom electrodes connect each column of the array. Each DIB inside the device can be addressed by one combination of a single top and bottom electrode pair. Once all DIBs have been sorted inside the device, the oil phase is solidified, locking all the droplets in place. The solidified oil phase inside the PDMS microfluidic makes for a durable, yet flexible material that is capable of energy-efficient computation.

8:40 AM SM03.04.06
Direct Laser Writing of Organic Electronics Omid Dadras, Milad Khorrami and Mohammad Reza Abidian;

University of Houston, United States

Development of soft and conductive microstructures has become a key research topic in organic electronics. Among various 3D printing techniques, Two-Photon Polymerization (TPP) based on direct laser writing technology stands out due to its unique capability to fabricate 3D complex architectures in sub-micron resolution. Herein, we have formulated a novel resin that can be fabricated into conductive microstructures via TPP lithography. We have also developed a strategy to fabricate multi-material (combination of conductive / non-conductive resin) microelectrodes with low impedance and high charge storage capacity.

Conductive resin consisted of poly(ethylene glycol) diacrylate (PEGDA), poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS), dimethyl sulfoxide, and ethyl (2,4,6-trimethylbenzoyl) phenylphosphinate. Microstructures were constructed on a glass slide through 3D movement of XYZ stages and irradiation of 130 femtosecond pulses, which solidified the resin at the laser focal point. I-V measurements revealed that conductivity of microstructures fabricated by non-conductive resin (PEGDA) significantly improved from 3.4 ± 0.8 S m^{-1} to 24248 ± 929.7 S m^{-1} (n=5) by incorporation of PEDOT:PSS in the resin.

Michigan-style neural microelectrodes were fabricated in two steps via TPP: 1. Construction of conductive microstructures including cylindrical electrode sites with diameters of 1 μm (site 1), 5 μm (site 2), 10 μm (site 3), 20 μm (site 4), 40 μm (site 5), and 80 μm (site 6) with height of 7 μm, which were individually connected to cubical contact pads with dimensions of 20 μm (width) × 20 μm (length) × 7 μm (height) by wire connectors with height of 2 μm, using conductive resin (PEGDA/PEDOT:PSS), 2. Fabrication of electrode shank with height of 5 μm using non-conductive resin (PEGDA), which isolated the wiring and partially exposed the cylindrical sites and cubic pads. Electrochemical characterization of microelectrodes indicated that the impedance at 1 kHz was 63.13 ± 4.56 kΩ, 49.33 ± 2.98 kΩ, 42.82 ± 2.95 kΩ, 33.21 ± 3.69 kΩ, 26.66 ± 2.07 kΩ, and 19.28 ± 3.08 kΩ, and charge storage capacity was 2.38 ± 0.18 nC μm^{-2}, 8.61 ± 1.03 nC μm^{-2}, 16.36 ± 1.67 nC μm^{-2}, 28.43 ± 4.28 nC μm^{-2}, 61.07 ± 5.96 nC μm^{-2}, and 89.73 ± 15.14 nC μm^{-2} for site 1, 2, 3, 4, 5, and 6, respectively (n=3). Development of these soft and electrically functional microelectrodes paves the way towards minimally invasive neural recording and stimulation.

8:50 AM SM03.04.07

Transparent Neuroelectronic Interfaces and Novel Modeling Paradigms to Elucidate the Dynamics of Neural Networks at Microscale Nicolette Driscoll[1], Richard Rosch[1], Brendan Murphy[1], Arian Ashourvan[1], Ramya Vishnubhotla[1], Olivia Dickens[1], A.T. Charlie Johnson[1], Kathryn A. Davis[1], Brian Litt[1], Danielle S. Bassett[1], Hajime Takano[2] and Flavia Vitale[1]; [1]University of Pennsylvania, United States; [2]Children's Hospital of Philadelphia, United States

Our current understanding of the spatiotemporal dynamics underlying neural function and disease is limited by (i) our inability to record brain dynamics at sufficient spatial and temporal resolutions and (ii) a lack of established frameworks for applying novel data analysis techniques to high-dimensional neuronal datasets. Light-based approaches to manipulate and monitor neuronal activity have established neuroimaging as the principle technique for mapping the brain at cell-specific resolution and at large scale ($>10^6$ cells). Optical imaging techniques, like calcium and voltage imaging, however, typically suffer from the slow kinetics, suboptimal intensity, and low photostability of the fluorescent reporter molecules, as well as from the limited speed of currently available imaging systems. Electrophysiological recordings with implantable microelectrode arrays can capture spikes from single neurons, but they can only resolve few tens of cells at a time. Combining electrophysiological and optical modalities presents a unique opportunity to harness the spatial resolution of optical imaging along with the temporal resolution of electrophysiology. However, such a combination requires imaging and recording simultaneously in the same location, which is not possible with conventional microelectrode arrays composed of opaque metallic materials, as these block optical access and suffer from photoelectric artifacts. Furthermore, there is no established framework to combine these multimodal datasets operating at different spatiotemporal scales to elucidate the dynamics of brain networks during normal function and disease.

Here, we show how to address this essential challenge by leveraging flexible, transparent graphene microelectrode arrays to map the dynamics of onset and evolution of epileptic seizures. Through the transparent arrays, we acquired simultaneous electrophysiology and calcium imaging *in vivo* in mouse models during the transition from baseline to chemically-induced epileptiform activity. To integrate data features from both modalities, we established an analytical framework based on non-negative matrix factorization to identify transitions in brain state that occur during an epileptic seizure. Our analysis demonstrates that it is possible to capture complementary and otherwise hidden aspects of ictal dynamics operating on different spatial and temporal scales by leveraging data features from multiple modalities. Furthermore, we show how microscale brain dynamics are linked to clinically measurable markers of seizure states.

9:00 AM SM03.04.08

Integrated Electrochemical and Electrophysiological *In Vivo* Micro Electrode Arrays with Zwitterionic Polymer Coating Bingchen Wu[1,2], Elisa Castagnola[1,2] and Xinyan T. Cui[1,1]; [1]University of Pittsburgh, United States; [2]Center for Neural Basis of Cognition, United States

The number of people using Illicit drug aged 12 years and older reached 30 million in 2016, among which 2 million are cocaine users based on the national data. In order to fully understand the mechanism of action and develop effective therapy for addiction, a tool that can reliably and consistently measure in vivo cocaine concentration and neural activity with high spatial and temporal resolution is needed. Integrated biochemical sensing devices based upon microelectrode arrays (MEA) have emerged as a powerful tool for such purpose. The implanted MEA devices often face challenges in the in vivo environment where biological reactions could have detrimental effects on the sensing and recording capability of the device. To protect implanted MEAs from biofouling and harmful tissue reaction, zwitterionic polymer coatings have recently emerged as a promising candidate. In current work, cocaine electrochemical sensors made from synthetic DNA aptamers were functionalized on flexible MEAs and protected with antifouling zwitterionic poly (sulfobetaine methacrylate) (PSB) coating which prevents sensors from being degraded by host tissue. In vitro experiments showed that biofouling of plasma protein doesn't play a significant role in sensor performance decline, while exposure to DNase have detrimental effects on sensor performance, causing a 57.2% signal reduction. The PSB coating successfully protected sensors from DNase enzyme digestion over a 24hrs period. Also, the sensor is stable after 12hrs of continuously applied square waver voltammetry (SWV). This novel integrated cocaine sensor can serve as a valuable tool for study of cocaine addiction mechanism, while the sensing and coating technology can be generalized to detect many other biochemicals of interest.

9:10 AM SM03.04.09

Imaging the Stimulation Efficiency of Electrodes Coated with PEDOT/CNT and Iridium Oxide Xin Sally Zheng[1,1], Alberto Vasquez[1,1,1] and Xinyan T. Cui[1,2,1]; [1]University of Pittsburgh, United States; [2]Center for Neural Basis of Cognition, United States

Intracortical microstimulation is not only a useful tool in neuroscience research for dissecting circuitry and modulating brain activity, it has also shown promise in restoring sensory functions in humans with neural deficits. Current electrode materials like platinum do not meet charge injection requirements for chronic microstimulation, which motivates the development of new stimulating electrode materials. One such material is the conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) doped with acid functionalized multi-wall carbon nanotubes (CNT). Although promising, the *in vivo* stimulation performance of PEDOT/CNT(PC) remains to be fully characterized. Traditionally, characterizations of stimulation performance have been based on electrophysiological, behavioral or endpoint histology. Using advanced imaging technologies, we directly measured neuronal activity evoked by microstimulation in transgenic animals in real-time. Herein, we implanted microelectrode arrays coated with PEDOT/CNT (PC) and iridium oxide (IrOx) (a commonly used high charge injection stimulation material) in GCAMP6s mice and applied electrical stimulation while imaging neuronal calcium responses. We observed that PC coated electrodes produce more intense and broader GCaMP responses than IrOx. Using TPM we examined the effect of stimulation modality and pulse-width modulation on neuronal activation. We found that stimulating via PC coated electrodes activates significantly more

neuronal soma and neuropil than via IrOx electrodes in constant-voltage stimulation and significantly more neuronal soma in constant-current stimulation. Furthermore, for both materials and the same injected charge, stimulating with a shorter pulse activated neural elements that are more spatially confined than longer pulses, providing an accessible means to tune stimulation selectivity. Using finite element analysis, we observed that the non-directional and rough edges of PC surfaces result in a more non-uniform and dense electric field, which increases the likelihood of activating nearby neural elements. Our results show that PC coated electrodes provide essential improvements in electrical stimulation applications in terms of energy efficiency for activating local excitable tissue.

9:20 AM SM03.04.10
Late News: Efficient Gating of PEDOT:PSS Organic Electrochemical Transistors with In-Plane Gate Electrodes Dimitrios Koutsouras[1], Fabrizio Torricelli[2], Paschalis Gkoupidenis[1] and Paul Blom[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]University of Brescia, Italy

Organic Electrochemical Transistors (OECTs) belong to a class of electrolyte-gated transistors with tremendous applications in bioelectronics due to their unique device architecture. The absence of an insulating layer between gate and channel and its replacement by an electrolyte creates an ideal environment for biological driven measurements as it allows for a direct integration of cell tissue on the device. For efficient gating, a non-polarizable Ag/AgCl electrode is used, which however limits the option for integrating more gates on a chip. Patterned polarizable Au gates on the other hand show strongly reduced gating due to a large voltage drop at the gate/electrolyte interface. Here, we demonstrate a novel method to induce efficient gating by patterned in-plane gate electrodes. For this, we make use of the fact that poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) exhibits a volumetric capacitance in an electrolyte. As a result, the capacity of PEDOT:PSS based gates can be strongly enhanced by increasing their thickness, thereby reducing the voltage loss at the gate/electrolyte interface. By combining two different fabrication approaches (spin coating and electrodeposition), we create gate electrodes of different thicknesses on the same chip. These electrodes gate the same channel revealing the effect of the gate film thickness on the gating efficiency. The results are compared to the ones of the typically used Ag/AgCl gate electrode, showing that the gating performed by a PEDOT:PSS electrode can be tuned to be comparable to the one from a Ag/AgCl electrode. Using these in-plane gates we study the device physics of multi-gated Organic Electrochemical Transistors and disentangle the part that the gate capacitance plays in gating. Our findings offer an extra degree of freedom in the design of OECT-based biosensors. Most importantly, they pave the way for an elegant integration of in-plane gate electrodes into the latter, leading towards the realization of “organ-on-a-chip” platforms.

Multifunctional Nanocarriers for Efficient Cancer Immunotherapy Yunching Chen[1], Shu-Yi Lin[2] and Kuan-Wei Huang[1]; [1]National Tsing Hua University, Taiwan; [2]National Health Research Institutes, Taiwan

While immunotherapy holds great promise for combating cancer, the limited efficacy due to an immunosuppressive tumor microenvironment and systemic toxicity hinder the broader application of cancer immunotherapy. We engineered tumor-targeted lipid-dendrimer-calcium-phosphate (TT-LDCP) nanoparticles (NPs) with thymine-functionalized dendrimers that not only exhibited enhanced gene delivery capacity but also immune adjuvant properties by activating the stimulator of interferon genes (STING)-cGAS pathway. TT-LDCP NPs delivered siRNA against immune checkpoint ligand PD-L1 and immunostimulatory IL-2-encoding plasmid DNA to hepatocellular carcinoma (HCC), increased tumoral infiltration and activation of CD8+ T cells, augmented the efficacy of cancer vaccine immunotherapy, and suppressed HCC progression. Our work presents nanotechnology-enabled dual delivery of siRNA and plasmid DNA that selectively targets and reprograms the immunosuppressive tumor microenvironment to improve cancer immunotherapy.

8:25 AM *SM04.01/SM01.06.02
Immuno-Engineered Biomaterials Reduce Implant-Related Infections Bingyun Li and Shichao Zhang; West Virginia University School of Medicine, United States

Introduction: Although responsible for reducing infection, widespread antibiotic use has also created the latest grave challenge in wound care, i.e., antibiotic resistant bacteria. Antibiotic resistance has been making our drug choices for infection control increasingly limited and more expensive. According to the Centers for Disease Control and Prevention (CDC), in the U.S. alone, antibiotic resistant bacteria cause at least 2.8 million infections and 35,000 deaths a year and $55-70 billion per year in economic impact. Meanwhile, it is known that trauma (e.g. open fractures) and major burns lead to decreased resistance to infection ("immunosuppression") and thereby have high infection rates. Here, we present the engineering of biomaterials with interleukin 12p70 (IL-12) and other cytokines to tune the immune responses locally against open fracture associated infections.
Methods: IL-12 nanocoatings and microcapsules were prepared using electrostatic layer-by-layer (LbL) self-assembly. Polymers like poly(L-lysine) or PLL, poly(L-glutamic acid) or PLGA, and bovine serum albumin (BSA) were used to prepare the coatings, and the release properties and stabilities of the nanocoatings were examined. Next, an open femur fracture infection model was created using Sprague-Dawley rats. The rats' femurs were fractured, inoculated with 100 mL 10^2 colony-forming unit (CFU/0.1mL) *Staphylococcus aureus*, left open for one hour, mimicking the "golden hour" of trauma patients, and then fixed with a stainless steel Kirschner wire (K-wire) with or without IL-12 nanocoatings. Animals were euthanized and samples of blood, bone, and K-wires were collected for analysis.
Results: IL-12 nanocoatings were prepared on orthopedic implant models (e.g., K-wires and stainless steel

sheets). The loading and release of IL-12 from polypeptide nanocoatings were tuned and a sustained release of IL-12 for approximately 10 days was achieved by controlling the LbL self-assembly process. Polypeptide microcapsules were also prepared and loaded with IL-12. Our *in vivo* studies showed that IL-12 nanocoatings and microcapsules reduced open fracture associated infection and were advantageous compared to systemic or percutaneous injections of IL-12.
Discussion and Conclusions: Trauma like open fractures have been reported to result in diminished production of IL-12, reduced type 1 helper T (Th1) responses, and decreased resistance to infection. IL-12 displays multiple biologic effects on immune cells; for instance, IL-12 stimulates natural killer (NK) cells to release interferon γ, induces Th1 cell and cytotoxic T lymphocyte proliferation, and promotes the progression of cell-mediated immunity. Local application of IL-12 may restore the capability of the host's inherent resistance to infection, and have led to decreased infection in open fractures.

Polydopamine Capped Gold Nanoparticles for Double NIR-Stimulated Photodynamic Therapy Miso Lee, Mao Wei, Ju Won Lee, Jae Keun Park, Vu O. Pham-Nguyen, Wan Ho Cho and Hyuk Sang Yoo; Kangwon National University, Korea (the Republic of)

Photodynamic therapy (PDT), a treatment method using reactive oxygen species (ROS), have recently been widely used in anticancer treatments. In this study, 130nm gold nanoparticles (AuNP) were stepwise coated with high biocompatible polydopamine(PDA) and photosensitizer chlorin-e-6 (Ce6). The PDA on AuNP surface allowed Ce6 to adhere on the particles through amide bond. Herein, we employed of 2 different NIR light wavelength (650nm and 808nm) to achieve PDT effect. Ce6@PDA@AuNP would absorb by 808nm laser light and generate heat by SPR effect, and Ce6 would absorb 650nm laser light and generate ROS, which can cause the death of target cells. To characterize the nanoparticle, DLS, zeta-potential and Raman spectroscopy of Ce6@PDA@AuNP particle were analyzed. There were an increase in hydrodynamic diameter of the AuNP in the order of AuNP (~130nm), PDA@AuNP (~210nm) and Ce6@PDA@AuNP (~240nm). Due to the anionic charge of PDA, the surface charge of the AuNP decreases after PDA coating, and Raman spectroscopy shows that Ce6@PDA@AuNP shows sharper peak at 1480cm^{-1} and 1580cm^{-1} than those of PDA@AuNP, and the 983cm^{-1} new peaks indicating that Ce6 is attached to the nanoparticle. Besides, Ce6 release behaviors under several pHs were recorded. The more Ce6 release was observed in the lower pH with laser irradiation. Moreover, when Ce6@PDA@AuNP were irradiated with lasers (650nm and 808nm), it was confirmed that the temperature would rise to 58°C and the PDA layer surrounding the AuNP was consequently peeled off after 20 minutes of the irradiation resulted in the release of Ce6 and enhanced ROS generation under the irradiation of 650nm laser. Likewise, since PDA affected by pH, more Ce6 was released from nanoparticles at lower pH, even during the same laser irradiation time resulting better cell apoptosis effect *in vitro*. These results suggested that Ce6@PDA@AuNP has antitumor effects under near-infrared (NIR) irradiation based on the PDT effect.

9:05 AM SM04.01/SM01.06.04
Less (Radiation) is More—Bi_2S_3 Nanoparticles as Efficient Radiosensitizers for Breast Cancer Cells
Isabel Galain[1], Emilia Tejeria[1], María Elena Cardoso[1], Gustavo Mourglia[1], Paula Arbildi[1], Mariella Terán[1], Maria Perez Barthaburu[2] and Ivana Aguiar[1]; [1]Facultad de Química - Universidad de la República, Uruguay; [2]Centro Universitario Regional del Este - Universidad de la República, Uruguay

Cancer is one of the main threats to human health, due to the large number of cases and high mortality rates. These rates are only expected to increase in future years. Although radiotherapy is the main course of treatment, it is not specific for tumor cells, affecting also healthy cells. Radiosensitizers provide a novel and simple solution to this problem, since they increase the amount of radiation a cell can absorb. This allows for cancer treatments that use a lower dose of radiation, leading to less secondary effects for the patient. Our group synthesized bismuth sulfide (Bi_2S_3) nanoscale particles using a hot injection method followed by a ligand

exchange, for use as radiosensitizers. We synthetized Bi_2S_3 nanorods measuring in average 4.1 ± 1.2 nm in width and 20.2 ± 7.0 nm in length. These nanoparticles were successfully coated with polyvynilpirrolidone (PVP) to improve their biocompatibility. According to IR and DSC results, we achieved a successful ligand exchange to PVP, with a defined binding with the nanoparticle. We studied the nanoparticles' stability in different biological media (water, culture medium, fetal bovine serum, and human plasma). The stability tests showed that the suspensions were more stable for media with higher protein components. This may aid in the ability of the nanoparticles to move through the bloodstream. We studied the nanoparticles' cytotoxicity in human breast cancer cells (MCF7), over 72 hours of incubation. The coated nanoparticles did not evidence cytotoxicity up to 2500 g/mL. Also, we conducted radiosensitivity tests using a Co-60 source. We determined that the best condition for adequate radiosensitizing test is a dose of 2 Gy and a post-irradiation incubationtime of 48 hours. MCF7 cells that were incubated with a nanoparticle concentration of 50 μg/mL and irradiated showed a 38% increase in cell death when compared to cells that were only irradiated, without nanoparticles. Our results confirm that PVP-coated Bi_2S_3 nanoparticles are stable in many biological media, and that they are not-cytotoxic in a wide range of concentrations. When combined with gamma radiation, the nanoparticles increase the efficiency of radiotherapy. This outstanding results certainly grant hope for this line of research, to develop cancer treatments that have less seconday effects and a better quality of life for patients.

9:20 AM SM04.01/SM01.06.05

Nucleic Acid Mediated Reversal of Charge—An Useful Methodology to Prevent the Immunostimulatory Activity of Positively Charged Lipid Nanocarrier Arindam Dey[1,2], Adrien Nougarede[1,3], Flora Clément[1,2,4], Carole Fournier[1,2], Evelyne J. Marche[1,2], Marie Escude[1,3], Dorothée Jary[1,3], Fabrice P. Navarro[1,3] and Patrice N. Marche[1,2]; [1]Université Grenoble Alpes, France; [2]Research Center, CNRS, France; [3]Microfluidic Systems and Bioengineering Lab, France; [4]CEA, INSERM, IRIG-BIOMICS, France

Use of nanotechnology in gene therapy to deliver therapeutic nucleic acid such as siRNA could open up a new avenue to cure genetic disorders. Lipid nanoparticles currently in use for several biomedical applications integrate cationic lipids in order to form complexes with nucleic acid cargo and enable their uptake by target cells. However, larger surface area and highly charged nature of these nanocarriers increase their interaction with host cells which might induce toxicity. While gene mediated off-target effects have been extensively studied, it is crucial to consider the carrier toxicity and side effects including immunological parameters. In the immune system, phagocytes can engulf foreign materials, therefore they are appropriate to screen for immunotoxicity by monitoring their functions in unspecific and specific immune responses.
In our study, we evaluated the function of primary bone marrow derived macrophages (BMDMs) in response to cationic nanostructured lipid carriers (cNLCs), which are positively charged (+45.8 mV). The effect of cNLCs was investigated in non-activated and IL-4 or LPS-activated BMDMs. We assessed the secretion of proinflammatory molecules including, IL-6, TNF-α, MCP-1, Nitric Oxide (NO). We also addressed the effect of cNLCs on metabolism by evaluating glycolytic activity (glycolysis and glycolytic capacity) and oxidative phosphorylation (basal respiration, proton leak, ATP production, maximal respiratory capacity, spare respiratory capacity). Our results showed that cNLCs remarkably enhanced the secretion of several molecules (IL-6, TNF-α, MCP-1, NO) as well as the energy flux in non-activated or LPS- or IL-4-activated BMDMs. Furthermore, we combined cNLCs with negatively charged siRNA at different N/P ratios (the ratio of positively-charged amine groups of cNLCs (N = nitrogen) to negatively-charged phosphate (P) groups of nucleic acid) (N/P = 8/4/2/1). Our experiments showed that reversing the surface charge prevent the effect induced by positively charged cNLCs on IL-6, TNF-α, MCP-1, and NO productions as well as on cellular metabolism (glycolysis and oxidative phosphorylation) of BMDMs. Our results highlight that reversing the surface charge of cationic lipid nanocarriers with an oppositely charged biomaterial, for instance nucleic acid, could attenuate immunostimulatory activities of the cationic nanocarrier. This issue needs to be addressed during the use of cationic nanocarriers in different biomedical applications, such as nucleic acid delivery for therapies or vaccines.
Finally, we propose to tune the nucleic acid load, hence the surface charge of lipid nanocarriers is critical for their therapeutic use, to prevent the alteration of immune cell response to positive charge stimuli. We also recommend to measure the zeta potential of the nanocomplexes, keeping in mind that charged nanocomplexes

can alter the immune cell function which may lead to several side-effects.

This project has received funding from the European Union's Horizon 2020 research and innovation program H2020 "NEWDEAL" (grant agreement No. 720905).

9:35 AM SM04.01/SM01.06.06
Tagging the Cancer Cell Surface for Innate Immune Recognition and Destruction by Bifunctional Multivalent Antibody-Recruiting Polymers Annemiek Uvyn[1], Bas de Waal[2], Bert Meijer[2] and Bruno G. De Geest[1]; [1]Ghent University, Belgium; [2]Technische Universiteit Eindhoven, Netherlands

Binding antibodies onto a cell surface triggers antibody-mediated effector killing by innate immune cells through complement activation (CDC), antibody-dependent cellular cytotoxicity (ADCC) and antibody-dependent phagocytosis (ADCP), which is the mechanism of action of many monoclonal antibody (mAbs) therapeutics. As an alternative to mAbs, synthetic systems that can recruit endogenous antibodies, i.e. antibodies against small molecule haptens that are found in the blood of virtually every human being, from the blood stream to a cancer cell surface could be of great relevance. Herein, we explore antibody-recruiting polymers as a novel class of immunotherapy. These polymers are functionalized on their surface with multiple cell-binding and antibody-binding hapten motifs such as dinitrophenol and rhamnose. As cell surface binding motifs, we employ alkyl lipid and dibenzoylcyclooctyne motifs, for respectively hydrophibically-driven insertion into the phospholipid cell membrane or strain promoted alkyne-azide cycloaddition with azide motifs in the glycocalyx of cancer cells. *In vitro* on cancer cell cultures, we demonstrate that antibody-recruiting polymers allow for high avidity antibody binding and drive antibody recruitment to treated cells for several days and elicit robust innate immune effector killing.

11:45 AM *SM04.02.01
Machine Learning-Enabled High-Throughput Virtual Screening for Novel Mitochondrial Membrane Dyes Kirill Shmilovich[1], Bernadette Mohr[2], Tristan Bereau[2] and Andrew Ferguson[1]; [1]The University of Chicago, United States; [2]University of Amsterdam, Netherlands

Mitochondria are energy-producing organelles that exist within eukaryotic cells contained within a double phospholipid membrane. The inner membrane is composed of about 20% cardiolipin (CL), an unusual dimeric phospholipid in which a pair of phosphatidic acids are linked by glycerol to yield a molecule with four acyl chains. CL is the hallmark of energy transducing membranes and is implicated in a number of critical pathways in mitochondrial metabolism, regulation, and apoptosis. Abnormalities in CL composition profiles are linked to several diseases, including Barth syndrome, Tangier disease, heart failure, and neurodegenerative disorders [1]. The acridine orange derivative, 10-N-nonyl acridine orange (NAO), is a high-affinity probe that is 30 times more specific for CL than for other cationic phospholipids and is used as a stain for fluorescent visualization and quantification of mitochondrial CL [2]. Enhancing probe uptake by CL enables the use of lower dye concentrations and lowers cellular toxicity, but efforts to rationally engineer NAO to increase staining efficiency have compromised its phospholipid selectivity [3]. In this work, we have combined coarse-grained molecular simulation, alchemical free energy calculations, deep representational learning, and Bayesian optimization to perform high-throughput virtual screening of candidate organic molecules as CL dyes with

superior uptake and selectivity than NAO. We consider as our search the $>10^{11}$ small organic molecules up to 400 Da molecular weight and use our computational platform to rationally traverse this space. Our analysis efficiently identifies novel high performing dye molecules and informs new understanding of the molecular properties responsible for good efficiency and selectivity. After just a few rounds of iterative molecular simulation and data-driven model building, we have identified three candidates predicted to have up to 4-fold superior uptake and 99 candidates with up to 34-fold superior selectivity relative to NAO. Future collaborative work is planned to synthesize and test the top compounds identified in the computational screen.

12:10 PM *SM04.02.02
Development of Kinase Inhibitor Nanomedicines for Intracranial Tumor Delivery Daniel Heller[1,2], Daniel Tylawsky[2], Yosi Shamay[3] and Kiroto Kiguchi[4]; [1]Memorial Sloan Kettering Cancer Center, United States; [2]Weill Cornell Medicine, United States; [3]Technion–Israel Institute of Technology, Israel; [4]Children's Hospital of Philadelphia, United States

Therapy based on personalized medicine has become a leading strategy to treat cancer. Small molecule drugs such as kinase inhibitors, which target key effectors of cancer signaling pathways, constitute a major component of this strategy. This class of drugs is diverse and each has different issues regarding pharmacokinetics, toxicity, and therapeutic index, especially in intracranial tumors due to the blood-brain barrier. Kinase inhibitors also inhabit a diverse chemical space, making it difficult to develop nanomedicines against the wide set of precision drug targets. We developed data science/machine learning-driven processes to predict and facilitate the encapsulation of diverse drug classes into nanoparticles based on the molecular structures of the drugs. These included quantitative structure-nanoparticle assembly prediction models for drug payload selection. We found molecular descriptors that are highly predictive indicators of nano-assembly and nanoparticle size. For the treatment of pediatric tumors with an intact blood-brain barrier, we developed a therapeutic nanoformulation capable of traversing the blood-brain barrier via transendothelial transport across tumor vasculature to improve kinase inhibitor therapeutic index.

12:35 PM SM04.02.03
Micro-Nozzle Integration for Controlled Drug Delivery via a Microfluidic Imaging Window Tristen Head[1,2], Natalya Tokranova[1] and Nathaniel Cady[1]; [1]State University of New York Polytechnic Institute, United States; [2]University at Albany, State University of New York, United States

Novel imaging and drug delivery methods are needed to understand the cellular and molecular events of cancer metastasis. We have developed a microfluidic imaging window (MFIW) platform that enables precise delivery of drugs, labeling agents, and cells during longitudinal intravital imaging of the tumor microenvironment. Intravital imaging with the MFIW platform enables *in vivo* evaluation of drug effects on tumors, and observation of cellular events, such as the intravasation of tumor cells into blood vessels. An important aspect of fluid delivery is to precisely control the fluid flow vector field and three-dimensional distribution of reagents in the target tissue. Using a dry film SU-8 photoresist we have implemented a novel photolithography process dubbed post-exposure lamination (PEL). Using PEL we have successfully integrated micro-nozzle structures with planar microfluidics, to significantly enhance three-dimensional control of fluid infusion. The PEL method enables control of the vertical and horizontal morphology of micro-nozzle structures, yielding nozzles that produce unique flow profiles. The micro-nozzle structure improves the convective transport of reagents into a projected delivery area that is 70% smaller than the projected delivery area of devices with a planar outlet. Confocal microscopy and computational fluid dynamic simulations are currently being used to assess the depth penetration and radial spreading of fluid in a tissue phantom, with initial results showing improved penetration

depth and radial profile when micro-nozzle outlets are employed. Ongoing work is focused on localized delivery of transfection reagents to cells in three-dimensional culture, to demonstrate the therapeutic potential of the platform.

12:50 PM SM04.02.04
Dialysate Regeneration by Efficient Urea Decomposition with TiO_2 Nanowire Photoelectrochemical Cell
Guozheng Shao, Yushi Zang and Bruce Hinds; University of Washington, United States

More than 2 million End Stage Renal Disease (ESRD) patients receive dialysis to sustain life, with this number likely to represent less than 10% of the actual need. In the United States alone, over 460,000 people are on dialysis. Conventional hemodialysis removes urea and other metabolic wastes from the body by running ~120 L of dialysate over hollow fiber dialysis membranes each session, which is typically 3-4 hours per session and thrice a week. The intermittent character of hemodialysis results in large fluctuations in blood metabolite concentrations. Observations show that long term survival in dialysis patients treated by extended hemodialysis are improved compared to conventional hemodialysis. Thus a portable dialysis machine that is working continuously would bring in significant health, quality of life and economic benefits.

To enable portable kidney dialysis for ESRD, the regeneration of the dialysate in a closed loop system is a primary critical technical barrier. Currently the ~120 L (kg) of dialysate per session, far exceeds usable weights for a portable system. We have developed an efficient photooxidation system based on hydrothermally grown TiO_2 nanowires, UV LEDs, and catalytic gas diffusion barriers to decompose urea from the dialysate at rates sufficient to remove daily production of urea at 15 g/day.

A photoelectrical decomposition cell with SiO_2/FTO/TiO_2 nanowire anode, 10 mM urea/0.15 M NaCl electrolyte, and 4 mg/cm^2 Pt black loaded carbon paper cathode was characterized for urea decomposition efficiency. Under 4 mW/cm^2 illumination of the 365 nm LED with 40% quantum efficiency, the device yielded a photocurrent density of ~ 1 mA/cm^2 in a dialysate simulant of corresponding to 40% quantum efficiency in urea decomposition per incident photon. From performance parameters, a feasible portable device with ~0.23 m^2 active area and a current draw of 11 A is able to decompose a daily 15 g urea production sufficient to regenerate dialysate. Also high selectivity (80%) for urea decomposition over Cl2 formation is shown. For comparison, prior reports in literature [J. Photochem. Photobiol. AChem, 2009, 205, 168] for urea fuel cells of agricultural waste, > 5000 A would be required. Improvements reported here are based on nanowire microstructure to efficiently separate electron holed pairs and efficiently adsorb incident UV irradiation.

1:05 PM SM04.02.05
Late News: Filamentous Self-Assembly Based on Lithocholic Acid-Polyethyleneimine Conjugate for Local Delivery of Drug and Gene Therapeutics
Jianping Wang, Fanfei Meng and Yoon Yeo; Purdue University, United States

Introduction: Filamentous nanoparticle (FN) refers to a polymeric self-assembly with a high aspect ratio, nanometer scale in diameter and micrometer scale in length. FN has great potential in drug delivery because it shows a longer circulation time, low phagocytic cell uptake, and longer retention in tissues as compared to spherical counterparts. FN is produced with amphiphilic block-co-polymers, which interact with each other via directional and reversible noncovalent interactions. For biomedical applications, FN is usually prepared with a peptide-drug conjugate, in which a drug is part of the building block of the FN. We report a lithocholic acid-polyethyleneimine conjugate (lp) that can form FN in the presence of hydrophobic drugs, with no need of the drug being part of the polymer, and serve as their carrier for local drug delivery. We characterized the properties of FN, studied the conditions that enable FN formation, and tested the feasibility of using FN for local drug delivery.
Methods: FN was prepared by the membrane hydration method. Various small molecule drugs or model compounds were screened to test the ability to form FN with lp. Retrospective quantitative structure-property relationship (QSPR) analysis was performed by Alvadesc software to identify common structure features of FN

formers. The formation of FN and FN hydrogel was studied varying the conditions such as aging time, temperature, lp/drug ratio, and drug concentration. Tissue retention of paclitaxel FN labeled with DiR was monitored by intratumoral injection of FN to CT26 colon tumors in Balb/c mice and whole-body fluorescence imaging.
Results: Out of 19 drugs screened, 6 drugs formed FN with lp, 4 formed short filaments, and 9 did not form FN. QSPR analysis revealed that FN formers had amido bond in common. The diameter of FN was measured to be 26.3 ± 4.3 nm, and the average length ranged from 1 to 2 μm depending on the type of drug and the weight ratio of lp to drug. The rate of FN formation increased with temperature. Paclitaxel-loaded FN formed a hydrogel at 37.8 mg/mL or higher, likely due to the physical entanglement of FN. FN injected at 4.46 mg/mL to subcutaneous CT26 tumors persisted for more than 8 days showing 80% of the initial FN signal in the tumor on day 8. In contrast, spherical counterparts diffused away with only 50% FN remaining after day 1 and all disappearing after 1 week. This result indicates the potential of FN to serve as a local drug delivery system.
Conclusion: Lithocholic acid-polyethyleneimine conjugate formed FN with a group of hydrophobic drugs. The drug-loaded FN can serve as a local depot of the drug in tumors. The lithocholic acid-polyethyleneimine conjugate can be combined with various hydrophobic drugs with amido bond structure to form FN and FN-based hydrogel for systemic and local drug delivery.

1:20 PM *SM04.02.07
Improving RNA Delivery by Testing Thousands of Nanoparticles *In Vivo* James Dahlman; Georgia Institute of Technology, United States

DNA and RNA can manipulate the expression of any gene, making these molecules promising drugs. However, whether the drug is comprised of DNA, siRNA, mRNA, lncRNA, or another nucleic acid, it is limited by one problem: drug delivery. Chemists design thousands of distinct nanoparticles to deliver DNA or RNA to the desired cell type. However, after nanoparticles are synthesized, their ability to deliver drugs is evaluated using *in vitro* systems devoid of a liver, kidney, spleen, immune system, pulsatile blood flow, and other selection pressures known to affect nanoparticle delivery *in vivo*.
We have designed a series of increasingly advanced DNA barcoding platforms to quantify how thousands of nanoparticles deliver nucleic acids *in vivo*. Our goal is to quantify how up to 300 nanoparticles deliver DNA, mRNA, ASOs, or siRNA into up to 30 cell types, all in a single animal. To analyze these large *in vivo* drug delivery datasets, we have also developed an open source bioinformatics pipeline to iteratively 'evolve' nanoparticles that target cells *in vivo.* Using this high throughput, iterative, *in vivo* approach, we have identified nanoparticles with tropism to many novel cell types, in many different tissues.

SESSION SM04.03: Biomaterials and Drug Delivery for Immunotherapy I
Session Chairs: John Wilson and Yoon Yeo
Tuesday Afternoon, April 20, 2021
SM04

2:15 PM *SM04.03.01
Engineering Innate Immune Activation with Amphiphillic Biomaterials Bruno G. De Geest; Ghent University, Belgium

Uncontrolled systemic inflammatory immune triggering hampers clinical translation of many classes of small molecule immunomodulators for vaccine design and cancer immunotherapy. Potent small molecule agonists of pathogen recognition receptors such as toll liker receptors and agonists of STING have been discovered, but like many other small molecule drugs, they are prone to rapid distribution throughout the body, thereby losing sitespecific activity and causing unwanted systemic inflammation.
Noncovalent albumin binding has proven a powerful strategy for lymphoid delivery. By taking advantage of the

inherent serum protein binding property of lipid motifs and their tendency to accumulate in lymphoid tissue, we designed lipid amphiphile conjugates that show robust lymphatic translocation by hitch hiking onto albumin molecules in the interstitial flow from the injection site to draining lymphoid tissue. By conjugating a small molecule immunomodulator (exemplified in our work by an imidazoquinoline TLR7/8 agonist) to lipid amphiphiles through a degradable linker we obtain well water soluble prodrugs that, upon subcutaneous or intramuscular administration provoke potent lymph node immune activation but suppress systemic overstimulation of the immune system.
Lipid conjugation of potent small molecule immunomodulators has shown to reduce systemic toxicity but comes at a cost of a dramatic reduction in biological activity due to the formation of an insoluble depot. Our approach results in a well water soluble lipid amphiphile prodrug, showing high biological activity in vitro and in vivo in mouse models.

2:40 PM *SM04.03.02
Engineering Approaches to Modulate the Immune System James J. Moon; University of Michigan–Ann Arbor, United States

With profound advances in immune-oncology, cancer immunotherapy is now considered the fourth pillar of cancer therapy, joining the ranks of surgery, radiotherapy, and chemotherapy. For some cancers, including advanced non-small cell lung cancer, combination immunotherapy is FDA-approved as the frontline therapy, showing promise for applying immunotherapy to a wide range of advanced cancers. Currently, immune checkpoint blockade involves systemic administration of monoclonal antibodies, which can cause off-target side effects by inducing activation of self-antigen reactive T-cells. The combination of multiple immune checkpoint blockers generally improves the clinical responses; however, this can lead to severe immune-related adverse events that result in clinical manifestations of dermatitis, colitis and hepatitis. Thus, to fully realize the potential of cancer immunotherapy, approaches are needed to amplify anti-tumour T-cell immune responses, to convert cold tumours into hot tumours and to sensitize tumours to immunotherapies with minimal off-target toxicity and immune-related adverse events. Here, we highlight new opportunities for combination immunotherapy based on nanomedicines that are well poised tackle the challenges faced by the field of cancer immunotherapy. We present biomaterial-based strategies for amplifying anti-tumor immune responses and sensitizing tumors to immunotherapies in a safe and effective manner. Briefly, we show that lipid-based nanodiscs can efficiently co-deliver antigen and immunostimulatory molecules to draining lymph nodes and elicit potent CD8+ cytotoxic T lymphocyte responses directed against tumor antigens, leading to substantially enhanced anti-tumor efficacy in multiple murine tumor models, including colon carcinoma, melanoma, and glioblastoma multiforme. In a second research thrust, we have shown that this nano-platform can deliver chemotherapeutic agents in a synergistic manner with immune checkpoint blockers. In a third research thrust, we are developing new biomaterials for *in situ* modulation of the gut microbiome for regulation of local and systemic immune responses. We will share our latest results showing the therapeutic potential of our gut modulation approach in the context of combination cancer immunotherapy. Owning to the facile manufacturing process, robust therapeutic efficacy, and good safety profiles, our biomaterial-based approaches may offer powerful and convenient platforms for combination cancer immunotherapy.

3:05 PM SM04.03.03
Late News: Poly(ethylene glycol)-b-poly(D,L-lactide) Nanoparticles as Potential Carriers for Anticancer Drug Oxaliplatin Nikita Sedush[1], Yulia Kadina[1], Ekaterina Razuvaeva[1], Dmitry Streltsov[1], Alevtina Kulebyakina[1], Alexander Puchkov[1], Alexey Nazarov[2] and Sergei Chvalun[1,3]; [1]National Research Center Kurchatov Institute, Russian Federation; [2]Department of Chemistry, Lomonosov Moscow State University, Russian Federation; [3]Enikolopov Institute of Synthetic Polymeric Materials Russian Academy of Sciences, Russian Federation

In the last decades, great attention has been paid to developing of nanoscale vehicles for drug delivery. Incorporation of drug molecules into nanocarriers allows to overcome poor water solubility of hydrophobic drugs as well as increase stability against hydrolytic degradation of hydrophilic ones. Moreover, nanoparticulate

drug formulations can act in a targeted and prolonged manner enhancing the efficacy of treatment, e.g. cancer treatment. Platinum-based complexes (cisplatin, carboplatin, oxaliplatin etc.) are widely used chemotherapeutics agents for the treatment of various types of cancer. Oxaliplatin ((trans-R,R-cyclohexane-1,2-diamine)oxalatoplatinum(II)) is the third-generation platinum complex that was designed to overcome cellular resistance to cisplatin and carboplatin. Oxaliplatin shows higher solubility and less toxicity than cisplatin. It is used as a standard treatment for colorectal cancer. Moreover, oxaliplatin can be active against refractory ovarian cancer, germ-cell cancers, non-small cell lung cancer etc. Nevertheless, its low water solubility, short half-life in the bloodstream and non-selective biodistribution reduces the effective dose of oxaliplatin in the targeted tissues and enhances the systemic toxicity. The design of new types of nanocarriers for delivery of oxaliplatin is of high interest. We believe that P(D,L)LA-b-PEG nanoparticles is a promising platform due to its flexibility and successful track record as a nanocarrier for development of targeted anticancer drug formulations.
Biodegradable drug-free and oxaliplatin-loaded $mPEG_{113}$-b-$P(D,L)LA_n$ nanoparticles were prepared by a simple nanoprecipitation technique. The effect of hydrophobic block length on the structure, size, morphology and drug loading content of $mPEG_{113}$-b-$P(D,L)LA_n$ nanoparticles was investigated. It was observed that in aqueous solution $mPEG_{113}$-b-$P(D,L)LA_n$ copolymers, where n = 62 – 173 monomer units, form spherical nanoparticles with hydrodynamic diameters ranging from 32 to 56 nm. The “core-corona” structure of the block copolymer nanoparticles was confirmed by SAXS. Tailoring of P(D,L)LA block length results in variation both core-corona interface area and tethering density of hydrophilic PEG chains on the surface of P(D,L)LA core of the $mPEG_{113}$-b-$P(D,L)LA_n$ nanoparticles, which affects oxaliplatin loading content. An increase in P(D,L)LA block length from 62 to 173 monomer units results in a decrease in core-corona interface area from $2.7x10^{20}$ to $1.5x10^{20}$ nm^2/g and tethering density of PEG chains from 1.6 to 1.0 nm^{-2} and a reduction in the oxaliplatin loading content from 3.8 to 1.5% wt./wt. Thus, we suppose that oxaliplatin is adsorbed on the core-corona interface of the $mPEG_{113}$-b-$P(D,L)LA_n$ nanoparticles. SAXS measurements revealed that oxaliplatin loading does not affect the size and structure of the block copolymer nanoparticles.
The size and structure of polymeric nanoparticles are crucial characteristics that should be considered in the design of targeted nanoformulations of anticancer agents. The developed formulations of oxaliplatin can be considered as promising candidates for treatment of various types of cancer. In vitro tests were performed in order to compare its efficacy and toxicological profile with pure oxaliplatin.
This research was funded by the Russian Science Foundation, grant number 18-73-10079.

3:20 PM SM04.03.04
Donor-Acceptor Based Photothermal Nanoparticles for Augmenting Oxaliplatin Chemotherapy Against Colorectal Cancer Santu Sarkar and Nicole Levi; Wake Forest University School of Medicine, United States

Colorectal Cancer (CRC) is the fourth leading cause of cancer-related deaths with few available treatment options. Common treatment techniques are surgery and chemotherapy. Among the available chemotherapeutic drugs, oxaliplatin is a cornerstone for the treatment of CRC. As an adjuvant technique, hyperthermia i.e. an elevated temperature (39–42 °C), has been shown to increase chemotherapy treatment outcomes clinically. Hyperthermia increases the drug uptake by affecting cell membranes and produces drug-induced DNA damage leading to enhanced tumor cell death. It has been demonstrated that the synergistic effect of hyperthermia with oxaliplatin can treat CRC. One of the major disadvantages is, due to the intermittent exposures of oxaliplatin the cells become chemo-resistance complicating the treatment procedure. To improve the precision of the technique, instead of using a bulk carrier fluid along with a heat exchanger in the traditional hyperthermia delivery, photothermal nanoparticles can be used to deliver more specific and effective hyperthermia.
In our laboratory, semiconducting polymer nanoparticles have been used as photothermal agents to ablate cancer cells. Recently, variable molecular weight nanoparticles (VMWNPs) produced from the oligomer and high MW segments of a single polymer poly[4,4-bis(2-ethylhexyl)–cyclopenta–[2,1-b:3,4-b″]–dithiophene-2,6-diyl-alt-2,1,3-benzoselenadiazole-4,7-diyl] (PCPDTBSe) were demonstrated as a promising photothermal agent for the ablation of breast cancer. VMWNPs generated heat upon 800 nm laser irradiation and produced fluorescence emission at 825 nm upon excitation at 550 nm. Therefore, VMWNPs can be used to detect CRC through near infra-red fluorescence imaging and hyperthermia delivery. Here we have explored the synergistic effect of oxaliplatin and hyperthermia generated through VMWNPs to augment chemotherapy treatment of

chemo-sensitive and chemo-resistant CRC cells.
The process of hyperthermia generation using VMWNPs was optimized, and it was found that a 25 µg/ml concentration of VMWNPs could produce hyperthermia (39–42 °C) effect upon 800 nm (3W) laser exposure for 20 seconds. Various concentrations of VMWNPs were incubated with mouse-derived CRC CT-26 cells for 24 hours and no cytotoxic effect was observed up to 100 µg/ml. Whereas upon incubation of oxaliplatin with increasing concentrations there was a 50% decrease in cell viability at 300 µM concentration was observed. To monitor the thermal dose, first, the chemo-sensitive and chemo-resistant CRC cells were incubated with varying concentrations of oxaliplatin and kept at 42 °C for two hours. An 80% and 75% decrease in cell viability was observed for chemo-sensitive cells and chemo-resistant cells respectively. To observe the effect of VMWNPs induced hyperthermia, CRC chemo-sensitive cells were incubated with oxaliplatin and VMWNPs followed by laser exposure (800 nm, 3W, 20 secs) in three cycles. A 63% reduction in cell viability was observed for VMWNPs generated hyperthermia. This result confirmed that VMWNPs could successfully deliver hyperthermia to augment chemotherapy. In the future, oxaliplatin, and hyperthermia using VMWNPs will be utilized to treat chemo-resistant CRC cells.

3:35 PM SM04.03.05
Late News: Polymersome Encapsulation of a Lipophilic Protein-Protein Interaction Inhibitor to Achieve Increased Solubility and Therapeutic Index Yu Tian, Mathew Schnorenberg, James LaBelle and Matthew Tirrell; The University of Chicago, United States

Protein-protein interactions (PPIs) dictate most biological processes, including those responsible for carcinogenesis. Targeted therapeutics acting on these oncogenic PPIs have naturally become the focus of novel drug discovery. Currently,one small molecule PPI inhibitor, Venetoclax (AbbVie) is FDA approved to treat a number of hematologic malignancies through its inhibition of an antiapoptotic protein, BCL-2. However, considering that there are ~650,000 human PPI s as potential targets, the development of other PPI inhibiting drugs has been lagging due to the off-target and delivery issues. For example, a PPI inhibitor, ABT-263, although possessing potent nanomolar binding affinity to BCL-2, can lead to sever thrombocytopenia when administered systemically, which is due to the off-target BCL-XL inhibition in platelets. This is limiting its therapeutic index. We have developed a nanocarrier system, targeted polymersome (PSOM) nanoparticle, made of biocompatible poly(ethylene glycol)-disulfide-poly(propylene sulfide) (PEG-SS-PPS) with surface conjugated anti-CD19 F(ab) antibody fragments (aCD19 Fabs) as targeting motif to B cell lymphoma. PSOMs are fabricated by flash nanoprecipitation (FNP) and extrusion resulting in uniform vesicular morphology and size distribution (~130 nm in diameter). Moreover, ABT-263 was successfully encapsulated by PSOM at an efficiency over 90%, which increases the solubility of the lipophilic ABT-263 to over 10mM in PBS. From *in vivo* platelet-counting experiment, the intravenous administration of PSOM encapsulated ABT-263, in contrast to orally administered non-encapsulated drug, led to the mitigated thrombocytopenia in mice. Importantly, flow cytometric analyses on a panel of human CD19 positive diffuse large B cell lymphoma cell lines demonstrated specific uptake of aCD19-PSOM nanoparticles. We believe the results indicate the great promise of *in vivo* targeted delivery of ABT-263 by PSOM to B cell lymphoma.

3:50 PM SM04.03.06
Late News: Activatable Perfluorocarbon Bubble Inflation and Drug Release Using Superheated Perfluorocarbon Nanodroplets Caroline de Gracia Lux, Jacques Lux and Robert F. Mattrey; University of Texas Southwestern Medical Center, United States

The field of acoustic droplet vaporization (ADV) was introduced nearly 20 years ago to embolize tissues non-invasively. ADV used 1-5 µm perfluorocarbon (PFC) droplets and converted them into large gas bodies in the feeding artery with ultrasound to embolize tissues downstream. Despite its potential clinical impact, the ADV field has not advanced. The manufacture of nanodroplets (ND) using PFC that boils near 0 ºC to ease vaporization, was introduced 10 years later to rescue ADV, and to capitalize on the nanosize ND for tumor detection. Despite this advance, the field remains stagnant because of critical efficacy and safety challenges hindering its translation and widespread use. Some important challenges include the energetics required to

cavitate the PFC into gas, and the resultant rapid expansion that could injure tissues.
We recently discovered that PFC nanobubbles (NBs) and microbubbles (MBs) inflate when exposed to superheated PFC NDs. While *in vitro* and *in vivo* preliminary data confirmed the proof of concept, the translational success of our novel approach will rely on our ability to control bubble inflation to safely improve tumor detection when NBs are used or occlude tumor microvascular when MBs are used. We showed that both rate and degree of expansion is affected by the type of PFC used, ND and NB/MB size and type of lipid emulsifier that affect both interfacial tension and the ability of bubbles to expand. We showed that MBs with a stiff polymeric shell made of denatured albumin when exposed to liquid PFC NDs expand more rapidly, but to only half the diameter of typical phospholipid-based MBs, encouraging us to optimize shell formulation to limit inflation.
As this non-invasive platform can be used to perform chemoembolization as is currently done to treat liver tumors but without the need for angiography or prior tumor visualization, one of our current goal is to load chemotherapeutics in NDs or MBs and promote drug release in only tissues expressing the receptor of interest, analogous to trans-arterial chemoembolization. However, since this approach is not image guided, tumors do not need to be visible pre-treatment. We believe that these accomplishments show promise and potential to translating our novel approach to the clinic while creating new paradigms for early detection and treatment of cancer. This talk will be focused on the impact of formulation on MB growth and translational opportunities.

4:05 PM PANEL DISCUSSION

SESSION SM04.04: Biomaterials and Drug Delivery for Immunotherapy II
Session Chairs: Ciana Lopez, Patrick Stayton and Yoon Yeo
Tuesday Afternoon, April 20, 2021
SM04

5:15 PM *SM04.04.02
Programming Immunity with Smart Materials John T. Wilson; Vanderbilt University, United States

Interventions that engage the power and specificity of the immune system have enormous potential to improve human health, yet the efficacy, safety, and utility of many promising immunomodulatory agents is limited by critical drug delivery barriers. This talk will describe current research in my laboratory focused on engineering nanomaterials for intracellular delivery of immunomodulatory proteins, nucleic acids, and small molecules. Specifically, I will discuss our recent efforts in developing environmentally-responsive “smart” materials that open access cytosolic immune surveillance pathways, including STING and RIG-I, and how we are leveraging these platforms to enhance responses in cancer immunotherapy and augment the efficacy of subunit vaccines against respiratory viral pathogens.

5:40 PM SM04.04.03
A Novel Upconversion Nano Platform for NIR Triggered Drug Release and PDT Therapy Lei Ma[1], Olivia Fernandez[1], Hao Zhang[2], Lu Li[2], Luis Echegoyen[1] and Xiujun J. Li[1]; [1]The University of Texas at El Paso, United States; [2]Shandong Normal University, China

The development of an efficient phototherapeutic system is highly desirable but still a big challenge, because of its significant limitations at tissue penetration. NIR photo upconversion can be an effective key to assist electromagnetic energy penetrating deep tissue into most tumor locations. Herein, a novel 808 nm triggered upconverting system was designed and applied for NIR triggered drug release and simultaneous photodynamic therapy. A core-shell $NaYF_4$:Nd/Yb@$NaYF_4$:Yb/Er nanocrystal was rationally synthesized, exhibiting photoluminescence emissions at the wavelength around 538 nm, under NIR laser radiation. The UCNPs were surface modified with silanization and amine terminals decoration. Subsequently, via a carbodiimide coupling

reaction, UCNPs were grafted with bifunctionalized C_{60} derivative, as the photosensitizer. Then the C_{60} coated UCNPs were further conjugated with chemotherapy model drug Doxorubicin (Dox), through a covalent oxalyl linkage. Notably, under NIR laser irradiation, singlet oxygen was effectively generated from an upconverting photodynamic combination of UCNPs and C_{60}. And Dox got a controlled release from cleavage of the peroxide sensitive oxalyl bridge. The drug release and therapeutic efficacy were investigated in vitro on breast cancer cell lines MCF-7 and MDA-MB-231 by various microscopic and biochemical studies under a significantly mild NIR irradiation and low dosage of the treatment. The combination of controlled release for localized chemotherapy with simultaneous photodynamic treatment has great potential for clinical photo cancer therapy.

5:55 PM SM04.04.04
Polymeric Microcapsules Designed for On-Demand Local Heating and Drug Release in Synergistic Chemo-Photothermal Therapy Ji-Won Kim, Sang Hoon Han and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

Photothermal therapy is promising for cancer treatment as it is noninvasive and localized. The way to treat tumors is elevating the temperature through conversion of radiation energy to heat under near-infrared (NIR) light. To further enhance the therapeutic effect of cancer treatment, anti-cancer drugs are released to the photothermally-heated tumors. The chemo-photothermal therapy can synergistically enhance the efficacy of tumor treatment. For the chemo-photothermal therapy, it is required to design drug carriers that provide photothermal heating and on-demand release of drugs. At the same time, the carriers should have high payload and high efficiency of encapsulation for the drugs. However, there have been few reports on such an advanced carrier for the synergistic chemo-photothermal therapy.
Herein, we report a pragmatic microfluidic approach to produce monodisperse microcapsules for chemo-photothermal therapy. The microcapsules contain highly concentrated polydomapine (PDA) nanoparticles and drugs in their aqueous lumens, enclosed by thermo-responsive membrane. The microcapsules are templated by water-in-oil-in-water (W/O/W) double-emulsion droplets. With a glass capillary microfluidic device, monodisperse double-emulsion droplets are produced to have the innermost water drops containing PDA nanoparticles and drug and the outer oil drops of photocurable monomer, phase-change materials (PCM), and molecular compatibilizer. As a continuous phase, an aqueous solution of high concentration of salt and surfactant is used to make a hypertonic condition. The double-emulsion drops shrink downstream as water in the innermost drops is pumped out through the oil shell by the osmotic-pressure difference, which concentrates the PDA nanoparticles and drugs during the flow. The resulting droplets are irradiated by ultraviolet (UV), which photopolymerizes the monomer in the oil shell. In the presence of a molecular compatibilizer between the monomer and PCM, the polymerization does not cause any macrophase separation, resulting in a composite membrane with continuous microscopic PCM domains. The polymer framework in the membrane provides mechanical stability, whereas PCM domains provide channels for transmembrane transport at the temperature above a melting point for molecules dissolvable in the molten PCM. To use the microcapsules for in-vivo drug release, tetradecanol with melting point of 38°C is chosen as a PCM so that the microcapsules retain drugs at body temperature while secreting them when temperature is elevated; many anti-cancer drugs are dissolvable in organic solvents as they are not highly polar.
The microcapsules show a rapid temperature increase under the irradiation of 808 nm laser as highly-concentrated PDA nanoparticles in the lumen provide a high photothermal conversion efficiency. Therefore, the PCM in the membrane is molten under the laser irradiation and the drugs in the lumen is gradually released out. As the heating is highly localized, the microcapsules are cooled down as the laser is off, holding up the release. Therefore, the release as well as local temperature can be controlled in a programmed manner by controlling the duration and interval of stepwise irradiation. With the microcapsules, we successfully treat breast cancers using animal models through chemo-photothermal therapy where palbociclib is used as an anti-cancer drug. The combination of drug and local heating shows higher efficacy of the treatment than the photothermal therapy or chemotherapy used only. We believe the resultant microcapsules with synergistic chemo-photothermal effect are highly attractive in use of advanced chemo-photothermal therapy.

Cancer Immunotherapy Using Nanomaterial-Based Delivery Systems of Oncolytic Adenovirus Chae-Ok Yun; Hanyang University, Korea (the Republic of)

Intratumoral injection of adenovirus (Ad) into diseased tissues remains a conventional route for viral gene delivery. Nonetheless, locally administered virus often disseminates to the surrounding nontarget tissues from the injection site, leading to poor localization and retainment of the virus in tumor tissues. Rapid induction of antiviral immune response against Ad also contributes to poor longevity of virus at tumor site. To address these limitations, diverse array of nanomaterial-based delivery systems for oncolytic Ad have been investigated to improve intratumoral retainment and accumulation of virus at tumor tissues, while attenuating nonspecific sequestration into healthy organs. Importantly, nanomaterial coating on the surface of viral capsid can facilely endow novel properties to the resulting nanohybrid complex, which cannot be achieved through genetic engineering of the virus genome. For instance, masking of viral capsid with nanomaterials can endow "stealth" ability to the virus, enabling it to evade the detection by host immune system and subsequently attenuate antiviral immune response against Ad, ultimately prolonging virus' biological activity at tumor tissues. Importantly, optimization of nanohybrid system can ensure that oncolytic Ad's ability to induce robust antitumor immune response can be preserved while selectively attenuating induction antiviral immune response, thus resulting in improved potency and safety profile. Another advantage of nanohybrid system is that diverse array of cancer targeting moieties, like antibodies and peptides, can be easily incorporated on the surface to redirect the virus tropism to wide range of tumors expressing complementary receptors. Sustained or controlled release of the virus at tumor sites can also be achieved by nanomaterial-based delivery system to improve and prolong virus retention at tumor sites. Collectively, nanomaterial-based delivery systems for oncolytic adenovirus is a promising strategy to overcome many of the clinical hurdles to achieving optimal virus delivery to tumor tissues.

6:35 PM *SM04.04.01
Modulating the Immune System with Nanostructured Biomaterials Tejal Desai; University of California, San Francisco, United States

Biomaterials can improve the safety and presentation of therapeutic agents for effective immunotherapy, and a high level of control over surface functionalization is essential for immune cell modulation. Here, I will discuss biocompatible immune cell engaging particles that use synthetic short DNA as scaffolds for efficient and tunable protein loading. The use of DNA scaffolds allows for ratiometric control and high-density biomolecular loading. Moreover, intratumorally injected immune cell engaging particles presenting a high density of priming antigens activated CAR-T cells drove local tumor clearance while sparing uninjected tumors in immunodeficient mice. The ratiometric control of costimulatory ligands and the surface presentation of a cytokine on immune cell engaging particles were shown to significantly impact human primary T cell activation phenotypes. I will also discuss ways to use nanostructured biomaterials to selectively capture endogenous cytokines in order to preferentially engage specific immune cells. These modular and versatile biomaterial platforms can provide new opportunities for immunotherapies.

Biomolecule-Based Nanostructures for Tumor Microenvironment Targeting and Regulation Guangjun

Nie; National Center for Nanoscience and Technology, China

It has witnessed that the rapid development on precision design and fabrication of intelligent next generation nanomedicines hold great potential to revolutionize the current landscape of drug development. It is also clear that tumor microenvironment plays critical roles on either promotion or restriction on primary tumor rapid growth and metastasis. Those achievements have made targeting and regulation of tumor microenvironment via responsive nanomedicines a feasible and fruitful strategy, to improve the therapeutic outcomes for cancer treatment. This presentation will feature our recent development on using biomolecule-based nanostructures as intelligent nanomedicines to regulate tumor microenvironment to block tumor microvessels or re-store the homeostasis of tumor stroma. Robotic molecular systems have great potential as intelligent vehicles to enable the delivery of various potent molecules, which otherwise never could be used as therapeutics due to numerous limitations. Yet, achieving in vivo, precise molecular-level, and on-demand targeting and delivery has proven extremely challenging. We developed nanorobotic systems for targeted cancer therapy, programmed to transport molecular payloads and cause on-site tumor infarction. Given the robust self-assembly behavior, exceptional designability, potent antitumor activity and minimal in vivo adversity, the development represents a promising strategy for precise drug design for cancer therapeutics.

Engineering Nano-Based Neurotherapeutics for Pediatric Brain Disease Elizabeth Nance; University of Washington, United States

Of the clinically approved nanotechnologies in 2019, none are indicated for non-cancerous neurological disease, which represents 13% of the global disease burden. Therefore, our lab has worked to develop tools that inform how we can more effectively treat the diseased brain, using nanotechnology as both a probe and as a therapeutic delivery vehicle. When delivery limitations of a nanoparticle platform are better understood, an optimal formulation can be engineered and evaluated for therapeutic efficacy in clinically relevant animal models of brain disease. We focus on developing nanoparticle-based therapeutic approaches for improved neurological

outcomes in perinatal brain injury. We use therapeutic nanoparticle platforms that are polymer-based, incorporate materials that are FDA approved, and have been utilized extensively in adult populations but have not been used in children or newborns. We identify drugs that can affect multiple pathways and have a solubility and/or delivery problem - that is, the drug is either not soluble in aqueous solutions or it is not able to reach its target site in high enough concentrations to be effective. We use a range of *in vitro*, *ex vivo*, and *in vivo* models to screen and evaluate efficacy of nanotherapeutic platforms. Our *ex vivo* cultures include stimuli that replicate aspects of *in vivo* injury conditions, such as oxygen-glucose deprivation, glutamate toxicity, or exposure to lipopolysaccharide. *In vitro* and *ex vivo*, we test for toxicity and dose response; *ex vivo*, we evaluate regionally dependent cellular uptake and downstream mechanistic effects of the nanotherapeutic platform; *in vivo*, we quantify biodistribution and measure improvements in gross injury and neuropathology in response to treatment. We have shown curcumin-loaded polymer nanoparticles could reduce brain injury via gross injury analysis and neuropathology in neonatal rats with hypoxic-ischemic (HI) brain injury. We expanded on this work to show that superoxide dismutase can be an effective treatment against HI injury in cultured rat brain slices, and screened promising preclinical therapeutics in a ferret brain slice model of HI injury. Importantly, we've furthered our targeting capabilities by showing how the (1) disease severity alters nanoparticle-cellular interactions, (2) formulation conditions can impart pathology-specific toxicity, and (3) surfactant used to stabilize polymer formulations can direct site-specific cell-specific uptake in the neonatal brain.
In this talk, we demonstrate the importance of using multiple platforms to evaluate nanotherapeutic behavior in the brain, and the impact formulation methods can have on polymeric nanoparticle effect and fate in the brain. Further, we show that we can engineer more effective nanotherapeutics for the treatment of neurological disease with a specific emphasis on the neonatal and pediatric populations, which are vastly underserved by technology development.

9:50 PM SM04.05.04
Polymeric Micelles for Delivery of Gasotransmitter Hydrogen Sulfide with Proangiogenic Activitiy Urara Hasegawa and Andre J. van der Vlies; The Pennsylvania State University, United States

Hydrogen sulfide (H_2S), a gaseous signal-transmitter molecule (gasotransmitter), has pivotal roles in the human body by regulating physiological and pathological processes such as angiogenesis, inflammation and neurotransmission. With the discovery of the biological significance of H_2S, the potential for H_2S-based therapies has attracted growing attention. However, the lack of H_2S delivery systems that enable controlled release of H_2S at the site of interest limits its biomedical applications. One common approach is to use H_2S donor compounds, such as anethole dithiolethione (ADT) derivatives, which generate H_2S under physiological conditions. However, the uncontrolled rate of H_2S release and toxic side effects of the donor compounds and/or their decomposition byproducts remain as the major problems associated with the use of small H_2S donor compounds. To address this issue, we developed polymeric micelles carrying H2S-donating ADT groups (H_2S donor micelles), which release H_2S in a sustained manner under physiological conditions. Here, we report design, synthesis and characterization of polymeric H_2S donor micelles. The proangiogenic activities of these micelles were also evaluated in the in vitro cell culture assays as well as the in ovo chick chorioallantoic membrane (CAM) assay.

10:05 PM *SM04.05.05
Theragnosis Inspired by Real-Time Molecular Imaging Ick Chan Kwon; Harvard Medical School, United States

Molecular imaging is recognized as a key technology for theragnosis which is known as an emerging paradigm for future personalized medicine. Peptide which have been used as a useful carrier for drug delivery system could also be served as an excellent tool for molecular imaging. Approaches to combine these two important functionalities all together in a peptide conjugate are proposed in this presentation. Recent advances in biotechnology have contributed to the development of various peptide conjugates that enable targeted delivery of imaging agents as well as therapeutic agents for biomedical applications. Compared to small molecules (e.g., imaging agents and therapeutic agents), peptide conjugates possess unique characteristics such as high target-

specificity and multi-functionality. As a result, peptide conjugates hold great potential in the future biomedical field such as molecular imaging, diagnostics, and the drug delivery system. Moreover, combination of both imaging agents and therapeutic agents within a single peptide conjugates, often referred to as theragnostics, make it possible to provide useful information in drug developments. Theragnostic peptide conjugates allow in vivo real-time imaging of the diseased site, monitoring the biodistribution of drug and determining the optimal therapeutic efficacy following treatments. These features can allow clinicians to select optimal therapeutic options for personalized medicine. In recent studies, we developed epidermal growth factor receptor (EGFR) and CD 47 receptor-specific self-quenched imaging probes, which can emit fluorescence (activate) via de-quenching reaction in lysosome, resulting in showing target-specific fluorescence signal in vitro as well as in vivo condition. This presentation will highlight our recent advances that have been made in the development of multifunctional peptide conjugates and the applications into theragnosis.

8:00 AM *SM04.06.01
The Direction of Nucleic Acid Drug Delivery—From RNA Interference to Genome Editing Jun Wang[1,2,2]; [1]South China University of Technology, Guangzhou International Campus, China; [2]South China University of Technology, China

Nucleic acids have paved new avenues for the development of therapeutic interventions against a spectrum of diseases; however, their clinical translation is limited by successful delivery to the target cells. To solve this problem, we fabricated cationic lipid-assisted nanoparticle (CLAN) by double emulsion method. In our initial design, the CLAN system was constructed using PEG-*b*-PLA and BHEM-Chol, which achieved >95% encapsulation efficiency of siRNA. Using CLAN, we and collaborators delivered siRNA, CpG and other nucleic acids for cancer and HBV treatment. To further improve its therapeutic efficacy, we synthesized a tumor pH-labile linkage-bridged block copolymer of poly(ethylene glycol) with poly(lacide-*co*-glycolide) (PEG-*Dlink*$_{m}$-PLGA) to prepare DCLAN$_{PLGA}$ for siRNA delivery. The PEG surface layer of DCLAN$_{PLGA}$ can be detached in response to the tumor acidic microenvironment to facilitate cellular uptake, and the siRNA was rapidly released within tumor cells due to the hydrophobic PLGA layer. Thus, PEG-*Dlink*$_{m}$-PLGA-based CLANs exhibited an enhanced siRNA delivery efficacy. Most recently, to rationally design the delivery system of CRISPR-Cas9 genome editing tools, we constructed a library of CLANs with different properties (e.g. surface PEG density, zeta potentials, cationic lipid types) by adjusting the weight and types of the cationic lipid and incorporating the homopolymer PLGA. After systemic administration, the uptake of these CLANs by different immune cells was evaluated, and the optimal CLANs were screened. Using this strategy, we efficiently delivered CRISPR-Cas9 into macrophages, neutrophils, B cells and dendritic cells for treating inflammatory diseases, type II diabetes, autoimmune diseases *et al*.. In summary, our CLAN is an effective platform for developing the delivery systems of siRNA, CRISPR-Cas9 and other nucleic acids.

Polyplexes for Local Delivery of siRNA. Tina Vermonden, Lies Fliervoet and Cristina Casadidio; Utrecht University, Netherlands

Purpose. Polymeric vectors have been extensively studied to function as gene delivery systems, but their widespread applications have been restricted by inefficient *in vivo* delivery of therapeutic nucleic acids. In our

studies, we investigate local and sustained delivery of nucleic acids making use of a polyplex-containing injectable hydrogel.

Methods. Complexes are formed between nucleic acids and cationic poly(2-dimethylaminoethyl methacrylate) (PDMAEMA)-based polymers (referred to a polyplexes), followed by the encapsulation of the polyplexes in a thermosensitive hydrogel. The designed triblock copolymer (PNIPAM-PEG-PDMAEMA, NPD) used for polyplex formation combines multiple functionalities, including cationic properties, needed for complexation with nucleic acids, and thermosensitive properties to anchor the polyplexes in the thermosensitive hydrogel. The physico-chemical properties of siRNA complexed to the multiresponsive polymer were evaluated and compared with polyplexes made with a non-thermosensitive polymer (PEG-PDMAEMA, PD) in 2D and 3D multicellular tumor spheroid models (MCTS).

Results. We found that stable polyplexes could be formed at physiological temperature by tuning the block lengths of the NPD polymers and the N/P ratio, reflecting the ratio between cationic nitrogen of the polymer and anionic phosphate groups in the nucleic acids, respectively. Upon encapsulation of siRNA polyplexes in the thermosensitive hydrogel, a sustained release profile was observed *in vitro* and thorough characterization of the released particles showed that they are stable, have the same size as before encapsulation and retain similar transfection activity. Penetration and diffusion of free siRNA polyplexes were monitored via live-cell imaging into MCTS, reaching the core of spheroids after 24 hours of incubation. A pilot *in vivo* study showed that fluorescently labeled polyplexes could be released locally for a least 7 days after injection intraperitoneally and subcutaneously.

Conclusions. Injectable hydrogels can enhance the local concentrations of delivered nanoparticles. We showed successful encapsulation of siRNA based polyplexes and sustained release from an injectable matrix both *in vitro* and *in vivo*. Moreover, *in situ* released polyplexes proved to easily penetrate hard tissue models. These formulations showed to extend the residence time of siRNA therapeutics and thereby have great potential for local therapeutic delivery.

Nucleic Acid Co-Delivery—How to Modulate Protein Co-Expression by Formulation of Payload Hanieh Moradian[1,2,3], Andreas Lendlein[1,2,3] and Manfred Gossen[1,2]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]Berlin-Brandenburg Center for Regenerative Therapies (BCRT), Germany; [3]University of Potsdam, Germany

Co-delivery of two genes into individual cells by means of polymeric or lipid nanocarriers is of utmost importance in many experimental settings, addressing either fundamental scientific questions or therapeutic applications. Examples are the expression of heterodimeric proteins such as antibodies or the co-introduction of an imaging marker. For widely used DNA-based gene transfer, multiple transcription units can be easily integrated on one molecule, e.g., plasmids. This strategy is not feasible for mRNA delivery. Here, co-delivery has to be achieved by mixing independent functional units or shifting the separation of functional entities to the level of proteins. In this study, we investigated multiple approaches to achieve simultaneous expression of two proteins at the same cells with a focus on formulation of nucleic acid (NA) payload, here mRNA as well as pDNA. The first strategy relies on the delivery of the genetic information via two independent “monocistronic” NAs, whereas in the second approach, this information is combined in a single NA molecule, referred here as “bicistronic”. The latter results in expression of two proteins from a single open reading frame and its co-translational separation by so called “2A” sequences. Two reporter proteins, enhanced green fluorescent protein (EGFP) and mCherry, as well as EGFP together with another non-fluorescent protein were utilized to evaluate these alternative methods, an advantageous feature of using NA as delivery entity. The data revealed that there was negligible differences between monocistronic and bicistronic delivery of genes of the same size, i.e. EGFP

and mCherry. However, a significant difference between cells transfected with two genes with different molecular size was observed, in terms of cell population expressing both proteins, i.e. double positive cells. More precisely quantified by flow cytometry, 36.76±2.03% of cells were double positive for bicistronic method versus 90.43±1.27 % double positive cells, which was recorded for cells co-transfected with two monocistronic NAs. Our findings could be served as guideline for selecting the best-suited approach by choosing payload properties that can be complemented by adapting the formulation, e.g., polymer- or lipid-based, to the intended application.

Antibacterial Activities of Cationic Porphyrins and Gold Nanorod Encapsulated Porphyrins and Their Activities on Bacterial Cell Lines Nthabeleng Hlapisi; University of Zululand, South Africa

Bacterial infections form part of the major causes of mortality and mobility around the world more especially in developing and under-developed countries. This study is based on the synthesis of two cationic porphyrins, 5,10,15,20-tetra-kis(4-aminophenyl)porphyrin (TAP) and 5,10,15,20-tetra-kis(4-pyridyl)porphyrin (TPyP) that are evaluated against bacterial strains by the micro-well assay and the micro-dilution method. Gold nanorods were encapsulated with each of these porphyrins and dissolved in DMSO. At 50mg/ml, the porphyrin-AuNRs produced zones of inhibition of 10-12mm against S. *aurea* (ATCC 25925)*, E. Faecalis* and *K. pneumonia* (ATCC 4352). The minimum inhibitory concentration (MIC) values that were obtained using the micro-dilution method were, 0.78, 1.5 and 2.6mg/ml for *S. aurea* (ATCC 25925)*, E. Faecalis* and *K. pneumonia* (ATCC 4352) respectively for all bacterial strains using TPyP@AuNRs, and 1.8, 0.42 and 0.76 mg/ml for *S. aurea* (ATCC 25925)*, E. Faecalis* and *K. pneumonia* (ATCC 4352) respectively using TAP@AuNRs. The results show the porphyrin-AuNR conjugates to have a potential as anti-bacterial agents.

PNAGA-based Hydrogels for Diverse Biomedical Applications Chunyan Cui, Chuanchuan Fan and Wenguang Liu; Tianjin University, China

It has been fifty-four years since N-acryloyl glycinamide (NAGA) monomer and its polymer (PNAGA) were reported in 1964. It is characterized by two amides in its side chain. The concentrated aqueous solution of PNAGA has been shown to form supramolecular polymer (SP) hydrogels which are physically crosslinked by dual-amide hydrogen bonds, and the SP hydrogels' mechanical properties can be tuned by varying initial monomer concentration, substitution groups as well as feature monomer copolymerization. Recently, our group has reported on high strength and soft PNAGA SP hydrogels by modulating hydrogen bonding density, and these SP hydrogels are developed as 3D printing bioinks for regeneration of osteochondral defect, an autolytic high strength instant adhesive hydrogel for emergency self-rescue, and a Janus hydrogel wet adhesive for internal tissue repair and anti-postoperative adhesion. The Janus hydrogel wet adhesive with strikingly distinct adhesive/nonadhesive properties on its two sides is fabricated by gradient polyelectrolyte complexation via one-sided dipping of carboxyl-containing hydrogel in cationic oligosaccharide solution. This Janus hydrogel demonstrates an instantly robust adhesion to soft tissues under water, and is successfully used for repairing perforated stomach of rabbits, meanwhile preventing post-operative tissue adhesion in vivo.

RNA Therapeutics Using Targeted Lipid Nanoparticles—From Gene Silencing to Gene Editing Dan Peer; Tel Aviv University, Israel

Accumulating work points out relevant genes and signaling pathways hampered in human disorders as potential candidates for therapeutics**.** Developing nucleic acid-based tools to manipulate gene expression, such as siRNAs, mRNA and genome editing strategies, open up opportunities for personalized medicine. Yet, although major progress was achieved in developing RNA targeted delivery carriers, mainly by utilizing monoclonal antibodies (mAbs) for targeting, their clinical translation has not occurred. In part because of massive development and production requirements and high batch-to-batch variability of current technologies, which relies on chemical conjugation. Here we present a self-assembled modular platform that enables to construct theoretically unlimited repertoire of RNA targeted carriers. The platform self-assembly is based on a membrane-anchored lipoprotein, incorporated into RNA-loaded lipid nanoparticles that interact with the antibody Fc domain. We show that a simple switch of 8 different mAbs, redirects specific uptake of siRNAs by diverse leukocyte subsets *in vivo.* The platform therapeutic potential is demonstrated in an inflammatory bowel disease model, by targeting colon macrophages to reduce inflammatory symptoms, and in Mantle Cell Lymphoma xenograft model, by targeting cancer cells to induce cell death and improve survival. In addition, I will discuss novel approach for delivering mRNA to specific cell types *in vivo* utilizing this platform. Finally, I will share new data showing high efficiency genome editing approaches in glioma and metastatic ovarian cancer. This modular delivery platform can serve as a milestone in turning precision medicine feasible.

12:10 PM *SM04.07.02
RNA Delivery Manfred Gossen; Helmholtz-Zentrum Geesthacht, Germany

The cellular uptake of engineered RNA, both as research tool or for (envisaged) therapeutic application came in the focus of nanomedicine by studies using short interfering RNAs (siRNA). While chemical modifications of the active ingredient siRNA proved important for efficacy of in vitro delivery, the major technological hurdles for in vivo delivery were targeting the RNA-containing nanoparticles to the right location and their in vivo delivery and survival. These bottlenecks have to be addressed by application-tailored formulations, mostly based on lipids or polymers. Part of the lessons learned can be applied for the more recent emergence of in vitro transcribed messenger RNAs (IVT-mRNA) for either vaccination of therapeutic gain-of-function approaches. Part of this spike in interest results from the safety profile (and record) of IVT-mRNA, due to its distinct chemical identity when compared to other “gene medicines”: mRNA only interferes transiently with the homeostasis of a cell’s transcriptome and does not effect the integrity of a cell’s genome composed of DNA, as has been shown for, e.g., viral delivery. Still, aside from the already mentioned hurdles in targeting and in vivo uptake, effective delivery of mRNAs requires further research in immune evasion strategies, as transfected mRNAs – among other reasons – are mistaken as viral invaders and tackled accordingly. I report on the proper use of chemically modified nucleotides as IVT-mRNA building blocks, and cell-based in vitro readout systems to monitor and ultimately modulate the innate immune response in the context of different formulations for delivery.

12:35 PM SM04.07.03

Late News: Effect of Nucleotide Chemistry on Expression of *In Vitro* Transcribed mRNA Hanieh Moradian[1,2,3], Andreas Lendlein[1,2,3] and Manfred Gossen[1,2]; [1]Helmholtz-Zentrum Geesthacht, Institute of Active Polymers, Germany; [2]Berlin-Brandenburg Center for Regenerative Therapies (BCRT), Germany; [3]Institute of Biochemistry and Biology, University of Potsdam, Germany

Recent technological advances in the production of *in vitro* transcribed mRNA (IVT-mRNA) facilitate its clinical use as well as application in basic research. In this regards, numerous chemical modifications, which are not observed in nature, have been introduced and successfully implemented to increase its stability, biological performance, and in particular the resulting protein production levels. Despite pronounced differences in expression levels of chemically modified IVT-mRNA as observed between different modifications, it is unclear whether these differences are exclusively due to translation capacity of chemically modified mRNAs, or if it is also caused by, e.g. differences in complex formation efficiency of modified mRNAs or in different uptake rates of IVT-mRNA/carrier complexes. Here a co-transfection experiment was designed using IVT-mRNA coding either of the two different fluorescent protein markers, i.e. EGFP and mCherry, which were synthesized with 5-methoxy-uridine (5moU) or a combination of pseudouridine and 5-methyl-cytidine (Ψ/5meC) modifications, respectively – and vice versa. We found that 5moU modified IVT-mRNA resulted in a much higher transgene expression, when transfected in human macrophages. This analysis was completed by biochemical experiments clarifying the contribution of other steps identified as possible causes for the observed differences in apparent expression levels. We predict that our findings shed light on the applicability of different mRNA modifications, and benefit future research by helping to select the proper chemical composition to accomplish their experimental/scientific requirements.

Competitive Binding and Molecular Crowding Regulate the Cytoplasmic Interactome of Non-Viral Polymeric Gene Delivery Vectors Alex Raynold, Danyang Li, Fengjin Qu and Julien Gautrot; Queen Mary, University of London, United Kingdom

Although polycationic vectors display excellent performance in vitro with many cellular systems, their clinical use remains very restricted. To some level, this is due to the poor compatibility of such systems with biological fluids and tissues. In addition, in contrast to the processes controlling the complexation, targeting and uptake of polycationic gene delivery vectors, such as poly(ethylene imine) and poly(dimethylaminoethly methacrylate), the detailed molecular mechanisms regulating their cytoplasmic dissociation remains poorly understood. Upon cytosolic entry, gene delivery vectors become exposed to a complex, concentrated mixture of molecules and biomacromolecules. To explore cytosolic release mechanisms, we characterised the cytoplasmic interactome associated with a polycationic vector based on poly(dimethylaminoethyl methacrylate) (PDMAEMA) brushes grafted from nanoparticles. Such cationic brushes were found to be particularly effective at trapping small RNAs, resulting in high knock down efficiencies[1-3]. However, how such stable association is disrupted in the cytosol was not clear. To quantify the contribution of different classes of low molar mass molecules and biomacromolecules to RNA release, we used fluorescence microscopy and developed a kinetic model based on competitive binding. We propose that the molecular structure and architecture (in particular the high surface density) of cationic brush-decorated nanoparticles, together with the cytosolic molecular crowding, modulate competitive binding and, in turn, the long term release of RNA. Based on these observations, we chemically designed polymer brushes with improved RNA retention in the cytosol, avoiding burst release, and enabling to achieve long term (at least 10 days) knock down (>70%) with one single transfection. Understanding the mechanism regulating cytosolic dissociation will enable the improved design of cationic vectors for long term gene release and therapeutic efficacy.

Cell Nucleus Decoration with Oxidized Nano-Graphene—A New Opportunity in Drug Delivery Martina Mugnano[1], Giuseppe Cesare Lama[2], Rachele Castaldo[2], Francesco Merola[1], Gennaro Gentile[2], Veronica Ambrogi[3], Piero Cerruti[2], Pasquale Memmolo[1], Vito Pagliarulo[1], Pietro Ferraro[1] and Simonetta Grilli[1]; [1]Institute of Applied Science & Intelligent Systems 'E. Caianiello', National Council of Research of Italy (ISASI-CNR), Italy; [2]Institute for Polymers, Composites and Biomaterials, National Council of Research of Italy (IPCB-CNR), Italy; [3]University of Naples Federico II, Italy

The perspective of using graphene and its derivatives in bionanotechnology opens innovative and fascinating scenarios in the future of biomedicine for drug delivery, DNA sensing, protein assays, tissue engineering and cell imaging studies. For these purposes, there is an increasing interest in shedding light on the interaction mechanisms of graphene oxide (GO) live matter. In fact, the effects on human health of GO, and on cytotoxicity, are still largely unknown. Here we show that, by minimizing the oxidation degree of GO, its toxicity is significantly reduced in mouse fibroblasts. We discover a peculiar internalization of the oxidised nano graphene (nGO) leading to an intriguing nucleus decoration (ND) that could open the route to new opportunities in drug delivery. We demonstrate that it is possible to quantitatively assess the cell morphology during decoration process with nGO by a time-lapse monitoring in phase-contrast digital holography configuration. This study could open the route for further investigations on the use of label-free and quantitative imaging for characterizing the effect of graphene-based nanomaterials and their interactions with biological systems.

2:15 PM *SM04.08.01
Developing Therapeutic Materials to Redirect Cellular Chatter Juliane Nguyen; University of North Carolina at Chapel Hill, United States

An increasing number of studies report that exosomes play critical roles in intercellular communication. While exosomes are essential to maintain physiological conditions, aberrant exosomal communication can lead to the development of cancer, diabetes, and many other diseases. Here we will describe new materials to redirect and modulate cellular communication mediated by exosomes for therapeutic applications. Specifically, we have identified RNA-based materials to modulate exosomal function by repackaging them with different types of cargoes. This presentation will discuss how beneficial exosomal communication can be enhanced for therapeutic purposes.

Nanoscale Metal-Organic Frameworks for Chemoradiation and Radioluminescent Imaging Megan Neufeld[1], Allison DuRoss[1], Madeleine Landry[1] and Conroy Sun[1,2]; [1]Oregon State University, United States; [2]Oregon Health & Science University, United States

Metal-organic frameworks (MOFs) have emerged as promising functional biomaterials for a wide range of applications in drug delivery and biomedical imaging. In particular, nanoscale MOFS (nMOFs) have drawn significant attention as novel therapeutic agents in oncology both as drug carriers and as stimuli-responsive materials. Here we present our recent findings utilizing nMOFs as a multipronged radiosensitizer for chemoradiation in breast and colorectal cancer models. Through incorporation of high-Z elements, such as Hf, we demonstrated an enhanced physical radiation dose deposition observed though increased production of reactive oxygen species generation and subsequent DNA double strand breaks in X-ray irradiated cells. Coupled with delivery of DNA repair inhibitors, such as talazoparib (PARPi), we found improved control of tumor growth when employing nMOFs with radiation therapy (RT). We further investigated the integration of functional coatings, including fucoidan targeting P-selectin expression, to improve delivery of these nanomaterials during fractionated RT. In addition, we describe here the interaction of X-rays with lanthanide-based nMOFs to serve as energy mediators in deep tissue photodynamic therapy (PDT) or molecular probes in radioluminescence imaging. Detailed physiochemical characterization and in vivo toxicity data will be presented to promote discussion on clinical translation challenges of these novel materials.

3:05 PM SM04.08.03
Late News: 3D Printing of Spatiotemporally Controlled Drug Delivery Dental Device Valentine M. Berger, Zhi Luo and Jean-Christophe Leroux; ETH Zurich, Switzerland

Sustained and localized drug delivery in the oral cavity remains an important challenge in pharmaceutical sciences.[1] Currently, existing self-applied dosage forms such as gels, toothpaste or mouthrinses are rapidly washed away after administration, resulting in modest efficacy and thus require repeated applications. Therefore, oral devices that fit precisely patient's anatomy[2] with spatiotemporally controlled drug release profiles represent a promising approach to improve drug delivery in the oral cavity. Here, we demonstrate how the 3D printing of drug-polymer composite materials could be utilized to achieve this goal. Thanks to the possibility of printing complex 3D geometries with multiple materials[3], the fused deposition modelling (FDM) technique was chosen to fabricate personalized mouthguards that allow local and prolonged elution of drugs. As a model drug compound, sodium fluoride (NaF), a salt commonly used to prevent tooth decay, was combined with a variety of polymer mixtures containing different ratios of poly(ε-caprolactone), poly(ethylene glycol) and poly(vinyl alcohol). Composite filaments with tunable hydrophobicity were then produced from the blends of thermoplastics with varying loads of NaF and fed into the FDM printer. The mechanical properties were assessed with standard tensile testing to confirm the suitable toughness and durability of the printed materials. *In vitro* dissolution studies further demonstrated the tunable release kinetics of the devices.

Finally, toothguard models that fit precisely the geometries of human teeth were designed after 3D scanning of the specimens and were then printed in high resolution. To evaluate the therapeutic effects of the devices, the toothguards were used *ex-vivo* on the decayed teeth for 7 days. The lesion was characterized by scanning electron microscopy and the fluoride incorporation was measured by energy-dispersive X-ray spectroscopy. A significant elevation of fluoride contents in the enamel was found in the specimen in contact with the fluoride-loaded devices compared with the one in contact with simple control solutions. In conclusion, the data show that a slow and local drug release of fluoride could improve the buccal delivery of therapeutic compounds.

3:20 PM SM04.08.05
Late News: Dissecting How Cells Internalize and Process Nano-Sized Drug Carriers for Nanomedicine Applications Anna Salvati; University of Groningen, Netherlands

Nano-sized materials have the unique capacity to distribute in organisms and enter cells easily using cellular pathways. This has opened up tremendous opportunity in nanomedicine for the use of nano-sized carriers to deliver drugs more efficiently to their site of action. However, the molecular details of the mechanisms of uptake and intracellular trafficking of nano-sized materials are in most cases still not clear. Such knowledge could allow us to further improve the design of truly targeted nanomedicines.
To this aim, we have combined the use of transport inhibitors and RNA interference with proteomic based methods to identify the cell surface receptor interacting with nano-sized materials and characterize the mechanisms by which they are internalized by cells.[1,2] Additional efforts have been focused on developing *in vitro* endothelial cell barriers more closely resembling the barriers nanomedicines encounter *in vivo*.[3] Uptake and distribution of nanoparticles have also been studied in precision cut tissue slices from the major organs in which nanoparticles distribute, such as the liver, lungs and kidneys, as an advanced *ex vivo* 3D model.[4,5]
Our results show that the same cells process nanoparticles in different ways when they are developed into an endothelial cell barrier rather than at different degrees of cell density, as commonly applied for *in vitro* studies.[3] Furthermore we show that liver tissue slices allow to resemble *ex vivo* some of the major outcomes of *in vivo* distribution studies, i.e. the preferential accumulation of nanoparticles by Kupffer cells, the liver macrophages.[4] Finally, we show that the corona molecules adsorbing on the nanoparticle surface once applied in serum or plasma can be recognized by specific cell receptors, and they can also affect the details of the following uptake mechanism by cells.[6] Thus, in other words, the same nanoparticles enter cells via different pathways when different coronas are formed on their surface. Using liposomes of different composition, we also show how the composition of the corona forming in serum can be tuned, thus affecting uptake efficiency and uptake kinetics.[7]

Late News: Controlling Porosity and Protein Release Profile of Nanofibrillar Chitosan Scaffolds

Muhammad Haji Mansor[1,2], Jean-Michel Thomassin[1], Alain Colige[1], Emmanuel Garcion[2], Frank Boury[2] and Christine Jerome[1]; [1]Univ de Liege, Belgium; [2]Université d'Angers, France

Chitosan is an abundantly common, naturally occurring, polysaccharide biopolymer. Its biocompatible, biodegradable, and antimicrobial properties have led to significant research toward biological applications such as drug delivery, artificial tissue scaffolds for functional tissue engineering, and wound-healing dressings. For applications such as tissue scaffolding, formation of highly porous mats of nanometer-sized fibers, such as those fabricated via electrospinning demonstrated high potentials.

In this framework, we have as first objective to control better the scaffold porosity by decreasing the fiber density while keeping enough mechanical performances to be handled and implanted. By playing on the design of the collector used for electrospinning, we have developed structured fiber mats that meet both targeted high porosity and mechanical resistance properties.

In a second objective, strategies have been developed allowing proteins encapsulation within the chitosan scaffolds for locoregional release. The electrospinning process has been optimized in order to preserve the protein integrity and its biological activity. Various release profiles of the protein have been achieved from the structured electrospun scaffolds. A sustained release has been obtained by the use of proteins loaded poly(lactic-co-glycolic acid) (PLGA) nanoparticles [1].

The developed electrospinning process allowing both the precise control of the porosity and of the release profile of a protein will be useful for elaborating porosity and concentration gradients which are critical when developing biomimetic scaffolds aiming to control cell migration and trapping.

Long-Acting Parenteral Products for Global Health—Challenges and Opportunities Dennis Lee[1,2]; [1]Bill & Melinda Gates Foundation, United States; [2]Global Health, United States

Daily drug regimen adherence is a widespread challenge for individuals living in all countries. For those in low and middle income countries (LMICs), there is an added layer of complexity due to a number of systemic factors, including poor access to medications in rural areas in combination with a shortage of healthcare workers and facilities, weak supply chains, and the challenge of “last mile” transportation. The lack of infrastructure in LMICs presents further challenges for product development. Cold chain is sporadic and often absent, and electricity often is not reliable or available. Hence, there is a need for products that provide long-term shelf stability at ambient temperatures. The Gates Foundation has built a broad portfolio of long-acting drug delivery technologies that address these several of these issues and have the potential to increase uptake of essential medicines. These investments span a spectrum of materials science approaches and support a diverse

array of use cases in HIV prevention and family planning contraception.

5:40 PM *SM04.09.02
***In Situ* 3D-Patterning of Electrospun Fibers Using Two-Layer Composite Materials** Kim Woodrow; University of Washington, United States

Polymeric electrospun nanofibers have extensive applications in filtration, sensing, drug delivery, and tissue engineering that often require the fibers to be patterned or integrated with a larger device. Here, we describe a highly versatile in situ strategy for three-dimensional electrospun fiber patterning using collectors with an insulative surface layer and conductive recessed patterns. We show that two-layer collectors with pattern dimensions down to 100-micrometers are easily fabricated using available laboratory equipment. We use finite element method simulation and experimental validation to demonstrate that the fiber patterning strategy is effective for a variety of pattern dimensions and fiber materials. Finally, the potential for this strategy to enable new applications of electrospun fibers is demonstrated by incorporating electrospun fibers into dissolving microneedles for the first time. These studies provide a framework for the adaptation of this fiber patterning strategy to many different applications of electrospun fibers.

Malleable Hydrogel Containing Micellar Cargo-Expellers for Prompt Transdermal Patch Sung-Ho Shin[1,2], Youngho Eom[3], Eun Seong Lee[4], Sung Yeon Hwang[1,5], Dongyeop X. Oh[1,5] and Jeyoung Park[1,5]; [1]Korea Research Institute of Chemical Technology, Korea (the Republic of); [2]Purdue University, United States; [3]Pukyong National University, Korea (the Republic of); [4]The Catholic University of Korea, Korea (the Republic of); [5]University of Science and Technology, Korea (the Republic of)

Hydrogels, water-swollen cross-linked polymeric networks, resemble natural soft tissues (e.g. skins) more than any other types of materials including silicones. They are representative soft biomedical materials in terms of a high water content over 70%, good biocompatibility, low foreign body sensation, and favorable capacity of water-soluble molecules. In this regard, hydrogels are promising materials for drug delivery system as the form of patches, contact lens, and synthetic skins. As a platform for drug delivery, simultaneously accomplishing the fast delivery of a drug and shape conformity of a hydrogel can find its use of pharmaceutical or cosmetic patches. However, there exists the trade-off between the liquid and solid properties that the liquid medium like eye-drops rapidly releases a drug but cannot be used as a patch on human skins, whereas a solid-state hydrogel realizes the stable drug delivery platform but inevitably exhibits a slow release of the drugs.
Herein, a malleable and biocompatible hydrogel containing micellar cargo-expellers was prepared. The *in situ* polymerization of poly(hydroxyethyl methacrylate) (PHEMA) within the poly(vinyl alcohol) (PVA)-borax hydrogel matrix produces large compound micelle particles (micelles) that are not bound by the matrix. Notably, as the micelles do not form any chemical crosslinks with the matrix, they rapidly release outside of the hydrogel network in a wet condition. The micelles act as cargo-expellers through a concentration gradient, which delivers a 25-fold larger quantity of a model cargo than the control hydrogel. Also, the dynamic borate-diol bonds of the hydrogel matrix engender the hydrogel with self-healing properties, and mechanical shock-absorbing property of micelles enables the hydrogel to tightly contact highly curved skin. Moreover, biocompatibility of the hydrogel was confirmed by both *in vivo* cytotoxicity and *in vivo* skin irritation tests. Consequently, this malleable hydrogel will inspire novel prompt skin-patch systems for pharmaceutical and cosmetic purposes. [1]

6:20 PM SM04.09.04
Late News: A Platform for Macrophage-Mediated Delivery of Polymeric Prodrugs to Solid Tumors Ciana L. Lopez[1,2], Katherine J. Brempelis[2], James F. Matthaei[2], Kate S. Montgomery[1], Selvi Srinivasan[1], Debashish Roy[1], Shannon Kreuser[2], John Chiefari[3], Courtney A. Crane[2] and Patrick S. Stayton[1]; [1]University of Washington, United States; [2]Seattle Children's Research Institute, United States; [3]CSIRO Manufacturing,

Australia

Current approaches for drug delivery to solid tumors like glioblastoma are insufficient. Delivery of passive- and active-targeting nanomaterials is diffusion-limited, hindered by heterogenous tumor vasculature, and has resulted in few improvements to the standard of care for rapid and lethal disease. Macrophages readily survey solid tumors and are actively involved at all stages of tumor development. Here we introduce genetically engineered macrophages (GEMs) with a fully bioorthogonal, genetically encoded receptor capable of loading with polymeric prodrugs (referred to as 'drugamers') in a titratable manner. These RAFT-based polymers are multi-functional: affording biocompatibility, solubility, and sustained release of a small molecule drug cargo. Using the PI3K inhibitor, PI-103, as a model drug, we demonstrate how our polymeric formulation's optimized release kinetics compliment the drug's mechanism of action, leading to improved and sustained activity against cancer cells. Furthermore, our drugamer-loaded GEM platform introduces a new cell-mediated and kinetically regulated mechanism for delivery of small molecule drugs to tumors. We have previously demonstrated that GEMs home to and persist in tumors following both intratumoral and intravenous delivery, suggesting the potential of this cellular therapeutic to be administered intravenously to localize to single sites or even metastases.

Boosting Intracellular Delivery of Messenger RNA Gaurav Sahay; Oregon State University, United States

Endosomal sequestration of lipid-based nanoparticles (LNPs) remains a formidable barrier to intracellular delivery of mRNA. Herein, structure-activity analysis of cholesterol analogues reveals that incorporation of C-24 alkyl phytosterols into LNPs (eLNPs) enhances gene transfection and the length of alkyl tail, flexibility of sterol ring and polarity due to -OH group is required to maintain high transfection. Cryo-TEM displays a polyhedral shape for eLNPs compared to spherical LNPs, while x-ray scattering shows little disparity in internal structure. eLNPs exhibit higher cellular uptake and retention, potentially leading to a steady release from the endosomes over time. 3D single-particle tracking shows enhanced intracellular diffusivity of eLNPs relative to LNPs, suggesting eLNP traffic to productive pathways for escape. Our findings show the importance of cholesterol in subcellular transport of LNPs carrying mRNA and emphasize the need for greater insights into surface composition and structural properties of nanoparticles, and their subcellular interactions which enable designs to boost intracellular delivery of mRNA. I will briefly discuss three applications of LNPs to deliver mRNA i.e. for the treatment of cystic fibrosis, retinal degeneration and COVID-19 therapeutics.

8:00 AM SM05.01.04
Late News: Selective Laser Sintering Process of Tungsten Oxide (WO3) Thin Films for Electrochromic Applications Jinhyeong Kwon[1], Hyunmin Cho[2], Jinki Min[2], Daeyeon Won[2] and Seung Hwan Ko[2]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

A selective laser sintering (SLS) process has opened a novel patterning way for advanced electronic applications. The SLS process bases on the photothermal effect and features for high precision, fast processing, and room temperature accessibility without inert gas. Therefore, the effectiveness of the interaction between the nanomaterials and laser has examined the various conductive metal nanomaterials such as gold, silver, and copper. Although the laser sintering process has shown many achievements on metal nanomaterials, it has rarely studied for the interaction for the metal oxide nanomaterials. In this study, WOx thin film layer employs the SLS process for post-processing which enables patterning and annealing simultaneously with inducing photochemical reaction as well as photothermal effect. The SLS-processed WOx thin film has shown similar electrochemical performances for the electrochromic application to the thermal annealed WOx thin film. We have established facile and fast fabrication for electrochromic devices with the SLS-processed WOx thin film layer and demonstrated feasibility for the indoor temperature controllable feature.

8:05 AM SM05.01.05
Shape Controllable Building Blocks for 3D Collective Assembly via Residual Stress Design Woongbi Cho[1,2], Dong Gyun Kim[3], Yong Seok Kim[3] and Jeong Jae Wie[1,2]; [1]Inha Univerisity, Korea (the Republic of); [2]Inha University, Korea (the Republic of); [3]Korea Research Institute of Chemical Technology, Korea (the Republic of)

In nature, the collective assembly is often observed which enrich the structural and functional diversities. For example, DNA for various creatures consist with double helix architecture via collective assembly of only 4 distinct types of building blocks (Adenine, Guanine, Cytosine, Tymine). The hierarchical structures via collective assembly can highly release the limitations on geometries and functionalities through a spatial arrangement of diversely designed 3D building blocks. In this presentation, geometrically tailorable 3D building blocks are introduced by controlling residual stress with rapid and reproducible fabrication without complicate and/or expensive equipment. Frontal photopolymerization (FPP) with variously designed photomask and different curing time are employed for spatiotemporal regulation of photopolymerization. The employed photocurable resin is composed of bio-compatible poly(ethylene glycol)diacrylate (PEGDA) matrix, photo-initiator and photo-absorber. The photo-absorber generates drastic gradient of light intensity during the photopolymerization, resulting in a residual stress via crosslinking density mismatch through the thickness. When the photopolymerization is terminated, a curvilinear 3D shape morphing occurs within 1 min as a result of shrinkage mismatch induced by immediate relaxation of the residual stress. The geometries of 3D building blocks are programmed by systematic change of spatiotemporal conditions of pre- and post-curing. The 3D

morphed structures are hierarchically assembled to achieve self-similar scaled-up structures inspired by designs of famous landmark (e.g. the great pyramid in Giza). The regularly stacked geometry allows 3D assembled structure to withstand 150 times of its own weight by homogeneous distribution of normal stress. Furthermore, the electrically conductive property is rendered to 3D assembled structural by applying conductive silver pastes on the 3D layered structures. Hence, our design strategy of tailorable 3D building blocks for collective assembly can be a promising candidate for prototyping several platforms of electronics, optics, and metamaterials.

8:10 AM SM05.01.06
Magnetic Collective Swimming of Bioinspired Ternary Nanocomposites Sukyoung Won[1], Hee Eun Lee[1], Young Shik Cho[2], Jeong Eun Park[1], Seung Jae Jang[1] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Stimuli-responsive unary materials and binary composites have employed for actuation of soft robots. However, collective motion of multiple soft robots is challenging when stimuli-responses are implemented without batteries and sensors. Herein, we present magnetic collective swimming of ternary polymeric nanocomposites capable of adaptably organizing. Core-shell design of nanoporous carbon nanotube yarn (CNTY) and magnetic particles is inspired by skeletal muscles surrounding spongy bone in musculoskeletal system. The magnetic particles are attached to the CNTY owing to sol-gel polymerized elastomers providing the function of connective tissue. The polymeric soft robots swim with multimodal motility of rectilinear translational motion and rotational motion under a rotating quadrupolar electromagnetic field. Multiple soft robots can be adaptably organized through magnetically interactive dynamic soft joints when varying the rotational frequency of the magnetic field. We will discuss collective swimming of modular soft robots that transport 850 microbeads above water and a semi-submerged milli-bead.

8:15 AM SM05.01.07
Late News: Cross-Reactive poly(ethylene oxide) and poly(ε-caprolactone) Stars Towards Covalent Adaptative Networks Exhibiting Water and Temperature Triggered Shape-Memory Properties Jérémie Caprasse, Jean-Michel Thomassin, Raphaël G. Riva and Christine Jerome; University of Liege, Belgium

Covalent networks of semi-crystalline poly(ε-caprolactone) (PCL) are highly performant shape-memory materials (SMM) i.e. high fixity of the temporary shape and high recovery of the thermally triggered permanent shape. Being in addition biocompatible and degradable, applications in the biomedical field are foreseen. Advantageously, inserting reversible bonds in the network, adaptative materials are obtained which allows reconfiguration of the permanent shape while preserving the shape memory properties at the body temperature [1].
As an answer to the increasingly demanding biomedical field, we aim at providing to such covalent adaptative networks, an additional shape transition triggered by the presence of water at constant temperature. For this purpose, poly(ethylene oxide) has been selected as a hydrophilic component introduced in the PCL networks.

In the present work, a covalent adaptative PEO/PCL hybrid network is formed by Diels-Alder reaction between PCL and PEO stars purposely end-capped by maleimide and furan, respectively. After melt-mixing of these cross-reacting stars and a post-curing, the resulting covalent adaptable hybrid networks shows high crosslinking density, as demonstrated by swelling experiments while preserving enough crystallinity to exhibit high thermal triggered shape-memory performances that remain as good as the ones of PCL covalent networks. Thanks to the insertion of furane-maleimide Diels-Alder adduct in the covalent networks, this material can be recycled by solvent-free hot-melt reprocessing and the permanent shape of this SMM can be reconfigured, e.g. by using mold of a complex shape. In addition, water triggered shape transition was evidenced allowing to achieve medical devices of complex shapes exhibiting in vivo self-deploying properties.

8:20 AM SM05.01.08
Late News: Silicon Nanowires Decorated with Gold Nanoparticles—Synthesis and Analytical Characterization Margherita Izzi[1,2], Rosaria Anna Picca[1,2], Antonio A. Leonardi[3,4], Maria J. Lo Faro[3,4], Maria C. Sportelli[1], Alessia Irrera[4] and Nicola Cioffi[1,2]; [1]University of Bari Aldo Moro, Italy; [2]CSGI (Center for Colloid and Surface Science) c/o Dept. Chemistry, University of Bari, Italy; [3]University of Catania, Italy; [4]IPCF-CNR, Italy

Hybrid nanomaterials combining semiconductor and metal nanostructures represent an efficient way to develop novel platforms for advanced applications, ranging from sensing to catalysis [1–3]. In particular, silicon nanowires (SiNWs) are a promising host matrix for the dispersion of metal nanoparticles (MeNPs). They exhibit excellent characteristics such as large surface area, relatively high mechanical stability and low cost [4]. SiNWs are prepared by a wet-etching technique, assisted by the deposition of an ultrathin metal film on (p-, n-doped or highly doped) Si single crystal. SiNWs with very high density and controllable aspect ratios can be obtained. In the last years, we have studied the decoration of the proposed SiNWs with different MeNPs, including gold, by pulsed laser deposition [2,3]. This technique allows for loading "naked" NPs on the NWs. As alternative approaches, wet-methods can be used to decorate the semiconductor nanostructures. In this communication, we report on the modification of SiNW platforms with chemically produced AuNPs by electrophoretic deposition (EPD). We exploit an innovative synthesis based on stainless steel as solid reductant for $HAuCl_4$ to prepare AuNPs [5,6]. This method is very easy, quick, cost-effective, and scalable, allowing the synthesis of highly stable NPs without additional capping agents [6]. Pros and cons of EPD of preformed NPs will be highlighted in comparison with direct reduction of gold precursor on SiNW surface. The role of silicon doping will be investigated in combination with the charge of AuNP surface to evaluate their influence on final material properties. To this aim, electrochemical, spectroscopic and morphological characterizations will be proposed.

8:25 AM SM05.01.09
Inkjet Printed Nanodielectrics for High-Energy Microcapacitors Jinkai Yuan, Fernando Torres-Canas and Philippe Poulin; Centre de recherche Paul Pascal, France

Micro-energy storage devices are appealing, and highly demanded for diverse miniaturized electronic devices, ranging from microelectromechanical system, robotics, to sensing microsystems and wearable electronics.[1,2] However, making high-energy microcapacitors with currently available printing technologies remains

challenging. Herein, we show the possibility to use latex polyvinylidene fluoride (PVDF) as aqueous ink for making dielectric capacitors on the microscale. The dielectric properties of printed microcapacitors can be optimized based on a novel approach, i.e., mixing PVDF latex with polyvinyl alcohol (PVA) to realize dielectric organic nanocomposites. The PVA prevents the coalescence of PVDF nanoparticles and serves as a continuous matrix phase with high dielectric breakdown strength. While the well-dispersed PVDF nanoparticles serve as highly polarizable and isolated domains, providing large electric displacement under high fields. Consequently, a high discharged energy density of 12 Jcm^{-3} is achieved at 550 MVm^{-1}. [3] These printed microcapacitors demonstrate mechanical robustness and dielectric stability over time.

8:40 AM SM05.01.10
Digital Microfluidic Activated by Physical Intelligence Sara Coppola, Veronica Vespini and Pietro Ferraro; Institute of Applied Sciences and Intelligent Systems “E. Caianiello”, Italy

Robots and intelligent systems will be the key factor of Industry 4.0 revolution for aiding at any stage engineering and manufacturing processes. One of the most challenging demanded issue is to make available appropriate tools for full control of liquids. In fact, the manipulation of the liquid matter is of strategic importance in many procedures and facilities involving many fields of applications i.e. biomedicine, biotechnologies, food, cosmetics, just to cite few. Liquids, polymers and more in general soft-matter requires even more accurate, precise and full controlled handling apparatuses. So far, several engineering methods have been proposed for furnishing intelligent responses to environmental changes in order to drive liquids by external magnetic, electric or optical fields. However, until now, very few and shy approaches for locomotion and remote control have been featured to manage liquid actuation. The design of innovative portable devices, working in non-contact mode, easy to use, totally safe for the medical staff and based on handling of small amount of reagent and liquid to be analysed, is certainly a strategic ambition for all the researchers, scientist and industries all over the world. Actually, most of the systems in use are made of rigid components, not friendly, unable to self-adapt to various configurations and most important require the manual intervention by the operators (i.e. classical manual pipetting) so exposed to cross-contamination problems. Here we introduce a new working principle for liquid manipulation and a complete exploration of the opportunities of a multipurpose platform guided by physical intelligence, enlarging the opportunity of liquid handling via pyro-electrohydrodynamics (EHD). The platform is able to handle liquid volumes by reacting to thermal external stimulus on a functionalized substrate (i.e. ferroelectric crystal). The innovation consists in creating a multiscale digital microfluidic system for handling small amount of liquids and multiphase samples with volumes in a wide range from microliter to milliliter, in air and in three-dimensions. In fact, the huge electric field generated via the pyroelectric effect allows to manage the on/off activation system of the pyro-Electro-Hydro-Dynamic driving force for commanding a fast response in a smart way and for easily moving units of liquid with different size and volumes. We prove remote locomotion of liquid volume as a sort of tweezers able to move liquids along desired paths. Beyond the guiding property, we proved also additional functionalities like merging, stretching, mixing and jumping of liquid volumes and millimeter objects using a working distance of millimeter, i.e. bigger than the conventional distances used for liquid handling in classical digital microfluidic.

8:55 AM *SM05.01.11
Rapid Synthesis of Elastomers and Thermosets with Tunable Multifunctional Properties Nancy R. Sottos, Leon Dean, Qiong Wu and Jeffrey Moore; University of Illinois at Urbana-Champaign, United States

Frontal polymerization (FP) has emerged as a promising technique for rapid, energy-efficient preparation of

bulk polymeric materials in ambient conditions without solvents. In FP, the monomer is converted to a polymer within a localized reaction zone that propagates spatially as a consequence of heat transfer from the exothermic polymerization to unreacted monomer. FP requires a minimal amount of energy to initiate the process, after which the polymerization front continues to propagate without further energy input. In this talk, we report the rapid, solvent-free synthesis of poly(1,4-butadiene) by FROMP of neat 1,5-cyclooctadiene (COD). Moreover, we find that FROMP of comonomer mixtures of COD and dicyclopentadiene (DCPD) produces mechanically robust cross-linked polymeric materials having a wide range of properties, from soft elastomers to rigid thermosets, which are tuned simply by varying the comonomer ratio. We use the ability to spatially control copolymer composition to rapidly fabricate materials with spatially varying properties capable of multistage shape memory actuation. By triggering instabilities in the front propagation, we can also create materials with complex gradients in materials properties.

Evolutionary Design of Cactus-Inspired Soft Robotics Based on 3D-Printed Multi-Material Construct
Anil K. Bastola[1], Marc Behl[1], Patricia Soffiatti[2], Nick P. Rowe[3] and Andreas Lendlein[1,4]; [1]Institute of Biomaterial Science, Helmholtz-Zentrum Geesthacht, Germany; [2]Federal University of Parana State, Brazil; [3]AMAP, Univ Montpellier, CIRAD, CNRS, INRAE, IRD, France; [4]Berlin-Brandenburg Center for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany

Nature is a magnificent source of inspiration to develop new technologies. The evolutionary development of plants leads to functional traits that can anchor, twine, vine, or search. An interesting representative in this context is *Selenicereus setaceus*, a cactus found in the Atlantic forest of Brazil capable of climbing[1]. Such biological functional system can serve as a source for bio-inspired robots with the potential ability to anchor, attach, and climb [2, 3]. We questioned how the process of development could be a shortcut to different forms. Our approach is the evolutionary design of a multi-material system inspired by the cactus. *Selenicereus setaceus* demonstrates a unique structural configuration along the different stages of the growth: the stem is circular at the base while the younger parts are star-like in shape at the apex. The cactus consists of soft tissues surrounded by a thin skin layer. The capability of transformation in shape not only optimizes its flexural rigidity but also provides flexibility to allow the cactus to search for light in the challenging environment of the seasonally dry Atlantic forest.
In our design concept for this evolutionary cactus-inspired artificial system, we selected the unique geometry, a star-like shape, of the cactus at the apex. Such a unique shape is 3D printed using a soft elastomeric polymer. Another soft material, a water-swollen polymer, hydrogel, is synthesized on the 3D printed structure. Herein, we demonstrated two developments directly inspired by the functional traits of the cactus. In the first, we demonstrated a controlled movement similar to the searcher component of the natural cactus, when the humidity is changed the hydrogel-elastomer system could bend toward low humidity through anisotropic swelling and de-swelling of the hydrogel. In the second, we demonstrated the change in geometry from star-like to circular shape, as the natural cactus does in nature as it grows, partly by means of isotropic swelling and de-swelling of the hydrogel. These evolutions show the possibility that we can directly learn from the behavior and structural configurations of plants to develop functional artificial systems. We hope that this study stimulates the design of novel plant-inspired ecological robotic systems.

12:00 PM SM05.02.03
Fabrication and Characterization of Ferromagnetic Organic Semi-Crystalline Polymers Scott Newacheck[1,2] and George Youssef[1]; [1]San Diego State University, United States; [2]University of California, San Diego, United States

Multifunctional material systems are breaking the elusive boundaries between functions previously deemed independent, necessitating a composite approach but with inferior response. While research in multifunctional materials for magnetoelectric coupling is thriving, polymeric (or organic) multiferroics are lagging behind due to several processing, characterization, and performance challenges. Commonly trending organic multiferroics exhibit lower magnetoelectric properties than their composite oxide-based counterparts, but report a measureable coupling at room temperature, positioning them as a superior class of materials in comparison to intrinsic single phase multiferroic materials. The latter has a diminished response at room temperature, deeming them impractical for any translational applications. The magnetoelectric response of organic multiferroics, on the other hand, can be further enhanced through the addition of mechanical or photonic energies. However, organic multiferroics suffer from complex phasic structure consisting of multiscale crystalline phases surrounded by amorphous regions, which can be tuned based on fundamental understanding of the process-structure-property interrelations. Thus, the objective of this research is to characterize a blend organic framework with multiferroic properties to elucidate the interdependence of the properties on the processing approach. Here, regioregular poly(3-hexylthiophene) polymer (P3HT) is blended with organic compound phenyl-C_{61}-butyric acid methyl ester (PCBM) to synthesize an excitonic multiferroic polymer with tunable properties. The structure of P3HT consists of a crystalline phase surrounded by amorphous regions, while PCBM forms nanocrystalline aggregates. The interrelationship between primary processing parameters, including the concentration of P3HT and the ratio of P3HT to PCBM, are discussed as a function of triphasic structure. The ferromagnetic polymers were characterized for their photomagnetic, piezomagnetic, and mechanical properties using a modified vibrating sample magnetometer with illumination source matching the absorbance band of the blend polymer and a mechanical loading mechanism. Overall, this study reports the first process-structure-property map of the blend P3HT:PCBM organic framework for magnetoelectric coupling, which will accelerate translation applications in flexible and wearable electronics. Future research will focus on multiscale characterization of the interaction between the boundaries separating the amorphous and crystalline phases of P3HT and the interfaces between P3HT and PCBM.

12:15 PM SM05.02.04
Harnessing Instabilities During Frontal Polymerization for Patterning Justine E. Paul, Julian C. Cooper, Anisha Sharma, Jeffrey Moore and Nancy R. Sottos; University of Illinois at Urbana-Champaign, United States

We have developed a new approach to manufacturing thermoset materials with complex morphology and function using frontal ring-opening metathesis polymerization (FROMP). Propagation of uniform fronts enables rapid, efficient fabrication of neat polymers and composites. In this work, we explore the instabilities that arise during FROMP, which lead to non-uniform front propagation and complex patterns and property gradients within the material. We utilize the synthetic reaction-thermal diffusion system that arises from the FROMP of dicyclopentadiene (DCPD), 5-ethylidene-2-norbornene (ENB), and 1,5-cyclooctadiene (COD) to take advantage of the positive and negative feedback loops for patterning. Spontaneous pattern formation is achieved in an open mold geometry which causes non-uniform front propagation and gives rise to the competition between thermal transport and reaction rates. The effects of boundary conditions, co-monomers, chemical inhibitors, and energy inputs are investigated and monitored visually using an infrared camera. By tuning the reaction kinetics, ambient temperature, and thermal initiation conditions, we achieve a spin mode propagation,

causing wavelike surface patterns to develop across the entire length of the material. The wavelength of the surface patterns is systematically varied by adjusting the parameters of the experimental system. By layering co-monomers based on density differences, we achieve materials with functionally graded properties. The thermophysical properties of these functional materials are tunable and highly reproduceable.

12:30 PM SM05.02.05
Stimuli-Responsive 2D Metal-Organic Frameworks Prepared by Chemical Vapor Deposition F. James Claire[1], Marina Solomos[1], Jungkil Kim[1], Gaoqiang Wang[2,3], Maxime Siegler[1], Michael Crommie[2,3] and Thomas J. Kempa[1,1]; [1]Johns Hopkins University, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

The incorporation of metal organic frameworks into advanced devices remains a desirable goal, but progress is hindered by difficulties in preparing high quality, multifunctional metal-organic framework (MOF) films with suitable electronic performance. We demonstrate the direct growth of large-area, high quality, and phase pure single MOF crystals through chemical vapor deposition of a dimolybdenum paddlewheel precursor, $Mo_2(INA)_4$. These exceptionally uniform crystals cover areas up to 8600 μm^2 and can be grown down to thicknesses of 30 nm. Scanning tunneling microscopy indicates that the $Mo_2(INA)_4$ clusters assemble into a two-dimensional, single-layer framework. Devices fabricated from single vapor-phase grown crystals exhibit reversible nearly 10-fold changes in conductivity upon illumination at modest powers. Moreover, we identify vapor-induced single crystal transitions that are reversible and responsible for 30-fold changes in conductivity of the MOF as monitored by *in situ* device measurements. Gas-phase methods, including chemical vapor deposition, show broader promise for the preparation of multifunctional molecular frameworks, and may enable the integration of these materials into devices, including detectors and actuators.

Late News: Design and Fabrication of Hybrid 3D-Printed Conductive Wires on Epoxy Substrates for Self-Sensing Applications Haley Hilborn and H. Jerry Qi; Georgia Institute of Technology, United States

Additive manufacturing (AM) allows for rapid fabrication of complex structures with the advantage of multi-material composition and high structural complexity, or a unique combination of the two. Recently, there is an increasing interest in creating multi-material components which have optimal interfacial interactions between layers. However, the challenge lies with determining optimal compatibility between printed components, and how those influence bulk property of the multi-material structure. Previous investigation of direct-ink write (DIW) printed epoxy-silver composite structures did not produce conductive parts. Therefore, we study silver conductive ink material composition and compatibility with epoxy, including interfacial connections and layer-by-layer material adhesion. As a result, an optimal material for multi-functional composite parts was developed for a variety of thermal, mechanical and electrical applications. Electronics such as strain gauges and light sensors were DIW 3D printed. Additionally, we demonstrate a deicing unit for potential use on an aircraft, such as unmanned aerial vehicle (UAV) wings. Thus, utilizing material science, we solve material compatibility issues that frequently arise when 3D printing multi-material components, eliciting desired features within a printed part.

Multi-Phase Multifunctional Materials that Sense Mechanical Loading and Adapt Sung H. Kang; Johns

Hopkins University, United States

Bone is a multi-phase multifunctional material that can sense the mechanical loading and adjust itself by adding more minerals to the region of high stress and reducing them to the low stress region so that it can increase the efficiency and lifespan of the material. However, it has been a challenge to synthesize load-bearing materials with such capabilities. Inspired by bone mineralization mechanisms, we have investigated a multi-phase material system that self-senses mechanical loading and proportionally triggers mineral formation from media with mineral ions so that the material can mitigate damages and increase lifespan. The mineralization rate within the material system is autonomously modulated in response to changing loading conditions, resulting in a 30-180% increase in the modulus of the material upon 1 to 5 N cyclic loadings. Moreover, the multifunctional material adds more minerals to the region of high stress and vice versa for that of low stress so that the material can mitigate the damage and enhance its lifetime. We envision that our findings can open new strategies for making synthetic multifunctional materials with self-adaptable mechanical properties.

Grayscale Digital Light Processing Enabled 3D/4D Printing for Multimaterial Multifunctional Composites H. Jerry Qi, Xiao Kuang and Stuart M. Montgomery; Georgia Institute of Technology, United States

Digital light processing (DLP) based 3D printing is an additive manufacturing process which utilizes light patterns to photopolymerize a liquid resin into a solid. Due to the accuracy of modern digital micromirror devices (DMD) and a layer of thin resin being cured rapidly (1-5s), DLP has the advantage of high speed and high resolution. However, conventional DLP method is not suitable for multimaterial printing because it uses a single vat of resin. Recent advances in resin chemistry now make it possible to create functionally graded structures using different light intensity values, also known as grey-scale DLP (g-DLP). In this talk, we present some our recent efforts in using g-DLP to 3D/4D print multimaterial multifunctional composites, including creating functionally graded materials with modulus spanning three orders of magnitude, creating inflatable structures. As digitally graded light pattern can impose concentration gradients upon the different reacting chemical species, which in turn can cause diffusion of these components throughout both the liquid resin and the solidified regions. This effect can affect both spatial resolution as well as physical property resolution in g-DLP printing. In this talk, we will briefly present a reaction-diffusion model coupled with radiative transfer to analyse the effects of component diffusion and its impact upon the resulting mechanical property resolution on a sub-pixel and macro scale. Our aim is to accurately model the underlying physics along with additive manufacturing process to quantify these phenomena and use the information gained to optimize printing parameters such as light exposure time, grey-scale distributions, and resin composition.

2:45 PM SM07.07.02
Structural and Electrical Properties of Self-Assembled Monolayers on Germanium as Passivating and Insulating Layers Mohamed-Amine Guerboukha[1], Virginie Gadenne[1], Hela Mrezguia[2], Luca Giovanelli[2], Younal Ksari[2], Guillaume Monier[3], Victorien Jeux[4], Jean-Manuel Raimundo[5] and Lionel Patrone[1]; [1]Aix Marseille Univ., Université de Toulon, CNRS, IM2NP UMR 7334, Yncréa Méditerranée, ISEN-Toulon, France; [2]Aix Marseille Univ., Université de Toulon, CNRS, IM2NP UMR 7334, Domaine de St Jérôme, Service 151, France; [3]Univ Clermont Auvergne, CNRS, SIGMA Clermont, Inst Pascal, France; [4]ESCOM Chimie, France; [5]Aix Marseille Univ, CNRS, CINaM UMR 7325, France

Due to its high intrinsic mobility, germanium (Ge) is emerging as a likely alternative material to replace silicon in the next generation of high-mobility and high-frequency field effect transistors. However, unlike silicon dioxide, Ge oxide is neither stable nor of good quality. Thus, the preparation of an interfacial layer enabling to passivate and insulate Ge surface is still problematic. A promising approach consists in using self-assembled molecular monolayers (SAMs) [1] with high dielectric constant K. In this perspective, the aim of this work is to design new SAMs grafted on Ge exhibiting highly insulating and passivating properties as new high-K self-assembled nanodielectrics [2].
We have studied SAMs of model molecules such as alkylthiols and fluoro-alkylthiols, and of specially synthesized non-charged novel push-pull chromophores bearing electron donor and acceptor groups, separated by a pi-conjugated bithiophene bridge which promotes electron transfer and a subsequent dipole formation [3]. Indeed, due to the alignment of the oriented dipoles promoted by the SAM deposition strategy, such push-pull chromophores have been shown to form highly polarizable insulating films in the literature [2]. We have adapted and developed the original Ge deoxidation/grafting technique in hydro-alcoholic solution [4] and shown that, compared to the usual deoxidizing acid treatment, it gives smoother surfaces and well-organized SAMs, which is proven by ellipsometry, wettability measurements, and scanning probe microscopy analyses. The grafting of alkylthiols and fluoro-alkylthiols on Ge has been performed directly in a single step thanks to the affinity of sulfur with Ge, whereas for the push-pull chromophores designed with a carboxylic anchoring group, we have achieved a two-step grafting with amide bonding on pre-assembled amine-terminated sticking layers. Among the latter, we have demonstrated aminothiophenol SAMs exhibit a better arrangement than cysteamine, with a smooth monolayer film suitable for grafting ordered push-pull SAMs on top. UV-Visible absorption spectroscopy has been carried out to probe push-pull chromophores in solution to determine the concentration limit to avoid aggregation. X-ray photoelectron spectroscopy (XPS) and infrared spectroscopy (FTIR) analyses demonstrate the oxide removal from the Ge surface after the SAM formation process. Statistical electrical analyses of the various SAMs on Ge have been carried out by using eutectic GaIn contacts. With such push-pull SAMs, we have been able to decrease the current by a factor of 10^5 compared to Ge, and 10^4 compared to dodecane SAMs of similar thickness. Results have been analyzed by transition voltage spectroscopy [5], and successfully correlated with spectroscopic analyses of molecular levels, using inverse photoemission spectroscopy and XPS valence band determination for probing the unoccupied and occupied molecular orbitals respectively, as well as with DFT calculations, thus allowing to identify the highest occupied molecular orbital as the level involved in the electronic transport through the push-pull SAM. Dipole formation has also been evidenced in the SAM. Further work will address multilayers of aligned organic push-pull chromophores to increase the overall dipole of the films for enhanced dielectric properties.

3:00 PM SM05.03.04
Magnetic Soft Composites with Multifunctional Shape Manipulations Ruike Renee Zhao; The Ohio State University, United States

Shape-programmable soft materials that exhibit integrated multifunctional shape manipulations, including reprogrammable, untethered, fast,
and reversible shape transformation and locking, are highly desirable for a plethora of applications, including soft robotics, morphing structures, and biomedical devices. Despite recent progress, it remains challenging to achieve multiple shape manipulations in one material system. Here, a novel magnetic shape memory polymer

composite is reported to achieve this. The composite consists of two types of magnetic particles in an amorphous shape memory polymer matrix. The matrix softens via magnetic inductive heating of low-coercivity particles, and high-remanence particles with reprogrammable magnetization profiles drive the rapid and reversible shape change under
actuation magnetic fields. Once cooled, the actuated shape can be locked. Additionally, varying the particle loadings for heating enables sequential actuation. The integrated multifunctional shape manipulations are further exploited for applications including soft magnetic grippers with large grabbing force, reconfigurable antennas, and sequential logic for computing.

3:15 PM *SM05.03.05
Layered Transition Metal Dichalcogenide Assemblies and Nanocomposites Ali Jawaid, Jason Streit, Peter Stevenson, Robert Busch, W. Joshua Kennedy, Jonathan Vernon and Richard A. Vaia; Air Force Research Laboratory, United States

Layered Transition Metal Dichalcogenides (LTMD, MX_2) exhibit metallic, semi-metallic, semiconducting, insulating, or superconducting character depending on chemical composition and structure. Recent high-yield, exfoliation methods (i.e. Redox Exfoliation), which are sonication and surfactant-free, are providing oxidatively-resistant and colloidally-stable dispersions of Group IV-VI TMDs (>14 compositions) at high volume fraction (>10% v/v) in a broad range of polar and anhydrous solvents (e.g. acetonitrile, acetone, alcohols). In addition to expanding the range of surface hybridization chemistries, these methods are transforming approaches to LTMD nanocomposite fabrication, ink formulation, and film processing. These opportunities will be highlighted by examples of multi-functional materials and hetero-structures with unique optical performance for optical filters, GRIN optics, and non-linear absorbers.

3:45 PM *SM05.03.06
Bio-enabled Nanocomposites with Novel Physical Properties Vladimir Tsukruk; Georgia Institute of Technology, United States

Bio-enabled nanocomposites represent a novel class of functional materials, which uses principles of bioinspiration to design hybrid materials and structures with co-assembled biological and synthetic components to bring best of two worlds: versatile functions with responses to mechanical, optical, chemical, and light stimuli and mechanical strength, flexibility, environmental robustness, and scalability (see general reviews [1, 2]). We discuss general principles of organization in most popular biological components frequently explored for bio-hybrid materials including proteins (silk fibroins), polysaccharides (nanocelluloses) and common synthetic components such as metal and semiconducting nanoparticles/nanowires and two-dimensional metal oxides, nanoclays and graphene derivatives. For specific illustrations, we select recent results from our research group on designing flexible and strong nanomaterials with electrical conductivity, actuation, bright emission, and controlled photonic properties. In particular, we demonstrated robust patterned metallized biographene papers from graphene oxide monolayers “glued” by silk fibroins with intriguing biosensing properties and corresponding Kirigami structures with large stretchability and ability to transform from planar to 3D structures. Among most recent results, we reported chiral emission in organized biopolymer photonic films with embedded carbon quantum dots mediated by polymer linkers [3], co-assembly of cellulose nanocrystals with amorphous polysaccharides resulted in the preservation of the original structural colors and intercalation into the interstitial defects of nematic monolayers [4], and stable and robust MXene-silk composites [5].

5:15 PM SM05.04.01
A New 3D Printing for Multiphase-Based Nanocomposites Dharneedar Ravichandran, Yuxiang Zhu, Weiheng Xu, Sayli Jambhulkar and Kenan Song; Arizona State University, United States

3D printing has been known as additive manufacturing, with advantages of flexible design and rapid prototyping over subtractive manufacturing. Current 3D printing on the market includes material extrusion, ink jetting, photopolymer curing, and powder fusion. However, these methods rely on simple blending or premixing to fabricate multiple materials or multiphase composites. As a result, the dispersion quality and interfacial interactions have been a bottleneck to overcome during the layer-by-layer manufacturing that leads to weak properties in 3D printed composites. Our study reports an in-house 3D printer based on multiphase printing that can selectively deposit polymers and nanoparticles within distinct phases. In this way, the particle dispersions and their interactions with neighbor polymer chains can be precisely manipulated. Therefore, the composites will demonstrate improved mechanical and functional properties. We will demonstrate the uses of polyvinyl alcohol (PVA) and polyacrylonitrile (PAN) in this unique multiphase 3D printing. Carbon nanotubes (CNTs) and carbon nanofibers (CNFs) with simple sonication will serve as printing inks. The composite structures (e.g., hierarchies, architectures), thermal transitions (e.g., glass transition or melting), and mechanical properties (e.g., strength and stiffness), as well as the performance of printed systems, will be the focus of our research.

5:30 PM SM05.04.02
Oxide-Mediated Mechanisms of Gallium Foam Formation During Ambient Shear Mixing Processes Wilson Kong[1], Najam U. Shah[1], Taylor V. Neumann[2], Man Hou Vong[2], Praveen Kotagama[1], Michael Dickey[2], Robert Y. Wang[1] and Konrad Rykaczewski[1]; [1]Arizona State University, United States; [2]North Carolina State University, United States

Liquid metals (LMs) based on gallium have been explored as prospective functional materials in soft electronics and wearable technology. LMs are useful in applications which require high electrical and thermal conductivity while remaining mechanically deformable. Their widespread use is hindered by its high surface tension, large density, high cost, and rapid surface oxidation in ambient conditions. Augmentation to its rheology through the addition of solid particles or air bubbles can enable LM to be patterned and dispensed onto different surfaces while reducing the overall LM used [1]. Previous studies have demonstrated the need for particle-induced stabilization of air bubbles for traditional metal foams while gallium foaming can occur through simple stirring in air [2-3]. Furthermore, the mechanism for gallium foam formation during shear mixing in air is currently not well understood. In this work, we elucidate the mechanisms for which this foaming process occurs for liquid gallium and the effects of air entrapment on its density, rheology, and thermal properties [4]. We systematically show the structure-property relationships of gallium foam during shear mixing in air and how the surface oxide contributes to the formation and stabilization of air bubbles. From this, it is revealed that a critical amount of surface oxide fragments is necessary to transition the gallium LM into a foam-like LM. These studies provide fundamental insights into the effects of LM-processing on its material properties and open a pathway for exploring other methods to engineer multifunctional LM soft composites.

5:45 PM SM05.04.03
Field-Assisted 3D-Printing of Functional Composites Tyler Ray[1], Drew Melchert[2], Matthew Begley[2] and Daniel Gianola[2]; [1]University of Hawaii at Manoa, United States; [2]University of California, Santa Barbara, United States

Acoustic forces are an attractive pathway to achieve directed assembly for multi-phase materials *via* additive processes. Programmatic integration of microstructure and structural features during deposition offers opportunities for optimizing printed component performance. Here, we demonstrate that acoustic fields can effectively assemble conductive particles into networks within polymer matrices, whose configuration is modulated prior to curing, to produce 2-D conductive, 1-D conductive, or insulating materials on-demand, all using the same precursor ink. Furthermore, patterning efficient percolated networks in this manner increases conductivity an order of magnitude over conventional dispersed-fiber composites with an order of magnitude lower particle loading, improving printability and allowing versatile orthogonal control of other properties. Although the focus is on electrical conductivity, the approach described is extensible to other transport phenomena. As a relatively material agnostic technique for microstructural control, acoustic-focusing-assisted additive manufacturing offers an expanded library of printable multiphase inks. This technology demonstrates a novel approach to modulating material properties via microstructure control to pave the way for 3D printing components with embedded electrical circuits or other spatially modulated properties.

6:00 PM SM05.04.04
Microcapsule-Based Self-Healing Chemistry for Glass Fiber-Reinforced Thermoplastic Composites Dhawal Thakare[1,2], Ian L. Flueck[1,2] and Nancy R. Sottos[1,2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Beckman Institute for Advanced Science and Technology, United States

Fiber-reinforced thermoplastic composites are increasingly being used for industrial applications as they reduce the weight versus traditional materials such as metals and thermosets without compromising structural strength while also allowing better stiffness, recyclability and short processing times. Traditional methods of healing thermoplastics by heating or inducing local heat through embedding heat sources requires external intervention and energy. This strategy may not be suitable for many large-scale industrial applications. Microcapsule-based strategies present an attractive alternative as they are autonomous, scalable and can be incorporated into traditional composite systems. Capsule-based self-healing has been widely shown in bulk polymers, and to some extent in thermoset composites, but autonomous healing in fiber-reinforced thermoplastic composites remains a challenge. The healing strategy proposed in this work utilizes a robust dual microcapsule system containing monomeric healing compositions which will undergo complete polymerization upon release from ruptured microcapsules within a damage zone. Multi-shell walled microcapsules coated with polydopamine are used to encapsulate a methacrylate-alkylborane based chemistry. One part of the microcapsule system contains a trialkyl borane-amine complex and the other microcapsule contains an acrylic monomer with an anhydride-based decomplexer. The microcapsule size has been tuned to the order of a few microns to avoid agglomeration and aid survival during composite manufacturing. The core content of the microcapsules is confirmed and quantified using ^{1}H NMR and elemental analysis techniques. Thermogravimetric analysis of the microcapsule system reveals enhanced thermal stability at temperatures up to 200 ºC, which is required to survive stringent composite manufacturing conditions. Subsequently, the microcapsules are incorporated into a model glass fiber-reinforced polyethylene composite to assess its ability to heal delamination and quantify its healing performance. In addition to autonomous healing, this healing strategy offers other advantages such applicability of the healing chemistry to a wide variety of inert low surface energy thermoplastics and healing at room temperature.

6:15 PM SM05.04.05
Soft Organic Multiferroic Polymer Composites Scott Newacheck and George Youssef; San Diego State University, United States

The prominence of interactions between multiphysical domains give rise to the need for multifunctional materials that satisfy the broad requirements for the emerging fields of soft robotics and biomedical devices. These fields require efficient coupling of electrical and magnetic energies for sensing, actuation, and communication, preferably done with the same components to reduce system complexity. Composite multiferroic materials offer tunable extrinsic magnetoelectric coupling by engineering the piezomagnetic and piezoelectric materials in different proportions, geometries, and configurations. A major limitation for nearly all multiferroic composites stems from their composition of brittle and stiff ceramic and metallic materials, highlighting a greater property mismatch between the constituents. Such mismatch is detrimental in straintronics, where the main mediator between electricity and magnetism is mechanical strain. On the other hand, organic multiferroic materials are attracting scientific and technological interest due to their tunable properties while reducing the mismatch challenges since the entire framework is made of compliant polymers. However, a shortcoming of organic multiferroics is the basis that the donor-acceptor paradigm is an inferior magnetoelectric coupling mechanism due to the limited excitonic interactions. Presented herein is a novel approach to enhance the magnetoelectric performance of organic multiferroics through the addition of lattice deformation and charge injection mechanisms. The novel organic ferromagnetic polymer blend, P3HT-PCBM is interfaced with a well-established electroactive polymer, PVDF-TrFE, for its piezoelectric properties. The application of an electric field across the PVDF-TrFE surfaces result in a mechanical strain that can transfer to the adjacent P3HT:PCBM framework, enhancing the spin-lattice interaction. The polarization of PVDF-TrFE is also dependent on the electric field resulting in an accumulation of charges on the surface, hence improving the spin-electron interactions of the blend polymer. Therefore, the addition of PVDF-TrFE strategically and dynamically tunes the magnetoelectric properties of the blend polymer on demand. Furthermore, monochromatic illumination of the newly created composite has shown to manipulate the magnetic behavior through photon-exciton-spin coupling. Future research will focus on gaining an insight into magnetoelastic and magnetocrystalline anisotropies of this novel class of material which is forecasted to be fundamentally different from traditional magnetic materials.

6:30 PM SM05.04.06
TEM Image Processing Analysis of BTO-polymer Nanocomposites to Construct a Finite Element Model for Extracting the Particle Dielectric Constant of BTO Dithi Ganjam[1], Giovanni Ferro[2], Maia Gibson[1], Katherine Partington[1], Akshay Trikha[1], Albert Dato[1] and Todd Monson[3]; [1]Harvey Mudd College, United States; [2]Pomona College, United States; [3]Sandia National Laboratories, United States

Barium titanate (BTO) is a ferroelectric perovskite material that is currently used in energy storage applications because of its high dielectric constant**.** Wada et al. reported that the size of BTO strongly affects its dielectric constant [2]. In the study, BTO powders with diameters larger than 300 nm were found to have a dielectric constant of 4000, while BTO nanoparticles with a diameter of 70 nm exhibited a dielectric constant of over 15,000. These results are highly contested, but their implications to energy storage have motivated us to investigate the dielectric constants of BTO nanoparticles of various sizes. Here we present the relationship between BTO diameter and BTO dielectric constant, which was obtained through (1) capacitance measurements of polymer-matrix nanocomposites containing BTO nanoparticles, (2) a novel method of processing transmission electron microscope (TEM) images of highly agglomerated nanocomposites, and (3) more accurate COMSOL models of the nanocomposites using data obtained from our image processing method. The positions, agglomeration, shapes, and diameters of BTO nanoparticles in a polymer matrix were determined through our image processing method that extracts this information directly from TEM images of nanocomposites. We then developed a COMSOL Multiphysics model that simulates BTO nanoparticles embedded in a polymer matrix. The COMSOL model takes the results of our image processing technique as inputs and computes the dielectric constants of nanocomposites. By comparing experimental composite

dielectric constants to those obtained through COMSOL modeling, we explored the relationship between BTO nanoparticle diameter and dielectric constant.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

6:45 PM SM05.04.07
Late News: Self-Healing Vitrimer Coating for Robust Hydrophobicity Jingcheng Ma, Laura E. Porath, Christopher Evans and Nenad Miljkovic; University of Illinois at Urbana-Champaign, United States

Durable hydrophobic coatings have seen considerable interest in the last decade. Currently, the most popular strategy to achieve mechanical robustness is by combining perfluoro-compounds (PFCs) with 'armor' structures for coating protection. These protective structures are usually large (>10 μm in thickness). However, in many cases thin (<100 nm) hydrophobic coatings are desired. For example, in dropwise condensation, atmospheric water harvesting, anti-icing, and water desalination, the heat and mass transfer rate can be significantly enhanced using hydrophobic surfaces that are less than 100 nm in thickness. Here, we achieve stable hydrophobicity with high mechanical robustness using polydimethylsiloxane-based self-healing thin films that are 1-10 nm thick. We designed and synthesized the vitrimer with polydimethylsiloxane network strands and dynamic boronic ester crosslinks (dyn-PDMS) to take advantage of the inherent hydrophobic nature of silicones. The dynamic bonds provide a mechanism for self-healing and damage resistance. We show that even for films having nanoscale thickness (<10 nm), the transparent coating maintains exceptional hydrophobicity after scratching, cutting, indenting, and steam condensation. The dynamic coating can also be easily deposited through scalable techniques like dip-coating on a variety of substrates including silicon wafer, aluminum, copper, and glass. The developed dynamic polymer chemistry is fluorine-free for better environmental sustainability compared to commonly used PFC-based materials. The presented work develops a paradigm shift in achieving long-term durable hydrophobicity enabling the implementation of self-cleaning, anti-icing, heat transfer, and microfluidic applications.

7:00 PM SM05.04.08
Late News: Encapsulation of Phase Change Materials in Fibers for Renewable Thermal Energy Storage Ping Lu, Wanying Wei, Ryan Hart, Dev Patel and Harmann Singh; Rowan University, United States

A natural phase change material, lauric acid (LA), was encapsulated in polystyrene (PS) hollow fibers through three green approaches: 1) co-fabrication of the mixture solutions, 2) thermally triggered nanocapillary transportation and encapsulation, and 3) solvent-assisted nanochannel encapsulation. By simply tuning the encapsulation parameters such as the LA/PS weight ratio, temperature and concentration, the obtained LAPS composite fibers achieved an unprecedented thermal energy storage capacity up to 82.0% (147.8 J/g) of pristine LA (180.2 J/g) owing to the high LA loading and the lightweight and porous nature of the PS matrix. Simultaneous TGA-DSC, ATR, Raman, and SEM measurements confirmed the homogeneous distribution of LA inside the fibers across the whole membranes. Further, the LAPS composite fibers showed a long-lasting stability during cycling without storage capacity deterioration, as well as an exceptional structural stability without LA leaking and fiber rupture during 100 heating-cooling cycles. The energy-dense and form-stable LAPS composite fibers have a great potential for various thermal energy storage applications including solar energy storage, "temperature-smart" buildings, thermal regulating textiles, and thermal therapy devices.

8:15 PM SM05.05.01
Late News: Microbubbles Cloaked with Hydrogels as pH-Activatable Ultrasound Contrast Agents Mary W. Burns, Robert F. Mattrey and Jacques Lux; UT Southwestern, United States

While microbubbles (MBs) are currently mainly used as cardiac and perfusion imaging agents in the clinic, engineering MBs with bioresponsive properties would expand their use to detect pathophysiologic changes. This can be achieved by stiffening the MBs shell with a bioresponsive “cloak” to decrease their oscillations and silence their signal, and rescuing the MB elasticity when they are exposed to a biomarker of interest. This strategy would allow the switching between a stiff 'OFF' state and an elastic 'ON' state that would allow MBs to become detectable only when exposed to biomarkers of interest (*e.g.,* pH, reactive oxygen species, hypoxia, or enzymes).
To validate our hypothesis, we used conjugated MBs with hyaluronic acid (HA) and crosslinked the resulting polymeric shell with pH-sensitive crosslinkers to obtain activatable pH-sensitive MBs (pH-MBs). We first validated the successful conjugation of HA to MBs and targeting of pH-MBs to CD44-positive cells. Using ultrasound imaging, we confirmed the harmonic signal loss that is associated with the stiffening of pH-MBs. We used a clinical ultrasound scanner equipped with Cadence contrast pulse sequencing to image pH-MBs before and after acidification and observed a fivefold increase in harmonic signal. Because the crosslinker cleavage is reversible, we were able to silence harmonic signal again by neutralizing the acidic suspension was neutralized, confirming that harmonic signal is dependent on the cross-linked HA. Interestingly, the rate of rise and the magnitude of harmonic signal increase could be manipulated by varying the phospholipid composition and the number of crosslinkers, indicating that the platform can be tuned to the desired response needed.

8:30 PM SM05.05.02
Late News: Highly Recyclable and Tough Polyurethane Elastomeric Thermosets for Soft Electronic via Well-Defined Network Design Jiancheng Luo[1], Sheng Zhao[2] and Pengfei Cao[1]; [1]Oak Ridge National Labortary, United States; [2]The University of Tennessee, Knoxville, United States

Jiancheng Luo, Sheng Zhao, and Pengfei Cao*
Chemical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37830, USA

Thermoset elastomers with multifunctionality such as self-healable and recyclable capability, stretchability, and stimuli-responsive shape, are attractive to numerous applications. In this work, polyurethane (PU) vitrimers with well-defined network topology are design by connecting tetra-armed crosslinkers with PDMS chains bearing disulfide bonds. Compared with the random network, the well-defined network endows elastomeric vitrimers significant improvement on their mechanical performance. Through tuning PDMS chain length, the elastomers exhibit outstanding mechanical properties with ultimate tensile stress ranging from 1.5 MPa to 11.2 MPa, and elongation at break ranging from 290% to 884%. The elastomers also exhibit good solvent resistance and self-healability, and meanwhile show no obvious loss on mechanical performance after 5 reprocessing cycles. By embedding carbon nanotubes (CNT) into polymer network, the as-prepared conductive elastomers can be used to fabricate various soft electronics, *i.e.*, strain and electrocardiogram sensors. The network design principle here provides a feasible approach to achieve recyclable thermoset elastomers with excellent mechanical performance.

8:45 PM SM05.05.03
Late News: Multifunctional Origami Patch for Minimally Invasive Tissue Sealing Sarah Wu, Hyunwoo Yuk, Jingjing Wu and Xuanhe Zhao; Massachusetts Institute of Technology, United States

For decades, bioadhesive materials have garnered great attention due to their potential to replace sutures and staples for sealing and repairing tissues during minimally invasive surgical procedures. However, the complexities of delivering bioadhesives through narrow spaces and achieving strong adhesion in fluid-rich

physiological environments continue to present substantial limitations to the surgical translation of existing glues and sealants. We introduce a new strategy for minimally invasive tissue sealing and repair based on a multilayer bioadhesive patch, which is designed to repel body fluids, form fast, pressure-triggered adhesion with wet tissue surfaces, and resist biofouling and inflammation. The multifunctional patch is realized by a synergistic combination of three distinct functional layers: (i) a micro-textured bioadhesive layer, (ii) a dynamic, blood-repellent hydrophobic fluid layer, and (iii) an antifouling zwitterionic non-adhesive layer. The bioadhesive patch is capable of forming fast and robust adhesion to tissue surfaces in the presence of blood, and exhibits superior resistance to bacterial adhesion, fibrinogen adsorption, and *in vivo* fibrous capsule formation. By adopting origami-based fabrication strategies, we demonstrate that the multilayer bioadhesive patch can be readily integrated with a variety of minimally invasive end effectors to provide facile and effective tissue sealing in ex vivo porcine models, offering new opportunities for minimally invasive tissue sealing and repair in diverse clinical scenarios.

Late News: Photo Patterning of Dynamic Covalent Polymer Hydrogels Towards Sustainable and Flexible Micromanufacturing Di Chen, Qian Zhao and Tao Xie; Zhejiang university, China

Dynamic covalent polymer networks will go through topological rearrangements under stimulations to relax internal stress and switch the features of materials. Via continuously exploring new internal force programming approaches, the structure of dynamic materials can be manipulated in a more and more controllable fashion. Here, besides the generally deformed by macroscopic stretching, bending or twisting, we present a microscopical way which is freezing, to impose internal force toward a dynamic hydrogel and establish a flexible micromanufacturing method. Specifically, the hydrogel is crosslinked by disulfide bonds and owns capability of photo-induced network rearangements. During freezing, microphase separation occurs, forming two phases: ice crystals and a squeezed polymer phase. After spatial UV exposure, polymer chains are relaxed due to the disulfide bond exchange and entropy of the network is increasing as well. Subsequent ice melting will lead to porous patterns with the feature size of 20 μm, and the obtained porous hydrogels can be directly utilized to spatially store functional inks for transfer printing. Additionally, the present ice-templating photo patterning method requires no solvent washing step, and uses mostly water (98%) with the remaining organic component easily recyclable, thus generating zero organic waste. Therefore, it can open up an avenue for sustainable and flexible micromanufacturing.

9:15 PM SM05.05.05
A One-Pot Immunosensor Composed of Metal-Enhanced Fluorescence Probes and a Photocatalytic Film Kihyeun Kim and Min-Gon Kim; Gwangju Institute of Science and Technology (GIST), Korea (the Republic of)

To overcome a limitation of typical immunoassays like an enzyme-linked immunosorbent assay (ELISA) in terms of multi-step procedure, one-pot immunoassays are in high demand for point-of-care (POC) testing that can be used by individuals at any time and anywhere.
In this study, we suggest a one-pot immunosensor composed of Cy5/capture antibody/gold nanorod conjugates and an Au/TiO_2 photocatalytic film. After injection of solution for an immunoassay, delayed production of H_2O_2 from the photocatalyst by ultraviolet illumination enabled a one-pot assay by quenching of Cy5 due to 4-chloro-1-naphthol precipitates that produced by the enzymes bound to the conjugates via interleukin 8 (IL-8) antigens. As a result, our one-pot immunosensors could detect IL-8 within the range of 1 pg mL^{-1} – 1,000 pg mL^{-1}, which was as sensitive as the purchased ELISA kit for IL-8 detection. Therefore, this sensor platform could pave the way for highly sensitive, portable, easy-to-use POC biosensors for individuals.

9:30 PM SM05.05.06
Late News: Light-Coded Digital Heterogeneity Toward Multifunctional Shape Shifting of Shape Memory Polymers Wenjun Peng and Tao Xie; Zhejiang University, China

Homogeneous single synthetic materials typically have limited functions as multifunction is always related to multimaterial systems. By mimicking the nature of biological species to introduce spatially heterogeneous distribution of active components in synthetic materials, the design space for advanced multifunction is widened. Here, we introduce the heterogeneity at the programming process after material synthesis/fabrication step by a digital photothermal effect. Our first work allows spatio-selective programming of crystallinity in a shape memory polymer (SMP). Consequently, a pre-stretched 2D film with spatial heterogeneity in shape recovery ratio can morph into designable 3D permanent shapes, achieving the 4D transformation. Following the first work, we design a supramolecular SMP with intrinsic time-temperature dependency. Spatial controlling of deformation temperature and time brings heterogeneity in shape recovery rate, thus leading to highly non-monotonic shape-shifting pathways and tunable evolution lifetime. The benefits of these unique features are demonstrated by multi-shape transformation, an "invisible" color based clock and a time-temperature indicator (TTI). Heterogeneous material in our work, as a novel kind of multimaterials, provides a versatile idea for manufacturing multifunctional devices.

8:00 AM SM05.06.02
Spatially Patterned Magnetic Hydrogels—Towards Controllable Structures and Responses Jacek Wychowaniec[1], Patricia Monks[1,2], Eoin P. Mckiernan[1], Krutika Singh[1], Danielle Winning[1], Katie McGarry[1], Esther R. Aluri[1], Shane Clerkin[1], Niall Treacy[1], Andreas Heise[2], John Crean[1], Emmanuel Reynaud[1], Brian Rodriguez[1,1] and Dermot Brougham[1]; [1]University College Dublin, Ireland; [2]Royal College of Surgeons in Ireland, Ireland

Multifunctional nanocomposites which exhibit well-defined physical properties and encode spatio-temporally controlled responses (including changes of shape, microscopic morphology, mechanical strength and permeability) are emerging as components for advanced responsive systems. For instance in the case of biomedical applications magnetic nanocomposite materials have attracted significant attention due to their ability to respond to spatially and temporally varying magnetic fields changing their intrinsic structure, undergoing time-dependent deformations, or releasing cargo on demand.[1-3]

The combination of MNPs and established 3D printable polymeric hydrogel formulations can provide multifunctional and stimuli-sensitive systems with spatial-, temporal- and dosage-controlled release properties. Here, our work towards bio-applications of magnetic hydrogels is described in two fabrication cases, (i) conventional manufacturing, where magnetic materials are utilized in conventional manufacturing processes during solidification/gelation, as well as (ii), magnetic structuring, where the presence of magnetic fields or 3D printing was used to spatially pattern materials with encoded magnetic responsiveness.

A combination of in-house built multi-head and commercial 3D printers was used to extrude selection of magnetic composite hydrogels. Magnetic nanoparticles were synthesised, stabilized and dispersed homogenously through the gels to optimise their hyperthermic responses. Oscillatory and rotational rheology measurements confirmed the viscoelastic properties providing ideal materials for 3D printing well-defined architectures with high fidelity for both magnetic and non-magnetic components of integrated multi-component builds. The hybrid inks showed complete shear- and temperature-recoverability/reversibility to their initial state, confirming that at particle concentrations that enable magnetic responses the necessary printability is not lost. Multiple complex structures were printed with high resolution (~150 mm) with independent magnetic and non-magnetic patterned components and these were shown to be reproducible and robust. Post-printing chemical

crosslinking was used to retain long-term fidelity of the printed structures, whilst retaining magnetically responsive hyperthermic responses at low particle concentrations. Thermoresponsive contractile elements were also embedded from selection of polymers based on poly(N-isopropylmethacrylamide) with chemically programmed volume temperature transitions at physiologically relevant range of 32 to 45°C.

For AC-magnetic field responsiveness, high resolution IR thermography confirmed that incorporated magnetic nanoparticles retain sufficient magnetic response to provide spatial temperature gradients for cell stimulus and for stimulus-responsive timed delivery of biomolecules. The advantages of spatial patterning of thermally active components will be described in the context of kidney and cerebral organoids, as well as for stem cell differentiation. Applications of DC-magnetic fields to physical stimulation of patterned magnetic gels will also be presented.

Artificial Tendrils Mimicking Plant Movements by Mismatching Modulus and Length in Multimaterial Polymeric Systems Muhammad Farhan[1], Andraz Resetic[2], Anil K. Bastola[1], Marc Behl[1] and Andreas Lendlein[1]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]Jozef Stefan Institute, Slovenia

Plants structures and their motions are a result of long-term interplay between evolution, failure, and adaptation to their local environments. Motions of plants are driven by their growth. Typical examples of the plant kingdom where the motion is relevant are searchers of liana or the tendrils of climbing plants. In both examples, the capability of coordinated actuation such as coiling upon response to specific external stimuli can be observed. To enable biomimetic innovations, special attention has been payed to understand the coiling of plant structures. [1, 2] A promising approach to mimic this behavior are multifunctional multimaterial systems, in which orchestrated interplay of functions could provide this coiling behavior. Here we report on development of a multimaterial fiber as an artificial tendril. The multimaterial fiber is composed of shape-memory polymer fiber core and an elastic outer matrix. As fiber core we selected a poly[ethylene-*co*-(vinyl acetate)] (PEVA) fiber ($d \approx 400$ µm), whereas a silicone based soft elastomer was chosen as a matrix. The core fiber provides a temperature dependent actuation (expansion/contraction) that propagates coiling of the tendril due to the mismatch in the modulus of outer matrix and inner core. Therefore, we considered the mismatch in elastic modulus as a control parameter. The modulus of the matrix (E_{matrix}) was varied between 0.1 and 0.5 MPa to achieve various coiling behaviors of such multimaterial tendrils. The maximum number of coiling per unit centimeter (N = 0.35) was observed for the tendril with an intermediate E_{matrix} = 0.29 MPa. Our study stimulates the design for plant inspired multimaterial tendrils with tunable coiling and reversible motion responses.

Control of Direct Crystallization by a Running Magnetic Field Sergey M. Karabanov, Dmitry V. Suvorov,

Dmitriy Y. Tarabrin, Evgeny V. Slivkin and Andrey S. Karabanov; Ryazan State Radio Engineering University, Russian Federation

Direct crystallization is widely used in the production of multicrystalline silicon for solar energy and electronics. In the process of direct crystallization, the melt flow is controlled by the heat convection force resulting from a temperature gradient. This leads to the appearance of convective disturbances and melt turbulence. These effects have a negative impact on the quality of the obtained material.
The efficient way to control the melt mixing is to use both continuous and variable magnetic fields. Continuous magnetic fields smooth effectively convection flows in the melt, and variable magnetic fields influence substantively on the melt mixing.
This paper presents the results of mathematical modeling of electromagnetic stirring of silicon melt under various conditions. Mathematical modeling was carried out using COMSOL Multiphysics software. In the course of modeling, the distributions of the magnetic field induction, the densities of the Lorentz force, and the melt stirring rates were obtained. The distribution of the surface rate of melt movement was determined.
Experimental studies were carried out on a direct crystallization unit with the crucible size of 860x860x450 mm and the ingot weight of up to 500 kg. To create a running magnetic field, a current pulse generator was made. The current amplitude of *an* inductor was regulated in the range from 10 A to 700 A, the frequency of current pulses was from 20 Hz to 200 Hz, and the phase shift was from zero to 180 degrees.
The research results are as follows:
- a physical and mathematical model of electromagnetic stirring of silicon melt was developed, modeling of electromagnetic stirring was carried out;
- on the basis of the developed model, the configuration of the pilot unit was selected;
- a pilot unit was created and experimental studies on the influence of the magnetic field parameters on the melt surface rate were carried out;
- the optimal conditions for obtaining a stable, repeatable process of silicon melt stirring were established.
The obtained results were used for multicrystalline silicon production. Studies on the effect of the current shape in inductors were conducted.

Stepwise Magnetic Self-Organization of Micropillar Arrays Jeong Eun Park[1], Augustine Urbas[2], Zahyun Ku[2] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Air Force Research Laboratory, United States

Long-range ordering of magnetic particles has been reported by generating magnetic dipole moments and dynamic swarming motion in aqueous medium under external magnetic field. However, the self-organization is not reversible and reliable because the position of magnetic particles is not stationary. Alternatively, we suggest periodic polymeric micropillar arrays with inclusion of magnetic particles for reversible and programmable magnetic self-organization in a stepwise manner. When magnetic field is applied, individual micropillars are magnetized and operate as micromagnets. The vicinal pair of pillar tops magnetically attract each other for magnetic self-organization while the pillar base is still fixed to the substrates. As the magnetic flux density increases, the paired micropillars undergo quad-body organization, and then the long-range connectivity of pillar tops is accomplished. We will discuss the influence of spacing and anisotropic cross-sections of the micropillars on the stepwise magnetic self-organization by investigating the geometry form factors such as rectangular, square and circular cross-section.

8:40 AM SM05.06.06
Thermo-Responsive Microcapsules with Tunable Cut-Off Threshold of Molecular Permeation for Temperature-Controlled Encapsulation and Release Yehun Choi[1], Seog-Jin Jeon[2] and Shin-Hyun Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Kumoh National Institute of Technology, Korea (the Republic of)

Microcapsules with a liquid core and solid shell have been used for storage and release of materials in various

purposes. The shells that have regular size of continuous pores or microchannels provide molecular-size-selective permeation so that they allow transmembrane transport for smaller molecules than the pores while excluding or retaining larger molecules. The size-selective permeation is of great importance for protection of delicate large encapsulants while allowing transmembrane transport of small molecules, in particular for encapsulation of catalysts or enzymes and nanoparticle-based sensors. The shells with tunable cut-off threshold of size-selective permeation are promising for reversible encapsulation and release of encapsulants in a highly controlled and programmed manner. The molecules smaller than the cut-off threshold can be inserted into the core of the microcapsules by diffusion, which is encapsulated by lowering the cut-off below the size of the molecules. The encapsulants will be released into surrounding by increasing the cut-off, which can be done in single step or multiple steps.
Hydrogels are one of the promising shell materials to achieve the tunable cut-off threshold. Hydrogels have three-dimensional network of hydrophilic polymers. When the network is swollen by water, large free volume is formed in the mesh, through which small molecules can diffuse. More importantly, the use of stimuli-responsive polymers to form the mesh enables to control the degree of swelling. However, the precursors for hydrogels are usually hydrophilic and soluble in water, which makes it challenging to produce microcapsules with water core and hydrogel shell using conventional templates of water-in-oil-in-water (W/O/W) or oil-in-water-in-oil (O/W/O) double-emulsion drops.
In this work, we use a novel thermoresponsive hydrogel precursor to produce the semipermeable microcapsules with tunable cut-off threshold of permeation with a template of W/O/W double-emulsion drops. The precursor is poly(N, N-diethylacrylamide) (PDEAM) functionalized with benzophenone (BP). BP self-initiates the reaction under the irradiation of ultraviolet (UV) in the absence of photoinitiator, crosslinking PDEAM to form a mesh. PDEAM has the lower critical solution temperature (LCST) around 34°C with water. Due to the hydrophobic BP moiety, PDEAM-BP is highly soluble in organic solvent and weakly soluble in water even at room temperature. Using the solution of PDEAM-BP in chloroform as an oil phase, we produce W/O/W double-emulsion drops with ultra-thin oil shell with a glass capillary microfluidic device. The innermost water drops and continuous phase contain a high concentration of salt, which exerts a osmotic pressure and helps prevent the formation of tiny water droplets in the oil shell. The double-emulsion drops are incubated at 50°C for removal of chloroform, which makes the PDEAM-BP more hydrophobic and further suppresses the formation of water droplets in the oil shell. After complete consolidation, PDEAM-BP is crosslinked by UV irradiation and the resulting microcapsules are washed with distilled water at room temperature. The microcapsules show temperature-dependent changes of diameter and shell thickness. The cut-off threshold is estimated to be below 4kDa in size at 50°C, whereas that is between 4kDa and 10kDa at 25°C and 4°C. The temperature-dependent change of the cut-off threshold is highly reversible, which enables us to load and release molecules in a programmed manner. In addition, the release can be done in multiple steps by repeating heating and cooling. Moreover, the cut-off threshold of the microcapsules can be further controlled through the controlled irradiation of near infrared light by encapsulating photothermal agent of polydopamine (PDA) nanoparticles in the core. We believe our microcapsules with tunable cut-off threshold will provide new opportunities for microreactors and microsensors as well as drug carriers.

8:45 AM SM05.06.07
Multi-Functional Curvilinear Shape-Morphing with Patterned Adhesive Tapes via Localized Photothermal Effects Jae Gyeong Lee, Sukyoung Won, Jeong Eun Park and Jeong Jae Wie; Inha university, Korea (the Republic of)

Construction of a 3D structure from 2D flat geometry has received great attention in the materials community. Although various methods are reported to achieve 2D to 3D shape-morphing, photothermal actuation has been emerged as a promising method for contactless shape-reconfiguration. The photothermal heating method often use black inks on the shape memory polymers to localize photothermal heating. However, this method could cause further undesirable actuation as the ink patterns remain even after creating the desirable 3D structures. In this study, adhesive tape patterns were employed instead of the ink patterns in order to achieve transparent 3D structures as well as prevent undesirable actuations. When black adhesive tapes were irradiated with NIR light, the patterned areas absorb photons and generate photothermal heating. When the temperature exceeds the

polymer glass transition temperature, shrinkage of polymer occurs by recovery of random coil conformation from biaxially pre-strained coils. We discuss the effects of various radial and chiral tape patterns on curvature control for complex 3D structures. Furthermore, we will demonstrate sequential folding by temporal regulation of the NIR irradiation. We will also discuss shape-reconfiguration of heterogeneous materials with the addition of compliable papers and introduction of conductive functions on 3D morphed polymers.

8:50 AM SM05.06.09
Late News: Gallium-Based Transformative Electronic System Integrated with Graphene and Flexible Thermoelectric Device for Rapid Bi-Directional Stiffness Tuning Sang-Hyuk Byun[1], Choong Sun Kim[1], Karen-Christian Agno[1], Simok Lee[1], Zhuo Li[2], Byung Jin Cho[1] and Jae-Woong Jeong[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Fudan University, China

While the predetermined mechanical properties of both conventional rigid electronics and emerging soft electronics allow them to perform target-specific functions, their fixed rigidity limits their extensive applications. Rigid electronics such as smartphones and laptops are easy to handle and can endure external stress owing to their robust structures. However, their high stiffness makes them incompatible with soft biological tissue, thus they are not suitable for use in wearables and implantable devices. While the compliant interface of soft electronics allows conformal contact with the curvilinear body, it does not provide sufficient load-bearing capability when operated in an off-body application. Stiffness tuning is one of the promising solutions in order to leverage the key features of both rigid and soft electronics. Recently, transformative electronic systems (TES) with reconfigurable shape and stiffness have been developed by using gallium as a thermally-tunable mechanical platform. However, the gallium platform experiences supercooling phenomenon during its liquid-to-solid phase transition which prevents soft-rigid TES mode conversion at its freezing temperature (29.76 °C) and makes the fast bi-directional soft-rigid conversion of TES a challenging task. Here, we present an advanced architecture for gallium-based TES, which integrates graphene and a flexible thermoelectric device (f-TED) to enable a rapid bi-directional soft-rigid transformation mode. Graphene facilitates the mitigation of the degree of supercooling as a catalyst to accelerate the nucleation of gallium during the liquid-to-solid phase transition, while the f-TED offers active temperature control to accelerate the overall phase transition of the gallium platform. During the solidification process, the f-TED lowers the temperature which assists in overcoming the supercooling of gallium that leads to a reduction in the liquid-to-solid transition time. In a similar way, the f-TED can shorten the time required for the solid-to-liquid transition of gallium by actively heating the TES platform. By integrating the graphene-gallium interface platform and f-TED, we could significantly reduce the time for the melting and freezing, by 91% (from 255 to 23 s) and 55% (from 175 to 79 s), respectively, as compared to TES design built with pure gallium. Based on this design strategy, we could successfully demonstrate a TES that can facilitate rapid conversion between a rigid handheld display and a flexible wearable pulsimeter/display. The proof-of-principle demonstration of TES capable of rapid bi-directional transformation suggests broad utility of the proposed design, which may open new opportunities for electronics, robotics, and biomedical devices.

9:05 AM *SM05.06.10
Micro- and Nano-Structured Dynamic Soft Matter Material Design by Light Christopher Barner-Kowollik; Queensland University of Technology, Australia

The tuning of both covalent bond formation as well as dissociation remains a grand challenge in the design of photodynamic systems. The light-responsive adaptation of polymer materials requires different wavelengths to induce reversible covalent bond formation and dissociation. Our efforts have been devoted to pioneer a toolbox of photocycloadditions that can be triggered by lower energy visible light, while their cycloreversion should function at the least energetic wavelength, too. The lecture will showcase the latest applications of reversible photochemistry for the generation of light adaptive micro-structured materials via 3D laser lithography.[1]

Further, the lecture will explore visible light-triggered reversible triazolinedione (TAD) chemistry and its application in materials science. We have recently pioneered the photo-chemically driven reaction of TADs

with naphthalene as a dynamic covalent cross-linking platform that enables green light-induced network formation (525 nm), while network degradation is triggered by merely switching off the light, thus introducing the new class of Light Stabilized Dynamic Materials (LSDMs).[2] These materials can undergo a repeatable change in morphology from a covalently cross-linked material into a liquid polymer formulation by switching the visible light source on-and-off without the need for any additional triggers. Furthermore, TADs exhibit a strong purple colour which fades upon reaction with suitable substrates, thus facilitating online monitoring of the material's property transformation with the naked eye.

We subsequently expanded TAD photochemistry in the field of light-fuelled covalent non-equilibrium chemistry. Under green light, naphthalene-containing polymers can be folded into single chain nanoparticles (SCNPs) driven by [2+4] cycloadditions with a bivalent TAD crosslinker, whereas the SCNPs unfold into their linear parent polymers in the absence of light.[3] Such photonic fuel driven dynamic SCNPs constitute the first example of a reversible light triggered folding of single polymer chains, mimicking their naturally observed spontaneous folding of proteins.

Moreover, we have established a new method for the photoinitiated, additive-free precipitation-driven synthesis of particles by crosslinking pre-synthesized low molecular weight polymers. Microspheres were produced by employing the nitrile-imine mediated tetrazole-ene cycloaddition reaction upon UV irradiation (λ = 300 nm), therefore forming intrinsically fluorescent particles.[4] The reaction wavelength was subsequently red-shifted to 415 nm by exploiting *o*-quinodimethanes that undergo [2+4] cycloadditions with suitable dienophiles or [4+4] via self-dimerization.[5] Critically, a variety of crosslinking molecules and dienophiles were investigated, imparting unique properties to the particles such as chemical degradability, chemiluminescence and acid triggered fluorescence switch-on. Finally, we combined our visible light driven particle design platform technology with the visible light-driven reversible [2+4] cycloaddition of TADs with naphthalene prepolymers, creating degradable microparticles that do not require any external degradation trigger other than darkness.[6]

Programmable Liquid Metal Microstructures for Multifunctional Soft Thermal Composites Michael D. Bartlett, A B M Tahidul Haque and Ravi Tutika; Virginia Tech, United States

Soft, elastically deformable composites can enable new generations of multifunctional materials for flexible devices and reconfigurable structures. An emerging material architecture is to create solid–liquid composites with liquid metal (LM) inclusions dispersed in elastomer matrices. These materials have shown exceptional combinations of soft mechanical response, tunable electrical properties, and high thermal conductivity. Such

properties are strongly dependent on the material composition and microstructure. However, approaches to control the liquid metal microdroplet morphology to program mechanical and functional properties are lacking. Here, we overcome this limitation by thermo–mechanically shaping LM droplets in soft composites to create programmable microstructures. This enables LM loadings up to 70% by volume with prescribed particle aspect ratios and orientation, enabling control of microstructure throughout the bulk of the material in stress–free conditions. The influence of microstructure on the mechanical and functional response is theoretically and experimentally determined and a general framework is developed to design soft composites with desired functional characteristics. Through this microstructural control in soft composites, we simultaneously achieve a thermal conductivity as high as 13 W/mK (> 70 x increase over polymer matrix) with low elastic modulus (<1.0 MPa) and high stretchability (>750% strain), representing one of the highest thermal conductivities for soft, deformable materials. The exceptional thermo–mechanical properties of LM programmed composites enables thermal control in rigid and highly deformable systems. We demonstrate this capability with electronics integrated into 3D printed materials, soft heat sinks, and thermal shielding in artificial muscles for a prosthetic hand. We envision that the ability to program microstructure in solid–liquid composites will enable further advances in flexible electronics and robotics, medical devices, and shape morphing structures.

10:45 AM SM05.07.02
Control of ROMP Polymer Architecture and Chemistry for High Temperature Stability and Recyclability Douglas Ivanoff[1], Julian C. Cooper[1], Peyton Shieh[2], Jeremiah A. Johnson[2], Jeffrey Moore[1] and Nancy R. Sottos[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Massachusetts Institute of Technology, United States

High temperature thermosets display exceptional thermomechanical behavior due to densely crosslinked networks and chemically resistant bonds. Traditionally, increases in polymer crosslink density present greater challenges for recyclability. Here we show incorporation of a selectively cleavable moiety at the crosslink junction allows for significant increases in crosslink density and glass transition temperature while maintaining a pathway for recyclability. Co-polymerization of multi-functional cyclic olefins featuring silyl ether moieties with dicyclopentadiene (DCPD) produces degradable poly(DCPD)-based thermosets with high glass transition temperatures (T_g). Crosslinking density and glass transition temperature are controlled by tuning structure and molar concentration of the degradable co-monomers. These robust thermosets are degraded via exposure to a triggering fluoride stimulus, and the resulting soluble products can be incorporated into new polymers networks. The effects of these multifunctional cyclic olefins on crosslink density, glass transition temperature, and the rate of structural degradation are studied, and the properties of the recycled materials are characterized. Incorporation of silyl ether crosslinking units leads to thermosetting materials with high T_g (>180 ºC) and that are readily recyclable.

11:00 AM SM05.07.03
Lightweight, Liquid Metal Elastomer Composite Ethan Krings and Eric Markvicka; University of Nebraska–Lincoln, United States

Soft, elastically deformable materials with high thermal conductivity are critical for numerous industries including healthcare, aerospace, automotive, and flexible electronics, where combinations of high mechanical compliance and high thermal conductivity are required. An emerging material architecture are elastomer composites that are composed of liquid-metal (LM) microdroplets embedded in hyperelastic polymers. These all soft-matter systems exhibit exceptional thermal properties, are electrical insulating even at high volume loadings, and remain soft and stretchable even at extremely low temperatures (-80 ºC). Although these materials exhibit a unique combination of properties, the high density and high volume loading of the LM filler significantly increases the density of the composite, which is problematic for large-area thermal management and weight sensitive applications such as wearable electronics, aerospace thermal control, and clothing. Here, we introduce a new lightweight, LM inclusion that has a unique combination of properties including high thermal conductivity, low mass density, and high deformability when embedded into an elastomer matrix. Furthermore, the composition of the lightweight, LM inclusion can be tailored, enabling a large range in density

with negligible changes to the thermal conductivity of the inclusion as the thermal conductivity is dominated by electrons. Experimental thermal conductivity results measured using the transient hot-wire method agree well with the Bruggeman and Cheng-Vachon models of effective medium theory. As with previously reported LM embedded elastomer composites, this composite shows increased thermal conductivity under strain and is able to achieve maximum strain above 400%. This work presents a new material architecture to enable independent control of the thermal conductivity and density of LM elastomer composites, offering new opportunities to tune functional properties of systems where weight is critical.

11:15 AM SM05.07.04
Inverted Shape Memory Elastomeric Composite (i-SMEC) with Matrix-Enabled Fixing and Fiber-Driven Recovery Caitlin D'Ambrosio[1], Melodie I. Lawton[2], Kelly Tillman[3], Devon Shipp[3] and Patrick T. Mather[1]; [1]Bucknell University, United States; [2]University of Rochester, United States; [3]Clarkson University, United States

The demand for shape memory polymer (SMP) development has risen due to their multifunctional abilities and numerous applications in a variety of industries. This project explores a new approach to reconfigurable shape memory elastomeric composites (Re-SMEC) by altering the roles of the individual phases to create an inverted shape memory elastomeric composite (i-SMEC). In our previous work, we confirmed the feasibility of reconfiguration attributed to a dynamic covalent exchange between neighboring anhydride groups occurred, enabling the customization of the target geometry during shape memory activation. In the present work, we exploit these properties in the form of a new type of shape memory elastomeric composite that features a fibrous thermoplastic elastomer web combined with a reconfigurable elastomeric polyanhydride (PAH) matrix in a novel geometry controlled and manipulated thermomechanically. Contrary to traditional fiber-reinforced composites, where the fibrous phase temporarily fixes the geometry, this shape memory system utilizes the reconfigurable matrix for shape-fixing and elastic fibers as the memory retaining phase. We report the morphology, quantification of the mechanical properties, and the effect of fiber diameter on the shape memory abilities. Further, we introduce a new shape memory testing methodology of particular use for SMPs with fixing via matrix reconfiguration.

Soft Multifunctional Composites Using Liquid Metals Michael Dickey; North Carolina State University, United States

This talk will discuss new work in our group (and with collaborators) on soft composites that utilize liquid metals. Liquid metals composed of gallium are compelling materials for multifunctional materials because they can be incorporated, patterned, or mixed readily into elastomer. The addition of the metal alters the electrical and thermal properties, but without significantly stiffening the composite relative to the pure elastomer. In addition to imparting metallic thermal or electrical properties (the latter of which is useful for creating wires, antennas, and electrodes), it can also tune the effective dielectric properties of the material and also go through phase transitions to produce enormous changes in modulus. I will discuss several aspects and implementations of these multifunctional properties. First, characterizing the dielectric and electrical properties of such soft composites for pressure sensor applications. Second, utilizing such materials for conductors and electrodes that can undergo enormous changes in mechanical properties. Third, describing composites with electrical conductivity that increases with deformation, which is highly unusual. Fourth, printing of such composites by modifying the rheology to enable 3D printing. This work has implications for stretchable electronics, responsive materials, and soft robotics.

11:55 AM *SM05.07.06
Sharpening and Amplifying the Actuation of Liquid Crystalline Elastomers Timothy White; University of Colorado Boulder, United States

Liquid crystalline materials are pervasive in our homes, purses, and pockets. It has been long-known that liquid

crystallinity in polymers enables exceptional characteristics in high performance applications such as transparent armor or bulletproof vests. This talk will generally focus on a class of polymeric liquid crystalline materials: liquid crystalline elastomers. These materials were predicted by de Gennes to have exceptional promise as artificial muscles, owing to the unique assimilation of anisotropy and elasticity. Subsequent experimental studies have confirmed the salient features of these materials, with respect to other forms of stimuli-responsive soft matter, are large stroke actuation up to 400% as well "soft elasticity" (stretch at minimal stress).

This presentation will survey our efforts in directing the self-assembly of these materials to realize distinctive functional behavior with implications to soft robotics, flexible electronics, and biology. Most notably, enabled by the chemistries and processing methods developed in my laboratories, we have prepared liquid crystal elastomers with distinctive actuation and mechanical properties realizing nearly 40 J/kg work capacities in homogenous material compositions.

Functional Materials in Soft, Skin-Interfaced Haptic Systems for Virtual/Augmented Reality John A. Rogers; Northwestern University, United States

Advanced, immersive systems for virtual and augmented reality (VR/AR) will transform the way that we interact with computer-generated environments and, by extension, with one another. Although audio-visual aspects of VR/AR hardware are increasingly well developed, a frontier, underexplored opportunity for engineering science is in the development of interfaces that add spatio-temporally controlled physical sensations to the VR/AR experience, with the skin as the input interface. This talk summarizes a collection of foundational ideas in materials science and electrical engineering that enable a unique class of technology for this purpose – thin, soft, lightweight sheets that embed wirelessly powered and programmed arrays of high-speed, millimeter-scale mechanical actuators, capable of gently laminating onto the skin at nearly any location on the body, including but not limited to the fingertips. These systems qualitatively expand the VR/AR interface through complex patterns of physical sensory inputs across substantial areas of the body, time-coordinated with visual and auditory cues. Three example applications – one in social media interactions, a second in feedback for the control of robotic prosthetics, and a third in video gaming – illustrate the operational possibilities.

1:30 PM SM05.08.02
Magnetic Multimaterials with Multiphysics Controls for Widely Tunable Physical Properties Shuai Wu; The Ohio State University, United States

Metamaterials are architected materials that possess unique properties not observed in nature, which makes them promising candidates for a broad range of applications. After fabrication, existing metamaterial systems can only tune their properties to a limited extent. The coupled multimaterial system and multiphysics control provide a new strategy to achieve active metamaterials with widely tunable physical properties. Fabricated by recently developed magnetic shape memory polymer, demonstrated metamaterials can soften upon heating, and the embedded high-remanence magnetic particles drive the rapid and reversible shape change under the application of magnetic field. Once cooled, the stiffness of the composite can increase by three orders of magnitude to lock the deformed shape. Furthermore, the coupled magneto-mechanical actuation at high temperature realizes various deformation modes, which lead to widely tunable physical properties including

stiffness, Poisson's ratio and elastic wave bandgaps. Additionally, the combination of magnetic shape memory polymers with magnetic soft materials, together with the cooperative stimuli of magnetic field, mechanical loading and temperature, enable dexterous manipulations of material systems with tunable physical properties and shiftable mechanical behaviors.

1:45 PM SM05.08.03
Wearable Thermoelectric Generator with Self-healing, Recycling and Lego-Like Reconfiguring Capabilities Jianliang Xiao; University of Colorado Boulder, United States

Thermoelectric generators (TEGs) can directly convert low-grade heat to electricity, and thus are very promising energy sources for wearable electronics and 'Internet of Things'. However, conventional TEGs are rigid and brittle, and thus are not adaptable to the complex geometrical and compliant material properties of human body. Recently, developing flexible TEG systems has attracted a lot of attention, including using thermoelectric (TE) films, TE bulks, printable TE inks, TE fibers and organic TE materials. However, very few studies reported TEGs with good stretchability, which is critical to ensure conformal contact with complex geometries of human body for optimal thermoelectric performance. Inspired by the self-healing capability of human skin, self-healable electronics has also shown promising potential in wearable electronics for improved reliability and durability. However, this capability has not been achieved in TEG systems yet.
In this work, a high-performance wearable thermoelectric generator with superior stretching, self-healing, recycling, and Lego-like reconfiguration capabilities is reported. To achieve these properties, high-performance modular thermoelectric chips, dynamic covalent thermoset polyimine as substrate and encapsulation, and flowable liquid metal as electrical wiring are integrated through a novel mechanical architecture design of "soft motherboard-rigid plugin modules". This TEG can self-heal when it's damaged by mechanical cut. When not needed, this TEG can be fully recycled, and the recycled polymer solution, thermoelectric chips and liquid metal can all be used to fabricate a new generation of TEG device. The lego-like reconfiguration capability allows reconfiguring multiple TEGs into a single TEG with increased power output. This TEG can produce a record high open-circuit voltage density of 1 V/cm^2 at temperature difference 95 K, which is promising for harvesting low-grade heat to power 'Internet of Things' and wearable electronics. These features enable TEGs to be adaptable to the rapidly changing mechanical and thermal conditions, and user requirements. The reported TEG demonstrate superior mechanical compliance and deformability. It can be bent and stretched without sacrificing the thermoelectric performance. Cyclic bending test of the TEG for 1000 times led to no obvious degradation. When subjected to a tensile strain of 120%, the TEG still functioned well. Furthermore, a wavelength-selective metamaterial film is integrated at the cold side of the TEG to simultaneously maximize the radiative cooling and minimize the absorption of solar irradiation. Therefore the thermoelectric performance can be greatly enhanced under solar irradiation, which is critically important for wearable energy harvesting during outdoor activities. The design concepts, approaches and properties of the TEG system reported in this work can pave the way for delivering the next-generation high-performance, adaptable, customizable, durable, economical and eco-friendly energy harvesting devices with wide applications.

2:00 PM SM05.08.05
Local Stiffness Control and Anti-Bacterial Properties by a Metal Redox Reaction in Double Network Hydrogels Sooik Im, Ethan Frey, Jinwoo Ma, Jan Genzer, Michael Dickey and Vi Khanh Truong; North Carolina State University, United States

Hydrogels are hydrophilic polymer networks, which contain water and electrolytes. Double network hydrogels have enhanced mechanical properties relative to single networks [1]. The presence of a secondary network that consists of a bioderived material, alginate, can dissipate energy through sacrificial bonds that break during elongation, while the first polymer network remains intact. The double network hydrogel can be toughened further by ionic crosslinking between carboxylic groups in alginate and di- or trivalent metal ions. With this interaction, hydrogel stiffness can be tuned locally. Previously, ionoprinting with Cu^{2+} was employed to increase stiffness locally to actuate and modify the stiffness of hydrogels [2]. However, this method can increase stiffness only at the surface of the gel. Here, we used metal redox reactions between Bi particles and

Ag^+ to tune hydrogel stiffness locally. By controlling particle distribution and reaction time, we control the properties of the gel. The gel is multifunctional since it has both tunable mechanical and anti-bacterial properties arising from the ions.
We fabricated polyacrylamide/alginate double network hydrogels embedded with Bi particles. The hydrogels were dipped into $AgNO_3$ solution to initiate a reaction between Bi and Ag^+. Bi particles are ionized into Bi^{3+}, which crosslinks with carboxylic groups (COO^-) of the alginate. The crosslinking bonds stiffen the hydrogels, leading to an increase of the dynamic modulus by two-fold. The local strain level within the hydrogel was mapped using digital image correlation (DIC). By correlating the particle distribution with the local strain level, we confirmed Bi^{3+} produced on the Bi particle surfaces caused a heterogeneous local strain level in the gel. Tuning the dipping time in $AgNO_3$ solution leads to the gradient of modulus in the hydrogels. We mapped dynamic gradient modulus by cutting the hydrogels into different parts, which were measured separately. Modulus gradient hydrogels from the reactions can act as a bridge between soft and hard materials. This modulus gradient was similar to that of cartilage. With Bi particles settling in the pre-gel solution, the hydrogel was found to bend toward the side with high particle density due to the difference in modulus within the hydrogels. As an application, we confirmed Ag particles generated by the redox reaction could be used as antibacterial agents. Bacterial inhibition zone increased with increasing concentration of $AgNO_3$.

Biomimetic Complexity and Graph Theory (GT) of Chiral Nanostructures Nicholas A. Kotov; University of Michigan–Ann Arbor, United States

The structural complexity and multifunctionality of composite biomaterials and biomineralized particles arises from the hierarchical ordering of inorganic building blocks over multiple scales. While empirical observations of complex nanoassemblies are abundant, physicochemical mechanisms leading to their geometrical complexity are still puzzling, especially for non-uniformly sized components. Here we report the assembly of hierarchically organized particles (HOPs) with twisted spikes and other morphologies from polydisperse Au-Cys nanoplatelets [1]. The complexity of Au-Cys HOPs is higher than biological counterparts or other complex particles as enumerated by graph theory (GT). Complexity Index (*CI*) and other GT parameters can be applied to a variety of different nanoscale materials to assess their structural organization. As the result of this analysis, we determined that intricate organization of HOPs emerges from competing chirality-dependent assembly restrictions that render assembly pathways primarily dependent on nanoparticle symmetry rather than size. These findings and HOPs phase diagrams open a pathway to a large family of colloids with complex architectures and unusual chiroptical and chemical properties. Developed GT methods and new index-property relations were also applied to design complex biomimetic composites for energy and robotics applications [2].

SM05

4:00 PM SM05.09.01
Energy-Efficient Adaptive Multimodal Thermal Management for Personal Health—The Nexus of Light, Heat and Smart Materials Po-Chun Hsu; Duke University, United States

As warm-blooded mammals, the human body is constantly maintaining its core temperature against ambient fluctuation. For extreme temperatures or suboptimal physiological conditions, it may result in serious health issues. For example, at low ambient temperature, blood pressure and viscosity may increase, which are strongly correlated with cardiovascular diseases. This is the reason why cardiovascular diseases often have seasonal dependence. On the other hand, at high ambient temperature, excessive sweating can cause electrolyte imbalance or even heat stroke. Commercial body heating/cooling devices, such as Joule heating or Peltier cooling, are prohibitively energy-intensive or bulky for continuous use. In this talk, I will demonstrate our recent research progress in energy-efficient adaptive textiles that can adjust the heat balance via controlling the heat transfer coefficients rather than actively supplying power. First, I will introduce the wearable varied emittance (WeaVE) device that modulates the human body radiative heat transfer to accomplish thermoregulation with ultralow energy consumption. The electrochemically-operated WeaVE can switch the mid-IR emissivity by more than 40% within less than one minute. Kirigami design enables superior stretchability and conformality when applying to the human body. By communicating with ambient temperature and humidity sensors, the WeaVE can autonomously stabilize the body heat loss to accomplish thermal comfort in a natural and continuous manner. Second, I will demonstrate the multimodal moisture-responsive wearable device that modulates both radiative and convective heat transfer to accomplish large tunability. In both projects, I will explain how the judicious choice of materials and design, based on fundamental physical principles, can directly result in high performances in multiple aspects.

4:15 PM SM05.09.02
Soft and Stretchable Energy Harvesting Using Liquid Metals Veenasri Vallem, Erin Roosa, Tyler Ledinh and Michael Dickey; North Carolina State University, United States

With a fast-growing interest in flexible and stretchable soft electronic devices (e.g. electronic skin, soft robotics, implantable devices, tactile sensors, wearable electronics, smart textiles, etc.), there has been an increasing demand for similar sustainable power sources. Commonly used power sources such as batteries are rigid and require frequent recharging. Rigidity inhibits the stretchability/wearability, limiting the usage of the device, and frequent recharging limits the operating range of the device. Moreover, implantable devices that utilize batteries exhibit a limited life-time and require additional surgeries to replace the battery thereby presenting a huge risk to the users. To address these limitations, efforts have been made to develop soft energy harvesters that can convert human motion/ambient mechanical energy to electrical energy. Energy harvesting can eliminate the need for frequent recharging, which allows the device to operate in a tether-free manner. Furthermore, users can generate mechanical energy at their will, which enables the harvesters to power the devices in remote settings. Triboelectric and piezoelectric generators are prominently used harvesters for converting mechanical energy to electrical energy. Triboelectric harvesters have gained great popularity due to their relatively straightforward fabrication. They induce electrical current based on contact electrification (rubbing two surfaces) and electrostatic induction (oscillating the distance between charged surfaces). Triboelectric harvesters generate high voltages and low currents. They require moisture-free environments and rubbing components to enable contact electrification. Piezoelectric generators, in contrast, generate electricity due to inherent polarization

when subjected to mechanical deformation. However, they require extensive fabrication techniques and suffer loss in energy conversion when converted to flexible/stretchable devices, as their fundamental materials are intrinsically hard and brittle. We report a new approach to energy harvesting that utilizes liquid metals. These devices generate about 0.2 mW m^{-2} by harnessing energy from mechanical motion. We have characterized the behavior of these devices as a function of a variety of parameters including material properties (chemical composition), design parameters (organization and volume of each component), and physical deformation (amplitude and frequency of the mechanical energy input). We have developed a physics-based model to predict device performance. The devices behave as expected and the response of the devices to deformation matches the model. The liquid metal-based soft device is stretchable and can generate an electrical signal when deformed, which may be useful for energy harvesting as well as wearable self-powered sensors. These devices can be used to monitor human activities thereby find many applications in wearable electronics, dynamic tactile surfaces, healthcare systems like rehabilitation and prosthetics.

4:30 PM SM05.09.03
Harnessing a Molecular Switch in an Energy-Efficient Thermal Actuating Bilayer Michael Leveille, Wenxin Fu, Jacqueline Bustamante, Sayantani Ghosh and Jennifer Lu; University of California, Merced, United States

Stimuli-responsive materials have proliferated in recent years due to their potential for a broad range of applications including switching, actuating, sensing, energy harvesting, and soft biorobotics and wearable devices. Herein we describe a bilayer system that can generate programmable deformation reversibly in response to photothermal stimuli (e.g. low-energy near infrared-induced photothermal heating) or heating a few degrees above room temperature.

The bilayer film consists of a polyarylamide layer containing a small amount of crosslinking dibenzocycloocta-1,5-diene (DBCOD) and is covalently bonded to a sheet of aligned carbon nanotubes (CNTs). Our design takes advantage of self-assembly of DBCOD units along the CNT longitudinal direction to generate directional thermal contraction upon the DBCOD conformational change. The coefficient of thermal expansion of CNTs is near zero while the polymer layer exhibits a large negative thermal expansion. This mismatch results in substantial thermal stress and thus large deflection of the bilayer with small changes in temperature. We have demonstrated a deflection of 6.5 mm per cm by heating from 20 to 60 °C. This deformation can be pre-programmed with the selection of CNT/cut pattern. Additionally, the bilayer inherits excellent cycle stability, moving as a single unit without separation due to the covalent bonds between polymer and CNT layers. This actuator offers thermal to mechanical energy conversion at an efficiency at least on par with state of the art of mechanoresponsive polymer systems. Finally, we have also demonstrated that electricity can be generated by photo- or thermal fluctuations by coupling the actuation to piezoelectric effects in a trilayer device.

Such a low-energy stimulus induced high-efficiency system paves pathways to develop remotely controlled actuators, low-energy driven artificial fingers as well as thermal-to-electric energy harvesting.

4:45 PM SM05.09.04
Late News: Amplification and Modulation of Compliant Mechanisms by Shape Memory Polymers Johan Dag Valentin Baeckemo[1,2], Yue Liu[1,2] and Andreas Lendlein[1,2]; [1]Institute of Active Polymers, Helmholtz-Zentrum Geesthacht, Germany; [2]Institute of Chemistry, University of Potsdam, Germany

Compliant mechanisms have attracted tremendous interest for application in fields such as consumer products, soft robotics, and even animatronics. The fundamental design principle is the non-linear bending behavior of beams, which for non-trivial geometry and large deformations cannot be solved for analytically by using classical Euler-Bernoulli and Timoshenko-based equations. Therefore models are demanded that can predict said behavior through numerical solvers, or even analytically. The improvement of computing performance and more sophisticated software enabled such models which have incidentally become an integral part in the design process.

Examples are the Pseudo-Rigid-Body (PRB)(*1*) model and the Beam Constraint Model (BCM)(*2*). Here the Chained Beam Constraint Model (CBCM)(*3*), a development on the BCM, was applied, which to a high degree of accuracy can predict the complex bending behaviour of thin beams. This model is applied to a selection of beam shapes and were further developed as 3D-structures. These were manufactured using a shape-memory polymer (SMP) which when programmed through a counter-mold could add additional functionalities such as the switching of bi-stability of a given design or the amplification of deformation. We explored a design and fabrication scheme from conception of compliant mechanisms through the application of the CBCM, the design of molds to create demonstrators out of SMP and later the evaluation of functionalities through mechanical testing.

The modelling was realized through Python programming and implementing its non-linear solvers from the SciPy package to solve the governing equations of the CBCM. 3D-printed master molds were created to cast the polydimethylsiloxane (PDMS) molds. Consequently, demonstrators were created by casting poly[ethylene-co(vinyl acetate)] (PEVA) as a SMP in the PDMS molds.
This study demonstrates how one can conceptualize design and forecast complex bending behaviours using computational tools, and in turn apply SMPs such as PEVA to further amplify or modulate functionalities. This study could be seen as a step to create novel manufacturing schemes for the use in growing fields such as soft robotics.

5:00 PM SM05.09.05
Late News: Dynamic, Remote-Controllable Electroactive Hydrogel Waveguide Architectures Oscar Alejandro Herrera Cortes and Kalaichelvi Saravanamuttu; McMaster University, Canada

We generated electroactive hydrogel light-guiding structures and demonstrated that their orientation, motion and - thereby the direction of their light output - can be precisely and remotely controlled through external electrical fields. This was achieved with a range of architectures including planar slab waveguides, individual and small arrays of cylindrical waveguides as well as long-range waveguide lattices (> 10 000 cm^{-2}). Waveguides were induced in electroactive photopolymerizable hydrogels by self-trapped visible beams from light-emitting diodes (LEDs). These nonlinear waves are elicited when photo-induced refractive index changes counter the natural divergence of light beams launched into the hydrogels. Because the refractive index changes are irreversible, self-trapped beams permanently inscribe cylindrical waveguides along their paths. Such structures would be impossible to fabricate through conventional photolithographic methods. Because they are electroactive, we could apply and vary external electric fields to dynamically control the bending, angular orientation, and rotation (up to 360°) of these pliant light-guiding structures.

5:15 PM SM05.09.06
Late News: A Practical Hydrogenated Graphene Gas Sensor for CO2 Monitoring Samuel Escobar, Solimar Collazo Hernandez, Marcel Grau, Ernesto Espada, Brad Weiner and Gerardo Morell; University of Puerto Rico, Río Piedras, Puerto Rico

The development of a practical gas sensor is of great interest for monitoring toxic and non-toxic gases that might endanger our safety and wellbeing in different settings. Hereby we present a practical gas sensor based on hydrogenated graphene for CO_2 monitoring. Hydrogenated graphene was synthesized by a

single-step method directly onto an Au-pattern insulating substrate. Hydrogenated graphene was then characterized using RAMAN spectroscopy, X-ray photoelectron spectroscopy (XPS), and X-ray Diffraction (XRD). The materials interaction with CO_2 was systematically study at different PPM to determine our sensor's detection limits. Some preliminary research reveals that the hydrogenated graphene-based sensor is capable of sensing CO_2 at the mid-ppm-level.

5:30 PM SM05.09.07
Late News: Single-Step Synthesis of Highly Ferromagnetic Hydrogenated Graphene Samuel Escobar[1], Marcel Grau[1], Solimar Collazo Hernandez[1], Ernesto Espada[2], Brad Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico, Río Piedras, Puerto Rico; [2]University of Puerto Rico at Río Piedras, Puerto Rico

Hydrogenated graphene has been of great interest for the scientific community due to properties like ferromagnetism that are not usually present in graphene; requiring subsequent functionalization after synthesis to obtain them. Hereby, we present a novel method for synthesizing hydrogenated graphene via a single-step process. Hydrogenated graphene was characterized primarily by Raman spectroscopy, X-ray Photoelectron Spectroscopy (XPS), X-ray Diffraction spectroscopy (XRD) and Physical Properties measurement system (PPMS). Our Raman spectra confirms the presence of the 2930 cm-1peak associated with hydrogen functionalization, while the PPMS reveals the strongest ferromagnetism at room-temperature of a carbon-based material with a curie temperature higher than 350 K. These results are strong evidence of hydrogenated graphene's capabilities for its implementation to spintronics & memory applications.

5:45 PM SM05.09.08
Late News: Waveguide Encoded Lattices (WELs)—Slim Polymer Films with Enhanced Fields of View Inspired by Arthropodal Compound Eyes Kathryn Benincasa, Hao Lin, Cécile Fradin and Kalaichelvi Saravanamuttu; McMaster University, Canada

We have generated slim (2 mm to 3 mm thick), soft polymer films inscribed with Waveguide Encoded Lattices which - like arthropodal compound eyes - have enhanced panoramic field of view (FOV) and multiple optical functionalities. [1-3] These include an exceptionally high density of light harvesting waveguide units (>15,000 cm^{-2}), excellent imaging resolution, infinite depth of field and operability at all visible wavelengths including broad incandescent spectra (like sunlight) and discrete spectral ranges of lasers and LEDs. WELs transmit, focus and invert images without need for bulky optics and conversely, control the shape and trajectory of light beams. Different from the curved architectures of compound eyes, WELs are plane-faced, optically flat, slim films, which due to their translational symmetry could be extended over large areas (e.g. through roll-to-roll manufacturing) and due to their flexibility, integrated with ease into technologies such as LCDs, solar cells, cameras and smart phones.

8:15 PM SM05.10.01
Enabling Near-Hysteresis-Free Tactile Sensitive Electronic Skin Haicheng Yao, Weidong Yang, Wen

Cheng and Benjamin Tee; National University of Singapore, Singapore

The development of polymeric electronic skins (e-skins) enables applications such as telehealthcare, human-machine interfaces, prosthesis, and robotic perceptions.[1,2] The reliable sensing and monitoring require e-skin sensors to respond to mechanical stimuli sensitively and accurately with minimal data variation between contact cycles. However, hysteresis is always a trade-off with sensitivity in polymer-based sensors to limit their reliability. We propose a soft indentation process to generate annular metallic cracks on three-dimensional (3D) micro-elastomers.[3] The cracking mechanism is explored via theoretical analysis and numerical simulations. Good control of crack morphology on elastomers enables a piezoresistive e-skin sensor (TRACE) with high tactile sensitivity yet a large reduction of hysteresis (2.99 ± 1.37 %). The assembled TRACE sensors array achieves precise monitoring of pulse waveforms and continuous track of pulse wave velocity (PWV). It also enables robotic perceptions on surface textures with improved reliability compared to large-hysteresis e-skin sensors.

8:30 PM SM05.10.02

Nanopillar-Guided Nuclear Deformation for Cancer Grading Yongpeng Zeng, Yinyin Zhuang, Aninda Mitra, Weibo Gao and Wenting Zhao; Nanyang Technological University, Singapore

Nuclear shape irregularities, especially subnuclear features like invagination and folds on the nuclear envelope, are commonly found in metastatic cancer cells. Assessment of nuclear irregularities, i.e. nuclear grading, has long been used to diagnose and grade cancer in clinical practice. However, the current evaluation of cancer nuclear morphology is mainly through human-based inspection of microscopy images, and largely relies on the experience and judgment of individual pathologist. Inevitably, it suffers from low consistency and reproducibility. Though the reproducibility and precision can be enhanced with the aid of artificial intelligence, the most available algorithm for automatic assessment only uses the whole-nucleus morphological parameters for grading. The subnuclear and nanoscale features are often overlooked due to the randomness of their distribution and thus difficult to locate and segment for quantitative analysis. In this work, we introduced vertically aligned nanopillar arrays with defined geometry and pattern to enable effective guidance on subnuclear abnormal features in cancer cells. Taking breast cancer cells as a model, we found that the low malignant MCF7 cells generated isotropic subnuclear deformation feature on nanopillars, while the high malignant MDA-MB-231 cells exhibited anisotropic patterns with the subnuclear features aligned with nanopillar arrays. By quantitative assessment of the isotropy of subnuclear features guided on nanopillars, differentiation of cancer cells in high and low malignancies was successfully achieved. We further demonstrated that the heterogeneity in a population of cancer cells can be quantitatively mapped. In addition, the therapeutic potential of drugs specifically targeting metastatic cells was also evaluated effectively using nanopillar arrays. We envision that the nanopillar-based nuclear grading will provide a new tool to improve both cancer diagnosis and anti-cancer drug screening.

8:45 PM SM05.10.03

Late News: Reconfigurable Soft Magnetic Actuators with Reprogrammable Magnetization Pattern Hyeonseo Song[1], Hajun Lee[1], Jaebyeong Lee[1], Jun Kyu Choi[1], Suwoo Lee[1], Jee Yoon Yi[1], Sunghoon Park[1], Jung-Woo Yoo[1], Min Sang Kwon[2] and Jiyun Kim[1]; [1]Ulsan National Institute of Science and Technology, Korea

(the Republic of); [2]Seoul National University, Korea (the Republic of)

Soft magnetic materials have shown promise in diverse applications due to their fast response, remote actuation, and large penetration range for various conditions. Those are usually composed of hard magnetic particles or discrete magnets incorporated in a base material, and the actuation of these materials arises from spatiotemporal interactions between the applied magnetic field, environment, and programmed magnetization. However, a limitation arises because actuation is constrained by the programmed magnetization profile because magnetic fillers are usually physically confined in the soft matrix after fabrication is completed. Here, we propose a new soft material composite, the ferromagnetic domain pattern of which can be reprogrammed without changing intrinsic magnetic properties of embedded magnetic particles or the molecular properties of the base material.

Our reprogrammable magnetic composite is composed of spatially separated magnetic microspheres embedded in the elastomeric matrix (Ecoflex 00-30). Each magnetic microsphere consists of neodymium-iron-boron (NdFeB) microparticles, with an average size of 5 μm, encapsulated in oligomeric polyethylene glycol (PEG). The magnetization profile of our composite can be easily reprogrammed using the phase transition of oligomeric polyethylene glycol which is encapsulating the magnetic microparticles.

If the encapsulating polymer changes from solid to liquid, the magnetic particles can freely move or rotate in the microspheres along the external magnetic field. As the material cools, the encapsulating polymer solidifies and it fixes the reprogrammed magnetic particle alignment. To verify the re-programmability of the magnetic composite, we measure the magnetic moment density in samples at various angles relative to the external magnetic field applied by the vibrating sample magnetometer.

As an illustrative example to demonstrate the ability to reprogram the magnetization pattern of our composite, we demonstrate several reconfigurable soft magnetic actuators. The actuators can be classified into three types; (1) complex transformations of a continuous magnetic membrane are realized as a fully functional origami. (2) various transformations of a magnetic origami sheet with discrete magnetic layers on a flexible substrate layer are demonstrated by utilizing our magnetic composite as a functional layer. (3) *in situ* reprogramming scenario is proposed by adding a conductive heating layer to the reprogrammable magnetic layer.

We expect that this soft magnetic composite with a reprogrammable magnetization pattern could be used to make reconfigurable soft material systems for a wide range of applications including biomedical engineering, flexible electronics, and soft robotics.

Modified Structures with Crack based Sensors for Physiology Detection Byeonghak Park and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

From so-called “smartwatches” to implantable pacemakers, wearable/implantable mechanosensors have been regarded as essentials and promising potentials for biomedical applications and even for raising the quality of daily life. Crack based mechanosensors have risen promising potentials for communicating with the human, so that they have been developed in the aspect of sensitivity, stretchability, durability, visualizing, and multi-functionality for few years. While valuable mechanical physiology is composed of complex stimuli such as strain, pressure, and torsion, however, due to the geometrical and mechanical properties of the cracks, the sensitivity of the crack based sensors is limited to the strain stimulus. Here, we describe the modified inner structures for transforming pressure to the plane strain, enabling the highly sensitive ability to the pressure. As a given pressure, the strain can be amplified over 3 times, which is a big advantage for the strain-sensitive mechanosensors. Attributed to the structure, the crack based sensor can detect the pressure up to 10 MPa with a 3x10^6/Pa sensitivity, which is more than 100 times sensitive than the normal crack based sensors. We found the advantages of the biomedical application which has complex strain and pressure, and especially, the jaw rehabilitation devices for the neck and head cancer patients. Despite the 3D printed supporters of the device, the sensor array can successfully discriminate each position and each pressure of the rehabilitating bite trials. The

structures can be huge potentials for the biomedical physiology detection for the electronics.

Scaling of Internal Dissipation of Polycrystalline Solids on Grain-Size and Frequency Chuangchuang Duan[1,2] and Yujie Wei[1,2]; [1]Chinese Academy of Sciences, China; [2]University of Chinese Academy of Sciences, China

Internal friction is essential for nearly all solids to dissipate kinetic energy through internal mechanisms. The pioneering analyses by Zener (Phys. Rev. 60 (1941) 906-908) and Kê (Phys. Rev. 71 (1947) 533-546) demonstrated the existence of a single friction peak in the loss modulus spectrum of polycrystalline solids, which is attributed to viscous sliding in grain boundaries. In this study, we establish a continuum model coupled elastic deformation, viscous creep and diffusion in grain boundaries and reveal the existence of a second loss modulus peak resulted from viscous deformation within grain boundaries [1]. The corresponding two frequencies, when internal dissipation reaches its local maximum, depend on grain size d: the lower frequency one is proportional to d^{-3}, and the higher frequency one is proportional to d^{-1}. The underlying deformation mechanisms accounting for the two peaks and the scaling laws are identified. The inherent scaling laws are related to the combination and architecture of the dissipative soft grain boundary layers and hard grains in polycrystalline solids. The effects of local elasticity and diffusion in grain boundaries on the loss modulus spectrum are examined. The findings can be applied to granular and porous materials, and complex rheology in geosciences, where internal dissipation is momentous for waves and seismic activities. The unifying picture revealed based on the combination of hard grains and soft grain boundary layers could be employed to many heterogeneous systems for their design for high damping performance.

Late News: Benchmarking of Molecular Dynamics Force Fields for Solid-Liquid and Solid-Solid Phase Transitions in Alkanes Stephen Burrows and Stoyan K. Smoukov; Queen Mary University of London, United Kingdom

Accurate prediction of alkane phase transitions involving solids are needed to prevent catastrophic pipeline blockages, improve lubrication formulations, smart insulation and energy storage, and bring fundamental understanding to processes such as artificial morphogenesis. Solid-solid phase transitions are rarely modeled due to difficulties in long timescales for nucleation and dynamics, as well as lack or order descriptors. We report on the applicability, accuracy and computational performance of seven representative molecular dynamics models (TraPPE, PYS, CHARMM36, L-OPLS, COMPASS, Williams, and the newly optimized Williams 7B).

Late News: Microfluidic-Assisted Phase Separation and Phase Transition of Liquid Proteinaceous Materials Yufan Xu[1], Yi Shen[1,2] and Tuomas P. Knowles[1,1]; [1]University of Cambridge, United Kingdom; [2]The University of Sydney, Australia

Liquid-liquid phase separation (LLPS) of proteinaceous materials and crowding agents is emerging as a significant model facilitating the understanding of protein functions and malfunctions, which can find healthcare-related applications in the understanding, diagnosis, and treatment of diseases. In this presentation, we will report the construction, characterisation, and application of multiphase-based all-aqueous materials generated from the concept and mechanism of LLPS of extracellular proteins and crowding agents using microfluidic devices. Smart multiphase-based protein microgels, dynamic phase-separated protein microgels, and spatially inhomogeneous one-phase protein microgels will be demonstrated. The demixed states of proteins in crowding agents highlight the LLPS of the all-aqueous material systems. We will report the LLPS findings and explanations in micron-scaled compartments containing multiphase-based materials, and the LLPS of extracellular proteins and their surrounding environments at a larger scale. As a control study, spatially inhomogeneous one-phase protein microgels will be displayed. The possible mechanisms, fabrication techniques, applications, as well as the opportunities and challenges of the multiphase-based material systems will be presented. Microfluidic platforms can open up new routes for the advanced processing and precise controlling of biocompatible and bioactive materials at the microscale, in a fashion where conventional manufacturing was thought to be impossible. The microgels are promising models for temperature sensing, soft robots, as well as cell-culture scaffolds, which can promote the development of bioengineering and biophysics.

Late News: Active Polymeric Sheets for Plant Protection Based on Pickering Emulsion Templating
Karthik Ananth Mani[1], Meche Tefang Aureole Berenice[1] and Guy Mechrez[2]; [1]The Hebrew University of Jerusalem, Israel; [2]Agricultural Research Organization, Israel

In the past few years, there has been a tremendous amount of scientific activity in the field of controlled release of volatile antimicrobial agents such as Thymol and Carvacrol, which have shown high antimicrobial activity and suitability for food and agriculture applications from the regulatory point of view. However, the ability to develop efficient and cost-effective controlled release formulations for essential oils is still highly challenging. This research presents the development of an active polymeric sheet for plant protection. Thymol is a natural monoterpenoid phenol, which is isomeric with Carvacrol found in thyme oil and has beneficial properties. Thymol will be dissolved and encapsulated in the minor phase of toluene-in-water Pickering emulsion or in the major phase of an inverse emulsion. Polycaprolactone or polydimethylsiloxane will be dissolved in the toluene phase. The studied emulsions with the encapsulated Thymol will be impregnated in a non-woven polypropylene sheet. After evaporation of the water and toluene, polymeric structures with Thymol in their matrix will be formed inside the non-woven sheet. The activity of the resulting sheets along with their release properties will be compressively investigated for protecting these plants; rosemary, mint, and thyme through bioassay infectivity analysis. The system, which will be developed in this proposed research, is expected to exhibit high tunability in terms of the release rates and clear ability to encapsulate known amounts of Thymol in the resulting capsule. In addition, this Pickering emulsion-based formulation has shown clear feasibility to be impregnated in polypropylene non-woven sheet, which results in the formation of active silica/polyacrylate microspheres on the filaments of the sheet.

3:00 PM SM05.11.05
Late News: The Role of End Groups in the Structure and Microscopic Dynamics of Unentangled Poly(ethylene glycol) Silica Nanocomposite Melts—Simulation and Theory
Emmanuel Skountzos[1,2], Katerina S. Karadima[1,2] and Vlasis Mavrantzas[1,2,3]; [1]University of Patras, Greece; [2]FORTH-ICE/HT, Greece; [3]ETH Zürich, Switzerland

Molecular dynamics simulations are employed to study an unentangled poly(ethylene glycol) (PEG) - silica

nanocomposite melt with emphasis on the structure of the adsorbed layer around the nanoparticle and the dynamics of adsorbed and free chains in the melt. The simulations reveal significant differences depending on the type of PEG terminal group assumed (hydroxyl versus methoxy) arising from the different ways that polymer chains adsorb on the silica surface in the two cases: hydroxyl-terminated PEG chains are adsorbed by their ends giving rise to a brush-like structure, whereas methoxy-terminated ones are adsorbed equally probably along their entire contour which results in better local packing of adsorbed segments. In both cases, the dominant mechanism for the strong adsorption of PEG chains onto silica is the development of hydrogen bonds. Hydroxyl-terminated chains, in particular, prefer to develop hydrogen bonds through their terminal OH groups implying the development of graft-like conformations. Additional information about the structure of the adsorbed layer on silica is provided through a detailed analysis of adsorbed chain conformations in terms of trains, loops and tails, revealing appreciable differences in the statistical properties (population per adsorbed chain and length) between the two nanocomposites examined. How the dense interfacial layer that develops in both cases affects the dynamic behavior of free chains, especially in the nanocomposite where PEG chains are terminated with hydroxyl groups, is also discussed. MD simulation results for the relative population of tails, trains and loops are used to parameterize a theoretical model based on the Rouse model[1] on the assumption of a set of mixing (additive) rules. Overall, the proposed analytical model seems to provide a very satisfactory description (qualitative and quantitative) of the simulation findings, which in turn are found to practically match experimentally measured data for the dynamic structure factor already reported in the literature[2,3] for the two types of nanocomposites addressed in our work under exactly the same conditions.

3:15 PM SM05.11.06
Late News: Single Cell Encapsulation via Pickering Emulsion Stabilized by TiO2 Nanoparticles Providing Biopesticides Resistance Against UV Radiation Reut Amar Feldbaum[1,2], Noga Yaakov[1], Karthik Ananth[1,3], Dana Ment[1] and Guy Mechrez[1]; [1]Agricultural Research Organization - the Volcani Center, Israel; [2]Bar-Ilan University, Israel; [3]The Hebrew University of Jerusalem, Israel

This study presents highly stable oil-in-water Pickering emulsions with tunable droplet size, suitable for individual encapsulation of fungal spores. The emulsions were stabilized by amine-functionalized TiO_2 (titania) nanoparticles (NPs). These emulsions were utilized for the development of a novel formulation for biological pest control with significant UV protection capability. The droplet size, stability, and structure of the emulsions were investigated at different titania contents and oil/water phase ratios. Most of the emulsions remained stable for 6 months. The Pickering emulsions' structural properties have been characterized by confocal microscopy and high-resolution cryogenic scanning electron microscopy (cryo-HRSEM). The presence of the titania particles at the interface was confirmed by both confocal microscopy and cryo-HRSEM. *Metarhizium brunneum* Ma7 conidia were incorporated into the emulsions. The successful encapsulation of individual conidia in the oil droplets was confirmed by confocal microscopy. The individual encapsulation of the conidia in the emulsions was significantly improved by dispersing the conidia in a 0.02% Triton X-100 solution prior to emulsification. Individually encapsulated conidia in a titania-based o/w Pickering emulsion have exhibited high UV protection levels, demonstrating the feasibility of the developed formulation to exhibit significant protection against UV for biopesticides.

Autonomous Material Robotics—From Self-Sensing and Movement to Molecular Dynamics Simulations Stoyan K. Smoukov; Queen Mary University of London, United Kingdom

Our combinatorial multi-functional materials have demonstrated self-sensing, movement, and programmability. Recent advances have allowed us to grow shapes from the bottom up. Now we are advancing to the ability to start growing autonomous material robots bottom-up from single molecules. In this invited talk reporting results of large collaborations, we highlight tools we have developed, including molecular dynamics simulations, to predict liquid-solid and solid-solid phase transitions. These enable the growth of functional swimming robots that are powered by environmental fluctuations and manufacturing processes by artificial morphogenesis.

5:15 PM SM05.12.01
Effects of Surfactants on the Microencapsulation of Off-the-Shelf Phase Change Thermochromic Materials for Thermal Storage Applications Abdullatif A. Hakami[1], Sesha Srinivasan[2], Keon Sahebkar[1], Mingyang Huang[1] and Elias Stefanakos[1]; [1]University of South Florida, United States; [2]Florida Polytechnic University, United States

We have investigated the effects of different surfactants and their concentrations in the microencapsulation of TiO_2 of phase change thermochromic materials procured commercially. These off-the-shelf phase change materials involve Leuco dye particles that has demonstrated color change (black to white) behavior at the low transition temperatures of about 36 ºC. The role of TiO_2 encapsulation is to protect these thermochromic particles from the degradation due to solar radiation. Various surfactants such as CTAB, SDBS, Hexadecanol and Tetradecanol at different concentrations have been used to synthesize the TiO_2 microencapsulated phase change thermochromic particles. A number of physico-chemical characterizations such as XRD, SEM, EDS, FTIR and TGA/DSC have been carried out to understand the surface morphology, composition and thermal behavior of TiO_2 microencapsulated phase change thermochromic materials for thermal storage applications.

Late News: Efficient and Accurate Modeling of Thermoset Systems Using a Synergistic Combination of First-Principles Quantum Chemistry and Molecular Dynamics Atif Afzal, Thomas Mustard, Andrea R. Browning and Mathew Halls; Schrodinger Inc., United States

Fiber-reinforced composites containing epoxy-matrix are one of the key structural materials used in designing high-performance aircraft, automobiles, and athletic equipment. Several properties, including the deformation characteristics, thermal stability, fluid sensitivity, and interfacial properties, of these composite materials are dependent on the polymer matrix. Thus, understanding the matrix chemistry would allow us to improve their performance by tailoring the chemical structure. For example, using multifunctional epoxides has shown to augment the thermophysical and mechanical properties of such composite materials. Using computational techniques, we can enumerate large combinations of epoxides and amines and evaluate their properties. To efficiently model such polymer systems, we have built robust workflows using both quantum mechanics (QM) and molecular dynamics (MD). The workflows employ automated QM tools to identify key reaction steps and their kinetics involved in polymer synthesis and matrix-crosslinking. In this work, we have screened the key reaction barriers of amine/epoxy/accelerant combinations yielding 252 reactive barriers. The kinetics information for a subset of these epoxy-amine systems was then cast into our crosslinking workflows to obtain realistic in-silico systems. Subsequently, we computed the structural, thermophysical, mechanical, and water uptake properties of these systems. We demonstrate that by combining our QM tools with our accurate forcefield and GPU accelerated MD code, we can generate physically meaningful morphologies and efficiently

study the properties of crosslinked polymer systems.

5:45 PM SM05.12.03
Alternating Polymer/Nanoparticle Layers for Enhanced Composite Performance Dharneedar Ravichandran, Yuxiang Zhu, Weiheng Xu, Sayli Jambhulkar and Kenan Song; Arizona State University, United States

Alternating layers originated from natural systems can display high-performance mechanical, thermal, electrical, optical, and other functional properties. We have developed new manufacturing that can blend polymers and nanoparticles from different channels and selectively place them in alternating layers. These layers contain nanoparticles confined within a phase and bond each of these phases via polymer phases. This structure is similar to the brick-and-mortar structure in nacre, namely, the stiff and rigid calcium carbonate and soft polymer materials. The interface formation is critical in forming superior properties. We studied the fabricated filaments, thin films, and laminates, thus confirming the layered structures' scalability. Our results also validated the high reinforcement efficiency of carbon nanotubes and nanofibers. We will also study how the particle loading, particle morphology, and interfacial interactions influence their electrical and other properties.

5:50 PM SM05.12.04
Kinetics of Crack Healing and Self-Repair Behaviors in a Sealant Glass for SOFC Application Padmanapan Rao and Raj N. Singh; Oklahoma State University, United States

A sealant is required for the Solid Oxide Fuel Cell (SOFC) to maintain hermeticity at high operating temperatures, keep fuel and oxidant from mixing, and avoid shorting of the cell stack. Glass and Glass-Ceramic materials are widely used as a sealant since their properties can be tailored to meet the stringent requirements of SOFC stack. This study used a self-repairable glass for crack healing kinetics and independent measurement of glass viscosity. The cracks on the glass surface are created using a Vickers's indenter to achieve a well-defined crack geometry, and then the glass is exposed to elevated temperatures for different length of time to study the crack-healing kinetics. The crack-healing kinetics is compared with the predictions of our theoretical model and found to be in good agreement. In addition, glass viscosity is extracted from the healing kinetics and compared with the independent measurement of viscosity from dilatometric and sintering data to further validate the crack-healing theoretical model. These results will be presented and discussed.

5:55 PM SM05.12.05
Late News: Integration of Aptamer-Based 3D Structures and Biological Reporters for Design of Multiplexed Biosensor Platform Irina Drachuk[1,2], Amy M. Ehrenworth Breedon[1,2], Yaroslav Chushak[3,2] and Jorge L. Chavez[2]; [1]UES, Inc., United States; [2]711 HPW, Airman Systems Directorate, WPAFB, United States; [3]Henry M. Jackson Foundation/ WPAFB, United States

Development of biological sensors that track basal and during-duty changes in biomarker levels can provide vital information for monitoring personnel workload and implementing remediation strategies. While biological systems (i.e. bacteria or yeast) have been proven to be robust systems for engineering sensing pathways to produce modular, tunable, and dynamic responses, the discovery or engineering of novel biorecognition elements (BREs) is a time consuming and tedious challenge. Aptamers, on the other hand, provide necessary selectivity and sensitivity. However, they do not provide easy means to capture a measurable signal. Therefore, we introduce a platform that combines *Biomarker-Responsive 3D Aptamer-based Structures* with *Biological Cell-based Reporters* to develop multiplexed sensing platform for rapid tracking of multiple stress- and fatigue-related biomarkers. The platform's design combines DNA-based microcapsules with a well-established cell-based biological reporter, *S. cerevisiae*. The activation of the biosensor platform is based on a step-wise mechanism involving release of encapsulated chemical cargo upon ligand binding to an aptamer-based structure, followed by the activation of a yeast-based biosensor by released cargo. The large dynamic range exhibited by both sensing units makes them ideal for use in pseudo two-component systems, where diverse

DNA aptamers can be reliably linked to a common whole-cell biosensor output without need for additional reengineering of the sensor with each novel analyte and/or reporter. Moreover, this design can include the activation of different genetic pathways to provide different type of readout outputs, including optical or electrochemical sensing. Alternatively, the genetic output can be linked to synthesizing active compounds for remediation purposes. Hence, by combining the best features of the biological systems and DNA structures, we aim to create a suitable multiplexed platform for monitoring of different analytes of interest and mitigation of performance degrading effects.

6:00 PM SM05.12.06
Late News: Improvement of Sensor Selectivity to Butanone by Modification of ZnO Hollow with NiS
Tarcísio M. Perfecto, Cecilia A. Zito and Diogo P. Volanti; Unesp - São Paulo State University, Brazil

With the exponential advance of industries in the world comes the great concern with the possible contaminants generated in industrial processes and the health of the population. Clean and contaminant-free air is essential for the well-being of the population and environmental preservation. In this sense, the need to detect toxic and harmful volatile organic compounds (VOCs) generated in industrial processes and environments is essential, requiring a system or a device for this task, with precision and low detection limits [1–4].
In addition to the harmful problems on human health caused by toxic VOCs, recent analyses of exhaled air have demonstrated the association of diseases and VOCs [5–9]. Some compounds have proven to be efficient disease biomarkers, such as diabetes [10] and lung cancer [11].
Developing a device or material to detect volatile organic compounds (VOC) is no longer a challenge, despite its great interest. The difficulty is linked to developing a material that does not suffer from interferences, such as from humidity, other gases, or volatiles present in the analyzes. In this sense, we present a new way to modify zinc oxide (ZnO) hollow spheres with nickel (II) sulfide (NiS) nanosheets, a barely studied material in the literature, to increase the butanone selectivity and to reduce the negative effect of humidity in the final response of the sensor.
Under dry conditions, pure ZnO hollow sphere presents the best sensing response of 705.3 to 100 ppm of butanone followed by the 5%-NiS-ZnO heterostructure with a response of 123.8. However, the selectivity of 5%-NiS-ZnO improves and reaches a value of 12.92, which is more than four times higher than the selectivity of pure ZnO (3.12). Furthermore, the performance under humidity atmospheres shows that NiS heterostructures suffer less effect of the humidity. The responses to 100 ppm of butanone under 55% of relative humidity were 40.2 and 23.7 for 5%-NiS-ZnO and pure ZnO, respectively. Therefore, the developed butanone sensor demonstrated excellent response, selectivity, and a promising possibility for its practical use in sensing devices under real conditions of humidity.

Late News: Revealing Surface Chemistry of Archaeological and Ethnographic Glass Beads Using X-Ray Photoelectron Spectroscopy Tamil Selvan Sakthivel[1], Joseph Lehner[2,1], Scott Branting[1] and Sudipta Seal[1]; [1]University of Central Florida, United States; [2]The University of Sydney, Australia

The scientific analysis of 2600-year-old archaeological and ethnographic materials has led to new perspectives on societies of past and present. Tangible cultural heritage objects are quite unlike materials prepared in known laboratory conditions because they were produced using traditional technologies in highly variable conditions. Particularly, In the Mediterranean region and Western Asia, the earliest man-made glasses in the Iron age were made from melting mixtures of natron (soda) and sand containing shell fragments (silica and lime), or ash derived from halophytic plants (soda and lime) and calcium-free sand or crushed quartzite (silica). Often knowledge about the source materials and technologies are lost, and they can only be reconstructed with careful scientific and forensic analyses. The present study focuses on two black glass beads decorated with either yellow or blue trails from 8th to 7th century BCE Sardis, glass beads that are exceptionally uncommon for this period, and on this site. A surface chemical analysis of the glass beads was made using high-resolution Imaging X-ray photoelectron spectroscopy (XPS) to understand the spatial relationships and historical evolution of chemical states inherent. We identified that the yellow glass is produced using lead stannate in which Tin in the glass is an opacifier. In the case of blue glass, copper and cobalt were the colorants. Exact chemical species identification of minerals and surface oxidation states of colorant metallic materials helps discriminate among source materials and thermodynamic processes, thereby permitting the reconstruction of technologies, provenance determination, and ancient trade routes. Funding is acknowledged NSF MRI: ECCS:1726636.

8:00 AM SM05.11.02
Late News: Silica Based Pickering Emulsions for Food and Agriculture Avital B. Benhaim and Guy Mechrez; Volcani Center, ARO, Israel, Israel

A simple and effective way to prepare multi walled carbon nanotubes (MWNT)/ /silica hybrid colloidosomes is presented. The colloidosomes have been generated by emulsion templating in a biphasic oil-in-water (o/w) system. Two trialkoxysilanes of complementary polarity, (3-aminopropyl)triethoxysilane and dodecyltriethoxysilane, were used to chemically immobilize the silica nanoparticles at the o/w interface and stabilize the as-generated PICKERING emulsions. The effects of varying the o/w ratio and the concentration of the added solids on the type of emulsion formed, the oil droplet size, as well as the emulsion stability have been investigated. The emulsion phase fraction was dependent on the silica content while the droplet size increased with increasing oil volume percentage. A solid shell emerged around the oil droplets from copolymerization between silane monomers. The thickness of the resulting shells was several hundreds of nm. Although MWNTs and silica nanoparticles both were co-assembled at the o/w interface, silica has shown to be the sole stabilizer, with APTES being crucial for the formation of the shell structure. Drop-casting of the emulsion and air-drying led to hierarchical open porous MWNT-silica nanocomposites. These new structures are promising as electrically conductive thin films for variety of applications, such as electro-optics, encapsulation, or chemical sensing. To the best of our knowledge, this is the first time that a CNT/silica colloidosome is prepared[1].

8:15 AM SM05.02.02
Fibers Deposition Control by Innovative Pyro-Electrospinning Romina Rega, Vito Pagliarulo, Sara Coppola, Veronica Vespini, Pietro Ferraro and Simonetta Grilli; National Research Council, Italy

The electrospinning (ES) technique is able to produce polymer fibres at micro- and nano-metric scale that find application in various technological and biomedical sectors. Although the technique is well established, it still has several limitations, such as the restricted variety of printable inks (due to nozzle clogging problems) and the low control of fiber deposition (due to bending phenomena). Indeed, for some applications, the orderly arrangement, and in general the control of the deposition of these fibers, is highly desirable and people try to achieve it typically by structuring the external electrodes or using very expensive masks. Here we propose an innovative approach, which turns out to be easy to apply and economical which we have called “pyro-electrospinning” (p-ES). This technology is able to print high viscosity inks by regulating the deposition of the fibers with true regularity at the microscale. The p-ES system is based on the pyroelectric effect of polar dielectric crystals such as lithium niobate (LN). The electric field generated by the pyroelectric effect acts electro-hydrodynamically on the liquid sample, allowing the ordered deposition of the fibers. Therefore, the use of syringes, electrodes, and nozzles generally used in standard technologies is avoided. The reliability of the technique has been demonstrated both in the production of ordered periodic array fibers mats of D, L-poly (lactic acid) (PDLLA) and in spiral-shaped polymethyl methacrylate (PMMA) fibers (up to 300 nm thick) directly on a support with a true regularity at the microscale. The technique proves valid also for the deposition of fibers of highly dense materials such as poly(lactic-co-glycolic acid) (PLGA) avoiding the limitations mentioned above. The results show that these structures are useful for cell patterning applications.

Multifunctional Helical Nanobots: Roles of Material and Geometry Ambarish Ghosh; Indian Institute of Science, India

Helical nanobots driven by magnetic fields can provide mechanical information about their local surrounding with sub-micron spatial resolution, probe complex, heterogenous biological environments, such as the intracellular environment, as well as the extracellular matrix; and provide a rich and powerful platform towards futuristic drug delivery. The same system can be used for sub-micron colloidal cargo manipulation in microfluidic devices and on-chip assembly applications. Their fabrication is based on shadow evaporation allowing a wafer scale route towards integration of many different functionalities in a single nanostructure. Crucially, their properties and functionalities can be tuned with great control using intelligent design of material and geometry, and I will present few examples of the same.

8:30 AM *SM06.01.02
Driven Nanomachines—Symmetry, Controlled Propulsion and Complex Environments Alexander Leshansky; Technion–Israel Institute of Technology, Israel

Steering of nano-/microhelices by a rotating magnetic field is considered a promising technique for controlled navigation of tiny objects through viscous fluidic environments. It was recently demonstrated that simple geometrically achiral planar structures can also be steered quite efficiently [1]. Such planar propellers are interesting for practical reasons, as they can be mass-fabricated using standard photolithography techniques. Following the earlier development of a theory of driven rotation and propulsion of magnetized object of an *arbitrary shape* in an in-plane rotating magnetic field [2], we propose general symmetry arguments (involving parity and charge conjugation) establishing correspondence between propulsive solutions of simple planar V-shaped structures on orientation of the dipolar magnetic moment [3]. In particular, it can be shown that in-plane magnetization results in propulsion due to a spontaneous symmetry breaking, whereas the rotating motors swim either parallel or anti-parallel to the field rotation axis depending on their initial orientation. Particular off-plane magnetization yields *unidirectional* propulsion typically associated with chiral structures, such as helices. Since planar micro/nano-structures are prone to in-plane magnetization and their uniform off-plane magnetization is not an easy task, the interesting question is whether they can be steered in a controllable fashion? Here we demonstrate that actuation by a *conical* rotating magnetic field (i.e., superposition of an in-plane rotating field and constant field orthogonal to it) can yield efficient unidirectional propulsion of planar and in-plane magnetized structures [4]. In particular, we found that the symmetrical V-shape magnetized along its symmetry axis which exhibits no net propulsion in in-plane rotating field, shows unidirectional in-sync propulsion with a *constant* (frequency-independent) velocity when actuated by the conical field. When the constant field is imposed in plane of the rotating field, it results in the net propulsion accompanied by the *drift* orthogonal to the axis of the field rotation [5]. Such setup can potentially be used to achieve *spatial* control over motion of individual propellers and their swarms.

Until now most of the theories considered propulsion through purely viscous Newtonian fluids. However, most practical (e.g., biomedical) applications of micro-/nanopropellers involve complex heterogeneous non-Newtonian (viscoelastic) fluidic environments. Modeling of such complex media would typically require advanced numerical approaches. In this talk I shall present the hydrodynamic slender-body theory based on phenomenological "two-fluid model" first introduced by de Gennes to study entangled polymer solutions. The model describes coupled dynamics of two phases – the viscous solvent and the embedded elastic polymer network. We demonstrate that the type of the boundary condition employed for the polymer network at the surface of the particle (e.g., slip, stick or depletion layer) plays a crucial role in determining its hydrodynamic mobility.

Materials for Magnetically Actuated Micro and Nanorobots Vincent M. Kadiri[1,2], Hyunah Kwon[1] and Peer Fischer[1,2]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Universität Stuttgart, Germany

Magnetic micromotors and microrobotic systems benefit from hard magnetic and biocompatible materials, as well as schemes to avoid adhesion and overcome biological barriers.
While chemical targeting enables tissue-specific delivery, magnetically propelled microrobots can navigate through complex biological media through surface functionalization[1-2] and can transport material towards individual cells. However, many commonly used magnetic materials or coatings are not biocompatible (Ni, Co) or possess weak magnetic moments (Fe, Fe_3O_4).
Here, we discuss both non-cytotoxic materials[3] and medically approved coatings[1-2] for magnetically actuated microrobots. Exciting applications range from targeted delivery through real tissues and to cells, as well as mobile contrast agents. In addition to passive coatings, it is also possible to consider chemically-active coatings where enzymes are immobilized[2] or assembled onto selected proteinaceous templates[4] which can facilitate the transport through complex biological fluids. Fully biocompatible magnetic microrobots combined with a suitable surface-chemistry are promising tools for biomedical applications.

Substantially Accelerating Sensing Speed of Low-Concentration Molecules with Motorized Microsensors and the Working Mechanism Zexi Liang, Jianhe Guo and Donglei (Emma) Fan; The University of Texas at

Austin, United States

Vigorous research efforts have advanced the state-of-the-art nanosensors with ultrahigh sensitivity for bioanalysis. However, a dilemmatic challenge remains: it is extremely difficult to obtain nanosensors that are both sensitive and high-speed for the detection of low-concentration molecules in aqueous samples. In this work, we demonstrate substantially accelerated sensing speed of low-concentration DNA molecules in aqueous suspension with retained high sensitivity by rotationally motorizing microsensors. An improvement of at least 3 to 4 times has been obtained from a sensor rotating at 630-1200 rpm. Theoretical analysis and modeling concerning both the convective-diffusion and the diffusion-absorption processes unveil the underlying working mechanism and the application range and limitation. This work provides a device scheme that could be applied to alleviate the dilemmatic challenge in biochemical sensing. The understanding of the complex interactions of molecules and moving micro-objects may assist the design of desired microrobotic systems for the capture, translocation, sensing, and release of biocargoes.

9:30 AM SM06.01.05
Late News: Synergistic Magnetism- and Light- Fields Manipulation Enables Omnidirectional Walking of Graphene Mini-Robots Bing Han[1], Zhuo-Chen Ma[2], Yong-Lai Zhang[3], Guang-Zhong Yang[2] and Hong-Bo Sun[1]; [1]Tsinghua University, China; [2]Institute of Medical Robotics Shanghai Jiao Tong University, China; [3]Jilin University, China

Miniaturized soft robots capable of omnidirectional walking through rough terrain are particularly promising for cutting-edge applications such as planetary exploration, military reconnaissance and disaster rescue. Especially, inspired by natural animals with sophisticated motion systems, great efforts have been devoted to developing walking robots based on different mechanisms. Nevertheless, most of the reported mini-robots are incapable of omnidirectional walking, which limits their controllability, active obstacle-avoidance ability, full space utilization and dead-corners elimination. The essential difficulty lies in that mini-robots with simplified components and reduced load-bearing are incapable of breaking motion symmetry in all directions through a highly controlled manner. In this study, we fabricated a small-scale crab robot (CraBot, overall dimension 2.5 cm) that enables omnidirectional walking via in-situ laser synergistic integration (LSI) of multiple graphene actuators at specified positions as joints. In this way, for the first time, we manipulated a mini-robot through coupled magnetism- and light- fields. The magnetic field regulates the center-of-mass of the CraBot, leading to an asymmetrical energy storage within the robot; meanwhile, the addressable light field selectively triggers the deformation of specific joints, releasing the accumulated energy into mechanical walk. In this way, the light field produces effective walking gait under the guidance of magnetic field synchronously. As a proof-of-concept walking to the left/right/front/back, as well as 45^{o} off its lateral directions are presented as typical walking paths. Such dual-field-coupled manipulation strategy may serve as a versatile mechanism for future robot designs.

9:45 AM SM06.01.06
3D Metal-Organic Microrobots Fabian Landers, Carlos C. Alcantara, Bradley J. Nelson and Salvador Pané; Swiss Federal Institute of Technology (ETH) Zurich, Switzerland

The last two decades have seen significant efforts in developing micro and nanoscale machines with the ability to locomote through fluids and realizing tasks that require small-scale precision. One of the primary motivations of this research has been the realization of machines that could navigate the human body's vessels and ultimately perform medical missions, such as targeted drug delivery, microsurgery, localized diagnosis, or tissue regeneration. To this end, the use of magnetically driven small-scale robots is among the most investigated strategies, as magnetic fields are biocompatible in a wide range of conditions and they allow for a rich spectrum of locomotion mechanisms. While traditionally, research on small-scale magnetic robots has been done with rigid magnetic micro- and nanostructures made of metals or ceramics, recent efforts are dedicated to creating softer versions with the incorporation of organic materials such as polymers or hydrogels. Soft materials are usually more biocompatible, their mechanical properties resemble those of biological tissues, and

they can be easily processed in different sizes and shapes. Composites consisting of small magnetic particulates dispersed in organic matrices are typically used to render these materials magnetic. Another approach involves coating polymers with magnetic films. Yet, these strategies are usually not optimal for magnetic manipulation. Note that the force or torque exerted in a magnetic body is proportional to the magnetic material's volume. Composites comprise a reduced number of particulates that can be hosted in their matrices, while films are limited in thickness. Additionally, when polymers are coated, some of their potential functionalities such as cargo transportation, shape transformation, or degradation can be severely compromised or inhibited.
To exploit the full capabilities of both stiff magnetic and soft organic materials, we present a process to manufacture interlocked metal-organic micromachines. The devices are fabricated by combining template-assisted metal electrodeposition and polymer microcasting in 3D printed molds obtained by two-photon polymerization (2PP). Sophisticated micrometric architectures such as cage-bar-ring metallic structures connected to multiple polymeric legs or metallic helices framed by a polymer casing can be successfully manufactured. We demonstrate the versatility of our approach by fabricating micromachines with iron as the magnetic component, and three prototypical polymers used for biomedical applications such as shape-memory polyurethane-based polymer (NOA-63), polydimethylsiloxane, and pure gelatin. Note that iron is the platable element with the highest saturation magnetization and displays optimal biocompatibility characteristics. Importantly, as our method involves mold-casting of polymers, the need for toxic cross-linkable moieties or photoinitiators can be avoided. In this talk, we will show the detailed manufacturing of these devices, the rich locomotion mechanisms of several complex interlocked microrobots, as well as strategies to tailor the buoyancy of the magnetic micromachines by means of the solvophobicity of the threaded polymeric structures. Finally, prospective applications such as control over the agglomeration of magnetic swarms will be discussed.

10:30 AM *SM06.02.01
High-Performance Soft Actuators Based on Electrostatic Forces Herbert R. Shea; Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland

Directly electrically driving soft actuators offers clear system-level advantages over pneumatic actuation, but adds a number of challenges. For a wide range of soft robotic applications, such as haptics, and mobile robots, getting rid of the compressor, with its bulk, noise and low overall energy efficiency is a key step towards untethered and portable operation.

Due to its high energy density, we have focused on electrostatic actuation, using high electric fields to deform elastomers or textile structures. By using thin dielectrics, high permittivity and high electrical breakdown strength films, and low stiffness electrodes, we can both push up energy density and reduced drive voltage.

For a fully stretchable device, we reduced the drive voltage of Dielectric Elastomer Actuators (DEAs) from several kV to 400 V, a level at which we can use SMD components for compact control electronics (mass 350 mg). We report “feel-through” untethered cutaneous haptics, with DEA actuators only 18 µm thick[1], so thin the user does not feel them mounted on his or her fingertip when they are off. However, when the 3 mm diameter devices are turned on, the user feels localized pulsation that allows receiving rich haptic information.

Using zipping electrostatic actuation, such as electro-ribbon from prof. Rossiter’s group and peano-HASELS from prof. Keplinger’s group allows for higher energy density than DEAs because thin flexible materials such a polyimide have generally much better electrical properties than thin elastomers. We have developed arrays of

sub-mm thick flexible actuators that generate over 60% strain and operate at over 300 Hz [2]. A 6 mm diameter actuator generates 300 mN normal force and 500 µm displacement. This is achieved using fluidically coupled electrostatic zipping and a combination of flexible polymers with high breakdown field and central silicone elastomer region in which no electric field is applied. We have made 5x5 arrays, mounted them directly on the arm and on consumer products, and report on user feedback for notification, control and navigation.

Finally, I will present an additive manufacturing approach to such devices, using ink jet printing to freely deposit elastomer, electrode and sacrificial layers for fluidic channels[3]. I will close by going over the challenges of integrating these technologies in a glove or suit and the promise of this field of soft electrostatic actuators.

11:00 AM *SM06.02.02

Soft Micro-Sensors and Micro-Actuators Fabricated by Direct Laser Writing Larisa Florea[1], Colm B. Delaney[1], Alexa Ennis[1], Deanna Nicdao[1], Marc del Pozo[2] and Albert P. Schenning[2]; [1]School of Chemistry and AMBER, the SFI Research Centre for Advanced Materials and BioEngineering Research, Trinity College Dublin, Ireland; [2]Department of Chemical Engineering, Eindhoven University of Technology, Netherlands

Reversible actuation through external stimuli is a critical component for the realization of smart devices in micro-mechanical, micro-optical and microfluidic systems. Significant advances in additive manufacturing has allowed for the creation of three-dimensional (3D) structures with sub-100 nm resolution(*1*). These advances in fabrication have allowed for considerable progress in the realization of micro-robots, such as micro-swimmers (*2*) or micro-grippers(*3*). Soft polymeric materials, such as responsive hydrogels, have the potential of augmenting the capabilities of hard micro-robotic units through the introduction of soft modules that mimic actuation of natural organisms. Hydrogels are hydrophilic, crosslinked polymer networks, that can absorb large quantities of water. Introduction of stimuli-responsive units in their structure, allows for their reversible transition from a hydrophilic (swollen) to a hydrophobic (contracted) state under external stimulation, in response to, for example, pH, temperature, light and magnetic fields. However, the main drawback of osmotically driven hydrogel actuators is their low actuation speed, where actuation force and response time are inextricably linked. This represents one of the major challenges for stimuli-responsive hydrogels which rely on the diffusion of analytes or bioanalytes. As response rate is dependent on the square of the hydrogel's characteristic dimensions, reduction of hydrogel size to a micro regime could yield an accelerated and augmented response.

Herein we demonstrate the use of Direct Laser Writing (DLW) by multi-photon polymerization for the realization of 3D micro-actuators and sensors based on stimuli-responsive hydrogels and soft polymeric materials. We present the high resolution fabrication of a variety of structures, in a wide range of materials, including acrylated monomers, liquid crystal elastomers (*4*) and poly(ionic liquids)(*5*). These 3D structures can increase their size by over 300% through the absorption of water or solvent and can expel a large amount of the hydration media upon photo-, thermal or chemical stimulation (4D effect). Furthermore, domains of varying stiffness (e.g. hinges, joints) are integrated on demand by altering the laser exposure. Regions of low stiffness (reduced laser exposure) allow for increased swelling of the hydrogel material whilst high stiffness (e.g. obtained via increased laser exposure) act as hinges to control the direction of the fold. The single fabrication step and single resist formulation used to tailor the mechanical properties of soft polymer structures enables a simple processing method for the fabrication of complex 4D architectures via DLW.

3D micro-fabrication by DLW coupled with intrinsic (molecular) alignment is also demonstrated for the realization of dual-responsive soft polymer micro-structures. In this example, a supramolecular cholesteric liquid crystalline (CLC) elastomer is used for the fabrication of 4D structures, where the on-demand actuation is coupled with a color change. The CLC networks exhibit a self-organized helical photonic structure that can selectively reflect light, giving the 3D structures an initial color. Upon stimulation, via humidity (directly) and temperature (indirectly) changes, the network expands triggering a change in pitch of the CLC's helical structure, therefore resulting in a shift of the reflection band. The micro-actuator's expansion (up to 42 % in height at 75 %RH and at 19 °C) is accompanied by a color change. Such dual-response would be beneficial in microrobotics, enabling real-time interrogation of actuator status, through observation of the intrinsic color of the material.

11:25 AM SM06.02.03
Soft Robots with Reconfigurable and Deactivatable Skeleton Yueping Wang, Xiyue Zou, Aaron Mazzeo and Howon Lee; Rutgers, The State University of New Jersey, United States

Soft robots have been attracting great attention for their high flexibility and versatility. One of the most significant shortcomings of inflatable soft robots is the low bending stiffness due to the intrinsic soft nature of elastomers. As a result, it becomes challenging to maintain the shape of a soft robot against gravitational force when the aspect ratio of a soft robotic manipulator increases (e.g. long and slender). To address this inherent drawback, we present a soft robot with reconfigurable and deactivatable skeleton. It consists of a soft elastomeric body reinforced with a rigid shape memory polymer (SMP) skeleton. Exploiting viscoelasticity of the SMP, the stiffness of the SMP skeleton can be varied over two orders of magnitude from ~1.2 GPa to ~2.4 MPa by resistive heating through an embedded liquid metal channel. At room temperature, the rigid SMP skeleton provides structural stability, making it possible for a large-scale soft robot to maintain its shape against gravity as vertebrates do. When flexible soft robotic actuation is needed, resistive heating is applied to deactivate the SMP skeleton mechanically, thereby rendering the soft robot flexible and pneumatically actuatable. Furthermore, the SMP allows the soft robot to be reconfigured into different shapes. This approach enables simple soft robotic gripping actuation with a large length scale of ~ 50 cm. We also demonstrate an amphibious locomotion of a soft robot which can reconfigure its four soft robotic limbs from straight flap for swimming in water, to curved legs for multi-pedal gaiting on rough terrains, to wheel-liked geometry for driving on flat surfaces. The reconfigurable and deactivatable skeleton may expand the applications of soft robots to diverse practical and industrial uses.

11:40 AM SM06.02.04
Late News: Electrically Responsive Elastomers—From Synthesis to Applications Dorina M. Opris; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Often the doors to major technological innovations are opened by the discovery of novel functional materials. Dielectric elastomer transducers (DET) are an emerging technology, which gained importance over the last years. For this technology, the need for high dielectric permittivity polymers is higher than ever before. They hold great promise as active components in actuators, sensors, energy harvesting, artificial muscles, and soft robotics.
This presentation will give an overview of how we synthesized high dielectric permittivity elastomers. One approach to increase the dielectric permittivity consists of blending highly polarizable fillers in matrices with good elasticity. This approach failed because the materials are inhomogeneous at the molecular level and the mechanical and electromechanical properties are deteriorated. The second approach uses a chemical

modification of polymers with polar groups. This allows the formation of homogenous materials, but it has the downside that the glass transition temperature (T_g) increases too much and turns unattractive for practical applications.
Using a highly flexible polymer backbone, we have shown that it is possible to achieve polymers with increased dielectric permittivity and low T_g. Our strategy is to chemically modify polymers that have a very low T_g with polar groups. Despite the increase in T_g due to dipolar interactions, the T_g of the modified polymers is still attractively low. Using this approach, we were able to achieve the highest dielectric permittivity ever for a neat elastomer, which exhibit unprecedentedly high dielectric breakdown fields. Such elastomers respond to both low electric fields and low voltages.

11:55 AM *SM06.02.05

Soft BioRobotics—Rethinking Material Role for Life-Like Robot Behaviour Cecilia Laschi[1,2], Matteo Cianchetti[2], Leonardo Ricotti[2], Marcello Calisti[2] and Hilda Gòmez Bernal[2]; [1]National University of Singapore, Singapore; [2]Scuola Superiore Sant'Anna, Italy

BioRobotics is a successful approach for designing robots from and for living beings. Bioinspired robot design is based on principles observed and modelled on living beings. In a beneficial loop, bioinspired robots also contribute to gain insight in biology. Either bioinspired or not, biorobots are those applied in the biomedical field.
A lesson learnt from living beings is that the physical body has a more important role in shaping intelligence than we think. Behaviour is not only controlled by the computation happening in the nervous system but emerges from the interaction of the body with the environment. It then depends on the physical properties of the body itself, on its morphology, on the environment it is operating in. This concept of embodied intelligence brought to rethink bodyware in robotics. Compliance became key and either compliant joints or soft materials have been used.
In this scenario, recent advances in materials, smart materials and fabrication techniques are enabling the development of soft robots, with new technologies for actuation, sensing, control, energy supply. Among the many possible applications of soft robots are the biomedical ones, e.g. surgery, prosthetics, rehabilitation [1]. Soft robotics technologies can also be used for building biomimetic organs or physical models of human body parts. The EU HybridHeart project is developing a fully soft artificial heart. A physical model of vocal cords was developed for studying larynx physiology and pathologies.
Bioinspired soft robots find applications in explorations, in natural environments. They can access remote areas, confined spaces, complex or collapsed structures, both in land and at sea. Marine applications of soft robots give interesting challenges and opportunities for developing bioinspired swimming and locomotion. While current underwater robots operate in the water column, soft robots can afford the interaction with the seabed or underwater plants [2].
Soft robots open up unprecedent abilities. The classical robot abilities of manipulation and locomotion assume new forms and new abilities become possible, like morphing, growing, self-healing, biodegrading [3]. Soft robots enable a vision for life-like abilities and behaviour, thanks to the bioinspired principles they embed and to the materials they are built of. In this framework, bio-hybrid robots are another intriguing paradigm, pursuing the integration between artificial materials and living cells/tissues. The unique features of living cells, optimized by millions of years of natural evolution, can be actually exploited to enable specific robot abilities and to achieve robots scaling toward small dimensions [4].
Overall, soft biorobots support a vision for future robots where they have a full life cycle, in analogy to living beings [5]. They are born but grow in body and intelligence, they learn and adapt their bodies, find their energy, self-heal their bodies and biodegrade at the end of their life. The vision for life-like robot behaviour is still in its infancy but shows an enormous potential. It provides challenges and opportunities for revolutionizing robotics and for exploring new materials and fabrications schemes.

1:00 PM *SM06.03.01
Pick-and-Place by Switchable Microstructures—A Sustainable Handling Paradigm Eduard Arzt[1,2] and Marc Schöneich[3]; [1]INM–Leibniz Institute for New Materials, Germany; [2]Universität des Saarlandes, Germany; [3]INNOCISE GmbH, Germany

Reliable and sustainable automated manufacturing is predicted to play an even greater role in future industrial value creation than today. Automated handling processes are currently facing unprecedented challenges in terms of miniaturization, sustainability, and demanding production environments. Systems in worldwide use are mechanical grippers, electromagnetic actuators or vacuum suction devices. Requiring electrical energy and other valuable resources, these systems leave a large environmental footprint. They are dysfunctional with sensitive materials that suffer damage easily or with micro objects, causing low yields and high scrap rates. In this talk, it will be demonstrated that the new paradigm involving the tailoring of surface microstructures can offer innovative gripping solutions. Inspired by natural examples such as geckos and insects, micropatterning of polymeric surfaces allows the creation of various structure-related functionalities including the controlled adhesion and release of objects. These effects are based on van der Waals interactions and are largely independent of – sometimes environmentally harmful - materials chemistry; in particular, microfibrils can impart switchable stickiness to a material which is intrinsically non-adhesive. The sticking action is provided by a multitude of fine polymeric fibers (imitating a gecko foot); unsticking is provoked by actively switching the orientation of these hairs, resulting in accurate placement of an object. An elegant mechanical approach is to apply a compressive overload to the adhesive structures: the resulting elastic instability due to buckling of the fibrils leads to contact loss and creates a transition to a non-adhesive state. Such a load-controlled stimulus constitutes a reliable strategy and is straightforward to implement in industrial robotic systems. Subsequently, multistep switchable adhesives were developed, in which fibrils of varying length enable tuning of the adhesion strength. Other actuation mechanisms involve thermal stimuli, e.g. in combination with trained shape memory polymers or magnetic fields, which can trigger the bending of fibrils and induce a loss of contact.

The resulting Gecomer® technology has decisive advantages over conventional technologies: It is highly energy saving, resource sustainable, noise-free, compatible with sensitive surfaces, and applicable under extreme conditions where conventional solutions fail, e.g. in micro dimensions and in vacuum (as in space applications). To ensure reliable adhesion and controlled release, the pick-and-place process has been modelled by considering the interfacial stress distribution in the contact area. Governing parameters are the compressive preload, the size, shape and modulus of the fibril, the assumed defect statistics and the properties of the backing layer. An emerging challenge in microfabrication is the controlled release of small objects, where the weight of the objects to be handled is insufficient for easy detachment; for this, novel microstructure designs were developed that minimize the residual adhesion while ensuring high lateral precision during the placement step. Current developments included in-situ monitoring and machine learning to improve the reliability of the handling process. The new, precise and universal system solutions provided for automation, robotics and handling have already proven their practical suitability in demanding pilot applications. Examples of successful

implementation will be demonstrated.

1:30 PM *SM06.03.02
Liquid Metals for Soft Robotics Michael Dickey; North Carolina State University, United States

This talk will discuss recent progress in utilizing liquid metals as conductors for stretchable, soft, and reconfigurable components for soft robotics. Alloys of gallium are noted for their low viscosity, low toxicity, and near-zero vapor pressure. Despite the large surface tension of the metal, it can be patterned into non-spherical 2D and 3D shapes due to the presence of an ultra-thin oxide skin that forms on its surface. Because it is a liquid, the metal is extremely soft and flows in response to stress to retain electrical continuity under extreme deformation. By embedding the metal into elastomeric or gel substrates, it is possible to form soft, flexible, and conformal electrical components, stretchable antennas, and ultra-stretchable wires that maintain metallic conductivity up to ~800% strain. Thus, these materials are well-suited for soft robotics because they decouple electrical conductivity and mechanical properties. In addition to introducing the advantages of these materials for soft robotics, this talk will focus on recent work to utilize liquid metal for tactile sensors and energy harvesters. These advances have implications for soft machines and robots that have ultra-soft mechanical properties.

Robotic Surfaces with Tunable Stiffness and Reversible Shape-Morphing Chiara Daraio; California Institute of Technology, United States

Robotic surfaces that can reshape and react to external stimuli offer opportunities to create soft, versatile machines that can multi-task, while interacting safely with their surroundings. Such systems are useful in applications that range from haptic interfaces, wearable exoskeletons and reconfigurable medical supports. Key properties of robotic surfaces include their ability to control their local stiffness, reprogram their target shape and have sufficient mechanical loadbearing ability, to support weights and manipulate objects. In this talk, I will describe recent solutions developed in our group, to create structured fabrics that have tunable bending stiffness and robotic surfaces that allow for large, reprogrammable, and pliable shape morphing into smooth 3D geometries. To develop these solutions, we design layered, architected materials, consisting of interlocking particles or networks of layered, polymeric ribbons. We employ different actuation methods, including vacuum pressure and Joule heating, to control the response of the surfaces. We demonstrate the ability to fabricate fabrics that become >25 times stiffer than their relaxed configuration, when a small external pressure (~93 kPa) is applied. We also show that robotic surfaces consisting of layers of heat responsive liquid crystal elastomers (LCEs) can be reprogrammed to assume arbitrary shapes.

Selective Curing of Carbon Fiber Reinforced Plastics to Fabricate Deployable Folding Structures Thomas Celenza, Matthew F. Campbell, George A. Popov, Luke Kasper, Wujoon Cha, Cynthia Sung, Mark Yim and Igor Bargatin; University of Pennsylvania, United States

We have developed a photolithography-inspired method of transferring predetermined fold patterns to carbon fiber veneers *via* selective ultraviolet epoxy curing, which allows us to create deployable structural components for microrobots and microflyers. Our technique uses photosensitive epoxies that require ultraviolet light for curing with a patterned mask to inhibit photopolymerization along fold lines but to allow light exposure and therefore hardening reactions to take place elsewhere. Using this technique, we constructed origami-inspired fold patterns on samples with thicknesses of 200 microns and areal densities of 20 mg/cm^2 from bi-woven carbon fiber fabrics without the need for cuts, living hinges, or buckling lines. This work represents, to our knowledge, the first use of ultraviolet epoxies to make folding composite materials.

Significant research has been devoted to improving aerial vehicles and robots by decreasing their sizes and reducing their masses. Toward the first strategy, small untethered microflyers with diameters of just 2 cm have

been demonstrated[1]; however, these robots' small sizes were achieved by sacrificing aerodynamic components that provide maneuverability. To overcome this, deployable structures have been proposed as methods to increase microflyer control while maintaining compact dormant footprints[2]. Toward the second strategy, new materials have been explored that provide enhanced strength with lower densities. A prime example is carbon fiber[3], which has been widely used to fabricate micro aerial vehicles with dimensions >10 cm. Examples combining both of these performance enhancement strategies, *i.e.*, foldable composite sheets, are currently limited to large space assemblies and composite load bearing structures that have a single degree of freedom[3-5]. Employing these methods for small-scale vehicles has required specialized joint actuation and other design limitations[6,7].

There is thus a significant need for lightweight structural components that can be folded in multiple directions to allow arbitrary modular robot and microflyer designs. To bridge this gap, we have developed a method of transferring predetermined fold lines onto carbon fiber sheets using photosensitive epoxy resin and light-obstructing mask patterns. This method results in veneers with areas of high stiffness where ultraviolet light was exposed but thin foldable elastic areas where radiation was blocked. Importantly, our folds do not require cuts or fractures; rather, due to the absence of cured epoxy in the hinge areas, the carbon fibers can undergo microbuckling in a repeatable fashion[8]. Moreover, our technique allows fold patterns, such as those previously used in space applications[9], to be quickly imparted to carbon fiber sheets in a reproducible and mass producible fashion at a smaller scale than previous work.

To fabricate our folding veneers, we impregnated a bi-woven carbon fiber fabric with photocurable epoxy, exposed it to ultraviolet light through a 2-mm-wide frame, additively manufactured mask, and cleaned the resulting veneer to remove excess uncured resin. We are currently subjecting our samples to mechanical testing to identify their bending stiffnesses and radii of curvature and are designing complex fold patterns to demonstrate these veneers' deployable functionality. Our results represent a significant step forward in modular design and assembly toward deployable and lightweight components for robots and microflyers at such a small scale.

Multi-Assembly of Soft Electroactive Polymeric Yarn Actuators by Using Textile Processes Carin Backe[1], Jose G. Martinez[2], Li Guo[1], Edwin Jager[2] and Nils-Krister Persson[1]; [1]University of Borås, Sweden; [2]University of Linköping, Sweden

Textile assembly methods offer great possibilities to create complex, large-scale, multi-functional 2D materials (fabrics) by a continuous process of structuring yarns together, in an architected manner. By designing a specific pattern and using functionalized yarns the properties of such a fabric can enable a variety of roles for example actuation and mechanical stimuli. Moreover, actuation can be achieved in several directions as the textile assembly enables the construction of a network where yarns can be independently addressed in X and/or Y direction. These are advantages that can be utilized in the field of soft robotics in many ways. The

requirements for human-robotic interactions call for soft and compliant materials that are safe for such collaborative interactions and involve several types of functionalities. Textiles are easily conformed to the body, whether that is a robotic or a human one. Here we report on the integration of novel functional actuating yarns in the purpose of creating pliable textile actuators that also exhibit versatile morphing capabilities. The yarns consist of three layers; two of which are made of thin poly (3, 4-ethylenedioxythiophene): poly (styrene sulfonate) (PEDOT: PSS) coatings that cover opposite sides of the third layer, an ionogel. This stretchable gel supplies the system with ions for the actuation mechanism and therefore enables in-air actuation. The yarns are transformed into fabrics by using woven assembly techniques. This is an additive method that structures one set of yarns in a parallel sequence that is perpendicular to another second set of yarns. By structuring a number of yarns together in parallel the performance in terms of force output including blocking force is shown to increase. The textile assembly process allows for two approaches, collective and individual addressing for the actuating yarns. For the former, arranging the yarns into different pre-determined segments enable collective actuation of each segment to change the overall shape of the textile structure. In regards to the latter, by individual addressing we show that a specific and targeted actuation can be achieved. Furthermore, the arrangement in which the yarns are interlaced in the fabric enables switching the modality of the actuation. This means that we can alter a motion specific to the yarns into another by their arrangement in the textile structure. With our developed textile assembly method, we are approaching low-cost, large-scale production of actuating systems for human-robotic applications.

Late News: Photoreversible Q-Silsesquioxane/Azo Network Sponges Joseph Furgal and Nai-hsuan Hu; Bowling Green State University, United States

The synthesis and mechanical properties of photoswitchable silsesquioxane/azobenzene hybrid 3D–polymers (“dynamic sponges”) are presented and discussed. The hybrid is capable of extensive macroscopic movement, and overcomes previously problematic crosslink locking issues. A hydride–functionalized Q–type silsesquioxane ($Q_8M_8^H$) was reacted with di-allyloxyazobenzene using hydrosilylation methods. The properties of the resulting materials are controlled via careful choice of starting material ratios and solvent, leading to gels or films. Both morphologies show pronounced photoresponsive behavior in and on the surfaces of different solvents. Photoactuation is tracked by microscopy, DMA and UV/Vis spectroscopy. The gel system has a porous structure similar to a sponge. It undergoes shrinkage in volume by 18.3% in toluene under UV irradiation, and shows excellent recovery to the swollen state after irradiation with visible light. These novel photodynamic materials offer reversible modulus switching from 160 kPa in the swollen state to 500 kPa in the “wrung–out” sponge. The sponges can engage in uptake and release of a range of substances (i.e., reversible hydrophobic sponging), with overall performance determined by substrate size and polarity. Such behavior gives these materials high potential for soft robotics applications and great promise as reusable environmental remediators.

SM06.04.03
Biomimicking the Property Modulation and Self-Healing Characteristics of Biological Tissues Through an Electrochemical Cell with Soluble Porous Anode Changquan Lai; Nanyang Technological University, Singapore

Current structural materials for robotics generally possess mechanical properties that are static and can operate only within a narrow range of environmental conditions. In an effort to imitate living biological tissues that can modulate their properties dynamically in response to an environmental stimulus, we developed an electrochemical cell with a soluble porous anode (ECSPA). This cell allows material to be added to or removed from the structural electrode according to the duration, polarity and magnitude of the applied potential difference, bringing about precise and reversible modulation in the material's modulus, strength and energy absorption characteristics over 3 orders of magnitude. In response to a complete fracture, the cell was shown to be able to self-heal, achieving ~ 50% of its original load-bearing capability with as little as 6 hours of treatment. A self-contained ECSPA setup was also demonstrated as a proof-of-concept for how the cell can possibly be integrated into a robotic assembly for real-world applications.

SM06.04.04
High Fracture Toughness and Self-Healable Elastomers for Soft Robotics Matthew Tan and Pooi See Lee; Nanyang Technological University, Singapore

Fracture toughness and self-healing capabilities in synthetic soft materials are attractive features to prolong the lifetime of soft robotics and enable their usability in extreme or harsh environment. To achieve these two attributes, soft materials such as elastomers are often endowed with dynamic supramolecular bonds such as hydrogen bonds. In this work, we describe two toughening modes that arise from tuning the polymeric chain mobilities of carboxyl functionalized polyurethane (CPU) using plasticizers. Without plasticizers, intrinsic toughening was found to dominate as a result of strong hydrogen bonds that resist crack propagation. Under such conditions, CPU achieves a fracture toughness of (~105 kJ m^{-2}) at which a sharp crack tends to propagate when stretched. In contrast, upon the addition of plasticizers, extrinsic toughening mechanism dominates with energy dissipation from the breakage of weaker hydrogen bond interactions. Furthermore, large blunted cracks propagate within plasticized CPU with larger stretchability. By tuning the content of plasticizers within CPU, both toughening mechanisms can be combined, enhancing the fracture toughness of CPU (~122 kJ m^{-2}). To prove this hypothesis, we perform in-situ studies where notched CPU was stretched at various temperatures to modulate the chain mobilities. Also, at higher plasticizer content, CPU was found to display higher self-healing capabilities, retaining greater mechanical toughness. Overall, this work provides a fundamental mechanical understanding to tune the fracture toughness and self-healing of elastomers, making them attractive for soft robotic applications.

SM06.04.05
Late News: 3D Printable Silicone Double Networks for Soft Robotics Thomas J. Wallin; Facebook Reality Labs, United States

We report a framework for creating tough, 3D printable silicone double networks (SilDNs) by combining thiol-ene and condensation cured polydimethylsiloxanes. These two chemical reactions are "orthogonal"—each proceeds without hindering the other. Thus, photocurable thiol-ene network forms the shape during 3D printing and entraps the precursors to our latent condensation network which dominates the final mechanical properties. Thus, we can break the endemic process-structure-property trade-off in 3D printed polymers and create a family of soft (100kPa<E<1MPa), highly extensible ($\varepsilon > 100\%$) elastomers. The slower condensation reaction can also form interfacial bonds with diverse materials including ceramics, metals, and other polymers. With this strategy, we can create mechanical gradients spanning almost seven orders of magnitude, a similar range found in natural systems. We demonstrate the utility of this system by building soft robotic devices cohesively affixed to electronic circuitry and commercial garments. Further, we use machine learning to generate mechanical metamaterial structures based on the assembled structures of 3D printed rigid bodies with SilDNs. Lastly, we demonstrate a ternary chemistry where this framework can be extended to create multimaterial foamed elastomers.

SM06.04.07
Late News: Synergistic Integration of Smart Materials into 3D Printed Programmable Tensegrity Hajun

Lee, Yeonwoo Jang, Jun Kyu Choi, Suwoo Lee, Hyeonseo Song, Jin Pyo Lee, Nasreena Lone and Jiyun Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Successful designs of soft robots rely on both clever morphology and material properties. Many researchers have pursued the intelligent embodiment of smart materials into the soft systems, which results in the dynamic interaction of architecture, material, and environment. However, body designs of soft robots have lagged behind biological analogs because of the inherent complexities in both form and function in generating suitable environmental behaviors at desired scales.
Structural approaches are essential to increasing the systematic complexity and the functional diversity of soft material–based intelligent systems. Smart structures can represent unconventional but programmable mechanical properties, reacting to environmental changes in morphologically and functionally adaptive ways. These features distinguish smart structures from typical static structures with a primary purpose of providing load capacity. However, in most smart structures, most loads are focused on the flexible joints or hinges, and thus, combining multiple materials has limited synergistic effects in programming system-level mechanics to include both morphology and structural mechanics efficiently. Therefore, to increase programmable complexity and synergistic integration in 3D, more scalable and systematic approaches should be promoted because of combinatorial issues brought about by embedding multiple distinct materials in a seamless and synergistic way.
We propose the adoption of tensegrity as a class of metamaterial strategy for smart material-based robotic systems. Tensegrity systems are composed of both isolated compressive “struts” and a network of elastic “tendons” with a specific configuration of nodes. The main advantages of tensegrity structures include high stiffness-to-mass ratio, controllability, reliability, structural flexibility, and large deployment. Furthermore, by preserving the self-equilibrium of normal forces applied to its elements, tensegrities are easily stabilized as the structure stands or is deformed. This harmonious balancing of forces enables distinctive material components to be formed in a network, instead of piling up simple cellular units, and thus provides ample design space of morphology and mechanical properties. Despite its advantages, smart materials are rarely used as mechanical elements for the construction of smart tensegrity structures because of a lack of proper manufacturing processes allowing generation of multi-material parts with intricate 3D shapes.
In this work, we adopted the tensegrity for the development of soft structures with programmable mechanical responses in 3D. We endowed tensegrity with additional functionality by using magnetic materials as tendon components and used a 3D printing technology combined with sacrificial molding to fabricate tensegrities at a diverse scale. This method makes the construction of tensegrity a lot easier because it eliminates any post-assembly process of beam elements.
As a result of printing tensegrity with coordinated soft and stiff elements, we could use design parameters (such as geometry, topology, density, coordination number, and complexity) to program structure-level mechanics in a soft structure. On the basis of the programmed mechanics of tensegrity structures, we developed diverse smart structures and demonstrated a tensegrity robot capable of walking in any direction. We demonstrated several tensegrity actuators (such as auxetic behavior, locomotion, and intaking) by leveraging smart tendons with magnetic functionality. This physical realization of complex 3D metamaterials with multiple mechanical components can pave the way toward more analytical and algorithmic designs of scalable geometry and contribute to complex morphing for 3D soft systems. Furthermore, this may provide new form factors for 3D flexible devices in the fields of flexible electronics, biomedicine, and soft robotics.

SM06.04.08
Rehealable and Highly Stretchable Strain Sensing System Enabled by Dynamic Covalent Thermoset
Jianliang Xiao; University of Colorado Boulder, United States

Soft and stretchable integrated electronic systems have gained wide popularity recently due to their superior mechanical compliance and conformability, which distinguishes them from conventional rigid electronic devices. Cutting-edge technologies of stretchable, skin-mountable, and wearable electronics are able to effectively accommodate large strain when integrated onto soft, elastic and curved surfaces. Ultralow modulus and high stretchability of electronic systems are achieved by designing new structural layouts and developing novel materials. However, stretchable conductors made of metallic materials often suffer from cycling induced

fatigue, which cannot be easily improved by new structural designs.
Recently, various wearable strain sensors with high stretchability have been developed for their broad applications in human motion detection, health care, human-machine interfaces. Strain sensors can be classified into two types: resistive-type and capacitive-type sensors. Resistive-type sensors are typically composed of composites combining electrically conductive sensing films with flexible substrates. When stretched, the microstructure of sensing films evolves, and the electrical resistance changes accordingly. On the other hand, a capacitive-type sensor consists of a highly compliant dielectric layer between a pair of stretchable electrodes. When stretched, two electrodes become closer, and the capacitance increases. Alternatively, stretchable and wearable strain sensors can also be classified according to their materials, into categories such as fiber, liquid metal (LM), and piezoelectricity based strain sensors. As a liquid-state conductor, the LM features excellent electrical conductivity, fatigue-free characteristics and extremely high deformability, thus is an ideal component for wearable strain sensors.
Moreover, materials that can heal/reheal like natural skins have also been developed in wearable electronics. Self-healing/rehealing can help wearable electronics to gain benefits of reliability, durability, cost and performance. While some self-healing mechanisms can automatically respond to damages without stimuli, most self-healing/rehealing materials still require moderate external stimulation—such as heat, light, water and chemicals—to trigger the healing process. Various strategies have also been investigated to achieve self-healability/rehealibility, including metal-ligand supramolecular, microvascular agents, hydrogen bonds, semiconducting polymers, and dynamic covalent bonds. Among the many self-healing mechanisms, dynamic covalent bonding in polymer networks is usually stronger than supramolecular interactions, thus making such materials more robust and can operate under a wider range of conditions[44]. More recently, a series of dynamic covalent thermoset polyimine that can self-heal/reheal under modest external stimuli have been developed. Here, we present a new type of flexible, highly stretchable, and rehealable strain sensing system enabled by eutectic LM alloy and dynamic covalent thermoset polyimine. As LM is a liquid, it doesn't add rigidity and provides excellent deformability to the strain sensing system. Moreover, unlike conventional metal conductors, LM conductors doesn't experience fatigue. Furthermore, a dynamic covalent thermoset polyimine matrix is not only highly stretchable, but also rehealable from damages. To provide prediction to the strain sensing system, we have also established an analytical model to describe the resistance change under applied strain, which shows good agreement with finite element simulations and experimental measurements.

8:00 AM *SM06.05.01
Mechanics and Thermodynamics of Hygroresponsive Soft Machines and Engines Ho-Young Kim, Beomjune Shin and Moonkyung Choi; Seoul National University, Korea (the Republic of)

Hygroresponsive soft materials can convert environmental humidity directly into mechanical motions, as can be mundanely observed in curling of wet paper, swelling of kitchen sponges, and opening of dry pine cones. Although the bending and coiling motions of such moisture-sensitive materials are recently explored for powering tiny robots, a lack of mechanistic and thermodynamic understanding of the soft actuation systems has hindered optimization of their mechanical designs and evaluation of energy conversion efficiency. Here, we construct a theoretical model to predict the temporal evolution of actuator shape and resulting force under environmental humidity change. We demonstrate how our mechanistic theory optimizes designs of various hygroresponsive machines developed in this work, including a crawler, a wheel, a seesaw, and a vehicle. Furthermore, we introduce a stress-volume diagram of soft power generators to calculate the thermodynamic efficiency of natural and artificial hygroresponsive engines.

Biologically Inspired Polymerization Motor Gels for Building Soft Robots Controlled by Biomolecular Reactions Rebecca Schulman, Ruohong Shi, Joshua Fern and David H. Gracias; Johns Hopkins University, United States

Shape-changing hydrogels that can bend, twist, or actuate in response are critical elements of soft robots. Chemomechanical devices, which are controlled by chemical signals, have critical advantages for miniaturizing soft robots. The chemicals that control these devices can diffuse over large distances and into small or tortuous spaces, and the huge number of chemicals that can be synthesized offers unprecedented tunability and specificity. Chemomechanical devices require no batteries and can easily be miniaturized and integrated with other devices. We demonstrate hydrogels differentially responsive to different DNA signals. Specific DNA molecules can induce 100-fold volumetric expansion of hydrogels by successive extension of cross-links via the operation of polymerization motors. These structures can be photopatterned at size scales up to centimeters to create composite gels containing multiple domains. The resulting devices undergo different shape changes in response to different DNA sequences that selectively swell different domains. A simple design rule derived from experiments and material simulations suggests a means to control shape change. Methods of rational DNA design and control of DNA stoichiometry can, by altering polymerization motor operation, alter the amount and rate of swelling. Finally, multicomponent hydrogels using a variety of scaffold polymers, including polyethylene-glycol, acrylamide can be photopatterned into distinct shapes, have a broad range of mechanical properties, including tunable shear moduli across more than an order of magnitude, and enhanced biocompatibility. These materials offer a new possible means of building soft robots: because DNA molecules can be outputs and inputs to molecular sensors, amplifiers, and logic circuits, this strategy introduces the possibility of building soft devices autonomously controlled by chemical networks.

Biohybrid Devices—Harnessing Biofunctional Materials in Micro-Devices Shoji Takeuchi[1,2,1]; [1]The University of Tokyo, Japan; [2]Kanagawa Institute of Industrial Science and Technology (KISTEC), Japan

Biohybrid devices can be categorized into 4 groups: (i) biohybrid-sensors that can detect target molecules at highly selective and sensitive manner, (ii) biohybrid-reactors that mimic biological reaction in our body, and thus are useful for drug testing or tissue transplant for cell therapy, (iii) biohybrid-actuators that shows highly energy efficient motion and (iv) biohybrid-processors that achieve low-energy and highly parallel computing like our brain. In this talk, I would like to talk about a couple of our recent results regarding biohybrid sensors and actuators.

9:25 AM SM06.05.04
Artificially Innervated Foams—Biomimetic Self-Healing Synthetic Piezo-Impedance Sensor Skins Hongchen Guo, Yu Jun Tan and Benjamin Tee; National University of Singapore, Singapore

The mechanoreceptors buried in human skin is known for enabling the skin to be tactile sensitive. Meanwhile, the innervations of the mechanoreceptors, which function via three-dimensionally distributed nerves extending from deep skin upwards, also enable the skin to detect complex tactile stimuli like normal and shear forces. Here, we design a biomimetic e-skin sensor by embedding three-dimensional metal wire electrodes as ‘nerves’ in a low-modulus yet elastic self-healing foam named Artificially Innervated Foam (AiFoam). The three-dimensional electrodes in the sensing material enable the sensor to detect both normal and shear forces, as opposed to the conventional sensors with two-dimensional planar electrodes which can only detect normal forces. We also develop a unique bimodal piezo-impedance pressure sensing foam material with both piezoresistive and piezocapacitive sensing capabilities. The near-percolation metal particle foam composite can be obtained through a new one-step self-foaming process. The elastic foam material has a low modulus of 600 kPa and self-heals through strong dipole-dipole interactions and hydrogen bonding. In addition to the detection of tactile signals, the AiFoam e-skin can also function beyond the human skin by perceiving proximity.[1]

9:40 AM SM06.05.05
Autonomously Self–Healable, Super–Stretchable, Highly Transparent and Energy-Harvesting Self–Powered Triboelectric Skins Ying-Chih Lai; National Chung Hsing University, Taiwan

Soft devices (including sensors, electronics, and machines) have attracted huge interest because they cannot only extend the scope of smart systems but also provide compliant and safer user experience. Particularly, power and electronic components that are self–healable, deformable, transparent, and even self–powered are highly desired for future robotic applications. Here, we present the first triboelectric–based energy–harvesting and self–powered robotic skin that is entirely, intrinsically, and autonomously self–healable and simultaneously highly transparent and extraordinarily stretchable. Not only can this energy–harvesting robotic skin serve as an untethered and robust power source for personal electronics, but it can also be used as elegant robotic sensing skin that combine all desired attributes including self–healing, self–powered, highly transparent, and super–stretchable. This is the first time that not only the structure of an slef-powered robitc skin is entirely and intrinsically self-healable at room conditions but also the device can be operated via self-generating electricity. Additionally, the self-powered robotic skin possesses a fast healing time (30 min, 100% efficiency at 900% strain), high transparency (88.6%), and extraordinary inherent stretchability (>900%). Even after 500 cutting-and-healing cycles or under extreme 900 %-strain, the energy-harvesting robotic skin can retain its functionality. The generated electricity form the robotic skin can be used directly or stored to power commercial electronics. Further, the robotic skin is designed for self-powered tactile-sensing matrix in diverse human−machine interfaces including smart glass, an epidermal controller, and cell phone panel. The unprecedented triboelectric-based robotic skin that is entirely and inherently ambient self-healable, highly transparent, and intrinsically stretchable, and possesses energy−harvesting and actively–sensing ability, can meet wide application needs ranging from deformable/portable/transparent electronics, smart interfaces, energy devices, artificial skins, to soft robotics.

Molecular and Supramolecular Design of Robotic Soft Matter Samuel I. Stupp; Northwestern University, United States

Molecular and supramolecular level engineering of soft matter that exhibits autonomous or externally guided locomotion and dynamic morphogenesis is a grand challenge for materials science. If this happens at macroscopic scales it would be a pathway to create robotic objects from soft materials; at the microscopic scales we could begin to emulate cell behaviors with chemical defined materials; and distantly organelles as we approach the nanoscale. In this lecture we report on bio-inspired systems synthesized in a chemistry and materials science laboratory to design bottom up macroscopic robots under water. These macroscopic robots have the capacity to respond synergistically to photons and magnetic fields and reveal locomotion under water at speeds that approach those of biological systems, namely one body length per second. We found that we could control speeds, trajectories, and gait on the fly by manipulating light intensity and magnetic fields, and most interestingly it is possible to predict theoretically the response of the robots to design their behaviors. The lecture will also present results on light responsive materials that exhibit origami-like morphogenesis using constructs with macromolecules in which it is possible to design their response to photons.

12:15 PM *SM06.06.02
Shape-Memory Actuator Blends by Stereocomplexation of PLA Karl Kratz[1], Victor Izraylit[1,2], Matthias Heuchel[1] and Andreas Lendlein[1,2]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]University of Potsdam, Germany

Current approaches to modify the material composition, and in this way the mechanical behavior, of physically cross-linked polymeric actuator materials are reliant on synthetic alteration of the polymer architecture.[1] Here, we introduce a reprocessable shape-memory polymer actuator consisting of a multiblock copolymer with poly(ε-caprolactone) and poly(L-lactide) (PLLA-PCL) segments, which is blended with a poly(D lactide) (PDLA) oligomeric additive. By careful molecular design, the incorporation of structural units capable of stereocomplexation enabled the formation of the stable physical network necessary for actuation. By varying the relative concentration of the two blend components, a material with tunable reversible bidirectional actuation performance and reprocessability was created.[2] Moreover, through the study of the strain recovery and stress relaxation the macroscopic deformation patterns of the investigated materials were attributed to the microscopic deformation mechanisms of PCL crystallites and PLA stereocomplexes. The strain and composition ranges could be defined, in which PLLA-PCL / PDLA blends having PLA stereocomplexes as physical netpoints maintain elastic behavior typically attributed to polymer networks. The polymer blend system is of potential relevance as thermally controlled artificial muscles in soft robotics.[3]

Can Active Gels of the Muscle Proteins Actin and Myosin be Used as Soft Robotic Actuators? José Alvarado; The University of Texas at Austin, United States

The proteins actin and myosin are well known for their roles as biological actuators, not only in muscle tissue, but also in the cytoskeleton of various non-muscle cells. When purified in a cell-free environment, these two proteins form the basis of an active gel, a material that is capable of undergoing deformation and exerting force. So far researchers have studied these gels to better understand actin-myosin contraction in living cells. Could these active gels find their way someday in robotics applications as actuators? In this talk, I will review the mechanical, force-generating, and rupture properties of active gels of actin and myosin. I will then explore the pros and cons of these materials as robotic actuators.

1:15 PM SM06.06.04
Self-Healing Biological Materials for Soft Robotics Abdon Pena-Francesch[1,2], Melik Demirel[3] and Metin

Sitti[2]; [1]University of Michigan, United States; [2]Max Planck Institute for Intelligent Systems, Germany; [3]The Pennsylvania State University, United States

Recent research efforts have focused on developing soft, flexible, compliant materials for robotics, biointerfacing, and biosensing applications. Because of their intrinsic softness, these materials are susceptible to cut, puncture, scratch, and/or tear damage that compromise their physical integrity, and therefore self-healing properties are indispensable for soft machines and devices operating in dynamic environments. However, current self-healing materials have shortcomings that limit their practical application, such as low healing strength (below MPa) and long healing times (hours).
Here, we introduce high-strength, biodegradable protein-based materials that self-heal micro- and macro-scale mechanical damage within a second via reversible physical cross-linking. These proteins are systematically optimized to improve their hydrogen-bonded nanostructure and network morphology, with healing properties (~25 MPa strength after 1 second of healing) surpassing those found in other natural and synthetic soft materials by several orders of magnitude. We demonstrate soft gripper and artificial muscle prototypes integrating such biological materials. Such healing performance opens new opportunities for bioinspired materials design, and addresses current limitations in self-healing materials for soft robotics and wearable technology.

Bioinspired Functional Soft Materials for Soft Robotics and Wearable Devices Ximin He; University of California, Los Angeles, United States

Soft robots, advantageous in their compliance and flexibility, have advanced smart soft materials towards multifunctionality with local sensing, control and powering capabilities that approach human dexterity. Mimicking biological neuromuscular systems' sensory motion requires the unification of sensing and actuation in a singular artificial-muscle material, which must not only actuate but also sense their own motions and even has built-in feedback loop for basic-level control functions. Stimuli-responsive hydrogels are a class of synthetic materials that can change their volume upon environmental cues (temperature, light, and chemicals) to act as soft actuators and chemical sensors. They can also provide flexible porous scaffolds to load conductive components for constructing soft strain sensors, supercapacitors and other soft electronics. Their biocompatibility, easy functionalization, solution-based processing, and 3D printability are their additional merits for soft robotics. These together may lead to all-soft robots with higher flexibility, autonomy, and performance. Towards this goal, we have developed a series of material systems based on hydrogels and conducting polymers, including (i) beetle-inspired ultrafast colorimetric sensing of chemical and biological species (*Adv. Mater.* 2018; Adv. Opt. Mater. 2019), (ii) muscle-inspired high contractile tough actuators (Sci. Adv. 2020, ACS Appl. Mater. Inter. 2020), (iii) plant-mimetic adaptive light tracking and harvesting (*Nat. Nanotech.* 2019), (iv) phototaxic soft swimming robot (*Sci. Robotics* 2019; *Sci. Adv.* 2020), (v) high-performance soft strain sensors and supercapacitors (*Adv. Funct. Mater.* 2020, *Matter* 2020), and (vi) a soft somatosensitive actuating material utilizing an electrically-conductive and photothermally-responsive hydrogel, which combines the functions of piezoresistive strain/pressure sensing and photo/thermal actuation into a single material. Overall, these intelligent material systems represent a step towards next-generation soft robots with life-like adaptiveness and higher-level autonomy.

Late News: 3D Printed Sweating Robots Anand K. Mishra[1], Thomas J. Wallin[1,2] and Robert Shepherd[1];

[1]Cornell University, United States; [2]Facebook Reality Labs, United States

Despite the promise of operation in extreme environments and the use of high energy density power sources, strategies for thermoregulation remain underdeveloped in soft robots. Here, we present autonomically perspiring fluidic actuators based on multimaterial 3D printing of smart gels. We developed two custom hydrogel photochemistries—one based on poly-N-isopropylacrylamide (PNIPAm) and the other based on polyacrylamide (PAAm)—with opposing thermo-mechanical responses. At elevated temperatures, PAAm expands, and NIPAm contracts. Our actuator designs contain a porous dorsal layer of PAAm micropores that cap the fluidic channel embedded in the PNIPAm body. As the temperature rises above ~37°C, the PNIPAm body collapses to expel water through the dilated PAAm pores. This material response is reversible and occurs without any additional control from the robot to enable localized sweating. We then create the experimental protocols to measure the thermoregulatory performance of soft robots and further develop mathematical models using Newton's Law of Cooling to quantify this behavior and compare it to that of their non-sweating counterparts under a variety of conditions. Our sweating actuator exhibit a 600% enhancement in cooling rate with >100 $W \bullet kg^{-1}$ of additional cooling capacity, comparable to the best animal systems. We further combine multiple actuators into a hand and demonstrate the ability to grasp and thermally manipulate objects in the environment.

Growing Material Robotics —A Novel Type of Active Matter Stoyan K. Smoukov; Queen Mary University of London, United Kingdom

We report on a novel kind of material robotics micro-swimmers, ones that could be assembled bottom-up. They are able to harvest energy from their environment to move, and recharge on demand. We quantify the movement and reveal their propulsion mechanism. The robots form a new type of active matter, that is sustainable, as they could be grown from single molecules and almost no energy or materials are wasted. In this invited talk I will report on the large collaborative effort that resulted in this discovery and directions in which new fields of study can develop.

3:15 PM SM06.07.05
Multifunctional High-Swelling DNA Gels for Building Soft Robots Ruohong Shi, Joshua Fern, Rebecca Schulman and David H. Gracias; Johns Hopkins University, United States

Hydrogels with the ability to change shape in response to biochemical stimuli are important for biosensing, smart medicine, drug delivery, and soft robotics. Here, we create a new family of multicomponent DNA polymerization motor gels with different polymer backbones, including acrylamide-co-bis-acrylamide (Am-BIS); poly(ethylene glycol) diacrylate (PEGDA); and gelatin-methacryloyl (GelMA) that swell extensively in response to specific DNA sequences. A common actuation mechanism, a polymerization motor that induces swelling is driven by a cascade of DNA hairpin insertions into hydrogel crosslinks. These multicomponent hydrogels can be photopatterned into distinct shapes and structures, have a broad range of mechanical properties, tunable moduli, and enhanced biocompatibility. Human cells adhere to the GelMA-DNA gels and remain viable during approximately 70% volumetric swelling of the gel scaffold induced by DNA sequences. The results demonstrate the generality of sequential DNA hairpin insertion as a mechanism for inducing shape change in multicomponent hydrogels, suggesting new ways of building soft robotic devices and widespread applicability in biomaterials science and engineering.

3:20 PM SM06.07.06
Physical Intelligence Drives Liquid Handling Sara Coppola, Giuseppe Nasti, Veronica Vespini and Pietro Ferraro; Institute of Applied Sciences and Intelligent Systems "E. Caianiello", Italy

Nature continually provides a riche and valuable source of inspiration for many fields of research. Looking to the natural development of life, researchers have been consistently inspired designing new functional and adaptive materials. Programmed and self-assembled deformations are widespread in nature, providing elegant paradigms to design self-morphing materials, responsive materials or engineered robots. In fact, it would be very powerful in different field of technology and, in particular for indwelling or external biomedical devices, to have elements capable of responding to external stimuli in a simple way. Within this context, there is a lot of interest in creating artificial structures that can walk, swim, move and perform various tasks answering to an external stimulus. Conventional robots are usually entirely composed of hard materials and require complex control systems to accomplish different tasks. Their fabrication process is long-lasting and complicated, inhibiting downscaling and constraining the device to a single predefined behavior. Recently, an emerging classes of soft robotics with flexible actuation, intelligent sensibility, and biomimetic functionality are driving advances in academic researches and commercial applications through the development in soft matter engineering and flexible actuation systems. One of the most challenging issues in developing enhanced robotic technology is making appropriate tools also for the full control of liquids. Liquid robots still represent an interesting outcome for the technology form micro to nano scale. In fact, liquid-manipulating systems extend to many fields with important industrial applications such as biomedicine, biotechnologies, food, chemistry, industry and cosmetics, to cite few. To build these systems, liquids, polymers, and soft matter require accurate, precise, and fully controllable methods to be handled and processed. So far, several engineering methods have been proposed to control and drive liquids in response to external magnetic, electric, or optical fields. However, until now, all the approaches proposed for locomotion and remote liquid control are complicated and very expensive. Here we introduce a new and simple working mechanism for actuation, liquid manipulation and a complete exploration of the opportunities of a multipurpose platform guided by physical intelligence. Physical intelligence is a new way of furnishing intelligent responses (outputs) as a function of environmental changes (inputs); in particular, this disruptive technology proposed is based on the use of a pyroelectric material (Lithium Niobate) that can provide an electric field (output) as a consequence of temperature changes (input). The electric field generated by the pyroelectric effect allows one to manage the on/off function of the system in order to command a fast response in a smart way, and to easily move units of liquid with different volumes. The pyroelectric platform allows to manage and displace liquid unit volumes from a starting position to the desired endpoint, controlling with good resolution any intermediate step until the final position. Beyond the guiding property, we prove additional functionalities like merging, stretching, mixing and jumping of liquid volumes and millimeter objects using a working distance of millimeter, bigger than the conventional distances used for liquid handling in classical digital microfluidic. Multiple volumes can be dragged over the surface, moved simultaneously and mixed in case of need. The proposed technology for locomotion and tweezing of liquids and particles could open a new route for soft robotics, biomedicine, material science, fluid dynamic and also for application in microgravity environment, where it is well known that the managing of liquid is difficult and have safety concerns.

Real Time Imaging of Dynamic Behavior of Individual Nanocrystals During Superlattice Phase Transformations Using *In Situ* Liquid Phase Transmission Electron Microscopy Haimei Zheng; Lawrence Berkeley National Laboratory, United States

Nanocrystals have attracted considerable attention because of their potential applications in catalysis, energy storage, microelectronic devices, biomedicines, etc. Monodisperse nanocrystals could form superlattices with emergent collective properties. Although there have been intensive studies on nanocrystal superlattices, how individual nanocrystals change and how they interact with each other during superlattice transformations are unclear. Direct observation with high spatial and temporal resolution using transmission electron microscopy (TEM) provides the opportunity to address these questions. This talk will introduce the development of high-resolution carbon-film liquid cells, which allow to directly observe nanocrystal superlattice transitions using TEM.

3:00 PM *
Quantum Dot Nanomaterials—Synthesis, Assembly and Applications Ou Chen; Brown University, United States

Nanocrystal materials are emerging as an important class of tools that are revolutionizing both fundamental science and technological applications due to their many unique properties. In particular, quantum dots

nanocrystals have demonstrated their great potential to be applied in a wide variety of applications as a unique emissive material. In my talk, I will describe our experimental efforts for the synthesis and characterization of high-quality quantum dot nanocrystals. These dots combine, in one material, great optical performance metrics desired in quantum dot nanomaterials. Then, I will show how we can use colloidal quantum dot nanocrystals as building blocks to generate higher-order architectures in assemblies. At last, several quantum dot based applications studied in my lab will be discussed.

***In Situ* and Liquid TEM for Investigating Nanoparticles** Jungwon Park[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

Molecular or atomistic mechanistic understanding of nucleation, growth, and structural changes of nanoparticles have not achieved enough at the nanoscale or below. It is mainly because of a lack of appropriate analytical methods that can obtain in-situ structural information with a spatial resolution at such small length scale along

with sub-msec temporal resolution. The in situ, both in liquid phase and dry state, transmission electron microscopy (TEM) offers an opportunity to directly observe diverse classes of chemical reactions. Here we introduce technical developments for those techniques. Topics will cover fabrication processes for TEM liquid cells with thin film window materials such as graphene and silicon nitride, and data processing of large sized in situ TEM images. In addition, we also present application of in situ TEM to study chemistry of colloidal nanoparticles. We reveal that the early stage of nanoparticle formation is driven by reversible transition between disordered and ordered phases before crystalline phase is stable above a certain size. It is also frequently observed that different types of non-classical pathway, including two-step nucleation, amorphous-to-crystalline transition, and coalescence of clusters, are heavily involved in different conditions of nanoparticle formation. We also present a new development using liquid phase TEM to investigate 3D atomic structures of nanoparticles directly in the colloidal synthesis batch.

Nucleation and Growth of Nanocrystals—Insights Derived from Direct TEM Imaging Utkur Mirsaidov; National University of Singapore, Singapore

Understanding how materials form at the nanoscale is fundamental for materials engineering and fabrication in many functional nanodevices. Nucleation, growth, and self-assembly are key “bottom-up” processes through which these materials form in solution. Despite the importance of these processes both from basic science principles and technological stand-point, many of the chemical and physical details of these dynamic processes remain unknown. This gap in knowledge stems mainly from a lack of proper experimental techniques that enables visualize these nanoscale solution-based processes in real-time. Here, using in situ liquid cell transmission electron microscopy (TEM), I will describe how direct observations can shed new light on nucleation and growth of both organic and inorganic crystals.
Specifically, I will show that organic crystals such as metal-organic frameworks nucleate via a nonclassical pathway, involving phase separation of the precursor solution into dense solute-rich and solute poor-regions, followed by condensation of the dense phase into crystals. I will also discuss the nucleation and crystallization of other organic materials such as perovskites and illustrate that visualizing these crystallization pathways can teach us a lot in terms of materials synthesis.
Our studies highlight the importance of direct visualization of nanoscale processes for the rational design of materials.

8:25 AM *SM07.01.02
Approaching the What, How, and Why of Crystallization with Self-Assembly Simulations Julia Dshemuchadse; Cornell University, United States

Many materials properties are determined through their underlying crystal structure, and often the search for new materials with improved functionalities requires the targeting of particular structure types and crystal geometries. While the science of crystallography has helped us to largely decipher the structure of materials over the past century, the art of structure prediction has remained elusive: our ability to rationalize why a certain system crystallizes in any given structure is severely constrained, for example by being applicable to only specific materials classes or by being predictive of ground-state structures without allowing to draw conclusions

about the aspect of synthesizability.

We investigate the enigma of crystal structure formation by simulating the growth of different crystal phases from particles with exquisitely simple interactions. By modeling the self-assembly of long-range ordered structures with varying complexity and symmetry, we aim to formulate the general principles of the development of crystallinity from local interactions. We hope to elucidate how complexity can emerge from simple particles, how long-range order emerges from short-range forces, and how symmetries are broken locally in concert with the appearance of global, crystal symmetries.

By developing a fundamental understanding of the process of self-assembly in crystalline matter, we can move forward with efforts of structure prediction at a level that will enable materials design from basic principles in the future.

8:50 AM SM07.01.03
Colloidal Quasicrystals Engineered with DNA Wenjie Zhou[1,2], Haixin Lin[1,2], Yein Lim[3], Sangmin Lee[3], Yuanwei Li[1,2], Ziyin Huang[1,2], Jingshan S. Du[1,2], Shunzhi Wang[1,2], Luis M. Liz-Marzán[4], Sharon Glotzer[3] and Chad Mirkin[1,2,2]; [1]International Institute for Nanotechnology, United States; [2]Northwestern University, United States; [3]University of Michigan–Ann Arbor, United States; [4]Ikerbasque, Basque Foundation for Science, Spain

Quasicrystals are structures that are ordered but not periodic. While they lack translational symmetry, they possess a high degree of rotational symmetry. Their experimental identification in 1984 brought the concept of aperiodic structures from mathematical tilings to physical existence. Since then, the experimental pursuit of these elusive materials has extended from atomic systems to colloidal superlattices. To date, all experimentally reported quasicrystalline superlattices possess either multiple sizes or the asymmetric functionalization of building blocks. The question of whether it is possible to synthetically achieve quasicrystals using one uniformly functionalized constituent remains elusive. Utilizing five-fold symmetric nanocrystals and elastically directional, oligonucleotide-based ligands, we report the first single-component dodecagonal colloidal quasicrystal assembled from DNA-functionalized decahedral nanocrystals. This discovery enriches the scope of colloidal quasicrystals, and sheds light on the design-based, enthalpy-driven crystallization of polyhedral nanocrystals.

9:05 AM SM07.01.04
Multivariate Analysis of Peptide-Driven Nucleation and Growth Processes in Plasmonic Nanoparticles
Kacper J. Lachowski and Lilo D. Pozzo; University of Washington, United States

The localized surface plasmon resonance of metallic nanoparticles continues to be studied for light harvesting applications such as photocatalysis and biosensing. Control over the light response depends on careful synthetic control of the particle structure, composition, and state of assembly. Whereas the current theoretical understanding of nanoparticle growth has been sufficient for enabling the synthesis of monodisperse spherical nanoparticles, shortcomings in current theories hinder the prediction of synthetic outcomes in more complex experimental systems (e.g. non-spherical morphologies, particle superstructures). An underlying challenge which we seek to address is the development of methodologies for connecting large experimental design spaces to the outcomes of nanoparticle syntheses that may also span over multiple length and time scales. Herein, we present a multivariate analysis of how amphiphilic solid binding peptides can mediate the nucleation, growth, morphogenesis, and self-assembly of gold nanoparticles over a broad range of conditions. High-throughput synthesis using programable liquid-handling robots is coupled with UV-Vis characterization to create state diagrams for visualizing the relationship between surface plasmon resonance or colloidal stability, and sample composition and peptide sequence. We then demonstrate the utility of unsupervised learning techniques to identify these relationships and for guiding selection of samples for lower-throughput characterization techniques. The structure of selected samples is investigated further using transmission electron microscopy (TEM) and small angle x-ray scattering (SAXS). Together, these results motivate targeted *in situ* experiments which reveal how peptide self-assembly and complexation with precursors lead to distinct modes of growth and

self-assembly. Finally, we discuss how these methodologies can also be extended to the study of other hybrid inorganic-organic systems that are driven by nucleation and growth phenomena.

9:20 AM *SM07.01.05
Chiral Nanostructures Nicholas A. Kotov; University of Michigan–Ann Arbor, United States

The early observation of strong circular dichroism for individual nanoparticles (NPs) and their assemblies have developed into a rapidly expanding field of chiral inorganic nanostructures. They encompass a large family of mirror-asymmetric constructs from metals, semiconductors, ceramics, and nanocarbons with multiple chiral geometries with characteristic scales from *Ångströms* to microns. Versatility in dimensions and polarizability of the inorganic materials enables their multiscale engineering to attain a broad range of optical and chemical properties. This talk will address (**1**) the origin of the uniquely high values of optical anisotropy; (**2**) mechanisms of chirality transfer in inorganic materials; and (**3**) emergence of complexity is self-organized chiral nanoassemblies. Special attention will be given to the emerging venues for practical realizations of chiral nanoassemblies related to (**1**) chiral catalysis and (**2**) circular polarization spectroscopy in terahertz spectral window.

Investigating Interparticle Interactions Mediating Fuel Driven Dissipative Self-Assembly of Colloids
Thilini U. Dissanayake, Justin Hughes and Taylor Woehl; University of Maryland, United States

Previous studies have demonstrated chemical fuel driven dissipative self-assembly of colloids initiated by adding a chemical fuel that converts hydrophilic surface groups to hydrophobic groups. The hydrophobic colloids aggregate over several hours while a slow hydrolysis back reaction converts hydrophobic groups back to hydrophilic, causing the aggregates to disassemble after tens of hours. While the chemical reactions involved in dissipative self-assembly process have been studied in detail, the colloidal scale interparticle interactions underlying self-assembly are not well understood. Here we demonstrate that the dissipative self-assembly of carboxylic acid functionalized polystyrene occurs over narrow ranges of fuel and particle concentrations that are dictated by the strength of hydrophobic interparticle interactions and the ligand-fuel reaction kinetics. We utilized optical microscopy to image dissipative self-assembly of sub-micron to micron sized particles to probe assembly behavior as a function of particle and fuel concentration. Particles showed either no assembly, dissipative self-assembly, or irreversible aggregation. A scaling analysis revealed that no assembly occurred if the lifetime of the surface hydrophobic groups was less than the characteristic time for colloidal aggregation as determined by the Fuch's stability parameter. Dissipative assembly occurred for fuel concentrations where there was a secondary minimum in the pairwise interaction potential, which lead to weak hydrophobic interparticle bonds and residual interstitial water layers that facilitated hydrolysis back reactions. Irreversible assembly occurred when hydrophobic attractive forces dominated electrostatic repulsion and caused permanent aggregation with no residual interstitial water layer. These results shed light on the interplay between colloidal interactions and kinetics that underly dissipative self-assembly of colloids and will enable rational design of

transient and reconfigurable colloid assemblies.

10:30 AM *SM07.02.01
Self-Organization of Colloidal Nanocrystals—From Intricate Structures to Functional Materials Igor Coropceanu, Eric Janke and Dmitri V. Talapin; The University of Chicago, United States

Nanocrystals of different functional materials can self-assemble from colloidal solutions into long-range ordered periodic and quasicrystalline structures (superlattices). Such assemblies offer a powerful platform for designing hierarchically organized macroscopic solids. Unlike atomic and molecular crystals where atoms, lattice geometry, and interatomic distances are fixed entities, arrays of nanocrystals represent solids made of "designer atoms" with potential for continuous tuning their physical and chemical properties. The self-assembly process is guided by an intricate interplay of entropy-driven crystallization and soft interparticle interactions. The surface ligands also play an important and sometimes counterintuitive role, supporting many-body interactions and stabilizing complex structures which can be explained by specific topological textures developed within surface ligands.
The properties of nanocrystal superlattices are determined by the nanocrystalline building blocks and by the electronic couplings between individual nanocrystals. Strong electronic coupling between nanocrystals within a superlattice is an important prerequisite for the emergence of non-additive physical properties. By using optimized surface chemistries, the electronic coupling can be significantly enhanced, approaching the metal-insulator transition. The formation of strongly-coupled nanocrystal assemblies represents an important step toward the bottom-up design of functional materials. We will demonstrate the power of "modular" materials fabrication for electronic and optoelectronic devices and the utility of engineered nanocrystal assemblies for real-world technologies.

10:55 AM *SM07.02.02
Growth of Metal Nanocubes, Nanowires, and Nanoplates Kristen A. Fichthorn; The Pennsylvania State University, United States

Metal nanocrystals have gained tremendous attention due to their superior performance in various applications, ranging from selective catalysis to electronic devices to plasmonic applications. For these and many other applications, the properties of the nanocrystals are highly sensitive to their shape. However, it remains a challenge to achieve high shape selectivity in solution-phase syntheses. I will discuss our efforts to understand the growth of Cu and Ag nanocubes, nanowires and nanoplates, which is facilitated by a synergy between halide ions (chloride, bromide, and iodide) and capping molecules in the synthesis protocol. We use ab initio thermodynamics based on quantum density-functional theory (DFT) to demonstrate how the combination of capping molecules and halides create thermodynamic driving forces for cubes, plates and wires, by selectively altering surface energies. Using a combination of DFT and the theory of absorbing Markov chains, we demonstrate how a synergy between capping molecules and halides affect deposition, surface diffusion, and interfacet transport to drive the growth of particular nanoshapes. Our results agree with experiment and indicate a promising way to exact control over nanocrystal synthesis.

11:20 AM SM07.02.03
Synthesis of Polymer-Patched Nanoparticles and Their Self-Assembly into Open Lattices Ahyoung Kim[1], Thi Vo[2], Chansong Kim[1], Lehan Yao[1], Shan Zhou[1], Hyosung An[1], Sharon C. Glotzer[2] and Qian Chen[1];

[1]University of Illinois at Urbana-Champaign, United States; [2]University of Michigan–Ann Arbor, United States

I will present our most recent experiment-computation collaboration on a new strategy of “atomic stencil” to site-specifically coat gold nanoparticles (NPs) with polymer patches. We experimentally demonstrate the general applicability of the strategy in patterning polymer patches of precise size and shapes on a variety of anisotropic gold NPs. We realize highly uniform patchy NPs, from tip to facet-patches, as well as from symmetric to broken-symmetry patch arrangements. The patch grafting simulation based on scaling theory reveals the vital roles of interpolymer attraction and local surface curvature of NPs in polymer portioning. Finally, we show that the as-prepared library of patchy NPs can assemble into various structures, including small clusters (dimers, trimers) via self-limited attraction, and large-scale open lattices, which are challenging to be achieved from NPs of uniform surface chemistry. We foresee the method can generate hybrid NPs with site-specifically programmable chemistries and interactions for the applications in catalytic, delivery, and their directed assembly into exotic functional structures, including a Kagome lattice.

11:35 AM *SM07.02.04
Enabling Kinetic Control in the Self-Assembly of Polymer-Grafted Nanocrystals Xingchen Ye; Indiana University Bloomington, United States

Polymer-inorganic nanocomposites based on polymer-grafted nanocrystals (PGNCs) are enabling technologically relevant applications owing to their unique physical and chemical properties. While diverse PGNC superstructures have been realized through evaporation-driven self-assembly, this approach presents multifaceted challenges in understanding and ultimately ucontrolling the assembly kinetics. In this talk, I will introduce our recent progress on the facile assembly of multicomponent superstructures from a homogeneous disordered PGNC mixture. We demonstrate that controlling the nature of assembly environment allows for exquisite control of the rate of PGNC assembly. Characterization of kinetically arrested intermediates reveals that assembly follows a multistep crystallization pathway. Our work opens up new avenues for the predictive synthesis of multicomponent PGNC superstructures exhibiting mutlifunctionality and emergent properties.

12:00 PM SM07.02.05
Crack-Free Colloid Self-Assembly for High-Strength Metallic Nanolattice Fabrication Zhimin Jiang and James H. Pikul; University of Pennsylvania, United States

Natural cellular materials have inspired researchers to created lightweight high-strength porous metals with chemical or physical functionalities. Traditional fabrication methods, however, have limited porous metals' strength to well below their theoretical limits because of the difficulties in controlling the pore morphology and the constituent metal's microstructure. 3D printing is one manufacturing technique that has realized nanolattices with periodic pores and nanostructures that approach the theoretical strength of their constituent materials [1], but it has inherent trade-offs between resolution and printing time that severely limit the scalability. In addition to 3D printing, advancements in self-assembly have realized relatively low cost and fast fabrication of large-area metallic and ceramic nanolattices with nanometer-sized features, but the assembled templates are subject to dense cracks unavoidable during solvent drying [2]. Filling the template voids with a solid material can fill the cracks, but these inverted crack structures divide the sample into small nanolattice domains (typically <0.01 mm^2 in area), cause stress concentrations, block fluid/gas transport, and increase optical scattering. A fabrication approach that uses self-assembled templates to produce large-area metallic nanolattices without inverted cracks has yet to be demonstrated.
This work overcomes these limitations by developing a crack-free colloid self-assembly approach to fabricate cm-scale porous nickel nanolattices with 30 nm grain size, 100 nm feature sizes, and an ultrahigh 227 MPa tensile strength, 3 times stronger than what has been reported for porous metals with the same relative density at any scale. We fabricate our nickel nanolattices by first self-assembling 400-800 nm diameter polystyrene (PS) particles with positive surface charges into single-crystalline FCC packed films on an indium tin oxide (ITO) coated substrate. We then electrodeposit nickel through the template voids and etch the PS by toluene. We found that the key to eliminating cracks in the colloid self-assembly process while maintaining high-quality

crystal growth, which reduces defects and improves optical properties, is to keep the template wet with 0.06% glycerol. After self-assembly of a wet uncracked colloid template, we then overcame the challenge of electrodepositing nickel in a wet unsintered template by taking advantage of electroosmotic forces on synthesized positively charged polystyrene particles that push the template onto the conductive substrate. Compared to traditional self-assembly, the new approach overcomes the long-standing cracking issues in self-assembled colloid templates to fabricate nanolattices, which have over 2 cm^2 area without inverted cracks, 20,000X increase in crack-free area compared to conventional self-assembled metallic nanolattices, 1,000X more units cells in the loaded direction than 3D printed nanolattices for tensile testing, and, for the first time, enable macroscopic tensile testing of metallic nanolattices.

Late News: 2D Magnetic Thin Sheets via Self-Assembly of Magnetic Nanoparticles Jiwoo Yu, Yeu-Wei Harn, Shuang Liang, Gyutae Nam, Zewei Wang, Martin Mourigal and Zhiqun Lin; Georgia Institute of Technology, United States

Centimeter-scale hydrophilic two-dimensional (2D) magnetic sheets are created via rapid self-assembly of magnetic nanoparticles at liquid-liquid interface. Such large-scale 2D sheets open up new avenue to engineering 2D materials. Assembly of nanoparticles at liquid interfaces has attracted much attention for decades. Yet, developing their assemblies of mechanically intact structure is comparatively few as most of assemblies collapsed when the interface is removed. Moreover, only a limited number of studies on the ability to form thin sheets with magnetic properties have been reported. In this context, our 2D magnetic thin sheets are structurally intact that retain the millimeter-scale continuity even after three times of centrifugation and washing with pure water, without additional crosslinking or polymerization processes. The formation of such mechanically robust sheets can be attributed to ligand interactions, hydrogen bonding, and favorable dipole-dipole interaction of magnetic nanoparticles. Furthermore, mechanical and magnetic properties of the 2D membrane are investigated. Finally, self-assembly is also carried out using magnetic nanoparticles of larger size distribution, demonstrating the versatility of this strategy for crafting 2D sheets.

Interfacial Structure, Interparticle Forces and Assembly Dynamics During Oriented Attachment James J. De Yoreo[1,2], Elias Nakouzi[1], Lili Liu[1], Guomin Zhu[2,1], Sebastien Kerisit[1], Maria Sushko[1], Jaehun Chun[1,3], Gregory Schenter[1] and Christopher Mundy[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]The City University of New York, United States

Growth of single crystals via oriented attachment of primary nanocrystals is widespread phenomenon in both synthetic and natural environments. This process exhibits a range of styles including face-specific oriented attachment (OA) in which the primary particles and final crystal are of the same phase, attachment of a nanoscopic phase to a bulk phase followed by transformation to form a crystal with crystallographically matched or twinned interfaces, and mis-oriented aggregation followed by coarsening through elimination of

dislocations to a single crystal. While descriptions of assembly in these systems must share a commonality with continuum-based DLVO-type theories for simple colloids, nanocrystals present additional complexities, including face-specificity of dielectric properties, surfaces that are periodically structured at the Å-scale structure, and consequent solvent-responses that are expected to be of a comparable length scale. To understand the relationship between nanocrystal and solution structure, interparticle forces and consequent motion leading to attachment, we are investigating oriented attachment in a number of crystal systems including ZnO, Fe_2O_3 and AlO(OH). We use in situ AFM to map the structure of both the crystal surface and the near surface solution, in situ TEM to observe assembly dynamics, force spectroscopy with custom-made single crystal tips to measure face-specific interparticle forces, and molecular-scale simulations to define the relationships between these features. AFM-based fast force mapping shows that the structure of the solution near the interface exhibits the symmetry of the underlying crystal with lateral variations in density on the same scale as the atomic lattice, but the extent of these variations away from the surface varies between crystal systems and with ionic strength. Moreover, measurements with different kinds of tips combined with molecular dynamic simulations show that the measured solvent structure is impacted by the probe chemistry, implying that, as particles approach, the structure of the solvent evolves in response to the changing interfacial chemical environment. In situ TEM demonstrates that direction-specific forces align randomly diffusing particles prior to contact and that attachment occurs on lattice matched faces via a sudden jump to contact followed by coarsening to produce compact single crystal structures. Direct measurements of the forces between crystal surfaces reveal orientation dependent attractive interactions that also exhibit the symmetry of the underlying lattice. Simulations show that orienting, attractive forces arise from a number of sources, including hydration, ion correlation and dispersion forces and barriers to attachment are caused by hydration layers, which vary with surface hydrophobicity. In at least one case — ZnO — electric dipole forces dominate the interparticle interactions and lead to coalignment long before contact occurs. The integration of these complimentary techniques and their application to multiple crystal systems is helping to provide a comprehensive physical picture of OA.

Role of the Solvent−Surfactant Duality of Ionic Liquids in Directing Two-Dimensional Particle Assembly
Lili Liu, Duo Song, Biao Jin, Michael Sinnwell, Jun Liu, James J. De Yoreo and Maria Sushko; Pacific Northwest National Laboratory, United States

Nanoparticle self-assembly plays a key role in the formation of superlattices, which exhibit remarkable physical and chemical properties. However, controlling the assembly remains a challenge partly due to a lack of understanding of the assembly dynamics and the difficulty in linking interfacial solution properties to interparticle forces. Using liquid-cell transmission electron microscopy, the self-assembly of gold nanoparticles (NPs) into superlattices in mixtures of water and ionic liquid (IL) was visualized, revealing a dual role of the IL in the assembly process. At intermediate concentrations, the IL acts as a surfactant stabilizing the particles at a well-defined equilibrium separation corresponding to the length of hydrogen-bonded IL cations adsorbed onto neighboring NPs. Analysis of the interparticle forces reveals attractive long-range interactions of a van der Waals nature. At separations of 1−3 nm, the interactions are dominated by attractive ion correlation and repulsive hydration forces giving rise to an energy minimum at 1.5 nm separation. The superlattice is further stabilized by hydrogen bonding, which shifts the equilibrium interparticle distance to 1.1 nm. In contrast, at higher concentrations, IL accumulates and forms a structured network in the gap between nanoparticles, where it acts as a solvent that eliminates the repulsive barrier and thus promotes particle coalescence. This solvent−surfactant duality of IL opens new opportunities for its use in directing particle assembly.

1:40 PM SM07.03.03
Liquid-Phase TEM Imaging of Oriented Attachment of Nanoparticle Superlattices Assisted by Machine Learning Chang Liu, Lehan Yao and Qian Chen; University of Illinois at Urbana-Champaign, United States

We utilize nanoparticle dispersion as a model system to study the fundamentals of order emergence and evolution at the nanoscale. Diverse superlattices are achieved under liquid-phase TEM which enables single-particle level imaging in real time and real space. To be specific, coalescence and oriented attachment of two

dimensional/three dimensional (2D/3D) superlattices are observed, where both attach–rotation and prealign–attach behaviors occur. Machine learning is used for the first time to extract the structural information in 3D superlattices, which further helps to identify single particle behaviors. Furthermore, the high spatiotemporal resolution enables us to identify single particles and to map out their trajectories sampling the energy landscape. The individual fast motion (e.g. surface and volume diffusion) along with collective motion (e.g. transient neck formation, translational and translational motion of the domains) drives the coarsening of the nanoparticle superlattice, which is attributed to the features of different interactions involved at the nanoscale. Our work proposes novel data acquisition protocol and offers new dynamic observations on the superlattice evolution with high spatial and temporal resolution, which can provide insight into material engineering at the nanoscale.

Nature's 3D Printing: Self-Assembly of Coral Skeletons Pupa Gilbert[1,2]; [1]University of Wisconsin–Madison, United States; [2]Lawrence Berkeley National Laboratory, United States

Corals reef ecosystems are extremely diverse, beautiful, and threatened by climate change. Learning how corals form their skeletons may be useful to save them from global warming, and to develop new synthesis strategies. Coral skeletons, in fact, are Nature's 3D printing. Recent synchrotron spectromicroscopy data reveal that all reef-building coral build their skeletons by two concomitant mechanisms:
1. Particle attachment, with nanoparticles of amorphous precursors nucleated in the tissue
2. Ion attachment, at the surface of the growing skeleton, from the calcifying fluid.
A new model for coral skeleton formation shows both mechanisms. See Sun et al. PNAS 2020.

Probing Particle Mediated Growth Pathways of Metal Oxides Kevin Rosso, Xin Zhang, Yining Wang, Jianbin Zhou, Sebastian Mergelsberg, Maria Sushko, Duo Song, Eric Bylaska and James J. De Yoreo; Pacific Northwest National Laboratory, United States

Understanding particle mediated growth is critical to geoscience, material synthesis, catalysis, energy storage, environmental conservation, biological medicine, etc. Using a combination of scanning/transmission electron microscopy (S/TEM), atomic force microscopy (AFM), small angle X-ray scattering (SAXS), and molecular computations, we are investigating these phenomena for several metal oxide systems and their relationship to interfacial structure in vacuum, water vapor, and solutions. Here we discuss two cases. In the first, we explore the aggregation behaviors of hematite nanocrystals with different exposed facets including {001}, {012}, {104} and {116} in aqueous solutions at room temperature or hydrothermal conditions (120-180 ºC). SAXS was used to study the aggregation behavior at room temperature. Remarkably, only {104} nanoparticles are well mono-dispersed in aqueous solutions from 1 to 30 mg/ml at 10, 30, and 60 days. In contrast, at similar conditions 001} and {116} nanoparticles are highly aggregated. High resolution TEM and scanning TEM (STEM) on aggregates formed at hydrothermal conditions suggest hematite crystallization by nanoparticle aggregation occurs predominantly on [001] facets. We then compare the results to the predictions of coupled plane-wave and classical density functional theory simulations to relate the behavior to surface interactions. In the second case, we report measurement of anisotropic forces between rutile TiO_2 (001) nanocrystals as a function of their azimuthal orientation and surface hydration extent using a combined environmental TEM-atomic force microscopy (AFM) technique. At tens of nanometers of separation, the attractive forces are weak and show no dependence on azimuthal alignment nor surface hydration. At separations of approximately one hydration layer, attractive forces are strongly dependent on azimuthal alignment and systematically decrease as intervening water density increases. Measured forces closely agree with predictions from Lifshitz theory and show that dispersion forces are capable of generating a torque between particles to align them. Ongoing adaptation of these modeling techniques to explain the observed aggregation behavior in the hematite system are motivated by the need to ultimately uncover common underlying mechanisms driving particle-mediated crystallization phenomena such as oriented aggregation.

2:45 PM SM07.03.06

Self-organization of Iron Sulfide Nanoparticles into Multi-Compartment Supraparticles Emine S. Turali-Emre, Ahmet Emre and Nicholas A. Kotov; University of Michigan–Ann Arbor, United States

Compartments are essential for any life, cells, prokaryotes, and even viruses. Recreation of their formation has both technological and fundamental importance. This study shows that *L*-cysteine stabilized iron sulfide NPs can self-assemble into multi-compartment supraparticles (SPs). The transmission electron microscopy results showed that NPs initially produce ~55nm cup-like structures and then mature into ~75nm SPs with *ca.*190 interconnected compartments. The color change of the solution from black to yellow suggests the SP formation and particle oxidation. The selected area electron diffraction and energy dispersive X-ray spectroscopy confirm that SPs are formed from FeS_2 and Fe_2O_3 NPs. Elemental mapping showed that Fe_2O_3 NPs are located on the SP's surface and protecting FeS_2 and compartments from the surroundings. These compartmentalized particles can be used for the successful encapsulation of the DNA fragments and gene delivery.

8:00 AM *SM07.04.01
Late News: Self-Assembly of AIEgens Benzhong Tang; Hong Kong University of Science and Technology, China

Self-assemblies have attracted great scientific interests in recent few decades due to their various potential applications. Scientists can obtain different elaborate assemblies with multiple on-demand functionalities using various noncovalent interactions, such as hydrophilic-hydrophobic interaction, hydrogen bonding, host-guest interaction, π-π interaction, metal coordination, *etc*. Although the formation or responsive process of these assemblies can be monitored by various methods, such as NMR, IR, MS and electron microscopy, *etc.*, a problem associated with these methods is that they are either invisible to our naked eye or rely on harsh preparation methods. Luminescence is a perfect choice as technique for the applications in self-assemblies, in the light of its rich advantages such as superior sensitivity, high selectivity, fast response, low background noise and simplicity. More importantly, it can provide high spatiotemporal resolution for precise visualization into complicated processes in a noninvasive and on-site way. Another thing that need to be considered is that most of the assemblies function in the condensed phase which show notoriously ACQ effect to result in compromised sensitivity. Diametrically opposed to conventional luminophores, AIEgens are nearly non-luminescent in the isolated state but luminesce strongly in the aggregate/clustered state. Based on different AIEgens, we have fabricated various functional self-assemblies, such as helical assemblies with circularly polarized luminescence signal, surfactant micelles and microemulsion droplets with visible transition processes, interfacial dynamic self-assembly with *in situ* imaging technology, supramolecular polymers formed from TPE-based luminescent monomer, *etc*.

8:25 AM *SM07.04.02
Molecular Self-Assembly in Solid Phase Leading to Large Scale Fabrication of Supramolecular Films Yun Yan; Peking University, China

General strategies leading to scale-span molecular self-assembly are of crucial importance in creating bulk supramolecular materials. We report that under mechanical pressure, caking of the precipitated molecular self-assemblies may lead to bulk supramolecular films. Massive fabrication of supramolecular films becomes possible using a simple house-hold noodle machine. The film can be endowed diversified functions by depositing various functional ingredients via co-precipitation. We expect the current work opens up a new

paradigm leading to large-scale functional solid molecular self-assembled materials.

8:50 AM *SM07.04.03
Assembling Dyes with Polymers into Small and Bright Fluorescent Nanoparticles for Biosensing and Bioimaging Andrey Klymchenko; University of Strasbourg, France

Dye-loaded fluorescent polymeric nanoparticles (NPs) appear as an attractive alternative to inorganic NPs, such as quantum dots (QDots).[1] However, preparation of polymeric NPs featuring small size and high fluorescence brightness remains a challenge. To address it, we introduced a concept of charge-controlled nanoprecipitation of hydrophobic polymers in aqueous media.[2] We found that a single charge in polymers, such as poly(methyl methacrylate) (PMMA), poly(lactic-co-glycolic acid) (PLGA) and polycaprolactone (PCL) can drive self-assembly of polymers into NPs of 20-40 nm size. Further addition of charges into these polymers (up to 10 mol%) can decrease particle size down to 7 nm.[3] On the other hand, to ensure high brightness of polymeric NPs, we proposed to encapsulate charged dyes with bulky hydrophobic counterions.[4] The later serve as spacers between dyes, thus preventing aggregation-cause quenching and, at the same time, favor the co-assembly of the dyes with the polymer into stable NPs without dye leakage.[5] Based on these design concepts, we obtained NPs that are ~100-fold brighter than QDots of similar size.[6] Their small size was found essential for their free diffusion in cytosol of live cells[3] and for their intracellular delivery by electroporation. Their high brightness enabled unprecedented single-particle tracking in the mice brain and visualization of crossing blood-brain barrier.[7] Assembling dyes inside small polymeric NPs revealed also a unique cooperative behavior of dyes through ultrafast dye-dye energy migration, which led to the collective switching of >100 dyes in a single particle.[4, 6] This collective behavior of dyes enabled efficient Förster resonance energy transfer (FRET) from ~10000 encapsulated dyes to a single acceptor. This light-harvesting nanoantenna provided >1000-fold signal amplification (antenna effect), allowing first single-molecule detection in ambient light.[8] Functionalization of these nanoatennas with nucleic acids yielded ultrabright FRET-based nanoprobes for amplified detection of oligonucleotides,[9] opening possibilities for rapid detection of cancer markers using a RGB camera of a smartphone.[10] Nanoantennas of 20 nm size enabled efficient FRET to a single acceptor at their surface and detection of RNA/DNA with a single-molecule sensitivity.[11] The light-harvesting concept was also applied to amplify phosphorescence of porphyrins for ratiometric sensing of oxygen with minimal phototoxicity.[12] The developed small dye-loaded polymeric NPs open the route to ultrabright tools for sensing and tracking biomolecules in biosensing, bioimaging and diagnostics applications.

This work was supported by ERC Consolidator grant BrightSens 648528.

Supramolecular Engineering Strategies to Enable Hierarchical Self-Assembly Alvaro Mata[1,2]; [1]University of Nottingham, United Kingdom; [2]The University of Nottingham, United Kingdom

Nature has evolved in a hierarchical manner to achieve outstanding material properties and complex organismal behaviours. While great progress has been made engineering precise nanostructures through the self-assembly of molecular building blocks, the capacity to organize them beyond the nanoscale and into functional macroscopic structures, remains a challenge. In the fields of tissue engineering and regenerative medicine, it is essential to design materials, structures, and processes with hierarchy as a central principle. This talk will present our laboratory's efforts to exploit biological organization principles to guide self-assembly of multiple types of building blocks across size scales and enable the design of functional biomaterials. Examples will include the use of supramolecular events found in nature based on multicomponent self-assembly, protein order-disorder synergies, diffusion-reaction processes, and/or organic-inorganic interactions to organize multiple types of biological (*e.g.* proteins, polysaccharides) and/or synthetic (e.g. peptides, surfactants, graphene oxide) building blocks hierarchically. The resulting materials exhibit properties such as hierarchical organization (1-4), the capacity to grow and heal (1,2), tuneable mechanical properties (1,4), and biomimicry (4,5).

10:55 AM SM07.05.02
Late News: Time-Domain Programming of Self-Assembly with Chemical Clocks Guido Panzarasa; ETH Zurich, Switzerland

Living systems can grow a huge variety of materials with the highest degree of sophistication, and an overall efficiency that remains largely unparalleled by artificial fabrication techniques. Moreover, living materials are adaptive *i.e.* they exist and perform autonomously under dissipative conditions. These features are made possible by the ability to control complex reactions networks, carefully organized in spatiotemporal sequences. Developing autonomous chemical systems that could imitate the properties of living matter is a challenge at the meeting point of materials science and systems chemistry. Chemical clocks thus become versatile tools to program in time the autonomous and transient self-assembly of organic as well as inorganic building blocks. The design of such *ad hoc* reaction networks is at the core of my current research efforts. I will show how to "clock" molecules, polymers and metal cations into different structures, from nanoparticles to gels, without the need for external control, and demonstrate how this approach paves the way to the development of (almost) living artificial materials.

11:10 AM SM07.05.03
Late News: Single-Step Annealing and Incorporation of a Metal Complex into Block Copolymer Matrix

Przemyslaw Pula, Arkadiusz A. Leniart and Pawel W. Majewski; University of Warsaw, Poland

Modern nanotechnology fabrication relies on two opposite approaches, namely the “top-down” and the “bottom-up”. The former typically employs lithography techniques with which one can obtain nanometer-sized (10-100 nm) structures. This conventional "top-down" approach meets ultimately the physical limits, thus the further progress of the lithographic methods is hindered. The alternative, "bottom-up" strategy, utilizes chemical compounds, which self-assemble into more complex structures. An example of such compounds are block copolymers (BCPs), consisting of at least two different homopolymer blocks joined together with a covalent bond.
Our aim is to explore principles governing each block location (degree of order) and control it, prior to subsequent metal/oxide functionalization of such organic template. A straightforward approach, which we call Solvent Evaporation Annealing (SEA), offers a sensible balance between simplicity and economic cost. Here, the ordering process occurs at the same time while the layer is deposited on the substrate in a time-extended spin-coating process. The key element is an introduction of a low volatile compound in the mixture with BCP along with normally present high volatile solvent. Lower solution viscosity combined with an elongated evaporation time delivers a large grain size (more specifically correlation length), which is on the order of single micrometers.
BCP ordered films are designed to serve as matrices for the templated synthesis of inorganic nanostructures. Conversion methods follow the general idea of the affinity of metal precursor molecules to a specific functional group present in a selected homopolymer block. Thus, the metal precursor renders a pattern marked by one domain. Wet techniques accomplish the idea by a solution-based chemical reaction with a polymer, sometimes acting destructively on the polymer morphology. In our research, we combined Solvent Evaporation Annealing with the addition of metal precursor salt to successfully obtain BCP-templated metal nanostructures. The technique requires only the use of the spin-coating device and a proper selection of cosolvent with dissolved metal precursor salt. We have tested several compounds with metals incorporated, which reproduce the pattern of preferential homopolymer block. We further characterized the morphology of the obtained samples. Our profound investigations about this convenient process may open the facile way for obtaining precisely tuned functional nanostructures with sizes not exceeding single nanometers, which potential area of application ranges from membranes through memory devices to optical coatings.

11:25 AM SM07.05.04
Late News: Solvent Evaporation Annealing—An Efficient Path of Block Copolymer Self-Assembly
Arkadiusz A. Leniart, Przemyslaw Pula and Pawel W. Majewski; University of Warsaw, Poland

Large scale block copolymer self-assembly is hindered by relatively low defect formation energy – leading to high defect density, and relatively slow ordering kinetics. There are many processing methods used to overcome these obstacles, all aiming at obtaining highly ordered morphologies in a time- and cost-efficient manner. Among them, the two most straightforward techniques have been extensively explored – thermal annealing and solvent vapor annealing (SVA).
Solvent evaporation annealing (SEA) is a method based on a concept similar to SVA – in both cases, the acceleration of block copolymers self-assembly is obtained by an increase of mobility of polymeric chains in a presence of solvent molecules. However, instead of swelling of dry polymer film, in SEA preferable ordering conditions are achieved by evaporation of the solvent during single-step casting. It is possible due to binary solvent mixtures, in which the dominant solvent is much more volatile than a second one. Unlike in conventional spin-coating, during the casting process, the non-volatile addition remains in a block copolymer film for a significantly longer time. This residual solvent in a polymer wet film prolongs the evaporation process. We monitor the block copolymer grain coarsening – the long-range ordering of polymer domains – by control of multiple parameters, such as residual solvent concentration, temperature, and pressure of the environment.
In this study, we present kinetic data of grain growth in cylindrical block copolymer with a molecular weight range from 58 kg/mol to 275 kg/mol, consisting of polystyrene and poly(vinyl pyridine) blocks, conditioned in

different solvents mixtures and varying environmental conditions. The evaporation rate was controlled in both isothermal and non-isothermal manner. We determined a critical concentration of solvent in block copolymer wet film, at which order-disorder transition occurs. Moreover, we conducted a series of experiments in which different pathways of evaporation were scrutinized, including rapid quenches at certain thicknesses and delay of evaporation. The image analysis results were corroborated by large-scale SEM images and GISAXS studies. The obtained results indicate, that there is a power-law scaling between grain coarsening and evaporation rate as well as the time of retention near ODT.
SEA is a convenient method for the fast and cost-effective production of large block copolymer grains. In contrast to many other self-assembly methods, this technique is relatively simple and can be utilized without any complex processing setup.

11:40 AM SM07.05.05
Knotted and Macromolecular Catenanes—Synthesis and Surface Directed Assemblies Rigoberto C. Advincula[1,2,3]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]Case Western Reserve University, United States

Nanostructured and hierarchical assemblies are important for demonstrating the ability to understand directed or self-directed forces in defining function for polymers. Knotted and catenated macromolecular architectures in polymers are a departure from typical linear polymers. The lack of chain-ends, the topologically exact order, size, and composition can influence properties and applications such as rheology modifiers, adhesion promoters, and compatibilizers. Herein we demonstrate a supramolecular assembly approach towards these topologically exact polymers and demonstrate their self-assembly properties at interfaces. First, we demonstrate their programmable synthesis—next, their complexation and assembly properties. The goal is to understand structure-composition-property correlation at the macromolecular assembly scale and compare it to other architectures such as stars, dendrimers, and brushes. The ability to self-assemble at the air-water interface is demonstrated with PLA-PCL copolymers and catenanes, and the role of metal complexation is highlighted. Different surface-sensitive analytical spectroscopic and microscopic properties are utilized and reported.

11:55 AM SM07.05.06
Monolayer Fluidic Water in Nanoscale Confinement Shuai Zhang[1,2], Qiang Li[3,2], Flemming Besenbacher[2] and Mingdong Dong[2]; [1]University of Washington, United States; [2]Aarhus University, Denmark; [3]Shandong University, China

With distinct intermolecular network and dynamics, interfacial water is essential to modulate the surface behaviors, like growth and dissolution, redistribution of surface charge, and dewetting/rewetting surfaces. It plays a crucial role in nano-fluidics, tribology, doping of semiconductors, (geo)-mineralization, and bio-macromolecule and nanoparticle assembly. Hence, characterizing and understanding the structures and dynamics of interfacial water is essential in designing and creating advanced materials.
In the last decade, it has been found that few-layer water confined between solid surfaces in sub-nanoscale can convert into two-dimensional (2D) ice-like structure (i-water). Although its growth dynamics and transition to three-dimensional phases, water droplets, and vapor, in response to humidity, temperature, organic vapor, and hydrophobicity of confining solid surface have been studied, it is unclear if there are other 2D water phases in sub-nanoscale confined space thermodynamically stable, and how it responses to environmental stimuli. The phase diagram of the confined 2D water in sub-nanoscale is not complete.
Recently, using in-situ thermal atomic force microscopy, we have confirmed the exitance of 2D monolayer fluidic water confined by few-layer graphene and muscovite mica. The new phase thickness is less than 0.2 nm, adapting one unique hydrogen-bond network different from bulk water and i-water. It is a thermodynamically stable phase that coexists with i-water. The discovery of this new 2D water phase fills one missing part of the phase diagram of the confined 2D water in sub-nanoscale. It provides another opportunity to understand the physics of fluidics in the nanoscale other than the classical carbon nanotubes and protein-based nanopores. It will also inspire the new theory and scheme in understanding how interfacial water response to confinement and how such modulation can adjust material assembly.

12:10 PM SM07.05.07

Competing Self-Assembly Pathways for Metal Nanomembranes Divya J. Prakash[1,1], Hassan Dibaji[1], Mengistie L. Debasu[1], Donald E. Savage[2], Max G. Lagally[2] and Francesca Cavallo[1,1]; [1]The University of New Mexico, United States; [2]University of Wisconsin–Madison, United States

Competing relaxation mechanisms have been extensively modeled for strained and single-crystalline semiconductor nanomembranes (NMs) upon release from their substrate surface. As a result, a variety of 3D structures can be obtained by self-assembly of semiconductor NMs with a high degree of predictive control on their geometry. These structures include wrinkles, helices, twists, and rolled-up tubes. Guided self-assembly of metal NMs into different 3D objects has also been demonstrated. However, the ability to determine the relaxation pathway of a free-hanging metal NM remains elusive. A significant challenge in achieving predictive control on the geometry of metal NMs upon release from their substrate surface relates to a varying stress distribution across the NM thickness for a given set of deposition parameters. Moreover, different stress vs. thickness distributions have been reported for metals with low and high adatom mobilities.

Here, we demonstrate predictive control on the relaxation of metal NMs upon release from their substrate surface. The work encompasses continuum mechanics modeling and synthesis of 3D microstructures via self-assembly of metal NMs.

We investigate NMs comprising Cr and Au, i.e., metals with low and high adatom mobility. We use a force balance model to determine the preferential geometry of a released Cr and Au-based NMs as a function of various parameters. These parameters include the Cr and Au layer thickness, the number of Cr and Au layers and their stacking order within the NM, the substrate surface, and the two metals' deposition rates. The focus is on metal NMs obtained by evaporation. We also establish how the NMs' lateral geometry on the substrate surface will affect its self-assembly pathway upon release.

Our theoretical study yields the conditions to obtain rolled-up and inverted rolled-up tubes, helices and twists with an unprecedented degree of control on their diameter and pitch in the microscale range.

We validate our predictions via a comparison with experimentally fabricated 3D structures via guided self-assembly of Cr and Au-based NMs. The NMs are deposited via e-beam evaporation on bulk Si substrates coated with a sacrificial layer. In our work, we use Ge, GeO_x, and SiO_2 sacrificial layers. Upon selective removal of the sacrificial layer, we observe the formation of rolled-up structures by either upward or downward bending of the NM based on the NM composition, sacrificial layer, and thickness of the Cr and Au layers. The fabricated structures include tubes, helices, and twists. The geometry of the fabricated structures is consistent with the prediction of our model.

In conclusion, we have provided the theoretical framework to fundamentally understand and determine competing relaxation pathways for metal NMs that have been released from their substrate surface. Our work is timely and relevant as self-assembled metal NMs are increasingly proposed for various device applications (e.g., integrated inductors and transformers, slow-wave structures, and unit cells of metamaterials).

Late News: Spectroscopic and Structural Characterization of Silver Nanoclusters with DNA Monomers and Dimers Using Mass Spectrometry Soonwoo Hong, Ines C. Santos, Yu-An Kuo, Yuan-I Chen, Trung D. Nguyen, Jennifer S. Brodbelt and Tim Yeh; The University of Texas at Austin, United States

As a special class of nanomaterial fluorophores, DNA-templated silver nanoclusters (DNA/AgNCs) have become important in molecular sensing, creating new tools for detection of metabolites, neurotransmitter and metal ions. Despite of their unique capabilities in molecular sensing, the mechanisms that mediate both the formation of DNA/AgNCs and the resulting optical properties are largely unknown. Here we utilized an advanced mass spectrometry, including electron spray ionization (ESI-MS) and activated-electron photodetachment mass spectrometry (aEPD-MS), to probe the fluorescence and structural properties of DNA/AgNCs, including stoichiometries, compositions and binding sites of DNA/AgNCs templated in seven DNA 10-mers. Our mass spectrum data revealed the presence of complexes containing one (monomeric) or two (dimeric) DNA hosts and a variable number of silver atoms. Interestingly, while monomeric species incorporated a low number of silver atoms (Ag_1 - Ag_4), the dimeric complexes contained a higher number of silver atoms (Ag_4 - Ag_{18}). Using polyacrylamide gel electrophoresis (PAGE), we validated that the higher number of silver atoms are associated with dimers responsible for the red fluorescence emission, while the low number of silver atoms are monomers that tend to give green fluorescence emission. The formation of nanocluster cores and the resulting spectroscopic properties vary by the base composition of the DNA template. Given the enhanced abundance of specific dimeric DNA/AgNCs, we hypothesize that certain magic-number of Ag atoms (e.g., Ag_6, Ag_{10}, and Ag_{11}) with dimerization of short DNA may be a clue for having fluorescence with the different emission wavelengths (490 – 680 nm) observed. This study suggests that fluorescence can be strategically controlled by the certain design (e.g., consecutive cytosines and GC contents ratio) of the DNA host to guide the formation of monomeric or dimeric species with magic-number of silver atoms.

Ionic Liquid Directed Self-Assembly of Block Copolymers in Epoxy Resins Deborah Liu and Daniel Krogstad; University of Illinois at Urbana-Champaign, United States

Epoxy/block copolymer (BCP) blends have shown great promise in a variety of applications. The BCPs can form nanostructures in the resins, which improve the toughness of the thermoset as well as provide a template for nanoparticles (NPs). However, the BCPs can either form the nanostructures through reaction induced microsphase separation (RIMPS) or by self-assembly. For toughness applications, the mechanism is not as critical, but for NP templating, the self-assembly mechanism is preferred in order to help mitigate NP aggregation. In this work, we demonstrated that using an ionic liquid (IL) hardener, rather than a traditional diamine hardener, results in the formation of the nanostructures through self-assembly rather than RIMPS for poly(ethylene oxide-b-propylene oxide-b-ethylene oxide) (Pluronic) BCPs. Small angle x-ray scattering (SAXS) was used to develop a ternary phase diagram that shows a range of stable nanostructures including higher ordered cubic, hexagonal and lamellar structures, even in these highly polydisperse BCPs. Additionally, *in situ* small angle x-ray scattering (SAXS) was used to show that there are significant morphological transitions during epoxy curing. These data show that there are competing changes that are driven by the epoxy cross-linking reactions and the increased thermal mobility of the BCPs in the epoxy. These results demonstrate new methods to drive self-assembly in epoxy/BCP blends, which is critical for their development as multifunctional nanocomposites.

Late News: Modulating and Modeling Charge of Hybrid Lipid/Polymer Vesicles Walter Paxton, Keith L. Willes, Trent Johnson, Sydney Johnson and Daniel R. Hart; Brigham Young University, United States

Amphiphilic block copolymers combined with lipid-based amphiphiles are capable of self-assembling into hybrid bilayers with properties of both lipid and polymer that are not always predictable. We aim to understand and predict the properties of polymer and hybrid vesicle membranes to better exploit them for use in drug delivery and modulating surface properties in biosensing devices. One of those key properties is the surface charge of vesicles, which influences how a membrane will interact with other materials and biological tissues, as well as the biological fate of vesicle assemblies in vivo. To study the modulation of surface charge in hybrid lipid/polymer bilayers, we have used DLS and zeta potential analysis to investigate the effects of incorporating charged lipids and polymers into hybrid lipid-polymer vesicles. We have found that polymer amphiphiles containing polyethylene oxide headgroups have a surprisingly strong ability to screen charged lipids within the vesicle membrane, complicating the task of predicting the surface properties of hybrid vesicles. To explain these results and provide a straightforward way of predicting the surface properties of synthetic, multicomponent membranes, we have devised a model that allows us to predict the zeta potential of hybrid vesicles quantitatively. We anticipate that our approach will greatly facilitate modulating zeta potential and other surface properties of biomimetic membrane materials.

Influence of Organic Solvent in Peptide Self-Assembly on Two-Dimensional Materials Robert Ccorahua, Hironaga Noguchi, Kazunori Motai and Yuhei Hayamizu; Tokyo Institute of Technology, Japan

The controllable nanoscale self-assembly of biomolecules, such as peptides, on solid surfaces is an important issue in establishing functional bio/solid interfaces for biosensors. Two-dimensional (2D) nanomaterials such as graphene and MoS2 are gaining a wide attention due to its unique electrical properties as a novel platform for biosensing. For this sake, we have established a method to control the self-assembly on these 2D materials by applying electrochemical bias[1] and designing new sequence of peptides[2]. In this work, we studied basics of the assembly process of the self-assembling peptide $Y(GA)_4Y$: (Y4Y) on 2D materials by employing methanol (MeOH) and other organic solvents as mediators.
Flakes of graphite and MoS_2 were transferred on to silicon wafers by mechanical exfoliation method. A solution of Y4Y peptide (100 nM) dissolved in a mixture of water and methanol (MeOH) at different concentrations ranging from 0% to 50% were placed on both substrate graphite and MoS_2. After 1 hour of the incubation, the solution was removed by blowing with N_2 gas and the sample was dried overnight. Finally, Atomic Force Microscopy (AFM) characterization and analysis were carried out.
AFM analysis showed that. by using aqueous solution as a medium for the self-assembly of Y4Y, more than 85% of self-assembled peptide covered (coverage) the surface of graphite and MoS_2 forming a monolayer in the shape of nanowires with a hexagonal structure. When MeOH was employed as the mediator of Y4Y self-assembly, the coverage decreased drastically for both substrates at distinct threshold concentrations. While the coverage of peptides decreased to ~60% at more than 30% of MeOH concentration on graphite, the peptide coverage resulted in ~50% at more than 20% of MeOH for MoS_2. Higher concentrations of MeOH resulted in no self-assembled peptide for both substrates, thus evidencing the effect of MeOH in controlling the coverage of Y4Y structure over graphite and MoS_2. Additionally, we evaluated the influence of other water-miscible organic solvents (DMSO and acetone) in the self-assembly process of peptide on graphite and MoS_2. These AFM characterizations suggested that the organic-solvent mediated self-assembly process of peptide on 2D materials correlates with the relative polarity of the respective organic solvent. These results unveil promising properties of organic solvents as peptide self-assembly mediator on 2D materials.

Layer-by-Layer Assembled Microparticle Vaccines for Combination Immunotherapy Apoorv Shanker[1], Imane Bouzit[1], Sandeep Koshy[2], Michael Nehil[2], Janelle Velez[2], Stephanie Schwartz[2] and Paula Hammond[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Novartis Institutes for BioMedical Research, United States

Recent clinical successes of checkpoint inhibitors have led to a renaissance in the field of cancer immunotherapy. Combinatorial immunotherapy that targets multiple immune pathways offers a more potent strategy to improve patient outcomes. However, combination immunotherapies generally suffer from increased risk of immune-related adverse events that limit their utility. Optimal sequencing, timing, and duration of exposure of immune-modulators that resonate with the natural immune cycle can help rescue systemic toxicity and unleash the full potency of combination immunotherapies. Rational biomaterials- and nanotechnology-based drug delivery strategies that allow precise spatiotemporal control of the *in vivo* presentation of the immune-modulators can open the door to more effective immunotherapies.

One such strategy is the layer-by-layer (LbL) self-assembly technology which enables the fabrication of a modular drug delivery platform with multiple immune-modulating drugs stacked in a layered structure. The sequence of assembly of the bioactive agents and the choice of intervening non-bioactive "glue" layers provide precise control over the timing and duration of exposure of the assembled immune-modulators. Here, we present LbL-assembled structures on injectable microparticles as a tractable drug delivery system to achieve appropriately-timed delivery of poly(I:C), a TLR3 agonist, and interleukin-2 (IL-2), a pro-inflammatory cytokine. To fabricate the microparticle vaccines, the heparin-binding capability of IL-2 was leveraged and poly(I:C), a negatively-charged synthetic mimic of viral dsRNA, was employed as one of the polyelectrolytes in the LbL assembly. The chosen polycation functions as the "glue" layer to enable sequential assembly of the negatively-charged heparin/IL-2 complexes and poly(I:C), as well as to control their rate of release. Encapsulation efficiencies of 30-50% and 60-90% for poly(I:C) and IL-2, respectively, at a high formulation yield (> 80%). For a milligram of the microparticle core, a single layer of IL-2 and poly(I:C) can hold 3-4 μg and 5-10 μg, respectively. Differential release rates of IL-2 from the LbL- microparticles were achieved by the choice of polycations. While LbL-microparticles built with the hydrolytically-degradable poly(β-amino ester) (PBAE) as the polycation released ~90% IL-2 over three days, less than 15% was released from the formulation with the non- degradable poly(L-lysine) (PLK) over eight days. A 4:1 mixture of PBAE and PLK yielded an intermediate release profile with 45% of loaded IL-2 released over eight days. For LbL-microparticles loaded with both poly(I:C) and IL- 2, the release kinetics were adjusted to achieve faster release of poly(I:C) (~90% over 3 days) required to trigger the innate immune response followed by a slow, sustained presentation of IL-2 over multiple weeks to augment the developing adaptive immunity. The microparticle vaccines were further characterized in subcutaneous murine tumor models to evaluate the time-course effects of the LbL-delivered poly(I:C) and IL-2 on immune activity, toxicity, and therapeutic efficacy.

LbL microparticle vaccines, thus, present a new paradigm to evaluate drug sequencing in combination immunotherapies in higher throughput than currently possible with conventional dosing in pre-clinical *in vivo* experiments.

2:15 PM SM07.06.06

Tracing the Formation of De Novo Binary Protein Arrays on Cells and Synthetic Membranes Ariel J. Ben-Sasson[1,1], Joseph Watson[2], Alice Bittleston[2], Ioanna Mela[2], Greg Hura[3], Clemens Kaminski[2], Emmanuel Derivery[2] and David Baker[1,1,1]; [1]University of Washington, United States; [2]University of Cambridge, United Kingdom; [3]Lawrence Berkeley National Lab, United States

Co-assembling genetically encoded protein materials represent a paradigm shift in engineering of complex biomaterials.[1,2] Compared to their single-component counterparts[3,4] they offer facile components production and functionalization, as well as control over the temporal, spatial, and composition aspects of the formation process, that is only initiated by mixing two different building

blocks.1 Here we go beyond homogeneous protein materials formation, whether in a tube or inside a living cell, and demonstrate formation of biologically-active hybrid arrays on mammalian cell membranes and their synthetic counterparts to tunable dimensions, showcasing ordered receptor clustering and tunable endocytosis properties.
To this end we first selected a membrane receptor, genetically- or peptide-fused a compatible ligand to one of the arrays components, saturated the cell membrane receptors with said component, removed unbound components from the cell environment, and triggered arrays formation by introducing the second component into the system. While this seemed as a valid assembly pathway we found that the arrays' dihedral building blocks that need to first anchor to the membrane, were not suited for this task. We hypothesized this is likely because cell membranes can wrap around the dihedral components' identical two sides, each displaying an equal number of binding sites, thereby blocking assembly. We therefore devised cyclic pseudo-dihedral versions of the array components, which are partly dihedral to allow proper formation of a 2D array, but overall cyclic to allow directional anchoring.
To follow array formation we label the array components and the targeted receptor's intracellular domain and demonstrate a fast, uniform, and synchronised assembly process that is robust to derive useful information from, using quantitative microscopy.
Through a rigorous quantitative microscopy study on cell membranes combined with AFM characterization of arrays assembled on supported bilayers we show that arrays formed on cells are likely of an ordered single layer structure and thus that our material can impose order onto fundamentally disordered substrates like cell membranes receptors.
We envision the design approach and the system demonstrated here will enable deeper investigation into assembly processes both in-vivo and in-vitro, and will pave the way towards a new generation of multi-protein and hybrid biomaterials designed to modulate cell responses and reshape synthetic and living systems.

AI Guided Discovery of Self-Assembly Peptide Sequences Using Monte Carlo Tree Search and Coarse-Grained Simulations Rohit Batra, Troy D. Loeffler, Henry Chan, Srilok Srinivasan, Christopher Fry and Subramanian Sankaranarayanan; Argonne National Laboratory, United States

Peptide materials have a wide array of functions from tissue engineering, surface coatings, catalysis, and sensing. This class of biopolymer is composed of a sequence of 20 naturally occurring amino acids. As the peptide sequence increases, so does the searchable sequence space (trimer = 20^3 or 8,000 peptides and a pentamer = 20^5 or 3.2 M). Empirically, peptide design is guided by the use of structural propensity tables, hydrophobicity scales, or other desired properties and typically yields <10 peptides per study, barely scraping the surface of the search space. Here, we combine machine learning techniques, such as Monte Carlo tree search and random forest, with coarse-grained molecular dynamics (MD) simulations to efficiently search large spaces of trimer, pentamer and octamer peptide sequences with high self-assembly propensity. Subsequent experiments on identified sequences support our findings, and demonstrate the ability of this approach for peptide design.

2:45 PM SM07.06.08
Reconfiguration of Amorphous Complex Oxides as a Route to Self-Assembly of Inorganic

Nanomembranes Divya J. Prakash[1,1], Mengistie L. Debasu[1], Yajin Chen[2], Donald E. Savage[2], Chaiyapat Tangpatjaroen[2], Christoph F. Deneke[3], Angelo M. Da Souza[4], Adam D. Alfieri[2], Izabela Szlufarska[2], Paul G. Evans[2] and Francesca Cavallo[1,1]; [1]The University of New Mexico, United States; [2]University of Wisconsin–Madison, United States; [3]Universidade Estadual de Campinas, Brazil; [4]Universidade Federal de Minas Gerais, Brazil

We report and investigate a novel approach to self-assembly of complex oxide-based nanomembranes (NMs) in radial geometries, including radially stacked complex oxides and complex oxides/single-crystalline semiconductors superlattices. These structures will offer a tremendous opportunity for discovery-driven science and new functionalities. For example, the proximity of single-crystalline semiconductors and complex oxides will potentially result in superlattices with intriguing magnetic and electronic properties through modulating the oxides' intrinsic spin-lattice coupling and other coupling effects. Moreover, we expect that curvature will significantly affect the electronic band structure of the stack and produce unique electrical and thermal transport features.
Amorphous $SrTiO_3$/Si/$Si_{1-x}Ge_x$ nanomembranes (NMs) roll up into micron-scale tubes upon release from the growth substrate due to the elastic relaxation of stress from two sources: (i) the epitaxial mismatch of SiGe and Si and (ii) stress resulting from the deposition of the amorphous $SrTiO_3$. Crucially, the NMs are in a metastable structural configuration after release because the $SrTiO_3$ layer remains in the amorphous state.
Heating transforms NMs scrolls into swiss roll structures that alternate single-crystalline semiconductors and amorphous complex oxides in a radial geometry. A detailed continuum mechanics study establishes that the relaxation of the hybrid NM during heating involves large irreversible compressive stress arising from structural changes in the oxide. Mechanical modeling also shows that this stress is responsible for NM assembly. X-ray reflectivity, x-ray diffraction, and transmission electron microscopy probe changes in the structure of the $SrTiO_3$ layer that are consistent with densification of the complex oxide.
Based on our experimental results and continuum mechanics modeling, we predict that a variety of complex oxides-based heterostructures can be obtained via reconfiguration-driven assembly of amorphous oxides, including $SrTiO_3$/Si and $SrTiO_3$/$LaAlO_3$.

Structure and Properties of Ice-Templated Cellulose Nanomaterial-Based Composite Foams for Thermal Insulation Pierre Munier, Varvara Apostolopoulou Kalkavoura and Lennart Bergström; Stockholm University, Sweden

Cellulose nanomaterials (CNM) have emerged in the last decades as a potential candidate for renewable thermally insulating foams and aerogels [1]. The intrinsic anisotropy of cellulose chains has been exploited in the design of anisotropic foams with aligned nanoparticles and lower-than-air thermal conductivities in a specific

direction [2]. It was recently shown [3] that the (nano)porosity, particle alignment and tailoring of heterogeneous interfaces can have a significant effect on the heat transfer properties within foams. Here, we will present work on the heat transfer and mechanical properties of ice-templated anisotropic foams based on TEMPO-oxidized cellulose nanofibrils (TCNF) and cellulose nanocrystals (CNC). Anisotropic CNM-based foams with a wide range of densities were prepared by freeze casting aqueous dispersions with different particle concentrations. We will discuss how the radial thermal conductivity (perpendicularly to the freezing direction) of the foams was related to the nanoporosity in the pore walls and the degree of particle alignment. It will also be shown that ice-templating of composite foams, by adding for instance montmorillonite clay nanoplatelets or colloidal silica [4], could mechanically strengthen the foams while specific co-assemblies could favor certain heat dissipation mechanisms and therefore preserve or even improve the thermal insulating performance.

3D Printed Pattern for Directing Nanoparticle Alignment for Device Applications Sayli Jambhulkar, Dharneedar Ravichandran, Weiheng Xu, Yuxiang Zhu and Kenan Song; Arizona State University, United States

Nanoparticle assembly can enable broad applications in electronics, optics, optoelectronics, resonators, and thermal dissipations or conductions. Current methods to tailor nanoparticle structures include electrical field, magnetism, mechanical stretching, surface functionalization, and template directing. Most subtracts for template-based nanoparticle assembly have crimpled surfaces from elastomer compression, transfer imprinting, and other methods with similar slow-manufacturing. Our study has demonstrated the use of different 3D printing, including stereolithography (SLA) and continuous liquid interface processing (CLIP), in making microscale surface patterns for nanoparticle assembly. Via the combination of 3D printing and layer-by-layer assembly (LbL), we demonstrated the capability of aligning nanoparticles between surface grooves. The density of the aligned particles will transport electrons or phonons with different efficiencies. As a result, these rapidly prototyped devices showed varied conductivity and sensitivity. We demonstrated the manufacturability and scalability of our manufacturing with different nanoparticles. The inclusion of these nanoparticles with different concentrations showed high sensitivity and selectivity to different gas analytes, making them ideal platforms for detecting toxic gases or monitoring human health.

4:30 PM SM07.07.04
Late News: Polymer and Surfactant Assisted Crystallization for Electronics and Ionics Applications Jihua Chen; Oak Ridge National Laboratory, United States

Crystallization is a process that can be affected by many internal and external factors, which can in turn correspond to varied crystal structures, polymorphism and stunning differences in functions. Numerous examples can be found in oxides, silicon carbide, organic electronics, pharmaceutical compounds, and energetic materials. Ways to navigate nucleation and crystallizations of molecular crystals are explored, including frontline boundary control, temperature, and most importantly modified microenvironment by polymer additive.[1-2] Low-dose energy filtered TEM was used in combination with impedance analysis and equivalent circuit modelling to study ion transport, while hole transport in organic thin film transistor was studied as a function of pi-pi interaction strength. Recently, a similar approach has been adapted to grow ionic crystals with a surfactant additive. Improved grain boundary structure and facet

distribution lead to enhanced capacitance performance. Explanation of these results are given in light of surface energy, growth kinetics, and nucleation.[3]

4:45 PM SM07.07.05
Late News: Ultrahigh- Block Copolymer Materials with Versatile Etch Selectivity for Sub-10 nm Pattern Transfer Jian Sun[1], Koei Azuma[2], Changyeon Lee[3], Youngwoo Choo[4], Teruaki Hayakawa[2], Chinedum Osuji[3] and Padma Gopalan[1]; [1]University of Wisconsin-Madison, United States; [2]Tokyo Institute of Technology, Japan; [3]University of Pennsylvania, United States; [4]Yale University, United States

Studies of block copolymer (BCP) materials and their phase separation in bulk and thin-film forms have exploded over the last decades, due to the wide range of accessible morphologies (e.g. spheres, cylinders, gyroid, and lamellae) and sizes (5-200 nm) of features. The phase separation of a BCP is governed by three factors which include the relative volume fraction (f) of the blocks A and B ($f_A = 1 - f_B$), the degree of polymerization (N), and the Flory-Huggins interaction parameter (χ). The basic BCP self-assembly principles have enabled the BCP community to control the morphology as well as to tune the domain size and have driven the community to target the smallest size possible by synthesizing BCPs with high interaction parameter. Accessing sub-5 nm feature size is no longer a challenge utilizing BCP self-assembly. However, transferring the self-assembled BCP features to a substrate over a large area with high fidelity presents additional challenges, especially at the 10 nm length scale. In this work, the highly polar, functional and hydrophilic poly(3-hydroxystyrene) (P3HS) is incorporated with the acid sensitive poly(dimethylsiloxane) (PDMS). A tetrahydroxydropyranyloxy (THP) protecting group which requires mild deprotection condition is introduced to the system and hence PDMS block remains intact after deprotection. We explore both P3HS/PDMS-based diblocks and triblocks synthesized by sequential living anionic polymerization and atom transfer radical polymerization, respectively. P3HS-*b*-PDMS shows well-defined lamellae or hexagonally packed cylinders with characteristic dimensions ranging from 7.4 to 17.7 nm. Mean-field theory analysis of the temperature-dependent correlation-hole scattering derived from a disordered symmetric P3HS-*b*-PDMS gives $\chi_{(T)} = 33.491/T + 0.3126$, which is more than 4-fold increase over PS-*b*-PDMS. Triblocks P3HS-*b*-PDMS-*b*-P3HS also show well-ordered lamellae and cylinder structures in bulk with the successful access to sub-5 nm feature size. Additionally, the unique architecture of ABA triblock allows the thin film of P3HS-*b*-PDMS-*b*-P3HS to be aligned vertically to the substrate, making this material a promising candidate for pattern transfer. Etching study indicates that the etch contrast between P3HS and PDMS is 15:1 under oxygen plasma treatment. Due to the functionality from the hydroxy group, inorganic precursors such as trimethylaluminium can selectively penetrate into P3HS domain which can be further converted into alumina mask for pattern transfer. These new BCPs not only exhibit high interaction parameter to achieve sub-10 nm feature size, but also present high etch contrast and versatile etch selectivity to facilitate the pattern transfer.

5:00 PM SM07.07.06

Late News: Domain-Selective Thermal Decomposition within Supramolecular Nanoribbons Yukio Cho[1], Ty Christoff-Tempesta[1], Dae-Yoon Kim[1,2] and Julia Ortony[1]; [1]Massachusetts Institute of Technology, United States; [2]Korea Institute of Science and Technology, Korea (the Republic of)

Self-assembly is a powerful way to organize small molecules with tunable molecular chemistries into nanostructures with high surface areas. However, in order to exploit molecular self-assembly, the molecules must be amphiphilic and must fulfill particular packing parameter guidelines. These constraints have limited the use of small molecule self-assembly to a narrow range of molecular species with specific chemical attributes. Here, we introduce a new approach to supramolecular nanoribbons composed of untraditional hydrophobic small molecules. We pre-program into the nanostructure thermal stability in hydrophobic domain, and we use thermal decomposition to selectively remove the hydrophilic labile groups. The selective decomposition of labile groups with maintained nanoribbon morphology was confirmed by the combination of thermogravimetric analysis with mass spectrometry, ^{1}H NMR, and infrared spectroscopy. This molecular design strategy represents a new pathway to non-amphiphilic small molecule nanostructures through domain-specific selective decomposition, and broadens the potential utility of this materials class for new targets, including superhydrophobic coatings and self-assembled molecular electronics.

Atomistic Simulation Studies of Synthetic Melanin Particles in Aqueous Solutions with Poly (ethylene glycol) and Chitin Utkarsh Kapoor and Arthi Jayaraman; University of Delaware, United States

Melanin, a natural pigment known for imparting color to human skin/hair, is mimicked in synthetic materials for use in a variety of applications with the desired optical, photonic, thermal, and electrical property. In the past decade, polydopamine has served as one such synthetic form dominating the fundamental and applied research on melanin-based materials. While past experimental studies have focused on the synthesis and characterization of these melanin synthetic mimics, much less is known about the preferential interactions of these materials with other polymers, biocompatible and/or bio-derived. In this work, we use atomistic molecular dynamics (MD) simulation to simulate synthetic melanin nanoparticles, self-assembled using oligomers (e.g., 2-mer, 4-mer, and 8-mer) of polydopamine in an explicit solvent with and without added polymers, poly (ethylene glycol), and chitin. Using these simulations, we understand the nature of the polydopamine nanoparticle surface and its interactions with these polymers. We quantify the hydrophobic vs. hydrophilic character of the surfaces of the different assembled polydopamine oligomers, behavior of water molecules near the surface in the presence and absence of biopolymers. The impact of the polydopamine nanoparticle surface on the polymer is quantified via pair-wise correlation functions, polymer-particle hydrogen bonds, chain conformations, and interaction with water in the presence/absence of the polydopamine particle.

8:00 PM SM07.08.02
The Effect of Crystal Morphology on Hydrophobicity and Electrical Charge Retention in Melt-Blown Isotactic Polypropylene Fibers Farshad Nazari[1,2] and Mohammad Reza Rahimpour[2]; [1]Florida State University, United States; [2]Shiraz University, Iran (the Islamic Republic of)

From extrusion, melt-blown Isotactic polypropylene (iPP) submicron fibers were produced to be used in air purification. Scanning Electron Microscopy images revealed the lower the iPP molecular weight (MW), the lower the resulting melt-blown fiber diameter. For iPP fibers with MW~50 kg/mol, the average diameter was

~0.7 µm. The base weight in the melt-blown mats was adjusted by tuning the collector speed. Filtration properties, namely air resistance (AR) and filtration efficiency (FE%), were measured for the melt-blown iPP mats with different base weight, 5-75 gsm. Filtration efficiency increased exponentially as air resistance increased almost linearly with base weight. However, the filtration quality factor (Qf=-ln(1-FE/100)/AR) was the highest, ~0.04 Pa^-1, at 50 gsm. The effect of discharging, using saturated isopropyl alcohol (IPA) vapor, on filtration quality factor was also studied. The mats maintained ~50% of their filtration quality factor, reflecting the existence of residual electrostatic charges from the melt-blown process and their significant effect on filtration.
Charge retention is crucial in air filter media, in which the nonwoven fibers are electrically charged. Nano-roughness is known to improve hydrophobicity at the solid-liquid interphase. In this work, nano-roughness is introduced to melt-blown iPP fibers via the formation of shish-kebab crystallites.
The shish- kebab formation seems to occur only in the presence of high MW iPP chains. Hence, using microscopy and thermal analysis, crystalline structure in melt-blown iPP fibers with MW~50 kg/mol was studied; at the presence of different amounts (0.0-12.8 wt.%) of high MW~500 kg/mol iPP, blended via melt extrusion. In addition, electrical charge retention in the resulting nonwoven media was investigated through discharging, using saturated IPA vapor. Not only from microscopy and thermal analysis was it evident that the shish-kebab structure was most prevailing for the iPP fibers with 3.0 wt.% high MW component, but also charge retention was the highest for these fibers. Based on the increasing trend in fiber diameter and melt viscosity among fibers with 3.0-12.8 wt.% high MW component, the smaller presence of shish-kebab in the crystalline structure of theses fibers is attributed to lower elongation in the melt-spinning process for these fibers. The shish-kebab structure adds nano-roughness to the surface of the melt-blown iPP fibers, causing the formation of IPA droplets to become more difficult. This seems to contribute to the resulting fibers' resistance to IPA-induced discharging.

8:15 PM SM07.08.03
Late News: A Fabrication Process Based on Block Copolymer Self-Assembly for Three-Dimensional and Hollow Composite Nanostructures with Noble Metal Nanoparticles Embedded in Carbon Matrices Gun Ho Lee and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In the last decades, growing concerns in global warming and environmental issues have inspired developments of diverse green and sustainable energy technologies. In particular, proton exchange membrane fuel cells (PEMFCs), which produce electrical energy from hydrogen fuel, have gained significant interests as one of the leading candidates to replace conventional internal combustion engines that rely on hydrocarbon fuels. Despite their low greenhouse gas emissions, PEMFCs have been limited to niche applications due to the high cost and scarcity of platinum, which is an essential electrocatalyst material in the energy conversion system. Consequently, most commercially available PEMFCs have adopted composite catalysts in forms of platinum nanoparticles randomly dispersed on zero- or one-dimensional carbon support materials to increase its catalytic efficiency and minimize the noble metal load. However, such platinum/carbon (Pt/C) electrocatalysts have yet to meet the cost, catalytic activity, and durability requirements to be commercially viable and demand further improvements in the electrocatalytic performance *via* morphological and compositional control.
Here, we present a fabrication method based on block copolymer self-assembly for highly controlled carbon-platinum composite electrocatalysts with superior catalytic performance. Self-assembled diblock copolymers were used as structure-directing frameworks, selectively incorporated with platinum precursor ions, and pyrolized to prepare carbon-metal composite nanostructures with well-defined, three-dimensional morphologies. The calcination process produced evenly distributed, size-controlled platinum nanoparticles embedded in the carbon matrices, which increased the carbon-metal interactions and enhanced the durability of the catalytic materials. We also discuss a novel self-assembly technique to develop hollow channels throughout the carbon support structures using the chemical differences between the two polymer blocks. The three-dimensional morphologies and hollow channels provided pathways for superior mass transport within the nanostructures and enhanced the catalytic activity of the noble metal nanoparticles. Electrochemical evaluations revealed that the fabricated composite nanostructures exhibited greater electrochemical surface area and durability compared to those of commercially available Pt/C catalysts, demonstrating the significant

enhancements in the catalytic properties made *via* morphological controls.
In addition, the fabrication process can be utilized to develop composite nanostructures with various noble metals other than platinum. We demonstrated three-dimensional composite nanostructures prepared with a number of noble metals nanoparticles, including ruthenium, rhodium, osmium, and iridium nanoparticles, embedded in carbon matrices. The block copolymer self-assembly technique was also employed here for flexible control of the nanostructures, including formation of the hollow channels. The versatility of the process can be utilized to fabricate composite nanostructures of carbon and noble metals arranged in diverse morphologies and compositions, optimized for respective applications.

8:30 PM SM07.08.04
Late News: Highly Dynamic BP-Based Nanocomposite Hydrogels for Biomedical Applications Weihao Yuan, Kunyu Zhang and Liming Bian; The Chinese University of Hong Kong, Hong Kong

Hydrogels are emerging biomaterials with desirable physicochemical characteristics. Doping of metal ions such as Ca^{2+}, Mg^{2+}, and Fe^{2+} provides the hydrogels with unique attributes, including bioactivity, conductivity, and tunability. Traditionally, this doping is achieved by the interaction between metal ions and corresponding ligands or the direct incorporation of as-prepared metal-based nanoparticles (NPs). However, these approaches rely on a complex and laborious preparation and are typically restricted to few selected ion species. Herein, by mixing aqueous solutions of ligands (bisphosphonates, BPs), polymer grafted with ligands, and metal ions, a series of self-assembled metallic-ion nanocomposite hydrogels that are stabilized by the in situ formed ligand-metal ion (BP–M) NPs are prepared. Owing to the universal coordination between BPs and multivalent metal ions, the strategy is highly versatile and can be generalized for a wide array of metal ions. Such hydrogels exhibit a wide spectrum of mechanical properties and remarkable dynamic properties, such as excellent injectability, rapid stress relaxation, efficient ion diffusion, and triggered disassembly for harvesting encapsulated cells. Meanwhile, the hydrogels can be conveniently coated or patterned onto the surface of metals via electrophoresis. This work presents a universal strategy to prepare designer nanocomposite materials with highly tunable and dynamic behaviors. Moreover, we demonstrated that the nanocomposite hydrogels doped with lanthanide ions exhibited a highly tunable fluorescent spectrum. We next applied the developed hydrogels to treat peripheral nerve injuries, which are of great clinical significance. We demonstrated that the nanocomposite hydrogels containing magnesium and bisphosphonates promoted peripheral nerve regeneration and achieved partial functional recovery in s sciatic nerve injury rat model.

Greener Synthesis of High Aspect Ratio Copper Oxide Nanowires for Potential Applications Gayani Chathurika Pathiraja and Hemali Rathnayake; University of North Carolina at Greensboro, United States

Controlled synthesis of one-dimensional nanostructures such as nanowires are most fascinating for wide range applications due to their superior performances based on quantum confinement effects. Here, we demonstrate a novel facile and greener synthesis method to fabricate high aspect ratio of one-dimensional CuO nanowires from directed self-assembly of $Cu(OH)_2$ nanocrystals guided by the oriented attachment mechanism via post-annealing. This surfactant free, one-pot sol-gel route at low temperature allows us to make higher aspect ratio of CuO nanowires with controlled-dimensions over a large area. The respective Raman, XRD and XPS spectroscopies confirm the chemical composition of CuO nanowires and their purity. The synthesized CuO nanowires has average diameter of 26.5±2.4 nm and aspect ratio of 280.9±18.0. Further, the analysis of electrochemical properties of synthesized CuO nanowires have shown the suitability for potential electrochemical applications of capacitors and energy storage devices.

9:20 PM SM07.08.06
Selective Nanoparticle Deposition in Polymers for Functional Composite Applications Sayli Jambhulkar, Dharneedar Ravichandran, Weiheng Xu, Yuxiang Zhu and Kenan Song; Arizona State University, United

States

Self-assembly can organize structures beyond the synthesis nanoscale and bridge to macroscale manufacturing, thus providing many device fabrications opportunities. For composite devices, the mixing of nanoparticles in polymers involves dispersion quality, interfacial interactions, and nanoparticle alignment. Among these parameters, the nanoparticle alignment is the most challenging. Our study has shown an efficient way to self-assemble nanoparticles based on surface topologies, roughness, and wetting conditions. In this research, we used photopolymers for the first layer deposition and surface topology control. Following the deposition of nanoparticles complies with this first layer and form cluster-based assembly with different densities. Our manipulation of the nanoparticle density via the secondary-bonding can tune the layered structure's mechanical and electrical properties, thus making them multifunctional devices. The same manufacturing is also applicable in general nanoparticles based on our observation of feasibility using 1D nanofibers and 2D nanoplatelets. The fabricated devices showed enormous potential in microelectronics, sensors, actuators, and smart materials in robotics.

9:25 PM SM07.08.09
High-Throughput Printing of Semiconducting Polymers by Meniscus Oscillated Self Assembly Jisoo Jeon[1,1], Alvin Tan[2], Jaeyong Lee[3], Jin Kon Kim[3], John Hart[2] and Jeong Jae Wie[1,1]; [1]Inha University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States; [3]Pohang University of Science and Technology, Korea (the Republic of)

Controlled evaporative self-assembly of semiconducting polymers has mostly been limited to time-consuming solvent evaporation or non-continuous blade-casting techniques. In this study, we report a novel high-throughput continuous printing of poly (3-hexylthiophene 2,5-diyl) (P3HT) by a custom-made oscillatory roller. The roller oscillation generates a cycle of meniscus stick and slip motion per single rotation of the roller that induces a rapid self-assembly of P3HT lines. The printed P3HT lines demonstrate hierarchical structures: nanometer scale thickness, micron scale width, sub-millimeter pattern intervals, and millimeter to centimeter scale length with highly defined boundaries. Remarkably, the line width and the interval of P3HT patterns can be independently controlled by varying polymer concentrations, the rotation rates of the roller, and the stage speed. Furthermore, grazing incidence wide angle X-ray scattering (GIWAXS) revealed that the roller-blading technique dramatically enhances crystallinity of P3HT by shear-induced crystallization. This high-throughput printing process for hierarchical assembly will open new opportunities for printed electronics with wide ranges of engineering capability.

9:30 PM SM07.08.12
Phase Behavior of Colloidal Particles with Attractive Potentials Sanghyuk Park, Seung Yeol Lee and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The behavior of colloidal particles has been widely studied with interests in their dynamics and self-assembly. Specifically, since the phase behavior and lattice structures of colloids are similar to those of atoms, the main focus is on how to treat colloids as model atoms. In previous studies, colloids have been primarily considered as hard spheres on which only the infinite repulsion at contact distance is acting. This is to reflect a repulsion between atoms due to the overlap of electron clouds when they are getting close. Such hard-sphere systems have also been realized by matching refractive indices. The real atomic interactions, however, are different from that due to van der Waals (vdW) attraction. They are represented by well-known models such as Lennard-Jones, Mie, and Morse potential. Therefore, a colloidal system that takes attractive interactions into account should be developed for the modeling. Here, in that sense, the phase behavior of colloidal particles with attractive potentials is studied. Systems are designed to have both repulsive and attractive force among particles and analyzed using both DLVO theory and a non-DLVO interaction. To observe crystals with an optical microscope and UV-Vis spectrometer, dielectric colloids are chosen properly so that crystal lattices diffract a selected wavelength in the visible range resulting in structural colors. In experiments, polystyrene nanoparticles (PS NPs) synthesized via emulsion polymerization are used as building blocks. Then, PS NPs, sodium chloride, and

poly(Acrylamide-*co*-acrylic acid) (p(Am-*co*-AAc)) are mixed with different compositions in de-ionized water. The suspensions are confined in glass cells immediately and observed continuously until reaching an equilibrium state. There are three interactions among PS NPs. VdW attraction arises from the different dielectric constants between PS and water. Electric double-layer repulsion is derived by sulfate groups on the surface of PS NPs, which is reduced by charge screening due to a salt, sodium chloride. A depletion attractive force is given and modulated by depletants, p(Am-*co*-AAc). Within two days, colloidal systems have been clearly distinguished into 4 phases depending on the composition; each phase is labeled as “fluid”, “crystal/fluid”, “crystal/glass/fluid”, and “glass/fluid“ phase based on whether crystals and aggregates are dominantly formed. At a low concentration of depletant and salt, none of the crystal or aggregate are observed at equilibrium, while only the aggregates are formed at high concentrations. In between, crystals with distinctive structural colors are detected. However, not all of the samples reach the equilibrium states in this short term. It was figured out that after a month, crystals are formed in the samples of which the compositions are at the boundary between the fluid and crystal/fluid phases, and their growth stops after 3 months. Interestingly, these crystals are dendritic-like and much larger over a few mm, while crystals formed in other conditions are polygon-shaped and smaller up to a few hundreds of μm. The interactions are then analyzed with pair-potentials derived from DLVO theory, Lifshitz’s continuum theory, and Asakura-Oosawa’s model. The osmotic contribution of depletants is adjusted theoretically because of its size-dependency. A total pair-potential is calculated by summing up three interaction potentials. From the developed potential curves, which are analogous to the atomic potentials, the information about equilibrium points as well as collision kinetics is obtained. By matching experimental results with pair-potentials, the energetic and kinetic range for the crystallization of spherical colloids have been demonstrated. The validity of analysis is verified using other types and sizes of colloids. In conclusion, the developed colloidal systems with attractive force will be a lot more reasonable to analyze the crystallization in terms of modeling the real atoms.

Expanding the Frontiers of Design and Additive Manufacturing for Biomaterials Joseph P. Crolla, Barnaby Hawthorn, Jackson C. Kirkman-Brown, Galane J. Luo, Rosemary J. Dyson and Lauren E. Thomas-Seale; University of Birmingham, United Kingdom

Design for Additive Manufacturing (AM) is widely acknowledged as a severe barrier to the progression of the technology. In terms of biomaterials, whilst AM provides unique opportunities for the design of geometries and material compositions, there remains a persistent problem in the trade-off between the desired mechanical properties and the material properties [1]. To overcome this challenge, a radically new interdisciplinary approach to the development of AM systems and design techniques for biomaterials is required. Rather than a bioinspired method towards designing a single product, this research outlines how the exploration of developmental biology can expand the frontiers of AM systems and design techniques [2].

The majority of AM techniques increase the part size through incremental fusion of the material. Considering the development of the human in-utero; life begins as a single cell, which eventually forms tissues and organs, growing and functioning in synergy. The essence of foetal development is a very sophisticated AM process; in-utero growth demonstrates intrinsically intertwined materials, design and manufacturing [2]. However, this synergy between materials, design and manufacturing is not reflected in AM.

The development of the foetus is fundamentally dependent on varying spatial and temporal stimuli through the pregnancy. Analogical reasoning between foetal development and AM highlights a complete lack of any tailored process parameters during manufacturing. Process parameters are currently predefined and remain constant. Yet the process parameters underpin the properties of the material. Temporal DfAM, the design of process parameters during an AM build, is proposed as a method of designing the properties of a material through a single part [3]. Whilst this approach has been demonstrated computationally, its application to biomaterials is novel.

Poly(vinyl alcohol) (PVA) cryogel is a biocompatible, synthetic hydrogel that can be physically cross-linked at sub-zero temperatures. The mechanical properties of PVA are tailored through concentration, molecular weight and the number and temperature profile of freezing and thawing cycles. This makes it a widely applicable biomaterial as a component of tissue constructs and diagnostic phantoms. A novel cryogenic 3D printer has been developed to facilitate the AM of PVA. In doing so, the geometric complexity of the meso and micro-structure of the material is vastly increased.

This presentation will demonstrate the application of the novel design technique TDfAM to a cryogenic 3D printing platform for PVA. Changing the fixed process parameters of cryogenic 3D printing leads to a change in the mechanical properties of the PVA. Thus, TDfAM, the variation of process parameters during an AM build, will be explored with respect to the local and global material heterogeneity and mechanical properties. This experimental work will be validated through computational simulations.

The limitations of the TDfAM technique and cryogenic 3D printing of PVA will be discussed with respect to the current barriers to their industrial and clinical translation. Finally, we will outline the next steps of this unique research trajectory, exploring new dimensions of developmental biology and how we can develop current research and extract more novel innovations in AM design and manufacturing systems.

3D Printing of Active Devices for Drug Delivery and Sensing Roger Narayan; North Carolina State University, United States

Two photon polymerization is a 3D printing process that relies on the use of ultrashort laser pulses to selectively polymerize and solidify photosensitive materials. The quadratic character of the two photon absorption probability and the well-defined polymerization threshold of this process allow for the diffraction limit to be exceeded and structures with features below one micrometer to be prepared. Two photon polymerization has recently been to fabricate many types of microstructured and nanostructured medical devices out of biocompatible inorganic-organic hybrid materials (such as zirconium oxide hybrid materials) and polymers for medical applications. The use of biocompatible photoinitiators, including a combination of riboflavin and triethanolamine, for two photon polymerization will be considered. Integration of electrochemical sensors with two photon polymerization-processed microneedles will be discussed. Assessment of the biocompatibility of two photon polymerization-processed materials using in vitro biological studies will be discussed. In addition, application-specific studies of two photon polymerization-processed medical devices for biosensing and drug delivery, including in vivo studies, will be described. Our results indicate that two photon polymerization provides many benefits for fabricating medical devices with small-scale features and unique drug delivery and biosensing functionalities.

Maneuvering and Printing Liquids by Means of a Pyro-Electrohydrodynamics—How Overcome the Current Limits of Micro- and Nanoscale Bio-Printing Pietro Ferraro, Veronica Vespini, Romina Rega and Simonetta Grilli; Intelligent Systems CNR, Italy

Inkjet printing is a powerful enabling technology for formation of structures at micro and nanoscale for current mosto advanced fileds of appplications. As it is a direct fabrication approach, it has the undisputed advantage to avoid any masks, molds or lithography steps. Furthermore, in addition to this great flexibility, recently it has been demonstrated the capability of inkjet printing approaches to reach very high spatial resolution, down to nanoscale and over large area. Direct printing of micro and nano structures has been proofed with a variety of different inks and different types of materials. Different technologies exist, such as thermal jetting, piezo-based jetting, Electrohydrodynamic (EHD) jetting, syringe-based pumping or simply contact-dispensing printing. Each of the above-mentioned technologies is based on liquid media to be delivered in the jet printing process. Moreover, most of the existing methods include needles for liquid dispensing. Unfortunately, the use of needles has some severe limitations such as clogging and cross contamination. Here it will be presented some recent developments about a novel and special platform based on EHD jetting driven by a pyroelectric effect activated in a bulk ferroelectric crystal. Waht we named Pyro-EHD exhibits significant potentialities in allowing liquid dispensing and printing for a number of applications ranging from microelectronics to biotechnologies. One of the interesting features is that pyro-EHD can easily work in nozzle-less modality thus avoiding needles and consequently the related clogging drawbacks. The pyro-EHD printer approach usually dispenses liquids from a liquid reservoir that can be a sessile droplet or even the free surface of a liquid. The high potentials easily attainable through the ignition of the pyroelectric effect allow to manouvering and dispense and print also high viscous polymers and liquids dropltes. Description of the pyro-EHD will be provided. The results obtained will be shown and discussed. Several examples will be illustrated for direct printing of liquids under both single and multiphase forms that can find useful exploitation in a multiplicity of fields from microelectronics to biomedical applications.

Osteoconduction and Bone Augmentation—When 3D-Printed Designs Meet Bone Biology Franz E. Weber; University Zurich, Switzerland

In the last decades, advances in bone tissue engineering mainly based on osteoinduction and on stem cell research. Only recently, new efforts by others and us focused on the micro- and nanoarchitecture needed to improve and accelerate bone regeneration. By the use of additive manufacturing, libraries of diverse microarchitectures were produced and tested to identify the ideal pore size or rod distance for osteoconduction to occur. Presently, we try to elucidate the dependency of osteoconduction on microporosity and expand our view on micro- and nanoarchitecture of bone substitutes for optimal bone augmentation.
For the production of scaffolds, we applied for titanium-based scaffolds selective laser melting and for ceramics the CeraFab 7500 from Lithoz, a lithography-based additive manufacturing machine. As in vivo test model, we used a calvarial defect and a bone augmentation model in rabbits. The histomorphometric analysis showed that bone formation was significantly increased with pores between 0.7-1.2 mm in diameter. Moreover, microporosity appeared to be a strong driver of osteoconduction and influenced osteoclastic degradation. Best microarchitecture for osteoconduction and bone augmentation are different.
In essence, additive manufacturing enabled us to generate libraries of microarchitectures to search for the most osteoconductive microarchitecture and the ideal microarchitecture for bone augmentation purposes. Moreover, additive manufacturing appears as a promising tool for the production of personalized bone tissue engineering scaffolds to be used in cranio-maxillofacial surgery, dentistry, and orthopedics.

9:15 AM *SM08.01.06
Light-Directed 3D Printing of Hydrogels and Elastomers for Microfluidic Devices Ian Y. Wong; Brown University, United States

Additive manufacturing of hydrogels or elastomers can be used to fabricate microfluidic channels with biomimetic functionality. For instance, atomically thin sheets of nanomaterials can augment organic polymers with enhanced mechanical and physical functionalities. These 3D printed structures can further exhibit stimuli-responsive behaviors such as actuation, self-adhesion, or degradation. Here, we present recent results on light-directed 3D printing of next generation materials using covalent and ionic crosslinking. First, we explore the use of versatile alginate hydrogels with graphene oxide to pattern collective cell migration, tune stimuli-responsive behaviors, and repel oil in seawater like conditions. Second, we demonstrate double network hydrogels that are stimuli-responsive and self-adhesive as a simple “do-it-yourself” construction set for soft machines and microfluidic devices. This approach enables “plug-and-play” hydrogel parts for ionic soft machines that emulate actuation, sensing, and fluid transport in living systems. Finally, we investigate the use of 3D printed elastomers for microfluidic devices to achieve perfusion of tissue fragments for preclinical testing of immunotherapies. Overall, 3D printing enables multiscale integration of nanomaterial and polymeric building blocks into bespoke larger scale structures for advanced materials and biomedicine.

11:45 AM INTRODUCTION

11:50 AM *SM08.02.02
Using Bioprinting to Create Personalized In Vitro Tumor Models Joseph Kinsella, Jacqueline Kort-Mascort, Salvador Flores-Torres and Veena Sangwan; McGill University, Canada

The tumor microenvironment (TME) is a dynamic cellular and biochemical system, integrating multiple positive and negative biological feedback loops that influence cell physiology. Cell-extracellular matrix, secreted factor-cell signaling pathways, and cell-cell interactions are known factors in tumorigenicity and drivers of therapeutic resistance. There is, therefore, an urgent need to develop clinically relevant in vitro platforms comprising epithelial and stromal cells in an extracellular matrix mimicking microenvironment. Three-dimensional (3D) cell culture and co-culture of cancer cells have demonstrated that creating physiologically representative tumor microenvironment in vitro models enables patient-specific experiments to be performed. Typically, these are performed by casting cells within a droplet of Matrigel, or commercially available biocompatible hydrogels, promoting the self-assembly of multi-cellular organoids. While these systems provide a more relevant microenvironment than monolayers, the resulting organoids have limited user input over parameters such as the initial location of different cell types.

We have recently developed extracellular matrix mimicking hydrogel biomaterials capable of hosting cells, and subsequently, being extruded to form complex in vitro tumor models. Our lab has previously demonstrated that composite materials constituted of sodium alginate, a seaweed-derived polysaccharide, and gelatin, a bovine or porcine-derived denatured collagen, can be tuned to recapitulate the mechanical properties of soft tissues while keeping their biocompatibility and printability. Here, we report a bioink prepared by decellularizing tissue and incorporating sodium alginate and gelatin at controlled weight percentages as rheological modifiers to reinforce and positively impact the composite material's mechanical integrity. dECM contains structural proteins, glycosaminoglycans, and growth factors preserved from the tissue of origin. Gelatin provides mechanical stability during the printing process, and crosslinked-alginate chains maintain sample integrity in long-term cell culture conditions.

We have demonstrated this methodology to create breast and head and neck tumor models using immortalized cell lines and, more recently, lung, gastric, and breast models derived from patient tumor samples to create precision interventional schemes. Of particular interest is the ability to build complex 3D geometric structures using soft materials (bioinks) that recapitulate the mechanical properties such as the stiffness of solid tumors and their microenvironment. Bioprinting permits more complex geometric matrices to be printed with high cell density, control over cell location, and viability. Bioprinted models can be created directly with precise reproducibility from cell-hydrogel suspensions with high throughput and scalability directly on to well plate platforms. In collaboration with the Sangwan and Ferri labs at the Goodman Cancer Research Centre at McGill University, we have further explored using biobanked tissue samples to develop personalized tumor models.

12:15 PM SM08.02.03
3D Printing of Cellulose with Controllable Mechanical Properties Jungang Jiang, Yuan Chen, Jason Yu and Feng Jiang; The University of British Columbia, Canada

Three-dimensional hierarchical structures with controllable mechanical properties are expected to have wide range of applications. In general, material properties depend on the building block and it remains challenging to develop materials with dramatically different mechanical properties from the same type of material. In this

presentation, cellulose was demonstrated for 3D printing of two types of structure. In one case, a lightweight (~90 mg/cm^3) and super-strong (16.6 MPa compressive Young's modulus) honeycomb structure is constructed by 3D printing of cellulose ink dissolved in NaOH/urea solution. The 3D printed cellulose structure demonstrated switchable high elasticity (to withstand varied repetitive elastic deformation) at the wet state and high rigidity (to support over 15,800 of its own weight) at dry state. In another case, we demonstrated a compressible and superelastic 3D printed structure based on cellulose nanofibrils. The 3D structure showed superb elasticity (over 91% strain recovery after 500 cycles of compressive test) and compressibility (up to 90% compressive strain). In addition, with the incorporation of salt, the 3D printed CNF structure was demonstrated to serve as pressure sensor with high pressure sensitivity of 0.337 kPa^{-1} at 43% relative humidity. These results indicate that the mechanical properties of the 3D printed cellulose structure can be facilely controlled by the inter-fibril interactions, leading to either super-strong or super-elastic materials properties.

12:25 PM SM08.02.04

3D Printed Bioplastics with Shape-Memory Behavior Based on Bovine Serum Albumin Eva Sanchez[1,2], Patrick Smith[1], Alvaro Gomez-Lopez[2], Maxence Fernandez[3], Aitziber Cortajarena[3], Haritz Sardon[2] and Alshakim Nelson[1]; [1]University of Washington, United States; [2]University of the Basque Country, Spain; [3]CIC biomaGUNE, Spain

Bio-sourced materials that can replace existing petroleum-based materials are an integral component of sustainability. Moreover, biomaterials with greater complexity and functionality will be required to meet the demands for the full spectrum of applications from aerospace to medicine. The unique features of proteins (such as the mechanical properties of spider silk) have inspired the development of protein-based plastics, but their application is limited by poor processability and limitations in mechanical performance.

Both 3D and 4D additive manufacturing (AM) processes that utilize vat photopolymerization have tremendous potential in industrial manufacturing for the future production of parts and supplies. Naturally occurring polymers often require modification with photocurable functionalities to become printable. Most notably, methacryl groups have been introduced onto the amines of biopolymers to afford polymerizable materials like gelatin methacrylamide (Gel-MA), silk fibroin methacrylate (Sil-MA), and methacrylated bovine serum albumin (MA-BSA). While 4D printed structures that undergo chemical or physical changes in response to their environment are often inspired by nature, there are relatively few examples that use bio-sourced and biodegradable materials.

Both structural and globular proteins are known as macromolecules that can introduce material plasticity or elasticity based on the unfolding or disassembly of the proteins. Proteins can be unravelled reversibly or irreversibly upon the application of a tensile force, thus, the secondary and tertiary structure of proteins have been utilized to achieve biomaterials with unique combinations of extensibility, strength, and resilience. More recently, BSA was incorporated into hydrogel networks to provide an energy dissipation mechanism via protein unfolding. However, there has not been a demonstration of a protein-based material that exhibits plasticity due to unfolding, with a corresponding shape recovery back to its original form.

We formulated a simple aqueous-based resin for laser-scanning SLA printing based on BSA in a photocurable resin. BSA is an abundant globular protein with excellent aqueous solubility and low viscosity at concentrations up to 30 wt%. Furthermore, we demonstrated that the native conformation of these globular proteins is largely retained in the 3D printed constructs, and that each protein molecule possesses a "stored length" that could be revealed during mechanical deformation (extension or compression) of the 3D bioplastic objects. Given the large molecular weight of BSA (66 kDa), the potential for unfolding individual protein chains can be significant, as exhibited by the plasticity observed in these thermoset materials. We expect this strategy – wherein globular proteins are utilized to afford 3D printed bioplastics with mechanical properties that utilize the stored length of these macromolecules – is broadly applicable to other forms of vat photopolymerization to create constructs that can create a closed loop life cycle with bioplastics. In short, we introduced a bio-sourced resin for additive manufacturing that can be used to fabricate in a rapid manner complex elements for a wide range of applications, with a very interesting stimuli response of the printed parts, due to the conformational changes of proteins at the molecular level.

NIR Excited, UV Emitting Nanoparticles Fiorenzo Vetrone; Institut National de la Recherche Scientifique, Université du Québec, Canada

Luminescent lanthanide doped nanoparticles have received significant attention due to their fascinating optical properties. At the core of this interest is their ability to convert near-infrared (NIR) excitation light (typically 980 or 800 nm) to higher energies spanning the ultraviolet (UV), visible and higher energy NIR regions of the spectrum through a multiphoton process known as upconversion. Upconversion differs from conventional multiphoton excitation in other materials where no real intermediate states are present necessitating the use of ultrafast lasers (in the femtosecond regime) for simultaneous excitation to the upper emitting state. The lanthanide ions possess a multitude of 4*f* electronic energy states that have long lifetimes (micro- to millisecond) thus act as population reservoirs in the upconversion process. Hence, upconversion occurs through real, long-lived intermediate states through a sequential photon absorption process. This eliminates the need for ultrafast excitation and as a result, upconversion can be observed using inexpensive, continuous wave diode lasers. Upconversion luminescence can be exploited for a number of applications in nanomedicine, theranostics, photovoltaics, photocatalysis, as well as many others.

In this presentation, we will discuss the synthesis of these nanoparticles, establish how changing their nanoscale architecture can affect their luminescence properties and upconversion, as well as discuss their applications in nanomedicine, theranostics and potentially in 3D printing.

1:00 PM SM08.02.06
Feedstock Engineering and Rheology Scaling of Metal-Polymer Composites for the Filament Extrusion and Fused Deposition Modeling Amm G. Hasib and Bruno Azeredo; Arizona State University, United States

Fused Deposition Modeling (FDM) has been adapted to metals using filaments made of metal particle reinforced polymer matrix composites (PMC). However, there is still a fundamental gap in understanding how its melt suspension rheology affects the ability to extrude and print filaments continuously without jamming. In this correlative study, a framework for studying rheological scaling is presented as function of increasing metal content (i.e. gas atomized NiCu) in a thermoplastic binder (i.e. PLA), and it was shown that, even with high zero-shear viscosities (more than $1x10^5$ Pa-s), high metal content composites showed a dramatic shear thinning behavior and hence were extrudable at a content of 54 vol% of metal. Extruded filaments were re-melted and submitted to flow sweep rheology test. The zero-shear viscosity scaling with metal content fits well with the existing theoretical model of Krieger and Daughtery, but it was not sufficient to predict the extrudability of the filament due to its complex shear thinning behavior. Additionally, the filaments displayed premature slippage onset at $<10\ s^{-1}$ which is typically below those observed inside of the die during extrusion indicating potential change in the flow regime during extrusion. The homogeneity of composite filaments was also analyzed in global scale (by doing thermogravimetric analysis of the 12 ft continuously extruded filaments along the length to find out the metal vol%) and local scale (by analyzing a small cross-section in X-ray micro-tomography). It was verified that the filament content was uniform up in filaments with a maximum metal content of 54%. This strategy of homogeneously packing gas atomized metal spheres at higher metal content, gave us the insights on how to scale and modulate the melt rheology to create consistently extrudable and uniform dense metal filaments easily without using any kind of additives.

1:10 PM SM08.02.07
Integrated Nonthermal Plasma Synthesis and Inkless Aerosol Jet Printing of Nanoparticles Alexander Ho and Rebecca Anthony; Michigan State University, United States

Nonthermal plasmas have proven to be an effective method for the synthesis of high-quality nanoparticles. The nonthermal plasma environment allows for crystallization despite the low temperature, suppression of particle agglomeration, and control over particle size through manipulation of the synthesis conditions. Typical nonthermal plasma reactors operating under vacuum are fairly large and costly. By operating at atmospheric

pressure and miniaturizing the reactor, costs of the system are reduced and the ability to scale the process is enhanced. Reactors often benefit from confinement to the microscale at atmospheric pressure, this reduction in size lends itself well to act as a deposition head for additive manufacturing processes.
Here we present our work on the synthesis and deposition of nanoparticles into ordered patterns and structures. A 13.56 MHz RF power supply was used to generate a plasma in a glass capillary tube between two external ring electrodes at atmospheric pressure. Supplied to the reactor was a precursor gas of silane and a background gas of argon for the synthesis of silicon nanoparticles. The reactor was attached to a computer-controlled gantry and stage for the controlled deposition of the nanoparticles. The gas phase synthesis method inherently produces an aerosol of nanoparticles without the need of an atomizer as is required in typical aerosol jet printing processes (AJP). Typical AJP requires the use of an ink for atomization whose properties must be precisely to known to reduce losses during transportation and deposition. From TEM and XRD analysis we have been able to deposit crystalline silicon nanoparticles with tunable particle sizes approaching the Bohr-exciton radius of silicon that also exhibit a fairly narrow size distribution without the use of an ink. Further by varying synthesis conditions during deposition we have been able to print materials whose properties vary spatially along the deposition. Further the particles were deposited with linewidths as small as 100 microns and layer thicknesses of 1.5 microns.

Water Confinement and Swelling Kinetics of Photo-Crosslinked Hydrogels Using Micro-3D Printing Afra S. Alketbi, Hongxia Li, Aikifa Raza and TieJun Zhang; Khalifa University of Science and Technology, United Arab Emirates

Hydrogels are recognized as one of the most promising functional materials, as it is dynamic, tunable, biocompatible, biodegradable and able to encapsulate large water content. Owing to these unique characteristics, hydrogel based systems are revolutionizing many applications in solar energy water nexus, biomedical engineering, drug delivery and soft electronics. Hydrogel materials endow an intriguing activation phenomenon on water molecules confined in hydrogel meshes. By altering resin formulation and crosslinking density of photocrosslinked hydrogels, we are able to manipulate the water states within the hydrogel. The water states as well as the degree of photopolymerization are characterized by confocal Raman microscopy. Moreover, 3D microstructures of responsive hydrogels are fabricated using high resolution micro projection stereolithography. The transition from 3D hydrogel microstructures to 4D is studied during its response to external stimuli such as temperature and moisture, and its swelling dynamics is monitored through in situ condensation experiments using the environmental scanning electron microscopy. Finally, by fabricating functional hydrogel devices with tunable water states, we aim at developing high resolution 3D printing technologies for broad energy and sustainability applications.

2:25 PM SM08.03.02
Wear Resistance and Microstructure of 3D-Printed High Density Polyethylene/Ultra High Molecular Weight Polyethylene Reactor Blend Sahitya Movva, Hamid Garmestani and Karl Jacob; Georgia Institute of Technology, United States

Wear resistance and microstructure of potential prosthetic hip and joint bioimplant material system, a reactor blend of high density polyethylene (HDPE) and 10 wt% ultra high molecular weight polyethylene (UHMWPE), 3D printed using fused deposition modeling (FDM) with different printing speeds and printing orientations have

been studied using microscratch tester and wide angle X-ray diffraction respectively and compared with those of injection molded samples. The microstructure has been represented in terms of texture components using pole figures and orientation distribution functions (ODFs). This study investigates how 3D printing parameters affect texture and how global combination of the texture components prevalent in different plastic regimes engender material responses to wear resistance. The effect of abrasion and change in wear resistance of the bioimplant material (HDPE+10wt%UHMWPE) system have been explored by varying the loads applied, scratch directions, scratch speeds and the number of recurring scratches within the microscratch tests. This study of correlation between wear resistance and texture suggests that improved wear resistance in the (HDPE+10wt%UHMWPE) system can be achieved by texturing the bioimplant material in the loading direction.
Keywords: High density polyethylene; Ultra high molecular weight polyethylene; 3D printing; Fused Deposition Modeling (FDM); Wear resistance; Texture; Bioimplant material;

2:35 PM SM08.03.03
Additively Manufactured Magnetoelectric Multifunctional Materials Steven Malley, Scott Newacheck and George Youssef; San Diego State University, United States

Magnetoelectric materials are an important class of multifunctional materials with applications spanning from wearable electronics to space exploration. The current state-of-the-art in processing this exciting class of materials heavily rely on vacuum-based methods, increasing the complexity and hindering their translational potential. Magnetoelectric materials couple, intrinsically or extrinsically, the magnetic and electric energies through several mediators, including strain, charge, and spin, making them imperative for straintronics, optoelectrics, and spintronics applications. The objective of this research is to report a novel processing method of polymer-based magnetoelectric composite materials using additive manufacturing technique. The latter is parametrically different than the state-of-the-art, resulting in reducing cost, increasing yield, and streamlining processing of multifunctional materials. The approach is realized composites of electroactive polymer with large piezoelectric properties and magnetic particles using digital light processing technique (DLP), whereas the application of an electric field across the surface results in change in magnetization while a magnetic field changes the state of polarization, hence the magnetoelectric coupling. Notably, previous research has shown that the suspension of nanoscale magnetic particles increased the dielectric properties of the electroactive phase without affecting its piezoelectric response. A photopolymer resin is use as the binder, which is activated by the light source in the printer within the ultraviolet spectrum. Additive manufacturing with DLP technique produces lightweight and nearly isotropic structures with high geometrical accuracy, in comparison with other methods such as material extrusion. Samples with different volume fractions of magnetic particles and electroactive polymers were fabricated and characterized. To establish the process-property-performance interrelationship, the mechanical, electrical, magnetic, and magnetoelectric properties were exhaustively investigated of DLP processed sample. The mechanical properties were investigated using a standard load frame equipped with a ±1 kN load cell and long travel extensometer. The response of the material to external load will describe the mechanical utility of the material. The electrical properties were characterized based on the hysteretic response collected using the Sawyer-Tower circuit while subjecting the sample to AC electric field. Finally, the magnetoelectric (ME) coupling coefficient was measured using vibrating-sample magnetometer (VSM), inducing an AC magnetization in the sample while measuring the resulting change in voltage. The ME coefficient, defined as the ratio between the resulting electric field to applied magnetic field, is the main performance matrix of the efficacy of the magnetic to electric energy conversion. The results indicate the suitability of DLP additive manufacturing to efficiently produce magnetoelectric composites. Future research will focus of enhancing the properties and further streamline the fabrication process.

2:45 PM *SM08.03.04
Hybrid Nanomanufacturing for Wearable Intelligence Wenzhuo Wu; Purdue University, United States

The seamless and adaptive interactions between functional devices and their environment (e.g., the human body) are critical for advancing emerging technologies, e.g., wearable devices, consumer electronics, and

human-machine interface. The state-of-the-art technologies, however, require a complex integration of heterogeneous components to interface the environmental mechanical stimulus, which is ubiquitous and abundant in the above applications. Moreover, all existing technologies require a power source, which complicates the system design and limits operation schemes.
I will discuss our recent progress in developing self-powered human-integrated nanodevices through the hybrid nanomanufacturing (e.g., 3D printing of self-assembled function materials) of heterostructured nanodevices with hierarchical architectures. This new class of wearable devices are conformable to human skins and can sustainably perform non-invasive functions, e.g., physiological monitoring and gesture recognition, by harvesting the operation power from the human body. This research is expected to have a positive impact and immediate relevance to many societally pervasive areas, e.g., biomedical monitoring, consumer electronics, and intelligent robotics.

3:10 PM SM08.03.05
Adaptive Multinozzle for Conformal Direct Ink Writing Sebastien Uzel[1,2], Robert Weeks[1], Michael Eriksson[1], Dimitri Kokkinis[1] and Jennifer Lewis[1,2]; [1]Harvard University, United States; [2]Wyss Institute, United States

Direct ink writing (DIW) is a versatile additive manufacturing technique for patterning a wide variety of materials in three dimensions and is particularly well suited for printing assemblies of multiple functional materials, with electrical, optical, structural or biological properties. Currently, DIW is hindered by a relatively low throughput, which limits the potential applications and suitability for larger-scale manufacturing. To increase the throughput of DIW while retaining its unique advantages, multinozzle DIW printheads have been developed in order to accommodate for the simultaneous deposition of up to 64 filaments. However, this process has been constrained to printing on flat substrates, thereby excluding its use for the functionalization of pre-existing surfaces. To circumvent this shortcoming, we designed an adaptive multinozzle printhead and combined it with non-contact surface profilometry for high throughput printing on non-planar surfaces. The printhead is comprised of 16 nozzles positioned in a linear array and individually actuatable by a set of stepper motors in order to conform its geometry to the underlying substrate topography. We demonstrate that this novel printhead can successfully and rapidly deposit viscoplastic inks onto surfaces with complex profiles. More importantly, we show that this adaptive multinozzle approach can be applied to restore the mechanical integrity of damaged solids via the conformal extrusion of structural elastomeric inks or cover wound regions of human limb models using biological inks.

3:20 PM DISCUSSION

3:45 PM SM08.03.07
Hydrogel 3D Fabrication to Introduce Vascular Networks Using Digital Light Processing Livia Kalossaka, Ali Mohammed and Connor Myant; Imperial College London, United Kingdom

Biomaterials that closely mimic the complex structural organization of natural tissues hold great promise for regeneration of tissues. Hydrogels have emerged as leading candidates to reproduce native extracellular matrix. In order to provide structures and functions similar to native tissues, controlled porosity and vascular networks are required. However, fabrication techniques to introduce these are still limited. In this study we propose a comparison on fabrication techniques to achieve 3D vascular networks using water based solvents only. Diagnostic methodologies to optimize printing parameters and mechanical characterization are performed on the formulated hydrogel compositions.
With the adequate choice of ingredients and fillers for photocurable formulations, structural and functional properties of the fabricates scaffold can be tailored, opening the path for advanced applications.
Exploring both natural and synthetic hydrogels formulations, fabrication of vascular networks using Digital Light Processing (DLP) is assessed. An analysis of the achieved vascularization morphologies is performed to yield a library of fabrication parameters and hydrogel formulations for future applications.

3:55 PM SM08.03.08
Printed Biofoams via Large Scale Additive Manufacturing: Microcellulose Fiber - PLA Foams Halil L. Tekinalp[1], Stefan Dopatka[2], Tyler Smith[1], Vipin Kumar[1], Katie Copenhaver[1], James Anderson[3], Yousoo Han[3], Douglas Gardner[3], William Peter[1] and Soydan Ozcan[1]; [1]Oak Ridge National Laboratory, United States; [2]Oak Ridge Associated Universities, United States; [3]University of Maine, United States

Polymer additive manufacturing (AM) is a rapidly growing technology and it is transitioning to become an advanced manufacturing technique with the introduction of fibrillar reinforcing materials and the recent developments in large scale AM. While carbon and glass fibers are mainly used as reinforcing phase in polymer composites, as a result of increasing environmental and long-term sustainability concerns, there is an increasing interest in using bio-derived cellulose fibers to reinforce polymers instead. The ability of freeform manufacturing of parts with complex geometries makes large scale AM attractive for various applications; however, different applications require different material properties. One of the interesting application areas for large scale AM is printing of lightweight materials via extrusion foaming. While density is a key property in light weighting, mechanical performance is also important for many lightweight applications. The purpose of this study is to understand the impact of microcellulose fibers (MCF) on foaming behavior and the mechanical properties of additively manufactured parts. MCF-PLA feedstock pellets at varying MCF content (5, 10, 15 and 20wt%) were prepared to understand the impact of cellulose fiber content on density and mechanical properties of the AM biocomposites. Also, the impact of foaming agent content as well as extrusion rate on the AM biocomposites are investigated. Although achieving printed parts with uniform foam structure with the presence of cellulose fibers was challenging, initial results are promising, reaching density values below 0.5g/cm^3.

4:05 PM SM08.03.09
Ex-Situ Surface Modification of Biocompatible 3D Printed Polylactic Acid (PLA) using Plasma Micro Discharge: Towards the Enhancement of Cell-Selective Surfaces Jack Luong[1], Mai T. Yang[1], Mandeep Singh[1], Shervin Zoghi[1], Subhadip Sarkar[1], Edbertho Leal-Quiros[2], Saquib Ahmed[3] and Sankha Banerjee[1]; [1]California State University, Fresno, United States; [2]University of California, Merced, United States; [3]Buffalo State College, United States

Cell growth and cell adhesion on biocompatible polymers are affected by the surface energy and the interfacial properties. One of the major factors that affect adhesion is contamination by different microorganisms. This contamination and simultaneous growth of microorganisms can affect the quality and quantity of healthy cells that grow on the surface. Polylactic Acid (PLA) is a biodegradable polyester material produced from renewable resources like biomass. Additionally, its biocompatibility has permitted its use in the food packaging and the biomedical industry. Despite its benefits, PLA intrinsically lacks in strength, durability, and adhesiveness. This study focuses on mitigating these problems by incorporating surface modification techniques to increase the surface roughness of PLA. PLA samples were 3D printed and then treated with Corona discharge, a method widely used in a variety of industries because of its safety, low cost, and overall effectiveness. After treatment and surface modification, the material properties of the samples were characterized by using Impedance Spectroscopy, Raman spectroscopy analysis, and Optical Profilometry. The results of these studies showed a significant improvement in the surface properties that promote cell affinity and adhesion.

Injectable Hydrogel Micro-Scaffolds Encapsulating Conjunctival Stem Cells for Subconjunctival Ocular

Delivery Zheng Zhong, Wisarut Kiratitanaporn, Jacob Schimelman, Min Tang and Shaochen Chen; University of California, San Diego, United States

Ocular surface diseases including conjunctival disorders are multifactorial progressive conditions that can severely affect vision and quality of life. With more than ten million new diagnosis worldwide each year, patients suffering from these severe forms of ocular diseases will often need surgical intervention to regenerate the ocular surface, especially the conjunctiva, to restore vision. With the development of advanced regenerative medicine and stem cell technologies, growing attention over the past decade has turned towards the utilization of stem cell therapy for ocular surface diseases, and stem cell therapies based on conjunctival stem cells (CjSCs) have become a potential solution for treating ocular surface diseases. However, neither an efficient culture of CjSCs nor the development of a minimally invasive ocular surface CjSC transplantation therapy has been reported. The goal of this study was to develop a robust *in vitro* expansion method for primary rabbit-derived CjSCs and applied digital light processing (DLP)-based bioprinting to produce CjSC-loaded hydrogel micro-scaffolds for injectable delivery. Expansion medium containing small molecule cocktail that performed dual SMAD signaling inhibition (dSMADi) and ROCK signaling inhibition (ROCKi) generated fast dividing and highly homogenous CjSCs for more than 10 passages in feeder-free culture while maintaining the expression of stemness markers (ABCG2, KRT14, P63). With our customized DLP-bioprinting system, the elastic modulus of gelatin methacryloyl (GelMA) hydrogel micro-scaffolds was tuned to enable the 3D culture of CjSCs while supporting their viability, stem cell phenotypes, and the differentiation potential into conjunctival goblet cells. Our bioprinting system also enabled rapid fabrication of 18 cellularized hydrogel micro-scaffolds simultaneously with customizable geometries in less than a minute. These hydrogel micro-scaffolds were well-suited for scalable dynamic suspension culture of CjSCs. The bioprinted hydrogel micro-scaffolds in (100 μm diameter and 100 μm in height) were shear thinning and successfully delivered to the bulbar conjunctival epithelium via minimally invasive subconjunctival injection. This is the first report on the development of bioprinted injectable CjSC-loaded hydrogel micro-scaffolds and the establishment of protocols for robust *in vitro* expansion of CjSCs. Overall, this work serves as an important framework for understanding the conjunctival stem cell population, conjunctival epithelial biology, as well as the application of CjSCs as a clinically translatable strategy for minimally invasive treatments of severe ocular surface diseases.

5:40 PM *SM08.04.02
***In Situ* Alloying by Powder Bed Fusion as a Rapid Alloy Design Tool for Biomedical Applications** Swee Leong Sing; Nanyang Technological University, Singapore

The design of new alloys for metal additive manufacturing (AM), or 3D printing, is an essential research field to encourage higher adaption of AM in the industries. Currently, pre-alloyed powders are typically used in metal AM. Pre-alloyed powders are expensive and inflexible in terms of chemical composition. *In-situ* alloying, which makes use of powder blends, enables high-throughput experimental alloy design and screening. This production approach allows high flexibility in varying the chemical composition.

For bulk sample production, laser powder bed fusion of elemental powder blends was applied to build up titanium-tantalum alloy as proof of concept. Tantalum is an excellent choice for alloying with titanium for biomedical applications due to its' high biocompatibility, corrosion resistance and good mechanical properties. Furthermore, titanium–tantalum alloys are promising materials for such applications because of high strength to modulus ratio. Despite the promising characteristics, they are still not widely used due to the difficulty in alloying titanium with tantalum as a result of their difference in melting point and density. *In-situ* alloying has been shown to be an effective approach in creating these alloys. The material processed were characterised using optical microscopy, electron backscatter diffraction, scanning electron microscopy, energy-dispersive X-ray spectroscopy, X-ray diffraction, hardness and tensile testing.

6:05 PM SM08.04.04
Mechanical Properties of Aligned Graphene-Polymer Composites Fabricated Through Stereolithographic 3D Printing Changquan Lai; Nanyang Technological University, Singapore

The advent of additive manufacturing has enabled many complex, optimized structures to be realized efficiently and reliably, improving the performance of many applications where these architected materials are employed. Nevertheless, many of the materials that are currently compatible with 3D printing exhibit mechanical properties that are far from the desired levels, significantly curtailing the benefits that this technique can provide. To address this, we have developed a method of incorporating graphene nanoplatelets into a commercial PMMA-based photosensitive resin and successfully demonstrated the 3D printing of graphene-polymer composites. The static and dynamic (*i.e.* viscoelastic and high strain rate) mechanical responses of the printed structures were characterized and found to improve tremendously with as little as 0.02wt% of graphene addition. An important reason for this improvement was that the 3D printing process of graphene-polymer resins involved the Selection of Naturally Aligned Graphene (SNAG), which lined the graphene platelets along the printing axis, reinforcing the stiffness and strength of the material in this direction. The effect of various processing parameters, such as the use of post-print baking and addition of acetone to disperse the graphene nanoplatelets, will be presented in detail as well.

6:20 PM SM08.04.05
Voxel-scale Conversion Mapping in Stereolithographic Additive Manufacturing Tobin Brown, Callie Higgins and Jason Killgore; National Institute of Standards and Technology, United States

Due to the parallelized nature of digital light processing (DLP), additive manufacturing based on this technique has the unique capability to deliver fine resolution over a large area with reasonable print times. This is advantageous in applications such as tissue bioprinting, where micron-scale complexity persists throughout a tissue which may be tens of centimeters in length. In practice, such high resolution is difficult to achieve due to diffusion of reactive species between light and dark regions of the printing plane. Partially crosslinked macromolecules diffuse away from initiating regions while oxygen and other inhibitors diffuse into them. The combined effect is overpolymerization in dark zones, undercuring in light regions, and a loss of print fidelity. Additionally, gradients within polymerized structures cause mechanical heterogeneity in the final part. Because these processes occur on the individual voxel scale, measurement techniques such as photorheology and infrared spectroscopy are unable to adequately measure them, and new measurement techniques are needed.

In this talk, I will describe an atomic force microscopy (AFM) technique to directly map the generation and diffusion of polymeric species during localized photopolymerization. We use an AFM cantilever with a nanocylinder extending from the tip, and when the cylindrical probe is inserted into a resin, the drag on the cylinder can be used to measure to the local viscosity of the liquid, and in turn, the local extent of reaction. Vibrating the cantilever at one of its resonance frequencies (10^4 Hz - 10^7 Hz) affords high temporal resolution. Computational fluid dynamics modeling indicates that the fluid motion induced by the oscillating cantilever is localized within 1 μm of the probe. Employing a custom-built instrument, we can direct arbitrary light patterns to resin in the imaging plane of the AFM to achieve photopolymerization. By translating the tip and light pattern relative to one another, the full spatial evolution of the reaction profile can be measured.

We employed this technique to measure the reaction dynamics during DLP photopolymerization of a thiol-ene resin. The thiol-ene click reaction has some advantages over the photopolymerization of acrylate resins, including reduced shrinkage stress and insensitivity to oxygen inhibition. We find a non-reciprocal dependence of the reaction on light intensity; increasing the light intensity decreases the efficiency of the reaction, likely by increasing the bi-radical termination rate. Thus, at constant light dose, lower light intensities lead to increased conversion in the reaction volume, even accounting for increased time for diffusion. This disproves a common assumption in stereolithography, namely that gelation depends solely on the light dose, often referred to as the "critical dose."

Mapping the spatial evolution of the polymer conversion profile also allows us to easily identify the diffusion length scales during the reaction, and we measure polymer accumulation 20 μm away from the illuminated region within one second of light exposure, identifying the relevant length scale of our process. We then created

an open ring test structure (inner diameter = 15 μm, outer diameter = 45 μm) based on this finding to determine the effect that diffusion plays on the resolution of a printed part. Consistent with our measurements of the reaction profile, we observe significant overpolymerization in the ring center, leading to gelation and loss of fidelity to the projected mask. This new technique provides adequate spatial (1 μm) and temporal (<1 ms) resolution for modern stereolithography applications, and it can be used to predict the ultimate printing resolution and rapidly determine the optimal exposure conditions for a given resin.

6:30 PM SM08.04.06
4D Printing of High-Performance Thermoset and Elastomer Materials Rigoberto C. Advincula[1,2,3]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]Case Western Reserve University, United States

3D printing can be used to create prototypes and devices from polymeric materials which have appended the design functionality for new materials including uses in biomedical devices enabling their rapid development. While 3D printed polymers can be further classified into thermoplastics, thermosets, and elastomers based on their thermo-mechanical properties – new opportunities for multi-materials and composites are possible. The processability and functionality of thermosets and elastomers make it a challenge to employ using most 3D printing methods for polymer additive manufacturing. The transition to a final phase or cross-linked structure results in new properties in combination with the processing method. However, 4D printing allows the design of new materials and applications based on integrating the chemistry of conversion with the printing mode and final stimuli-responsive property on the printed part. In this talk, we will demonstrate the 4D fabrication of multi-materials including thermosets and thermoset elastomers with concept objects and elastomeric properties unlock with stimuli-response. This is based on the use of extruded viscous solutions. The result is an extrudable precursor and nancomposite elastomers which can be printed via viscous extrusion printing (VEP) or viscous solution printing (VSP) and then converted to an elastomeric actuating material with very high cyclic compressibility or a shape memory thermoset. Other works based on the use of SLA, SLS, FDM, towards high strength epoxy, silicones and nanocomposite materials will be discussed.

6:40 PM *SM08.04.07
Automated Biofabrication of Tailored Dense Collagen Tissue Building Blocks Gabriele Griffanti, Ehsan Rezabeigi, William Lepry and Showan Nazhat; McGill University, Canada

The convergence of three-dimensional (3D) printing of cell seeded bioinks and regenerative medicine offers promise in the biofabrication of tissue building blocks with tailored structural, biological and mechanical properties. However, current 3D bioprinting approaches are limited in their ability to print fibrous collagen bioinks at different length scales that replicate the complex hierarchical architecture of native tissues. Collagen-based hydrogel bioinks are restricted by their narrow printability range, where protein structure, seeded cell viability, and bioactivity of incorporated biomolecules all need to be maintained within physiological boundaries. Herein, a unique approach to biofabricate tissues has been developed to overcome these challenges. Automated gel aspiration-ejection (GAE) leverages the properties of dense collagen gels as tissue models and templates for regenerative medicine. Automated-GAE fabricates highly defined mini-tissue building blocks of various dimensions and shapes, *e.g.*, cylindrical, quadrangular and tubular as well as with tunable microstructural and mechanical properties that modulate seeded cellular responses.
Acellular and cell seeded cylindrical highly hydrated precursor gels were initially cast in different volumes. Automated-GAE was carried out using a uniquely configured instrument equipped with multiple syringe pumps connected to various densification needles to generate dense collagen gel bioinks of different sizes and microstructures. Through the creation of a pressure differential, GAE aspirates the precursor highly hydrated gels into the needles, expelling their unbound fluid and simultaneously inducing their compaction and meso-scale anisotropy. By subsequent reversal of the pressure, dense collagen gel bioinks can be controllably ejected that can be cylindrical, quadrangular or tubular in shape. The incorporation of bioactive materials can also facilitate the production of rapidly mineralizable tissue blocks.

A simple mathematical relationship defining the bioink compaction factor by relating changes between initial highly hydrated hydrogel precursor and final dense gel dimensions was found to be surprisingly highly effective in predicting the initial and temporal properties of the bioinks in culture. Bioink collagen fibrillar density and alignment, tissue building block mechanical properties, as well as seeded cell density, morphology, viability and proliferation were all quantitatively correlated with fabrication compaction factor. Furthermore, by controlling initial bioink parameters, seeded cellular function, in terms of differentiation and extent of matrix remodelling ability were modulated. To this end, automated-GAE will potentially also enable a fourth dimension to biofabrication, where cell-cell communications and cell-extracellular matrix interactions as a function of time in culture can be predicted and modelled.
Therefore, by initially using naturally derived reconstituted collagen hydrogels incorporating cells, and negating the need to directly extrude pre-polymerized collagen molecules, the automated-GAE fabricated mini tissue blocks can be tailored to mimic protein fibril density and alignment of target native tissues, as well as cell loading, density and orientation according to the intended use. Furthermore, the mini tissue blocks can be combined to generate more intricate structures resembling those found in native tissues. Thus, a pre-defined microenvironment can be designed and tuned along with controlling cellular function to meet specific structural requirements of both, mineralized and soft tissues. This breakthrough development will also potentially enable the rapid 3D printing of tissues with varying architectures based on a platform bioink system.

Hydroxyapatite/Collagen Bone-Like Nanocomposite Paste for 3D Printing Masanori Kikuchi; National Institute for Materials Science, Japan

Hydroxyapatite/collagen nanocomposite (HAp/Col) is a material mimicking bone nanostructure and chemical composition and the world first material reported as completely incorporated into bone remodeling process and substituted with new bone. Porous HAp/Col has been already applied in Japan as a bone void filler and is also considered as a scaffold for bone tissue regenerative medicine. The HAp/Col contains collagen molecules; thus the porous body is prepared by freeze casting and pore structure is only controlled by ice crystals formation in its suspension. Since pore structure influences on cell behaviors including activation of various functions, control of pore structure is one topic for the HAp/Col functionalization. Extrusion type 3D printing is a good technique to fabricate designed pore structure for collagen containing materials. Alginate-based and silane coupling agent (SCA)-based HAp/Col pastes were prepared for 3D printing. The alginate-based HAp/Col paste was immediately hardened to viscoelastic body by extruding into Ca^{2+} containing solution and can be applied to fabricate cell-scaffold construct. The SCA-based HAp/Col paste maintains its shape even if it extrudes directly into water and hardened in 30 min.
The SCA-based HAp/Col pastes were directly injected into bone hole of SD-Rat and remained the injected site by hardened. They were started to remodeled in 7 days without any bad symptoms. The SCA-based HAp/Col paste injected directly into holes of porcine tibia completely substituted with new bone in 3 months without any bad symptoms. The HAp/Col pastes are good candidate for fabrication of cell-scaffold constructs in bone and maybe other tissues due to their bioresorbable and viscoelastic nature.

3D Printing of Personalized Medical Device—From Material Properties to Scale-Up Production Sze Yi Mak[1], Chun Hong Jasper Yeung[1], Ah Yiu Chong[1], Tsz Wai Boris Lee[1] and Ching Hang Bob Yung[2]; [1]The University of Hong Kong, Hong Kong; [2]Koln 3D Technology (Medical) Limited, Hong Kong

Personalized medical device fabricated by additive manufacturing is a booming research field for it enables innovative solutions to cater for patients' specific needs. Seemingly, the predominant limitations to scale up in the medical industry arise from the suboptimal biomechanical properties and challenge in boosting the productivity. In this study, we introduce a hybrid laser sintering-heat treatment approach to address this problem. We first examine the microstructure of additive manufactured components under various sintering and heat treatment parameters, and thereby reveal the optimization in terms of material and biomechanical properties, efficacy of bio-functions, and efficiency in cost and time of manufacturing. In addition, the biocompatibility of the 3D printed alloy is validated via haemolysis assay, cytotoxicity and implantation tests. We further present a pathway from proof-of-concept to clinical application with our state-of-the-art examples. Our work will shed lights on the industrialization of additive manufacturing in medical device industry.

8:50 PM *SM08.05.03
Active Hydrogel Towards Miniaturized Robots Yong Feng Mei and Hong Zhu; Fudan University, China

Hydrogels are promising material candidates in diverse applications including drug delivery, tissue engineering and soft robotics, owing to their excellent properties of biocompatibility, wetness, softness, deformability and responsiveness [1]. However, the intrinsic activeness of hydrogels for autonomous locomotion is not achieved yet. The existing activeness of hydrogels are realized by capping active nanoparticles like MnO_2 and TiO_2, which undergo relative catalytic reactions to perform tasks for environmental applications [2,3]. Furthermore, we fabricated versatile printable active hydrogels which possesses the ability to move on water surface. Utilizing the surface tension, the homogeneous active hydrogels propel themselves and show well-controlled and intelligent locomotion on water surface. Incorporated with stimuli-responsive groups, the active hydrogels are able to change their geometries with time under relative stimulus, which adds the dimension of time (4^{th} dimension) to the 3D-printable active hydrogels. The processing technique of these active hydrogels are fully compatible to existing photo-curing 3D-printing equipment. These active hydrogels provide new opportunities for 3D-printing technology to be applied in the field of miniaturized robots.

9:15 PM SM08.05.04
Soft Hydrogels as Anti-Adhesion Interfaces for Rapid Digital Light 3D Printing Jingjun Wu; Zhejiang University, China

3D printing is ideal for prototyping yet its low productivity prevents it from being further applied in large-scale manufacture. Some innovative techniques have been developed to break the limitation of printing speed, however, sophisticated facilities or costly consumables are required, which still substantially restricts the economic efficiency. Here we report that a most common stereolithographic 3D printing facility can achieve a very high printing speed (400 mm/h) using a green and inexpensive hydrogel as an anti-adhesion interface (release films). The anti-adhesion mechanism relies on large deformation of the soft hydrogel, which is distinct from that of other techniques. Adhesive force of the solid-solid interface during the layer-by-layer photo curing can be largely reduced according to such mechanism. The technique shows an excellent printing stability even for fabricating large continuous solid structures, which is challenging for other rapid 3D printing techniques.

9:25 PM SM08.05.05
High-Speed VEGF Recognition via Microbead-Based Fluorescence-Linked Immunosorbent Assay Using the 3D-Printed Micro Incubation Chamber in the Lab-on-a-Disk Dong Hee Kang, Na Kyong Kim and Hyun Wook Kang; Chonnam National University, Korea (the Republic of)

A commercialized fluorescence-linked immunosorbent assay (FLISA) is a quantitative technique for detecting bio-chemicals through antigen-antibody binding reaction using well-plate platform. As the manufacturing technology of microfluidic systems has improved, the FLISA is implemented onto the microfluidic disk platform which shows detection of trace bio-chemicals with high resolution. It is possible to reduce time from the reagent loading to the detection step within an hour, in addition to benefits of reducing the amount of reagents to 1/10. Since the high density antibodies on the surface of microbeads, the potential is increased for immobilization of bio-molecules. The incubation process requires not only the binding the antigen-antibody, but also the several steps for binding fluorogenic substrates to target protein. And the unbound reagents should be removed by a washing process. The FLISA protocol in the microfluidic platform, it is necessary to properly execute of liquid reagents movement in each process of FLISA in order to perform the binding reaction sufficiently. The precise control of reagent liquids is required such as fluidic isolation of the incubation chamber and repetitive angular rotation control of disk. We suggest a novel microfluidic disk including a 3D incubation chamber using multi-material to low cost which is fabricated to simple mechanical assembly. VEGF detection is performed sequentially one-step using a 3D microfluidic disk within an hour. On the 3D microfluidic disk, the microbead-based FLISA protocol is operated from the incubation process to the detection process in hand-free without additional components to liquid control. For the incubation process, the microbead movement is controlled through the centrifugal force by disk rotation and gravitational force by bead sedimentation on a slope of chamber.

A Magnetically Actuated Microrobot by on Two-Photon Polymerization for Targeted Neural Cell Delivery and Active Connection Hongsoo Choi[1,2,3]; [1]Daegu Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of); [2]DGIST-ETH Microrobotics Research Center, Korea (the Republic of); [3]DGIST, Korea (the Republic of)

Several *in vitro* neural network models have been developed to mimic the reconstruction and interconnection of neural networks and to study brain function and related diseases. Such *in vitro* neural networks require predefined neural connections at the target location and the measurement of neural activity using a multi-electrode array (MEA). The predefined neural connections sometimes limit the adaptation of the user to the change in the neural connection patterns. Here we report a three-dimensional (3D) magnetically actuated microrobot fabricated by 3D laser lithography based on two-photon polymerization for selective neurite alignment and neuronal connections. Using confocal immunofluorescence imaging, the aligned neurite outgrowth and synaptic connections in the neural network were measured. The microrobot, in which the rat's primary hippocampal cells were cultivated, was transmitted between two neural clusters by a magnetic field and then structurally and functionally connected to a neural network that can transmit neural activity signals. Neuronal activities were measured with a complementary metal-oxide-semiconductor-based MEA system to monitor the propagation of extracellular axonal signals from the neural clusters. The proposed microrobot shows the potential for *in vitro* neural experiments to understand how neurons communicate in the neural network by actively connecting neural clusters.

10:00 PM SM08.05.07

Late News: One-Step 3D Structuring of Protein-Based Microneedles Using Digital Light Processing Donghyeok Shin and Jinho Hyun; Seoul National University, Korea (the Republic of)

Microneedles are a transdermal drug delivery system with length dimensions of several hundred micrometers. To be considered in biomedical applications, the biocompatibility and safety of materials are critical factors. The use of protein-based biomaterials such as silk fibroin(SF) can clearly reduce immunological risks resulting from accidental breakage of microneedles during injection into the skin. In the experiment, one-step 3D structuring of SF-based microneedles is challenged using riboflavin as an enzymatic photoinitiator. Digital light processing (DLP) 3D printing is adopted because it is advantageous for direct 3D construction of molecules dissolved in aqueous solution at relatively low concentration through photocrosslinking. Oblique and sharp microneedles are printed using an anti-aliasing strategy and shrinkage of the hydrogel in a dehydration process.

The SF microneedle is strong and showed no severe damage to the structure upon application of ~300 mN of compressive stress. A flexible SF microneedle array pad is fabricated and subsequently utilized for delivery of fluorescence dye molecules into pig skin.

10:10 PM SM08.05.08
Late News: Reversible Morphing of 3D Printed Reinforced Multifunctional Composites Wing Chung Liu[1], Shanthini Puthanveetil[1], Katherine Riley[2], Andres Arrieta[2] and Hortense Le Ferrand[1]; [1]Nanyang Technological University, Singapore; [2]Purdue University, United States

4D printing gives 3D printed structures shape morphing properties when exposed to external stimuli. Many such materials have been reported using hydrogels, liquid crystals and shape memory polymers. However, these materials generally lack the mechanical strength and stiffness required for common applications in the robotics and aerospace industries. In this work, we employ direct-ink-writing to fabricate stiff fibre-reinforced epoxy composites which exhibit temperature controlled reversible morphing. The composite is printed flat initially and the morphing behaviour is activated by heating the material to a temperature above its glass transition temperature. The reversible morphing is enabled by the microstructuring of the printed material arising from the shear-induced fibre alignment during printing. This local alignment controls local anisotropy in the material properties that drives deformation upon heating.

The experimental results, along with finite elemental analysis reveal that by varying the layer print orientation and activation temperature of the prints, the resultant shape and curvature of the morphed material can be controlled precisely as desired. Using an appropriate print design, structures which exhibit high temperature bistability could be achieved, which allows reversible morphing into multiple stable shapes in stiff materials. Furthermore, the ink composition can be tuned to generate shape-dependent functional properties, such as electrical conductivity. Therefore, our method has the potential to fabricate functional composites with tailored made morphing behaviours for applications such as actuators and sensors.

SM08

8:00 AM *SM08.06.01
Fabrication of Multi-Analyte Microbiosensors by Microcontact Printing of Enzymes Harold Monbouquette, Bo Wang, Bonhye Koo, I-wen Huang and Yan Cao; University of California, Los Angeles, United States

High performance microprobes for combined sensing of glucose and choline were fabricated using microcontact printing (μCP) to transfer choline oxidase (ChOx) and glucose oxidase (GOx) onto targeted sites on implantable microelectrode arrays (MEAs). Many neuroscience studies require the monitoring of multiple species, including metabolites and neurotransmitters, with high spatiotemporal resolution *in vivo*. Choline is of interest as a surrogate for the neurotransmitter, acetylcholine, which is turned over rapidly by acetylcholinesterase in the brain. Most electroenzymatic sensing sites on MEAs for neuroscience applications have been created by manual enzyme deposition, however this approach becomes problematic when the array feature size is less than or equal to ~100 μm. The μCP process used here relies on use of soft lithography to create features on a polydimethylsiloxane (PDMS) microstamp that correspond to the dimensions and array locations of targeted, microscale sites on a MEA. Precise alignment of the stamp with the MEA is also required to transfer enzyme only onto the specified microelectrode(s). The dual sensor fabrication process began with polyphenylenediamine (PPD) electrodeposition on all Pt microelectrodes to block common interferents (*e.g.*,

ascorbic acid and dopamine) found in brain extracellular fluid. Next, a chitosan film was electrodeposited to serve as an adhesive layer. The two enzymes, ChOx and GOx, were transferred onto different microelectrodes of 2 × 2 arrays using two different PDMS stamps and a microscope for stamp alignment. Using constant potential amperometry, the combined sensing microprobe was confirmed to have high sensitivity for both choline and glucose (286 and 117 $\mu A\ mM^{-1}\ cm^{-2}$, respectively) accompanied by low detection limits (1 and 3 μM, respectively) and rapid response times (≤2 s). The performance of the dual sensing microprobe was validated in the dorsal striatum of anesthetized rats. This work demonstrates the use of μCP for facile creation of multi-analyte sensing microprobes by targeted deposition of enzymes onto preselected sites of a microelectrode array. Such technology will enable neuroscientists to monitor multiple species at the same location in the brain and to integrate chemical sensing sites with microelectrodes for electrophysiological recordings so as to better correlate neurochemical signaling with neuronal activity.

8:25 AM *SM08.06.02
Diatom-Based 3D Printed Hierarchical Materials Aaron Stapel and Hannes C. Schniepp; William and Mary, United States

We synthesize 3D-printable inks containing live diatoms and diatom nutrients. The glass skeletons of the diatoms form the basis for structures of high complexity and with many levels of hierarchy reaching from the nanometer scale to the centimeter scale. The diatoms survive the printing process and keep reproducing in the printed structures. We have succeeded implementing this method for several types of diatoms featuring different morphologies and sizes. The printed structures can be converted into several types of material, such as composites with diatoms as the reinforcing agent, or into materials entirely consisting of glass. Due to their nano-structured morphology, the highly heat resistant all-glass materials exhibit significantly enhanced mechanical properties compared to bulk glass, while being much lighter. Based on home-grown biological feedstock, we consider this a promising approach for the scalable production of sustainable performance materials with a negative carbon footprint and widely tunable properties and functionality.

8:50 AM *SM08.06.03
5D Printing and Its Application in Tissue Engineering Min Wang; The University of Hong Kong, Hong Kong

Tissue engineering offers a promising approach to treat difficult problems in human body tissue repair. It involves using live cells to form implantable devices for body tissue regeneration. In scaffold-based tissue engineering, a porous scaffold provides a microenvironment for cells to adhere, proliferate and differentiate and a structural framework for new tissue formation. Most human body tissues are complex and their regeneration requires structurally complex scaffolds that resemble tissue structures and can provide biochemical cues such as growth factors (GFs). Incorporating GFs and even live cells in scaffolds can greatly facilitate tissue regeneration. 3D printing has many advantages in scaffold fabrication, such as control of pore shape, size, porosity, etc. Furthermore, 3D printing can make complex tissue engineering scaffolds, including multilayered scaffolds with different layer characteristics for regenerating body tissues that exhibit multilayered structures such as osteochondral tissue. Therefore, like in other industries, 3D printing has already made a high impact in the tissue engineering field, with numerous researchers around the world using 3D printing technologies to produce various tissue engineering products. 4D printing emerged in 2013 and immediately attracted world's attention. 4D printing uses 3D printing technologies to produce shape-morphing objects. Such objects can meet the demanding requirements in particular applications. The concept of 4D printing has been evolving and one current popular definition of 4D printing is that the shape, property and functionality of a 3D printed object can change with time in a predefined design. 4D printing relies on advances in 3D printing technologies, smart materials, and smart designs. It has become an actively pursued subject in both academia of different disciplines and industry, including tissue engineering. We have conceptualized 5D printing and are applying it in tissue engineering. 5D printing produces shape-morphing and information-embedded structures, and the information, which is the 5th dimension in 5D printed structures, is delivered *in situ* during applications of these structures. More importantly, with 5D printed structures, the delivered information affects the surrounding environment (or

5D printed structures) and guide changes in the environment (or 5D printed structures). For 5D printing in tissue engineering, the embedded information can be biomolecules such as GFs. Using 5D printing, shape-morphing, mesenchymal stem cell (MSC)-containing and GF-delivering multilayered complex scaffolds may be constructed for gastrointestinal (GI) tissue engineering. Under GFs' guidance, MSCs will differentiate into different types of cells in the cell-scaffold constructs for GI tissue regeneration. This talk will present our work in 3D/4D/5D printing of scaffolds for body tissue regeneration. It will focus on the design and construction of complex tissue engineering scaffolds.

9:15 AM SM08.06.04
3D Printed Nanofiber Reinforced Tissue Engineering Scaffolds with Controlled Release of Growth Factor Jiahui Lai and Min Wang; The University of Hong Kong, Hong Kong

3D printing has greatly improved our ability to create complex tissue engineering scaffolds with high precision. Biomaterials, growth factors or even living cells are accurately deposited layer-by-layer in 3D printing to construct the scaffolds. Hydrogels have been commonly used biomaterials in 3D printing of scaffolds owing to their various advantages. However, most hydrogels, particularly natural hydrogels, have poor mechanical properties, which severely limit their tissue engineering applications. It has been shown that adding polymer nanofibers into hydrogels can lead to improved mechanical properties that can be comparable to the body tissues. Growth factors (GFs) in the body can promote wound healing, cell growth, proliferation and differentiation. Incorporating GFs into scaffolds may accelerate tissue regeneration. Fibroblast growth factor (FGF) is generally used in the regeneration of tissues such as cornea and skin. In this study, nanofiber reinforced scaffolds with the controlled release of GF were investigated with 3D printing of PLGA nanofiber (PLGA*f*) reinforced alginate hydrogel containing FGF. To control the FGF release, two strategies were adopted: (1) FGF was directly included in the biomaterial (PLGA*f* and alginate hydrogel mixture) for 3D printing, (2) FGF was firstly encapsulated in PLGA nanofibers via emulsion electrospinning and the nanofibers were then dispersed in alginate hydrogel for 3D printing. Thus two types of inks were made for 3D printing: FGF/alginate/PLGA*f* ink, and alginate/PLGA*f*-FGF ink. They were used in an extrusion-based 3D bioprinter to fabricate reinforced scaffolds according to the CAD design. The experiments showed that the addition of PLGA*f* into alginate hydrogel greatly improved its viscosity and mechanical strength. *In vitro* release studies were conducted for scaffolds 3D printed from the two type of inks. Release results showed that both types of scaffolds exhibited two-stage release profiles: an initial fast release period in the first 2 days, and the subsequent slower and sustained release period. In addition, alginate/PLGA*f*-FGF scaffolds displayed a slower release than FGF/alginate/PLGA*f* scaffolds, which was mainly due to the different incorporation site of FGF within the scaffolds. It can be concluded that the GF release behaviour from 3D printed scaffolds can be controlled through choosing the loading site in scaffolds for GFs, which enables designing personalized GF delivery specific for the targeted tissue engineering application.

Synthesis, Rheology and 3D Printability of Novel Polyesters for Solvent- and Additive-Free Extrusion-Based 3D Printing Tanmay Jain, David Kaplan and Irada Isayeva; U.S. Food and Drug Administration, United States

Three-dimensional (3D) printing offers the unparalleled capability to create medical devices with complex architectures matched to the patient's anatomy. However, most of the currently used polymers require high

processing temperatures and pressures and/or a combination with leachable additives like initiators, crosslinkers, plasticizers, and solvents to enable extrusion-based direct-write 3D printing (EDP). Such conditions may raise safety concerns for the final medical product. Therefore, it is desirable to develop polymers that could be printed at ambient conditions and without additives. To develop such polymers, it is necessary to systematically understand the relationship between polymer molecular structure, rheology, and 3D printability. Herein, we present a library of novel polyesters with modular functionalities, which can be used to create customized 3D constructs using EDP. The polyesters with various pendant functional groups were synthesized and their physical properties, rheology, and 3D printability were analyzed.
Methods: The polyesters were synthesized at room temperature using carbodiimide-mediated polymerization of pendant functionalized diols and succinic acid, and characterized using ^{1}H-NMR and variable temperature-FTIR. Polymer viscosity as a function of shear rate was measured under steady state shear flow. Small amplitude oscillatory shear experiments were done to plot master curves of viscoelastic properties for each polyester over a wide frequency range using the time-temperature superposition (TTS) principle. The 3D printability of the polyesters was assessed based on parameters such as the ability to extrude polymer as continuous filaments through a narrow nozzle at a consistent flow rate, retain the printed shape, form bridge-spanning filaments without significant sagging or collapse, and form multilayer constructs.
Results: Data demonstrated that the synthesized polyesters exhibit properties that are desirable for the extrusion-based 3D printing. ^{1}H-NMR confirmed the presence of the appropriate functional groups for each synthesized polyester suggesting successful synthesis. All synthesized polyesters exhibit shear thinning behavior at EDP relevant shear rates and respective 3D printing temperatures, which is important for solvent-free printing. The tangent delta peak observed at temperatures higher than polymer T_g indicated the presence of a "secondary network" and supramolecular interactions. Variable temperature-FTIR supported the presence of supramolecular interactions, such as H-bonding. The presence of "secondary network" along with supramolecular interactions appear to facilitate the retention of printed shape and improve the overall quality of the 3D printed constructs. Based on observed correlations between 3D printability and the rheology of each polyester a "3D printability window" is proposed. The insights derived from this study can be used to inform the design of new biodegradable polymers for extrusion-based direct-write 3D printing for biomedical applications.

10:55 AM SM08.07.02
Late News: Sub-10 nm Resolution Patterning of Pockets for Enzyme Immobilization via tc-SPL Annalisa Calo[1,2]; [1]University of Barcelona, Spain; [2]Institute for Bioengineering of Catalonia, Spain

The ability to precisely control the localization of enzymes on a surface is critical for several applications including biosensing, nano-bioreactors and single molecule studies. Despite recent advances, fabrication of enzyme patterns with resolution at the single enzyme level is limited by the lack of lithography methods that combine high resolution, compatibility with soft, polymeric structures, ease of fabrication and high throughput. Here, a method to generate enzyme nanopatterns on a polymer surface is demonstrated using thermochemical scanning probe lithography (tc-SPL) and the enzyme Thermolysin as a model system. Electrostatic immobilization of negatively charged sulfonated enzymes occurs selectively at positively charged amine nanopatterns produced by thermal deprotection of amines along the side-chain of a methacrylate-based copolymer film via tc-SPL. This process occurs simultaneously with local thermal quasi-3D topographical patterning of the same polymer, offering lateral sub-10 nm resolution and vertical 1 nm resolution, as well as high throughput (5.2×10^4 mm^2/h). The obtained patterns with single enzyme resolution are characterized by atomic force microscopy (AFM) and fluorescent microscopy. The enzyme density, the surface passivation and the quasi 3D arbitrary geometry of these patterned pockets are directly controlled in a single step, without the need of markers or masks. Other unique features of this patterning approach include the combined single-enzyme resolution over mm^2 areas and the possibility of fabricating enzymes gradients at the nanoscale.

11:05 AM SM08.07.03
Late News: Vapor-Phase Organic Electronic Processes to Pattern Cells Jeffrey Horowitz, Xiaoyang Zhong, Samuel DePalma, Maria Ward Rashidi, Brendon Baker, Joerg Lahann and Stephen Forrest; University of

Michigan–Ann Arbor, United States

With the development of stem cells, *in vitro* tissue engineering has become a promising technology for research, clinical testing, and medical treatment. One consistent focus of research has been the high-precision patterning of cells, necessary because material surface properties, environment, and organization of cells in two- and three-dimensions all significantly impact the growth and development of tissue. While many different cell patterning techniques have been explored for cell patterning, the integration of organic electronic processes has been previously overlooked. In this presentation, we demonstrate a process whereby organic semiconductors are used to pattern cells and discuss the unique advantages of such a process. Using vacuum thermal evaporation (VTE) and organic vapor jet printing (OVJP), two organic electronic materials are precisely deposited in the vapor-phase as adhesion points on a biocompatible poly(p-xylylene) surface. The small molecular weight organics prevent the subsequent growth of anti-fouling polyethylene glycol methacrylate (PEGMA) polymer brushes, rendering the background areas of the substrate protein and cell resistant. Fibronectin then attaches to the deposited organic semiconductor regions, followed by the selective adhesion of fibroblasts. For VTE, the adhesion regions consist of hexagons with side-lengths of 25 μm, while OVJP is used to form patterns varying in width from several hundred micrometers to about 10 μm. At smaller widths, cells show considerable alignment to the OVJP-formed patterns, moving to random orientation at a threshold width of about 110 μm. The surface properties of the different organic semiconductor materials also prove important, demonstrating different patterning tendencies. The cell-patterning process presented here diverges from other techniques in i) the usage of organic small-molecule semiconductors as adhesion regions, ii) the formation of adhesion via vapor-phase deposition. Some of the many advantages include the vast number of evaporable organic semiconductor materials, the ability to deposit onto a fragile scaffold without contact, and the potential for high-throughput manufacturing. Therefore, this process is a useful development in cell patterning with many potential applications.

11:15 AM SM08.07.04
Late News: Roll-to-Roll Large-Scale Manufacturing of Polymer Biochips for Multiplexed DNA Testing
Pelin Toren[1], Martin Smolka[1], Anja Haase[1], Dieter Nees[1], Stephan Ruttloff[1], Markus Rumpler[1], Manuel W. Thesen[2], Max Sonnleitner[3], Wilfried Weigel[4], Barbara Stadlober[1] and Jan Hesse[1]; [1]Joanneum Research Forschungsgesellschaft mbH, Austria; [2]micro resist technology GmbH, Germany; [3]GENSPEED Biotech GmbH, Austria; [4]SCIENION AG, Germany

We successfully developed a complete process chain of production lines for foil-based bioanalytical lab-on-chip devices. The process is based on high-throughput structuring and lamination using roll-to-roll (R2R) UV micro or nano-imprinting on several hundred meters-long flexible, polymeric foils. Bio-functionalization of the imprinted structures is achieved via R2R microarray printing. In our pilot line, the polymer foil is roto-gravure coated using a photopolymer with tuneable properties, which is then structured via R2R UV nanoimprint lithography (NIL).**[1]** The technology allows producing various kinds of fluidic structures; such as, capillary force-driven fluidic channels, reservoirs or pumps as well as production of optical structures with different geometries for effective guiding of light for *in-vitro* diagnostic (*IVD*) products. Following R2R UV NIL imprinting, bio-functionalization is achieved using a custom-made, semi-automated R2R microarray spotting unit. For specific bio-detections via *IVD* chips, various probe DNAs or proteins can be printed at different sections of biochips. With layout design flexibility and rapid prototyping possibilities, up to 7500 biochips per 100 meters are produced via our technology. The feasibility of the approach for massively parallel production of lab-on-a-foil products is demonstrated based on a model application of *in-vitro* multiplexed DNA testing for markers of a methicillin resistant pathogen.**[2]** The manufactured foil chips show similar detection performance as commercial injection-moulded chips, thus demonstrating that our lab-on-a-foil technology is a potential replacement for the commercially available, disposable chips for *IVD* applications.

11:25 AM SM08.07.07

Late News: Development of a Bionic Patient-Specific Temporomandibular Joint Prosthesis Stijn Huys[1], Nikolas De Meurechy[2], Annabel Braem[1], Maurice Mommaerts[3] and Jos Vander Sloten[1]; [1]KU Leuven, Belgium; [2]VUB, Belgium; [3]UZ Brussel, Belgium

With vital functions like talking, chewing, and swallowing, an optimized implant should replace a diseased temporomandibular joint (TMJ). Moreover, it is unique as the only bilateral joint in the human body acting as one unit, its movements are a combination of rotations and translations, and it is the most regularly used joint on a daily basis, suggesting a broad range of highly customized TMJ prostheses. In reality, the vast majority of available options contradict these prerequisites, because they are mainly focused on shape reconstruction, rather than functional reconstruction, e.g., no features are foreseen for laterotrusive movements (which are necessary for proper grinding of food) and the implants are not adapted to allow contralateral movements. This leads to partial improvement in functionality (an increase of maximum mouth opening of ±1 cm), but there is room for optimization.

During this research, the entire concept was revised based on all prerequisites and new advances in technology and surgery. Based on experience and various simulations, a thorough analysis was conducted to determine the optimal building blocks for this concept; crosslinked ultrahigh molecular weight polyethylene has shown its excellence in various medical joints, while biocompatible Ti6Al4V (Grade 23, ELI) allows for high customization when using three-dimensional printing (Selective Laser Melting). Combining these raw materials with biofunctionalization (e.g., surface treatments and lattice structures) and a promising HadSat®-coating has led to excellent wear properties and long-term *in vivo* results (simulated in a sheep study).

The importance of function-reconstruction translated into specific design parameters; the bilateral nature of the TMJ's caused the prosthetic side to greatly influence the healthy side (and vice versa) and, with that, all mandibular movements (e.g., opening, closing, protrusive, and lateral movements). To consider these challenges during the patient-specific design of the implant, it was reverse-engineered. Starting from the desired mandibular movements for a specific patient, the topology of the custom-made implant was derived. These desired mandibular movements were based on the pre-diseased anatomy of the patient, using a statistical shape model. This methodology allowed the designers to incorporate important anatomical features (such as condylar path angulation and Bennet movements), and to achieve the optimized patient-specific design.

By incorporating several additional distinctive features, the "bionic" prosthesis was developed. Several lattice structures (scaffolds) were used in the design, to allow for bone ingrowth. This osseointegration served as a secondary fixation method and, together with a lateral movement-restricting lip, reduced the number of necessary screws and thus surgical time. Furthermore, by implementing a scaffold into the condylar neck, the pterygoideus lateralis muscle could be reattached, which helped the patient during lateral movements. This unique feature, together with the abovementioned materials and patient-specific design, next to the sheep experiments, resulted in extensive simulation using finite element analyses to ensure both patient safety and long-term results.

By incorporating all of the abovementioned features into a novel TMJ prosthesis concept, a major advance in function-reconstructive temporomandibular joint replacement was achieved. Early *in vivo* results (1 year after surgery) showed promising outcomes, involving both high increases in mandibular movements and decreases in pain scores.

11:35 AM SM08.07.08

Late News: Additive Manufacturing of Conductive and High-Strength Epoxy-Nanocaly-Carbon Nanotube Composites Masoud Kasraie and Parisa Pour Shahid Saeed Abadi; Michigan Technological

University, United States

Additive Manufacturing has increased our ability to fabricate complex shapes and multi-material structures. Epoxy is excellent as the base for structural composite materials. Furthermore, carbon nanotube (CNT) is an outstanding filler due to its unique properties and functionalities. Here, conductive epoxy-nanoclay-CNT nanocomposite structures were fabricated by direct-write 3D printing. In this process, 3D-printable composite inks were synthesized by incorporation of nanoclay and different concentrations of CNTs – 0.25, 0.5, and 1 vol%, 0.43, 0.86, and 1.7 wt% – in epoxy. CNTs were found to significantly improve the electrical and mechanical properties. Rheological characterization of the inks revealed a shear-thinning behavior for all the nanocomposite inks and an increase in the complex viscosity, storage, and loss moduli with the incorporation of CNTs. The CNT concentration of 0.5 vol% was found to be the optimum condition for enhancement of mechanical properties; an average increase of 61, 59, and 31% was measured for flexural strength, flexural modulus, and tensile strength, respectively, compared to the 3D printed epoxy-nanoclay nanocomposite structures. The electrical conductivity of 2.4×10^{-8} and 2.2×10^{-6} S/cm was measured for the nanocomposites containing 0.5 and 1 vol% CNTs, respectively. Multi-scale characterization of the morphology revealed partial alignment of CNTs in the direction of printing, CNT pull-out and breakage at the fracture surfaces, and nano-scale interactions of the constituents, all of which contribute to the superiority of the nanocomposite with CNTs. The findings show the promise of this ink material and printing method for various applications such as aerospace structures and electronics.

Late News: 3D Printing of MXene Composite Sensor and Capacitor via Binder Jetting Technique Terek L. Li; University of Toronto, Canada

This work presents a MXene polymer composite directly 3D printed via binder jet technique. We introduce a strategy to print poly(vinyl alcohol) (PVOH) composite with optimized MXene ink. By ejecting highly conductive MXene particles onto a PVOH matrix, the resulting sample is able to achieve semi-conducting behaviour with the potential for strain sensing and energy storage. The printed component can be used as a strain sensor capable of sensing tensile strains between 11 to 250%. The component could also be used as electrode material in a sandwich-structured pseudo-capacitor with an energy density of 36.4mJcm^3 and a power density of 2.8mWcm^-3. This study demonstrates that binder jet printing has the potential to directly fabricate polymer composite materials end different end applications.

In order to briefly explain why this submission will appeal to broad and interdisciplinary researchers in both 3D manufacturing and 2D materials, it should be noted that although binder jet printing is widely adopted in industrial setting to print ceramic and metallic components. However, it has only been proven very recently as a viable method to print polymer composite materials. The submitted manuscript not only offers a guideline toward ink optimization for binder jet printing with polymeric material, but also for the first time demonstrates different end applications of printed components. This work is believed to be highly capable of providing the readers in the field of 3D printing with a framework on the modification of particle morphology and ink composition in order to further explore the potential limit of binder jet printing of polymeric composite.

11:55 AM SM08.07.10
3D-Printed Organ Phantom for Simulation and Quantitative Evaluation of Medical Procedures Eunjin Choi[1,2], Moonkwang Jeong[2], Dandan Li[1], Rodrigo Suarez-Ibarrola[3], Arkadiusz Miernik[3], Frank Waldbillig[4], Tian Qiu[1,2] and Peer Fischer[1,2]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]University of Stuttgart, Germany; [3]University Medical Center Freiburg, Germany; [4]University Medical Centre Mannheim, Germany

Organ phantoms have been recognized as a testing platform in medicine and have become more realistic as the 3D printing technology has advanced. Typical 3D printers can achieve resolutions of tens of microns and offer a number of printing materials [1]. This allows detailed anatomical features to be resolved by choosing different

materials [2,3]. While most printing materials do not have properties that reflect those of tissues, 3D printing with biocompatible hydrogels show tissue-like properties [4]. However, most of the work to date has focused on reproducing structural details resemblance, which is mainly of interest for visual comparison.
Here, we present high-fidelity organ phantoms of the full urinary tract that can also be used to simulate and evaluate medical procedures, including surgery. We used 3D-printed molds to build the phantom. The 3D-printed molds were designed with computer-aided design (CAD) and are based on high-resolution X-Ray images. The casting method allows the use of materials that match the mechanical, optical, and imaging contrast properties of biological tissues.
Our phantom has been validated for the simulation and evaluation of many medical procedures, such as lithotripsy [5], cystoscopy [6], and the transurethral resection of the prostate [7]. A major advantage of the phantom is that the surgery can be quantitatively evaluated using multi-modality medical imaging to an extent that cannot be achieved in a real surgery. Both user-feedback as well as the physical parameters of time, accuracy, geometrical centricity, and surface smoothness of the surgical resection can be quantitatively evaluated. These phantom are expected to be important tools for medical training, surgical planning as well as the development of new medical instruments.

SESSION SM08.08: 3D Printing and Bioprinting VIII
Session Chair: Chrystelle Salameh
Thursday Afternoon, April 22, 2021
SM08

1:00 PM SM08.08.01
3D Printing of Ingestible Gastric Resident Electronics and Biomedical Devices Yong Lin Kong; The University of Utah, United States

The integration of electronics with the human body, such as wireless sensors and a drug delivery system can enable a personalized digital-based diagnosis and treatment strategies. Nevertheless, surgically placed medical implants are associated with eliciting foreign body immune responses and can serve as a nidus for infection. Recent advances in 3D printing have enabled the creation of novel 3D architecture and devices with an unprecedented level of complexity, properties, and functionalities. The development of a multi-scale, multi-material 3D printing approach can overcome the geometrical, mechanical and material dichotomies between conventional manufacturing technologies and a broad range of three-dimensional systems. Here, we discuss the creation of 3D printed gastric resident electronics (GRE) that can circumvent the potential complications associated with surgically placed medical implants by leveraging the significant space and immune-tolerant of the stomach. We propose biomedical applications with the further advancement of this system that can be

potentially realized with a multiscale 3D printing process that synergistically integrates functional nanomaterials.

1:10 PM SM08.08.02
Late News: Tissue Specific 3D Bioprinting Using Ready-to-Use TissueFabTM Bioinks Kevin T. Dicker, Juyi Li, David Settles, Hanying Luo, Nicolynn E. Davis and Gangadhar Panambur; MilliporeSigma, United States

3D bioprinting is an enabling tool for regenerative medicine and drug discovery. Despite promising advancements 3D bioprinting technology, a need remains for reproducible commercially available ready-to-use bioinks to replicate 3D tissue microenvironments. To address this, we have developed a platform of bioink formulations, *TissueFab™*, that are compatible with diverse cell types, bioprinting platforms and have high batch-to-batch consistency. *TissueFab™* is a family of general purpose and tissue specific ready-to-use bioinks based on natural proteins and polysaccharides and synthetic polymers. *These bioinks are designed for* optimal viscosity and mechanical properties for high resolution bioprinting and to maintain high cell viability (>80%) in a wide range of curing wavelengths. Printability of our bioinks are assessed on multiple microextrusion based commercial bioprinters thus demonstrating the printer agnostic characteristic of the bioinks. Bioink formulations were validated for high cell viability, proliferation and metabolic activity using C2C12 mouse myoblast cells, human mesenchymal stem cells (hMSCs) or human adult dermal fibroblasts (HDFa). For bone tissue engineering applications, we have shown that hMSCs bioprinted in *TissueFab™ - Bone bioinks* show an increase in osteogenic differentiation. Additionally, *TissueFab™- Conductive bioinks* exhibit enhanced conductivity making them attractive for bioprinting electroactive tissues such as neural or muscular tissue. *TissueFab™* bioinks provide a robust tissue-mimetic platform for microextrusion-based bioprinting various cell types with both high printability and cell viability. *TissueFab™* bioinks enable on-demand tissue printing which is a tangible step forward for addressing drug testing and tissue engineering challenges.

1:20 PM SM08.08.03
Late News: Multimaterial 3D Printing of Functional Objects Using Polymerization-Induced-Phase-Separation Chantal Paquet[1], Bhavana Deore[1], Katie Sampson[1], Thomas Lacelle[1], Derek Aranguren van Egmond[1] and Hendrick W. de Haan[2]; [1]National Research Council of Canada, Canada; [2]Ontarion Tech University, Canada

Advances in materials and processes are required to transform 3D printing into a manufacturing platform capable of generating complex objects with integrated function. Despite its high dimensional accuracy and resolution, excellent surface finish, versatile modification of feedstock chemistry, and low cost printers, vat polymerization 3D printing lacks the versatility to generate multimaterial objects. In this presentation, we describe a strategy to generate functional multimaterial objects by vat polymerization 3D printing that relies on controlled phase separation. Using photoresins comprising of judiciously selected components, the diffusion of phase separating components are modulated via the kinetics of gelation, the density of the polymer network and the diffusivity of materials to control the material phases spatially. The insight gained in controlling the material phases allows a rationalized approach to formulating resins to access a wide range of material morphologies for specific applications. The approach was used to fabricate dipole antenna arrays that function at 2.4 GHz, trusses that response to compression and anti-bacterial surface. Due to the universality of this approach 3D PIPS represents a powerful method to create materials with controlled sub-phases and will accelerate the adoption of vat polymerization as a viable technique to generate functional 3D objects.

1:30 PM SM08.08.04
Late News: 3D Printed Porous Polymer-Derived Bioceramics for Bone Tissue Engineering Joelle El Hayek, Mikhael Bechelany, Philippe Miele and Chrystelle Salameh; European Institute of Membranes, France

The production of biomaterials for tissue and bone engineering is still a real challenge for repairing, implanting or filling damaged bone or connective tissue. Silicate-based bioceramics have excellent bioactivity and are

considered promising materials for bone regeneration; however, their synthesis and design in complex geometric forms using conventional techniques is still challenging. The design of scaffolds for tissue engineering with the mechanical and microstructural properties required to promoting cell attachment, growth and new tissue formation is one of the major challenges facing researchers in the field. Their main disadvantage is their low strength and high brittleness under applied loads.
The Polymer-Derived Ceramics (PDCs) route is one of the most advantageous approaches in the manufacture of bioceramics due to the ability to control both synthesis and shaping.
In this work, we investigated 3D printing of two preceramic polymers precursors of Ca_2SiO_4 using Stereolithography (SLA). We studied the effect of the precursor's composition and ceramic yield on the physico-chemical properties of the glass-ceramic. After pyrolysis, the scaffolds were functionalized with silver-reduced graphe oxide composites in order to assess their antibacterial activity.
The bioceramics, characterized with good mechanical strength, showed regular geometries and a high interconnected porosity (60%) with an average pore size between 200 and 400 μm. Cell viability and cytotoxicity tests showed that the scaffolds were biocampatible and nontoxic suggeting that such 3D bioceramics are suitable for tissue engineering.

1:40 PM SM08.08.05
Late News: Tailoring Slurry Formulation to Manufacture Fine-Scale Ceramic Structures via Material Extrusion Huseyin Utkucan Kayaci and Simge Cinar; Middle East Technical University, Turkey

Additive manufacturing is a highly advantageous manufacturing technique that enables the production of complex shapes which cannot be produced by any other technique, and it provides an opportunity for fast prototyping and personal based productions. Despite the advantages of additive ceramics manufacturing, obtaining superior mechanical properties using this technique is still a challenge because of the need to use inks with significant additive percentage. Among the other ceramic additive manufacturing techniques, extrusion-based robocasting technique offers a low-cost opportunity for the production of high-density and high strength bodies; yet, it requires strict control over the rheological behavior of the ceramic ink and the processing conditions. The increasing interest in the topic leads to significant improvements in the design of the printing parameters. However, the studies on the relation between the slurry properties, the rheological properties, the processing conditions, and the resulting properties of the green and sintered bodies are overlooked. In this study, the importance of the powder properties on the suspension rheology and the resulting properties of the extruded green and sintered bodies were investigated. Proper choice of particles, particle size and the processing additives enabled better controlled rheological properties of suspensions, smoother extrusion through narrow channels, and eliminated clogging during extrusion and crack formation in green bodies. Moreover, sintered ceramic bodies with even 200 – 300 μm size features could be produced. The sintered bodies exhibited densities above 97% of their theoretical density. In the present work, alumina was used as a model ceramic material, but the findings can certainly be extrapolated to other ceramic systems. Such findings are particularly critical for the biological, electronic and robotic applications where the mechanical requirements are demanding.

This work has been supported by Scientific Research Projects Coordination Unit of Middle East Technical University under grant number YOP-308-2018-2677.

1:50 PM *SM08.08.06
One-Shot Bioprinting with Ultrasound Zhichao Ma[1], Kai Melde[1] and Peer Fischer[1,2]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]University of Stuttgart, Germany

Ultrasound is benign and can exert forces on particles and cells. A recent advance makes it possible to form high-resolution arbitrary shaped ultrasound pressure distributions [1]. By encoding the necessary phase information into the topography of a 3D-printed plate that is placed in front of a simple ultrasound transducer, it is now possible to generate sophisticated acoustic fields inside a fluid volume. We have shown that particles can be assembled into pre-defined shapes and that the particle-assemblies can be fixed to form permanent objects [2]. The advantage of directed-assembly via ultrasound fields is that the particles assemble at once to form the

object. This promises a general one-shot fabrication method. Of particular interest is to apply this method to the patterning of biological cells. We could show that the acoustic amplitude distribution of a complex image, defined by the hologram, exerts forces on biological cells and the biocompatible hydrogel they are suspended in. The resultant convection flow gently delivers the suspended cells to the image plane where they form the desired pattern [3]. The hydrogel can then crosslink to immobilize the cell pattern. The use of acoustic holography for the assembly of cells structures shows great potential to grow tissue-like structures. A spatial ultrasound modulator based on microbubble arrays [4] can replace the static 3D-printed hologram and opens the possibility to form dynamic, reconfigurable assemblies.

Late News: Additive Manufacturing of Ceramic Components via UV-Assisted Direct Ink Writing Connor Wyckoff[1,2], Matthew Dickerson[1] and Lisa Rueschhoff[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Ceramic additive manufacturing has the potential to be a disruptive technology enabling rapid prototyping and the production of complex geometries. A relatively new approach for ceramic part fabrication is additive manufacturing via UV-assisted direct ink writing (UV-DIW). UV photopolymerization during the print process modifies ink rheology to enable the fabrication of more complex geometries such as overhanging or spanning structures that are otherwise difficult to make with traditional DIW processes. We have developed a UV-DIW optimized ink that consists of a preceramic polymer-based system loaded with ceramic powder, containing all off the shelf components. This ink shows easy printability as well as limited shrinkage after pyrolysis, making it ideal for near net shape fabrication and rapid prototyping without the need for time consuming synthesis steps. The relationship between ink formulation, rheology, printability, as well as the structure of the final ceramic components will be presented

2:25 PM *SM08.06.05

Engineering The Cellular Niche Via CAD/CAM Laser Processing Douglas B. Chrisey[1], Jayant Saksena[1] and Yong Huang[2]; [1]Tulane University, United States; [2]University of Florida, United States

We have developed a laser-biomaterial interaction-based prototyping platform capable of three fabrication modes: (1) laser direct write of cells, microbeads, and other biomaterials; (2) fabrication of cell encapsulating microspheres (microcapsules); and (3) laser micromachining of substrates. Using this system, we are able to precisely place biomaterials, such as cells, into substrates with spatial constraints from laser micromachining or wholly fabricate scaffolds that are cell laden. This enables fabrication of co-cultures in almost any geometry and controlled gradients of chemical factors. In addition, the process is parallelizable, thus allowing for numerous potential bioassay applications. One such assay is a differential system for quantifying multiple outcomes in response to multiple parallel biophysicochemical cues in competition. These novel assays are complex, reproducible, and disposable microenvironments. This presentation will summarize the control integration developed for Laser Direct Write, a 2D model of laser ablation, with a computational method demonstrating preliminary results. The biofabrication methods discussed are applied to an Organ-On-a-Chip model to develop a fully automated fabrication process.

8:00 AM *SM09.01.01
Socially Distant at the Nanoscale—It's a (Soft) Matter of Heterochirality Silvia Marchesan; Università degli Studi di Trieste, Italy

Diphenylalanine (Phe-Phe) is a popular building block in nanotechnology and materials science. This motif derives from the sequence of Amyloid beta peptide that is prone to self-aggregation and it is associated to Alzheimer's disease. Phe-Phe is well-known to self-assemble into nanotubes with an inner water-channel, but their uncontrolled growth results into hierarchical assembly into toxic microtubes. In this work, we show that the hydrophobic inter-molecular (social) interactions are responsible for the association into microtubes, and their replacement with intra-molecular (asocial) contacts is key to avoid microtube formation and alleviate cytotoxicity in vitro.

Interestingly, substitution of one amino acid with its mirror-image to yield D-Phe-L-Phe is sufficient to hinder microtube formation. As a result, a homogenous population of 4-nm wide fibrils is obtained that form a network yielding a macroscopic hydrogel. Full-atom molecular dynamics simulations, single-crystal XRD data and spectroscopic analyses allowed us to unravel the fine (supra)molecular details of
the process. Furthermore, halogenation of the building blocks is an additional variable proved to be effective to fine-tune self-organization.

The soft matter formed by self-assembly of short, heterochiral peptides is reversible and gel/sol transitions can be triggered by a variety of stimuli, including not only temperature and pH, but also light for instance. The talk will provide examples of the recent research avenues undertaken on using heterochirality as a design strategy to achieve supramolecular soft matter to serve different functions.

S.Kralj et al. ACS Nano 2020 doi:10.1021/acsnano.0c06041

8:25 AM SM09.01.02
Ultra-Short Ionic-Complementary Constrained Peptides (UICPs) as a Chemical Platform for the Development of Bioinspired Multifunctional Nanofibrous Materials Mohamed Elsawy[1], Joseph Hayes[2] and Jacek Wychowaniec[3]; [1]De Montfort University, United Kingdom; [2]University of Central Lancashire, United Kingdom; [3]University College Dublin, Ireland

Peptide non-covalent assembly has been classically studied as the main culprit implicated in a variety of 'protein aggregation' diseases, such as Alzheimer's, Parkinson's, Huntington's, Prion diseases, and others. In the last three decades, the process has attracted material designers as a bioinspired strategy for the development of peptide-based assembling functional nanomaterials; which showed great potential for a wide variety of biomedical and pharmaceutical applications (X. Zhao & S. Zhang. Macromol Biosci. 2007, 7, 13; R.V. Ulijn & A.M. Smith. Chem. Soc. Rev. 2008, 37, 664; A.L. Boyle & D.N. Woolfson. Chem. Soc. Rev. 2011, 40, 4295; A. Altunbas & D.J. Pochan. Top Curr Chem. 2012, 310, 135; Dasgupta et al. RSC Advances 2013, 3, 9117; C. Edwards-Gayle & I. Hamley. Org. Biomol. Chem. 2017, 15, 5867). The high versatility of material requirements for different applications makes it important to have a tuneable and multifunctional system by molecular design.

Recent endeavours in our group focus on the molecular engineering of Ultra-short Ionic-complementary Constrained Peptides (UICPs) as a chemical platform for the development of bioinspired cost-effective multifunctional materials. Using bottom-up rational design approach combined with computational modelling, we have developed the parent UICP tetrapeptide sequence Phg4, which is the shortest reported ionic-complementary peptide that self-assemble into thermodynamically stable β-sheet structures forming amphiphilic nanofibers capable of both gelation and emulsification (J. Wychowaniec *et al.* Biomacromolecules 2020, 21, 2670). Phg4 nanofibers demonstrated unique surface activity in the presence of immiscible oils and were superior to commercial emulsifiers in stabilizing emulsions and emulgels (EMGs) under a range of storage and stress conditions. These results imply the considerable potential of UICPs as biocompatible excipients in pharmaceutical, cosmetics, and food industries. In addition, interfacial self-assembly has led to the fabrication of nanofibrillar microspheres suitable for cell microencapsulation and scaffolding for supporting cells proliferation and differentiation processes. UICP microspheres were also manipulated for fine-tuning release kinetics of multiple drug cargos, both of hydrophobic and hydrophilic nature.

We are currently developing a range of next generation UICP sequences with a variety of aromatic residue designs and charged residues distributions, for further adjusting molecular assembly, gelation and interfacial properties to meet the intended application needs.

ACKNOWLEDGMENTS

8:40 AM *SM09.01.03
Harnessing Biological Organization Principles to Engineer Active and Dynamic Materials Alvaro Mata; The University of Nottingham, United Kingdom

Living systems have evolved to grow and heal through self-assembling processes capable of organizing a wide variety of molecular building-blocks at multiple size scales. While advances in nanotechnology and biofabrication are enhancing our capacity to emulate features of some of these biological structures, it is increasingly evident that recreation of their complexity and adaptability will require new ways to build with molecules such as peptides and proteins. This talk will present our laboratory's efforts to combine

supramolecular events found in nature such as disorder-to-order transitions(1,2), diffusion-reaction processes(2,3), and organic-inorganic interactions(1) with engineering (e.g. biofabrication techniques)(4) or materials science (e.g. host-guest complexes)(5) approaches to organize peptides and proteins into hierarchical and functional materials with emergent properties.

Protein-Based Conductive Polymers—From Flexible and Stretchable Electronics to a Platform for Light-Stimuli-Responsive Material Nadav Amdursky; Technion–Israel Institute of Technology, Israel

We are inspired by nature for its utilization of proteins for a variety of function, and specifically to our work, the ability of proteins to form high-hierarchical structures and the ability of proteins to mediate charges (electrons, protons and ions) across specific pathways from the nm-scale up to the μm scale. and we use proteins for the formation of responsive materials. With this biological inspiration, we report here on a new family of conductive and free-standing biological materials, where we use different types of proteins as building blocks to form various types of materials. With this in mind, we focus only on proteins that can be produced in bulk quantities and in low cost from raw materials, in which most of our work to date has been focused on the bovine serum albumin protein. We show that using our (bio-)polymerization approach we can form highly elastic polymers in large scale, capable of stretching more than 5 times their length. Due to the relatively high water uptake of our protein-based polymers and the presence of many amino acids residues that can participate in hydrogen bonding, our new protein-based polymers showing good protonic and ionic conductivity. Following the formation of the biopolymer, we show that it can be further functionalized in different ways. For enhanced protonic conductivity we add oxo-acids to the polymer, resulting in measured ionic conduction of >10 mS/cm at room temperature. For enhanced electronic conductivity we can dope the formed polymer with natural electron mediating small molecules. For gaining new light-stimuli-responsive we attach to the protein-based polymer light-responsive molecules, resulting in the large light attenuation of its electrical properties. From blue skies research perspective, the protein-based nature of our materials enables us to explore the governing factors and mechanisms of long-range biological charge transport. Nonetheless, our new protein-based biopolymers have several attractive properties for their possible integration in various applications. Our materials are environmentally friendly, they possess inherent biodegradability and biocompatibility, they have attractive mechanical propeties and their formation obeys to most principals of green chemistry. From a practical point of view, we introduce here a very easy polymerization method that requires no synthesis and it is energy efficient, and in addition, our chosen proteins are having low price tag, resulting in a materials cost of around $\$1/cm^2$. Currently, our main targeted application for our new family of materials is for biological interfaces, while other lines of applications include the use of our biopolymers for biomedical application (tissue engineering) and for energy applications such as membranes for fuel cells.

9:20 AM SM09.01.05
Late News: Artificial Protein Design Rules to Harness Protein Tertiary Structures for Polymeric Materials with Exotic Mechanical Behaviors Minkyu Kim; The University of Arizona, United States

Unprecedented physical, chemical, and biological properties of natural materials inspire next-generation polymeric materials for healthcare, defense, and industrial applications. For example, muscle tissues and red blood cells (RBC) largely alter their structures under mechanical stresses to dissipate energy and prevent tissue or cellular damage before recovering when environmental stresses decrease. Single molecule studies revealed that the macroscopic mechanical behaviors are strongly correlated to exotic nanomechanics from their protein

tertiary structures. Design rules are in place to guide the incorporation of intrinsically disordered proteins into polymeric materials, which have been established using synthetic polymers. However, design rules to harness protein tertiary structures into macroscopic polymeric materials are unclear because the strand flexibility with structured proteins is significantly dissimilar with nonstructured polymer-based strands.

Here, we designed artificial proteins, composed of rigid tertiary and flexible nonstructured protein modules in specific ratios and arrangements to identify design rules for incorporating protein tertiary structures in polymeric materials. The rigid module consists of RBC ankyrin repeats, known for its solenoidal shape and nanospring behavior under applied external forces. The flexible module comprises polyelectrolytic, nonstructured protein repeats. These protein modules were genetically inserted into a telechelic, associative construct with self-oligomerizing protein endblocks to form hydrogels in aqueous conditions. Using mechanical testing, we identified that an asymmetric flexible-rigid protein design with an optimal flexible length enhances the hydrogel rheological properties compared to hydrogels composed of only flexible or rigid protein modules. This indicates that controlling strand flexibility can improve the crosslinking effectiveness in polymeric materials, which can potentially enhance the macroscopic material performance. Furthermore, our current effort to identify specific and strong self-oligomerizing protein endblocks that will properly exhibit protein nanomechanics at the macroscopic material level will be discussed. This design discovery will culminate in an artificial protein platform that harnesses mechanical proteins with diverse tertiary structures into self-assembled materials for exotic mechanical behaviors, which we expect to advance a wide variety of healthcare applications, including but not limited to tissue engineering, drug delivery, and regenerative medicine.

9:35 AM SM09.01.07
A Protein-Based Free-Standing and Proton-Conducting Transparent Elastomer as a Sustainable Material for Large Scale Sensing Applications Ramesh Nandi; Technion–Israel Institute of Technology, Israel

A most important endeavor in modern materials research is shifting toward green environmental and sustainable materials. Natural resources are one of the attractive sustainable building-blocks for making environmentally-friendly materials. However, in most cases, the performance of nature-derived materials does not match the performance of carefully designed synthetic materials, particularly for conductive polymers, which is the topic here. Inspired by the natural role of proteins in mediating protons, we show here their utilization for making free-standing transparent polymer having highly-elastic nature and proton conductivity comparable to synthetic polymers. Importantly, the polymerization process is relying on the natural protein crosslinkers and is spontaneous and energy-efficient. The used protein, bovine serum albumin, is one of the most affordable proteins, resulting in the ability to form large-scale materials at low cost. Due to the inherent biodegradability and biocompatibility of the elastomer, it is promising for biomedical application, and here we show its immediate utilization as a solid-state electrode for sensing physiological signals.

9:39 AM SM09.01.08
Late News: Artificial Protein Design as an Effective Material Platform for Antimicrobial Peptides Fathima T. Doole[1], Lauren G. Melcher[1], Christopher P. Camp[1], Anne M. Wertheimer[1,1], Abhishek Singharoy[2], Michael F. Brown[1,1] and Minkyu Kim[1,1]; [1]University of Arizona, United States; [2]Arizona State University, United States

Antimicrobial peptides (AMPs) are a promising solution to combat antibiotic-resistant superbugs. The major drawbacks of AMPs are their rapid *in vivo* degradation and renal filtration which have led to poor AMP efficacy. Anchoring AMPs with synthetic polymer tethers on biomaterial surfaces can overcome these obstacles by enhancing AMP stability and protecting AMPs from renal filtration. Further, modulating the physicochemical properties of synthetic polymer tethers can potentially maximize AMP efficacy. However, intricate material synthesis and inconsistent yields of tethering AMPs on material surfaces result in varying material performance.

Using artificial protein technology, we developed an “All-in-One” (AiO) protein-based antimicrobial material that contains three major components, similar to conventional AMP-incorporated materials: a material scaffold, biopolymer tether, and an AMP. An elastin-like protein (ELP) was designed as the material scaffold that when in aqueous solution under physiological temperature will make micelles or the ELP can be photo-crosslinked to make hydrogels. Next, a hydrophilic, flexible protein sequence was introduced to the material scaffold to act as a biopolymer tether. Finally, two of the most common AMPs, LL37 and Pexiganan, were chosen to demonstrate and evaluate AiO protein-based antimicrobial materials. To investigate the role of the biopolymer tether, AiO antimicrobial materials with and without tethers were biosynthesized. The AiO material with the tether reduced the growth of *Staphylococcus aureus*, gram-positive bacteria, by 50% more than the material with non-tethered AMP. This could be due to greater flexibility and degrees of freedom of tethered AMPs, which can effectively interact with the bacteria. To investigate this hypothesis, all-atom molecular dynamics simulations are being employed to understand the atomistic level details of the biopolymer tether on AMP activity and membrane interaction. Artificial AiO protein development provides consistent yields and materials performance, as well as the opportunity to engineer material components at a single amino acid level precision to improve the AMP efficacy. Therefore, we anticipate that the AiO protein will advance the use of diverse AMPs as an effective and wide-reaching therapeutic strategy to mitigate antimicrobial resistance

Role of Calcium Signaling on Regulated Cell Death Induced by Membrane-Interacting Peptide Amphiphiles Damien Samways[1], Shantanu Sur[1], Samuel I. Stupp[2], Morgan Reynolds[1], Michael Sanborn[1] and Manal A. Binqabbus[1]; [1]Clarkson University, United States; [2]Northwestern University, United States

Peptide amphiphiles (PA) consist of short peptide chains linked to an alkyl tail that can undergo self-assembly into nanofibers. Previous studies have shown that exposure to many types of PA results in cell death, and the assumption has been that this is primarily due to disruption of cell plasma membrane integrity. However, preliminary data in our laboratory has indicated that the effects of certain weak beta-sheet forming cationic PAs on inducing cell death might involve specific stimulation of signal transduction pathways rather than coarse disruption of biological membranes. Our goal was to investigate the effect of PA exposure on intracellular Ca^{2+} homeostasis, which is known to be a major regulator of cell survival. Utilizing live cell Ca^{2+} imaging with the Ca^{2+} indicator Fluo-4, we found that exposure to PA stimulated slow sustained elevations in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$). This PA-induced $[Ca^{2+}]_i$ persisted in the absence of added extracellular Ca^{2+} ruling out the possibility that it was due to Ca^{2+} leak across a disrupted plasma membrane. Rather, the elevation in $[Ca^{2+}]_i$ appears consistent with the mobilization of Ca^{2+} from the intracellular endoplasmic reticulum stores, in part through a phospholipase C (PLC)-dependent signal transduction pathway. We hypothesized that the PA-dependent elevation in $[Ca^{2+}]_i$ marked the first step in the observed PA-induced cell death. However, surprisingly the cytotoxicity of PA was not significantly reduced by either PLC inhibition or by suppressing Ca^{2+} elevations in the cervical cancer cells by pre-incubating them with the intracellularly active Ca^{2+} chelator, BAPTA-AM. While PA-induced changes in $[Ca^{2+}]_i$ do not appear to cause the subsequent PA-associated cell death, these data nevertheless support the hypothesis that PAs can influence vital intracellular singling processes.

Identifying New Strategies to Promoted Adhesion to Non-Polar Substrates by Bacterial Surface Display Mark T. Kozlowski, Joshua Orlicki, Randall A. Hughes, Thomas H. Segall-Shapiro, Randi M. Pullen and Jimmy Gollihar; U.S. Army Research Laboratory, United States

Polystyrene (PS) and polypropylene (PP) are ubiquitous plastics in our modern world. However, their highly non-polar characteristics can lead to difficulty forming a good adhesive bond. Current methods for PS and PP adhesion rely on high temperatures, solvent plasticization, or extensive pre-treatment and priming. Identifying new strategies to enable good adhesive bonding would provide opportunities for facile repair in the field, new designs for capacitors, and the creation of new types of composite materials.
Biology may point the way to these new strategies for chemically-based adhesion of non-polar substrates. For

example, the filamentous projections (hyphae) of fungi must breach an air-water interface when colonizing new environments and seeking nutrients, and do so by the secretion of a family of natural surfactants known as hydrophobins [1]. Hydrophobins have already been shown to adhere to highly non-polar surfaces, such as Teflon [2], and there is at least one previous report of a designed chimeric hydrophobin successfully adhering to polystyrene [3], meaning this is a promising class of materials deserving further exploration.

Screening the chemical compositional space afforded by peptides and the natural amino acids would be nearly impossible if undertaken in a serial fashion. Recently, the Army Research Laboratory developed a peptide surface display and high-throughput library screening system to find candidate peptides capable of adhering to polylactic acid [4], and to gold nanoparticles [5]. The on-cell peptide screening has the advantages of easy recoverability, the ability to propagate and sequence the genetic code of the adhesive peptides, and possible further improvements of the peptides by directed evolution. In the present work, we use these previously-developed surface display methodology, a peptide library, and a separate hydrophobin library, to screen for affinity and (hopefully) adhesion to non-polar plastics. We believe this work will encourage further exploration of biologically-inspired adhesive agents for non-polar plastics, and provide key insights for the chemical synthesis of new types of non-polar material adhesives.

Late News: A Peptide Based Latent Crosslinker Activated by Thiol-Thioester Exchange Reaction

Makafui Y. Folikumah[1,2], Marc Behl[1] and Andreas Lendlein[1,2]; [1]Institute of Active Polymers and Berlin-Brandenburg Centre for Regenerative Therapies, Helmholtz-Zentrum Geesthacht, Germany; [2]University of Potsdam, Germany

Thiol-thioester exchange (TTE) reaction can occur smoothly in neutral aqueous media and is therefore worthwhile to be considered as potential dynamic covalent chemistry for physiological environments [1-2]. Typically, the thiol and the thioester functionalities reacting here are part of two separate molecules. Systems making use of a single molecule providing both functional groups employ hydrophobic aromatic moieties. In these cases, a catalyst might be required in order to control the direction of the equilibrium [3].
The hydrophobicity of these substrates and the liberation of foul-smelling aromatic thiols limit their use for biomedical application. Here we report on a thio-depsipeptide (TDP), Ac-Pro-Leu-Gly-SLeu-Leu-Gly-NEtSH synthesized by the modification of a standard collagenase activity peptide, Ac-Pro-Leu-Gly-SLeu-Leu-Gly-OEt. TDP was capable of a ‘pseudo’ intramolecular TTE reaction to yield α, ω-free thiol bearing peptide crosslinker without perceivable foul-smell. We could demonstrate in electrospray ionization mass spectrometry studies that the TDP, Ac-Pro-Leu-Gly-SLeu-Leu-Gly-NEtSH, self-generates a dithiol peptide crosslinker, HSLeu-Leu-Gly-NEtSH (BTDP) as a TTE product in aqueous medium in addition to Ac-Pro-Leu-Gly-SLeu-Leu-Gly-NEtS-Gly-

Leu-AcPro (TXP). When mixed with a panel of thiols, cysteine (pKa 10.8), glutathione (pKa 9.6), methylthioglycolate (pKa 7.8), 4-mercaptobenzoic (pKa 5.9), and *para*-nitrophenol (pKa 4.6) in equimolar concentrations, the fate of exchange products between TDP and the external thiols was found to be dependent on the relative pK_a of these thiols to the attacking TDP thiol. *L*-cysteine with similar thiol pK_a as the attacking TDP thiol yields an additional exchange product Ac-Pro-Leu-Gly-SCys-OH, with a corresponding increase in BTDP peak intensity than observed for TDP only. 4-mercaptobenzoic and *para*-nitrophenol with more acidic thiols relative to the attacking TDP thiol however resulted in a decrease of BTDP peak intensity caused by the lack of breakdown of their respective tetrahedral intermediates, which were clearly visible in the recorded spectra.
A concept for the design of water-soluble single TTE substrates without the need for incorporation of acidic aromatic thiols is presented. Since aromatic thiols are known for their toxicity and unpleasant smell after TTE reactions the newly developed TDP could potentially enable in situ bioconjugation and crosslinking applications.

β-Sheet Forming Peptide Hydrogels—From Self-Assembly to Functional Biomaterials Alberto Saiani; The University of Manchester, United Kingdom

The use of non-covalent self-assembly to construct materials has become a prominent strategy in biomaterials science offering practical routes for the construction of increasingly functional materials for a variety of applications ranging from cell culture and tissue engineering to in-vivo cell and drug delivery.[1] A variety of molecular building blocks can be used for this purpose, one such block that has attracted considerable attention in the last 20 years is *de-novo* designed peptides.[2] The β-sheet motif is of particular interest as short peptides can be designed to form β-sheet rich fibres that entangle and consequently form very stable hydrogels. These hydrogels can be easily functionalised using specific biological signals and can also be made responsive through the use of enzymatic catalysis [3-4] and/or conjugation with responsive polymers [5]. Through the fundamental understanding of the self-assembly and gelation of these peptides across length scales [6-8] we have been able to design hydrogels with tailored properties for a range of applications including for the culture of a variety of cells[9-11], injectable and sprayable hydrogels for cell and drug delivery [12-13] as well as shear thinning hydrogel for 3D bio-printing [14-15]. The intrinsic biocompatibility [16] and low immunogenicity [17] of these materials makes them also ideal for TERM applications. Recently we have demonstrated their potential in a range of TERM applications including, oesophagus [18], nerve [19], intervertebral disk [20] and cardiac [21] regeneration.

Simulating Peptide Self-Assembly on Single Layer Materials via Asynchronous Markov Chain Algorithms Siddharth S. Rath, Michael Malone, Chandler King and Mehmet Sarikaya; University of Washington, United States

Predictively controlling the self-assembly of biomolecules at solid interfaces is crucial for the development of functional substrates at bio/nano soft interfaces. The self-assembly of peptides is largely impacted by environmental conditions such as temperature, pH, and concentration. However, the extent to which these environmental conditions dictate peptide self-assembly on atomically single-layer materials is largely unknown. Here we show a computational modeling approach that enables a greater understanding of how adjustments of environmental conditions affect peptide self-assembly. We modify asynchronous Markov chain algorithms to investigate the impact of environmental conditions on peptide self-assembly. The original purpose of the Markov model was to visualize programmable matter that can achieve complex self-organizing ensembles. This is carried out using particles with extremely limited computational power. We modify these algorithms to achieve a virtual self-organizing particle system representative of self-organizing solid binding peptides. The overall self-assembly process is simplified to include the most significant steps: 1. Peptide adsorption/desorption, 2. Diffusion across substrate, 3. Clustering of peptides, and 4. Break-up of clusters into linear formations based on favorable conformation-mediated intermolecular interactions. Our Markov model currently allows for variable adjustments in particle surface concentration, adsorption rate, strength of intermolecular interactions, and diffusion coefficients. Various combinations of these bias parameters yield unique self-organizing particle systems with distinct characteristics, similar to the differences in self-assembly characteristics between various solid binding peptides. We show, therefore, that Asynchronous Markov Models provide a simple modeling platform for biomolecular self-assembly on atomically flat solids along with avenues to tune binding energies, absorption/desorption rates, temperature, effects of concentration, pH, and structure-mediated intermolecular interaction energies as well as lattice mismatch parameters. Such models allow one to fit simulated models with AFM images, including grain size, chiral angles, degree of ordering, and surface coverage, estimate several energetic parameters involved in the self-assembly process, towards better characterization and understanding of interfacial properties in soft bio/nano interfaces and their implementation into practical devices. The research is supported by NSF-DMREF program.

Programming Sequence-Defined Peptoids for Bio-Inspired Synthesis of Functional Nanomaterials Chun-Long Chen; Pacific Northwest National Laboratory, United States

Proteins are the molecular machines that carry out the vast array of functions needed for the survival and propagation of all cellular organisms. Many proteins form this machinery by folding into functional building blocks that self-assemble into extended networks to deliver sequence-specific functions ranging from photosynthesis, to molecular separation, selective ion transport, and tissue mineralization. Inspired by nature, many sequence-defined molecules have been exploited for the preparation of nanostructured functional materials. Peptoids are one of the most advanced classes of sequence-defined synthetic foldamers. By bridging

the properties of proteins and polymers, they offer unique opportunities for the synthesis of biomimetic materials with controlled structures and tunable functions.

In this talk, I will discuss our recent efforts in designing amphiphilic peptoid sequences for bio-inspired synthesis of functional materials (e.g. membrane-mimetic 2D nanosheets, dynamic nanotubes, pore-forming networks, and flower-like fluorinated nanoparticles). For these self-assembly systems, peptoid-peptoid and peptoid-substrate interactions play critical roles in the peptoid assembly and can be tuned through the peptoid sidechain chemistry. By programming these peptoids with responsive functional groups and sidechains, we developed a variety of responsive hierarchical nanomaterials. Due to the high stability and programmability of these biomimetic materials, we further demonstrated the incorporation of various functional groups into these peptoid-based materials for specific applications. Our results indicate that self-assembly of amphiphilic peptoids into hierarchical structures can be used as a robust platform to develop biomimetic materials with tunable structures and controllable functions.

Designed Interfaces Between Proteins and Inorganic Crystals for Templated Assembly and Co-Assembly
Sakshi Yadav; Pacific Northwest National Laboratory, United States

Previously we have shown we could use Rosetta to design proteins that exhibited a lattice match to mineral surfaces. We discovered that we could exploit those interactions and designed protein-protein interfaces to generate a variety of ordered 2D phases (micrometer-long wires and extensive honeycomb arrays) that were strongly dependent on electrolyte type, electrolyte and protein concentration, and protein sequence. Even without designed protein-protein interfaces, rod shaped proteins with the protein-mineral interface assembled into 2D ordered phase with defined planes characteristic of smectic phases, which is surprising considering that 2D smectic phases have not been observed in colloidal nanorod systems nor are they predicted by Monte Carlo simulations of non-interacting rods. Thus, these assemblies must result from the competition between protein-protein interactions, protein-mineral interactions, and colloidal forces. Our knowledge of the protein-mineral interactions is informed by machine learning analysis that shows the orientation dependent energy landscape is complex and depends on electrolyte type and concentration, and theoretical analysis that shows a far-field reversal in the polarization response which may be the cause the distinct behavior seen with Na^+ vs K^+. We are now exploring the co-assembly of different proteins at a solid-liquid interface to both investigate the role of complementarity and frustration in defining order and to generate higher-order assemblies. In addition, we are working to “lock” the protein assemblies formed in one set of conditions as a means of creating extensive, anisotropic 2D protein layers as scaffolds for subsequent mineralization and 2nd component assembly under disparate conditions.

Understanding the Impact of Sequence Length, Composition, and Dispersity on the Melting Transition and Assembly of Collagen-Like-Peptide (CLP) Triple Helices Phillip Taylor, April Kloxin and Arthi Jayaraman; University of Delaware, United States

Recent advances in materials design, synthesis, and simulation have allowed the creation of biomimetic materials with responsive yet controllable physicochemical properties. Materials that self-assemble into desired morphologies such as fibrils and supramolecular networks are of particular interest, where their ability to self-assemble can be tuned by applying external stimuli such as heat, light, pH, and salt for a range of applications including in drug delivery and tissue engineering. In this talk, we will present our recent work involving coarse-grained (CG) simulation studies on the melting transitions, fibrillar assembly, and gelation of collagen-like peptides (CLPs). CLPs are thermoresponsive biopolymers in which each CLP chain is made up of repeat units of amino acid triplets, (X-Y-G), where X and Y are usually proline (P) and hydroxyproline (O), respectively. Like native collagen, CLPs have been shown to assemble to form triple helices, fibrils, and gels in aqueous solutions thus exhibiting self-assembly at multiple length scales. In this work, we extend our CG CLP model to simulate CLP heterotrimers in which the length of each of the three CLP strands forming the triple helix can be

different. Inspired by the heterotrimeric nature of natural collagens, we investigate CLP heterotrimers with sticky ends which self-assemble to form fibrils and fibrillar networks driven by interchain hydrogen bonding. We explore how various design parameters including the length and number of sticky ends in each CLP triple helix, CLP triple helix concentration, and temperature (above and below CLP melting transition) impact CLP assembly. Overall, our work highlights the predictive capabilities of MD simulations in guiding experiments, as these complex peptide systems with unique molecular insights can inform new system designs and streamline the discovery of new, biomimetic platforms.

1:05 PM *SM09.02.06
Stimuli Responsive Protein Vesicles for Biocatalysis and Drug Delivery Julie Champion; Georgia Institute of Technology, United States

Protein vesicles incorporating functional, globular proteins have potential in a number of bio-applications such as drug delivery, biocatalysis, and sensing. We have previously created protein vesicles from mCherry-zipper-ELP protein complexes where ELP is a thermo-responsive elastin-like polypeptide, zipper is a coiled-coil, and mCherry is a model folded protein. As we utilize these vesicles, we have replaced mCherry with more useful functional proteins and have engineered the vesicles to provide both stability and responsiveness. We implemented non-natural amino acid incorporation to enable photocrosslinking strategies to stabilize vesicles and control their swelling and release of cargo as a function of salt concentration. We have modified the ELP amino acid sequence to create vesicles that are pH sensitive and swell or disassemble at acidic pH. With this information, we have demonstrated assembly of biocatalytic vesicles with significant improvements in activity over soluble enzyme and produced vesicles for drug delivery capable of carrying and releasing therapeutic cargoes. The wide range of vesicle properties and functions exhibited in these examples, highlight the versatility of protein vesicles as functional and responsive protein materials.

Controlling Blood Coagulation in Supramolecular Vascular Access Grafts via a Feedback-Response Mechanism Boris Arts[1,2] and Patricia Dankers[1,2]; [1]Technische Universiteit Eindhoven, Netherlands; [2]Institute for Complex Molecular Systems, Netherlands

Introduction
Currently 1 in 1000 people in Europe suffer from end-stage renal disease and require hemodialysis[1]. Hemodialysis is a medical procedure to remove waste products from the blood where the blood circulation of the patient is directly connected to a dialysis machine, often, *via* a vascular access graft (VAG). The primary failure of VAGs are due to its low patency rate. Several studies showed that coating the inner lining of the graft, e.g. with heparin, improves the patency rate[2]. However major concerns are expressed regarding the long-term efficacy of those coatings. Hereto the aim of this study is to improve the hemocompatibility of these grafts by controlling blood coagulation through a feedback-response mechanism.

Here we make use of bisurea (BU)-based supramolecular polymers. BU motifs can self-assemble *via* hydrogen bonding resulting in dynamic crosslinks embedded in a soft amorphous polymer phase. Bioactive molecules, e.g. peptides, can be functionalized with BU and mixed in through a modular approach to implement specific properties in the material[3].

In our approach heparin is conjugated to the surface of our VAGs *via* a thrombin cleavable peptide (TCP). When in contact with whole blood the enzyme thrombin is designed to cleave the peptide causing heparin to be released (response). In turn heparin can form an inhibitory complex with anti-thrombin, naturally present in blood, thereby inhibiting thrombin activity and decreasing heparin release (feedback).

Experimental methods
TCPs were synthesized by solid phase peptide synthesis. Next, heparin (Hep) was functionalized with TCPs (Hep-TCP). To surface functionalize the graft material an inverse electron demand Diels Alder (iEDDA)

reaction was utilized between tetrazine (Tz) and bicyclooctyne (BCN). Hereto BU-Tz motifs were mixed in the material, while TCPs were functionalized with a BCN moiety.
Fibrous scaffolds were produced by electrospinning of the BU-polymer with or without BU-Tz. Scaffold morphology and fiber diameter were assessed by scanning electron microscopy (SEM). The iEDDA reaction was carried out by incubating the scaffold in reaction mixture containing Hep-TCP. Surface functionalization was investigated through x-ray photoelectron spectroscopy (XPS), water contact angle (WCA) measurements, and toluidine blue staining.

Results and discussion
TCPs were successfully synthesized. The grafting density of TCP on heparin was analysed by ^{1}H-NMR and UV/vis spectroscopy. A grafting density of 7 was obtained. Scaffolds were obtained by electrospinning with an average fiber diameter of 0.9 ± 0.1 µm and 1.0 ± 0.1 µm for pristine and BU-Tz containing scaffolds, respectively, as observed by SEM.
Activity of thrombin towards TCP and Hep-TCP was assessed in solution by fluorescence spectroscopy. Michaelis-Menten kinetics was used to determine the Michaelis-Menten constant (K_m) and maximum rate of cleavage (V_{max}). Both TCP and Hep-TCP showed similar values of K_m. However, V_{max} almost decreased by a factor 2. This difference might be attributed to inhibitory effects of heparin towards thrombin. Next, scaffolds were surface functionalized with Hep-TCP by incubation in reaction mixture. XPS, WCA and toluidine blue staining revealed the presence of heparin at the surface of the scaffold.

Conclusion
It was shown that heparin could be successfully functionalized at the surface of our supramolecular polymer scaffolds. Next, further investigation towards the cleavage of heparin from the surface of the scaffold should be carried out.

Late News: Binding Affinity of Oligomers Towards SARS CoV 2 S-Protein Through Machine Learning and Experimental Validation Craig J. Neal[1], Katalina Biondi[1], Elayaraja Kolanthai[1], Aida Tayebi[1], Niloofar Yousefi[1], Ganesh Balasubramanian[2], Ozlem Ozmen[1,1], Ivan Garibay[1] and Sudipta Seal[1,1]; [1]University of Central Florida, United States; [2]Lehigh University, United States

The COVID-19 pandemic has led to over 80 million people becoming infected and has claimed more than 1.7 million lives worldwide. As the pandemic progresses, it has become evident that long term solutions for what can be considered as “new normal” are needed. In this work, we ultimately aim to develop a multi-layer, functional coating architecture to *capture-and-kill* SARS-CoV-2, the virus responsible for COVID-19, which can be formed over personal protective equipment and high-touch surfaces requiring frequent sanitation such as in airports, airplanes, hospitals, public spaces, etc. To facilitate the initial *capture* of SARS-CoV-2, a high-specificity binding element must be determined. Given the immediate, dire need to block viral transmission: our approach aims to accelerate the discovery of such components. We use machine learning techniques such as transfer learning to leverage the vast amount of data that exists in drug discovery databases to overcome limitations of data sparsity for COVID-19-related protein/molecular interactions. First, graph convolutional neural network (GCNN) is pre-trained using a dataset curated from public databases such as DrugBank, ChemBL, and DUDE to build a binary classifier. This classifier is used for virtual screening of binding affinities between small molecules (ligands, aptamers) and relevant proteins (targets). Next, we fine-tune the

resulting GCNN on COVID-19-related data. This GCNN model automatically extracts features from defined "protein pockets" (i.e. binding regions; e.g. SARS-CoV2 S-protein receptor binding domain site) and molecular graph representations of ligands, and classifies them as inactive or active. We rank candidate ligands based on binding scores using molecular docking studies for test priority/potential efficacy. Umbrella sampling simulations using molecular dynamics are employed to determine the free energy of binding for the protein-ligand complex as well as to examine the hydrogen bonding, hydrophobic and non-bonded interaction energies to identify possible stimulus for enhancing the specificity of the binding element. Finally, higher priority candidates are further evaluated and experimentally validated using a commercial binding (S-protein/ACE2) inhibition based assay.

1:43 PM SM09.02.09
High Performance Computing and the Covid-19 Virus Bhushan V. Dharmadhikari[1], Sreejita Patra[2] and Prabir Patra[3,4]; [1]MInnesota State University, Mankato, United States; [2]Fairfield Warde High School, United States; [3]University of Bridgeport, Bridgeport, United States; [4]University of Bridgeport, United States

An effective way to predict the binding sites of SARS-COV-2 proteins, and enzymes in pulmonary surfactant, is by taking advantage of present-day High-Performance Computing (HPC) capabilities. These are able to identify the response of various pulmonary surfactant proteins, as well as enzymes on the Covid-19 spike proteins. The fundamental dynamics of COVID-19 and lung defender proteins; such as, but not limited to, pulmonary surfactant protein D (SP-D); need to be understood at the atomic level in order to develop new target-specific drugs that can fight against the infection. Amongst many computational and bioinformatics tools available today, the Molecular dynamics (MD) simulation is of great importance.
We performed an MD simulation on two pulmonary surfactant proteins: SP-A and SP-D, using NAMD and CHARMM27 force field parameters. Molecules were solvated using the TIP3P water model with 150 mM of sodium and chloride ions. All the parameters of the simulation were set according to the parameters described in Jeong et al., 2020. The goal of our simulation study is to help develop a carbon nanotube-based (CNT) protein sensor, which will detect the ultra-low quantity of pulmonary surfactant protein levels with a potential of lung disease implications. The MD results show higher readings of RMSD and SASA in the case of SP-D and CNT interactions. SP-D considers CNT to be a foreign body, and shows a higher level of protein structure change in comparison to SP-A. This may also be the case in the presence of COVID-19 pathogens, and could be a factor in the elevated levels of SP-D. Performing similar HPC simulations with COVID-19 can give us insight into how the proteins and lipid complex inside the pulmonary surfactant are affected by the deadly pathogen.

Modulating the Temperature Response and Performance of Elastin-Based Adhesives Julie C. Liu; Purdue University, United States

Our group has developed bioinspired protein-based adhesives that combine adhesion from DOPA residues found in mussel adhesive proteins with the mechanical properties of elastin, which can also coacervate in response to the environment. These proteins are cytocompatible, provide the strongest bonds of any rationally designed protein when used completely underwater, and can be easily applied underwater because they coacervate in physiological conditions. Recently, we demonstrated that incorporating short, charged peptide tags can be used to tune the coacervation temperature of these proteins. Furthermore, the recombinant protein

design allowed us to systematically probe the individual contributions and interactions of DOPA and thiol chemistries to adhesion.

3:05 PM SM09.03.03
Hierarchically Organized Structure of Electrospun Nanofibers from Computationally Designed Peptide Bundlemers Kyunghee Kim[1], Chris Kloxin[1], Jeffery Saven[2] and Darrin J. Pochan[1]; [1]University of Delaware, United States; [2]University of Pennsylvania, United States

Fiber materials from natural proteins or synthetic polymers are ubiquitous in technology due to many features including a high aspect ratio, large surface area, structural tunability, and excellent/tunable mechanical properties. In contrast to synthetic polymers, which involve a distribution of chain lengths/molecular weights and random coil structures, proteins and peptides can have defined sequences of amino acids with uniform lengths/molecular weights, allowing for precise control over molecules, supramolecular structures, and overall hierarchical assemblies. Herein, computationally designed peptides were used to assemble coiled-coil, or 'bundlemer' building blocks for the construction of higher-order fiber materials. The two different, designed bundlemers are coiled-coil bundles that, subsequent to coiled-coil formation, covalently interact with each other to produce rigid-rod, peptide-based polymers. The extreme rod-like morphology and resultant properties of the bundlemer polymers are confirmed by transmission microscopy (TEM) and rheology. Due to its molecular rigidity, the rod chains can exhibit lyotropic liquid crystalline behavior in concentrated solution. The resultant rod chains are subsequently employed to fabricate fiber materials via electrospinning, preserving their unique orientational behavior within the fibers. The rod chains are preferentially aligned along the fiber axis, which is confirmed by x-ray scattering, scanning microscopy, and polarized optical microscopy. Additionally, the mechanical properties of the final nanofibers will be presented.

Programming Phase Separation of (Poly)Peptides for Controlled Nano- and Micro-Structured Materials Kristi Kiick; University of Delaware, United States

Significant attention has been paid to the sequence specificity of intrinsically disordered peptide and proteins owing to their importance in regulating spatiotemporal organization of membraneless organelles in cells and their demonstrated versatility in producing hydrogels, nanoparticles, and sensor platforms. In our laboratory, we have employed amino acid sequences inspired by structural proteins such as collagen, elastin, and resilin, and have tailored their stimuli-responsive behavior to enable finely tuned control over both microscale and nanoscale structures. Their conjugation via chemical methods affords biomaterials with diverse properties responsive to multiple triggers, and select modification of their sequences facilitates nuanced manipulation of their assembly and responsiveness. We have also investigated the controlled retention and release of cargo via biomimetic mechanisms, offering substantial improvement in activity for both small molecule and macromolecular cargo, with targeted applications in tissue repair.

3:40 PM *SM09.03.05
Adaptable Hydrogels for Organoid Culture Sarah C. Heilshorn; Stanford University, United States

The term "organoid" refers to an artificially grown collection of cells that resembles aspects of a native organ. While organoid culture has the potential to revolutionize our understanding of human biology, current protocols rely on the use of Matrigel, a complex, heterogeneous protein-based material with large batch-to-batch variations that hinder reproducibility. In response, several groups have begun designing synthetic hydrogel systems based on polyethylene glycol to enable the reproducible culture of organoids. As a fully biodegradable alternative, here we present the design of an engineered protein hydrogel system for reproducible organoid culture. Our family of double-network hydrogels undergo two stages of crosslinking: the first stage uses reversibly dynamic covalent chemistry bonds, while the second stage reinforces the hydrogel through thermal-

induced protein aggregation. Recently, the matrix stress relaxation rate (i.e. the ability of a hydrogel to remodel its network connectivity in response to an applied stress) has been demonstrated to have profound effects on encapsulated cells. To date, the role of matrix stress relaxation on organoid cultures has been underexplored. Our engineered double-network of physical interactions results in a gel with a broad dynamic range of tunable mechanical properties, where the gel stiffness is set by the number of crosslinks and the gel stress relaxation rate is independently set by the kinetics of the crosslink binding and unbinding. These novel, double-network hydrogels are being used to study the role of mechanotransduction in the culture of several different types of patient-derived, human organoids.

4:05 PM SM09.03.06

Designed 2D Binary Protein Materials Geared to Modulate Cells Behavior Ariel J. Ben-Sasson[1], Joseph Watson[2], Alice Bittleston[2], Logeshwaran Somasundaram[1], Justin Decarreau[1], Andrew Drabek[3], Stephen Blacklow[3,4], Hannele Ruohola-Baker[1,1], Emmanuel Derivery[2] and David Baker[1,1,1]; [1]University of Washington, United States; [2]University of Cambridge, United Kingdom; [3]Harvard Medical School, United States; [4]Dana-Farber Cancer Institute, United States

Imposing order onto the fundamentally disordered 2D cell membrane matrix upon introduction of an external cue, enables to modulate and reshape the cell behavior. We recently designed a de novo binary 2D protein co-assembling system[1] which, unlike its natural single component counterparts such as S-layers,[2,3] rapidly assemble into an ordered hexagonal array only upon mixing of its two distinct building blocks (protein components). In a binary architecture, individual components can be designed to remain soluble and amenable for facile functionalization in ambient conditions, and the assembly onset timing and location can be directed and determined by the experimental setup.[4] We leverage these novel properties of the binary 2D material and repurpose the system to specifically interact with cell membrane proteins and modulate their surface distribution and downstream signaling.

To this end we first selected a membrane receptor, genetically- or peptide-fused a compatible ligand to one of the arrays components, saturated the cell membrane receptors with said component, removed unbound components from the cell environment, and triggered arrays formation by introducing the second component into the system. We found that the arrays' dihedral building blocks (each component monomer first forms a dihedral homooligomer and the mixture of these forms the arrays) that need to first anchor to the membrane, were not suited for this task. We hypothesized this is likely because cell membranes can wrap around the dihedral components' identical two sides, each displaying an equal number of binding sites, thereby blocking assembly. We therefore devised cyclic pseudo-dihedral versions of the array components, which are partly dihedral to allow proper formation of a 2D array, but overall cyclic to allow directional anchoring.

Because the components are individually stable in ambient conditions and peptide fusion provides a rapid and simple way to diversify the components' functionality prior to array formation (and thereby the system functionality post-array formation), we fused to either or both components optical labels as well as ligands to specifically interact with cell surface receptors. A partial list includes: sfGPF to GBP, a GFP binding peptide, F domain to Tie2, EGFR-binder[5] to EGFR, etc. We exploit the system's multi-parameter controllability to demonstrate formation of biologically-active structures on mammalian cell membranes to tunable dimensions, showcasing ordered receptor clustering and tunable endocytosis properties.

The system's functional modularity, temporal controllability, and targeted location assembly demonstrated here will enable new methods for characterization of structural-functional relations in living systems. This work marries protein engineering and cell biology into a brand new field that would allow probing and elucidating fundamental biological questions.

Terpenes as Feedstock for Polymers—Structural Diversity and Post-Synthetic Opportunities Arjan W. Kleij, Francesco Della Monica and Jeroen Rintjema; ICIQ & ICREA, Spain

Terpenes are naturally occuring unsaturated hydrocarbon compounds produced predominantly by plants. Their unsaturation in combination with their rich structural diversity make them interesting building block candidates for biosourced polymer development. While direct homopolymerization of terpenes is a well-known approach to more complex polyolefin analogues, formation of polyester or polycarbonate macrostructures that incorporate terpene monomers is still at its infancy. In this regard, development of novel catalysts that can address the copolymerization of terpene oxides with either cyclic anhydrides (to form polyesters) or CO_2 (to provide polycarbonates) is of high current interest. Our group has been interested in the use of renewable compounds for heterocyclic and polymer synthesis, and initially our focus was on the copolymerization of *D*-limonene and CO_2. The resultant polycarbonates demonstrated a versatile synthetic behavior allowing to fine-tune functionality, thermal behavior and application potential such as increasing the hydrophobicity. At a later stage, we developed polyesters from a range of terpene oxides (including those on limonene, menthene and carene) illustrating a further diversity of structurally useful polymer backbones that allowed to fine-tune the thermal properties over an extensive glass transition temperature range (50-235 deg). In a more recent embodiment of our work, we have used beta-elemene (a terpene with three distinct double bonds) as a precursor towards functional polymer structures by copolymerization with cyclic anhydrides. This has allowed us to devise polyesters with two built-in functional groups that can be addressed and transformed individually giving

impetus to materials with tunable mechanical and thermal features that are not easily feasible through conventional polymerization processes. Key to the development of all these poly-carbonates and poly-esters has been the enabling power of aluminium- and iron-based aminotriphenolate complexes that have priviliged catalytic reactivity in the activation of sterically congested terpene oxide monomers. In this presentation, both the importance of catalyst design and the potential of the functional terpene-derived polymers will be discussed in detail.

8:30 AM SM10.01.03
Late News: Recyclable Epoxy Vitrimers Based on Imidazolium-Catalyzed Dynamic Ester Cross-Links
Antoine Debuigne, Panagiotis Falireas and Jean-Michel Thomassin; University of Liege, Belgium

Thermosets, and epoxy resins in particular, constitute an important class of materials on the global polymer market that are valued in plethora of applications requiring superior mechanical properties as well as thermal and chemical stability. As downside, however, they can hardly be recycled and reprocessed due to their permanent cross-linked architecture. In response to this concern, adaptable covalent networks featuring dynamic cross-linking based on associative exchange reactions, also called vitrimers, emerged some years ago.[1-4] Above a certain temperature, the kinetic of the exchange reactions increases significantly, the topology of the network changes and the material can be reshaped or healed. In the case of epoxy-acid vitrimers, the relaxation of the network relies on transesterification exchanges promoted by catalysts such as zinc carboxylates, organotin compounds, triphenylphosphine, etc.[1-4] Despite the recognized activity of the latter, the search for alternative non-toxic catalysts with high efficiency, low leaching tendency as well as heat and air sensitivity is still relevant.
As will be discussed in the communication, driven by the attractive properties and catalytic activity of ionic liquids (ILs),[5-6] we designed epoxy-acid resins in the presence of ILs for the first time and produced unprecedented imidazolium-catalyzed epoxy vitrimers.[7] In addition to outstanding features such as chemical and thermal stability, low vapor pressure, high conductivity, imidazolium salts are known as very efficient homogeneous and heterogeneous catalysts especially in transesterification reactions.[5-6] In practice, a series of cross-linked epoxy-acid networks were synthesized from diepoxy and diacid compounds cured in the presence of imidazolium acetate catalysts obtained via a single-step and atom economical Radziszewski multicomponent reaction. The impact of the imidazolium on the course of the curing reaction, the structure of networks and the mechanical properties, will be discussed. The vitrimer-like properties of these IL-containing networks, and so the ability of the imidazolium additives to catalyze the transesterification exchange reactions, will also be demonstrated via stress relaxation experiments. The effect of the nature and concentration of the imidazolium derivatives on the network dynamics will also be discussed. Finally, it will be shown that such imidazolium-containing resins can be recycled several times while preserving their excellent mechanical properties.
In addition to demonstrate the capacity of ILs to play the role of catalysts in the field of adaptable networks, this contribution also emphasizes that a low amount of imidazolium within ester networks is likely to induce some relaxation. Moreover, given the great variety of ILs and the large set of reactions they can catalyze, this approach should be applicable to adaptable networks governed by other types of crosslinking bonds and could contribute to the recycling of various polymer resins in the future.

Late News: Predicting Polymer Degradation by Combining Monte Carlo Simulations and Analytical Models Falk Hoffmann[1], Rainhard Machatschek[1] and Andreas Lendlein[1,2]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]University of Potsdam, Germany

Degradability as a material function is characterized by its kinetics and the degradation time period depending on the specific system environment. (Co)Polyesters like PLGA (poly[rac-lactide-*co*-glycolide]) or PCL (poly(ε-caprolactone)) degrade in aqueous environments via a hydrolysis reaction, which can be catalyzed by enzymes. In case of these two polymers, water molecules diffuse into the polymer in order to reach the ester bonds in the bulk. The degradation depends on the crystallinity and starts in the amorphous region of the polymer. In these regions, polymers are degraded by chain cuts that are occurring either randomly between all repeating units of the polymer (random chain cut mechanism) or preferentially at the end of the polymer chains (chain end cut mechanism). If the generated fragments are small enough, they dissolve in water and diffuse away, which leads to polymer mass loss. We recently showed with a Monte Carlo simulation that the direction of the diffusion of water molecules or small fragments through a semi-crystalline polymer is not influenced by the internal morphology of its crystalline regions and can be described with a random walk behavior through the amorphous regions of the polymer. [1] Here, we present an equation for the degradation of polymer chains for the random chain cut and the end chain cut mechanism depending on the initial number of repeating units, the initial number of chain ends and the length of diffusive fragments. The degradation function of molecular mass consists of three regions, which are characterized by the current molecular weight of the polymer. It is further investigated, how the type of the chain cut mechanism changes the degradation behavior and additional modifications, e.g. the effect of increasing water sorption and/or autocatalysis, are discussed.
Based on the analytical models, which are verified with a Monte Carlo model, we suggest new ways to present and evaluate experimental polymer degradation data that are more precise than the currently established first order assumptions. We demonstrate this by evaluating experimental data and discuss how the model helps to advance degradable material design.

8:50 AM SM10.01.05
Late News: Supercritical CO2 Foaming of PCL Covalent Networks—Taking Benefit From the Thermoreversible Diels–Alder Cycloaddition Maxime Houbben and Jérôme Christine; Center for Education and Research on Macromolecules (CERM), University of Liege (ULiege), Belgium

Foams are versatile materials encountered in our daily life for a wide variety of uses such as cushioning, thermal and acoustic insulation or medical applications. The combination of the mixed properties between a continuous matrix and gas cells and the diversity of pore structures represent a powerful tool for the design of new materials. Among the different polymer foam fabrication processes, the use of supercritical CO_2 has been one of the most investigated in the past decade. Nevertheless, the design of crosslinked polymer foams with high foaming ratio still remains a challenge. Various crosslinking processes mainly based on heating, irradiation with the addition of an external agent have been applied after foaming but remain difficult to perform due to mass transfer issues of the crosslinking agent. When crosslinking occurs before foaming, it dramatically limits the material expansion.

In order to overcome these drawbacks, the present work aims taking advantage of the thermoreversible Diels-Alder cycloaddition to elaborate foams of poly(ε-caprolactone) (PCL) covalent networks. Based on this reaction, we considered to induce cross-linking after the foam expansion by playing on the thermal equilibrium of the thermoreversible Diels-Alder cycloaddition. Therefore, low molar mass star-shape PCL end-capped by furan or maleimide were impregnated with CO_2 under supercritical conditions and then foamed under appropriate control of the pressure and temperature. The resulting foam possesses a much higher volume expansion than a pre-crosslinked sample foamed in the same conditions, thanks to the low crosslinking ratio during foaming. These foams exhibit also improved thermal stability thanks to its chemical crosslinking as

compared to non-crosslinked PCL foams. Interestingly, these foams possess shape memory properties due to the semi-crystallinity of the PCL. Thermal stability and shape memory properties were evaluated by dynamic mechanical analysis in both tensile and compression testing with controlled force mode, stress and temperature ramps. Since significant maleimide/furan adduct cycloreversion can be achieved at high temperature, system reversibility and recyclability have also been attested.

This foaming process proves itself very interesting by the formation of highly physically expanded and recyclable crosslinked foams from a non-initially foamable material. This contribution aims at reporting a new concept that can be used for the preparation of highly expanded and crosslinked polymers foams from any semi-crystalline polymers.

8:55 AM SM10.01.06
Late News: Decarbonization and Sustainability Assessment of the Aerospace Phenolic Resin Supply Chain Alicia Piscitelli and Ross Lee; Villanova University, United States

The establishment of fiber reinforced polymers (FRPs) as lightweight structural components is driven by the need for strong, stable materials in stressful environments. Mainly fashioned from glass or carbon reinforcing fibers impregnated with polymer matrices, these composites can significantly reduce fuel consumption in aircrafts, lowering carbon emissions. Nevertheless, they are currently derived from depletable, greenhouse gas (GHG) emitting fossil fuel sources. FRPs present an opportunity to aid the effort of mitigating climate change, a global phenomenon attributed to the accumulation of atmospheric GHGs and associated with negative, irreparable impacts on ecosystems and humanity. Polymer synthesis using alternative, renewable monomer feedstocks would allow for regenerative material origins while providing a pathway to GHG reductions associated with virgin supplies.
One of the most common polymer matrices in aerospace composites is phenolic resin, a material used in secondary structural components for its low flammability and high temperature resistance. Due to strict material specifications within the aerospace industry, the phenol and formaldehyde monomers used to synthesize phenolics must be identical to current supplies. Therefore, the foundational requirements in decarbonizing phenolic's supply chain are scaling up benchtop methods or leveraging currently industrialized processes that produce pure monomers which are also renewably sourced. Current efforts include thermochemical conversion of biomass and fermentation of sugars for phenol and oxidation of bio-methanol for formaldehyde. Another benefit of creating pure supplies is the opportunity to directly substitute feedstocks taking advantage of downstream infrastructure.
Establishing the sustainability of renewable polymer feedstocks requires a balance of whole system perspectives which include social, technical, economic, environmental, and political aspects. This work will assess material criticality and resiliency of feedstocks for organic materials through metrics such as the magnitude and location of material reserves, material substitutability, and corporate importance from a whole systems perspective.

9:10 AM *SM10.01.07
Development and Applications of Self-Immolative Polyglyoxylates Quinton E. Sirianni, Amir Rabiee Kenaree, Rebecca Yardley and Elizabeth Gillies; The University of Western Ontario, Canada

Many traditional applications of polymers have relied on their high long-term stability. For example, it is desired that plastic packaging retains its structure and properties for months or years, while the plastic used in joint replacements should survive for decades in the human body. However, there are growing concerns about the impact of plastic pollution on humans and the environment. It is predicted that almost 12,000 metric tons of plastic will have accumulated in landfills and the environment by 2050. Furthermore, for many applications of polymers in therapeutics and regenerative medicine, it is desired that polymers break down, rather than accumulate in the body. Therefore, interest in developing degradable polymers has been growing. Significant progress has been made in the preparation and application of polyesters and polysaccharides. However, these polymers degrade gradually in many different environments, sometimes more slowly or more rapidly than desired, which hinders their widespread application. To gain a new level of control over when and where

polymers degrade, we have been developing “self-immolative polymers” (SIPs). These polymers are designed to be stable during their use, but then to degrade (depolymerize) rapidly when triggered by a stimulus. Their mechanism of degradation involves a reaction cascade such that a single stimulus event is sufficient to degrade an entire polymer chain. In addition, the stimulus to which they respond can be easily changed by switching a single capping molecule at the end of the polymer. This presentation will describe our research on polyglyoxylates. Polyglyoxylates were synthesized by anionic-like polymerization mechanisms. A diverse library of end-caps was developed, allowing depolymerization to be triggered by stimuli including light, heat, pH changes, reducing agents, and reactive oxygen species. The properties of the polyglyoxylates were tuned by incorporating different pendent groups, either through polymerization of different glyoxylate monomers or through post-polymerization transesterification reactions. Furthermore, amidation reactions were used to convert readily accessible poly(ethyl glyoxylate) to various polyglyoxylamides, which exhibit very different properties than the polyglyoxylates. The function of these degradable polymers was demonstrated through formation of polymer particles, micelles, and vesicles that were capable of loading and releasing molecules on demand. In addition, polyglyoxylates were applied as coatings to release agricultural chemicals in response to stimuli. Overall, this work demonstrates the versatility and applicability of self-immolative polymers across a range of fields.

10:30 AM *SM10.02.01
From Natural Phenols to High Properties Sustainable Polymers—A Platform Approach Sylvain Caillol; Université de Montpellier, France

Recent years have witnessed an increasing demand on renewable resource-derived polymers owing to increasing environmental concern and restricted availability of petrochemical re-sources. Thus, a great deal of attention was paid to renewable resources-derived polymers and to thermosetting materials especially, since they are crosslinked polymers and thus cannot be recycled. Also, most of thermosetting materials contain aromatic monomers, able to confer high mechanical and thermal properties to the network. Therefore, the access to biobased, non-harmful, and available aromatic monomers is one of the main challenges of the years to come. Starting from phenols available in large volumes from renewable resources, our team designed platforms of chemicals usable for the synthesis of various polymers. Hence, we studied, tanins, lignin-derived vanillin, eugenol or cardanol. Various aromatic building blocks bearing polymerizable functions were synthesized: epoxy, amine, acid, carbonate, alcohol, (meth)acrylates... (Figure 1). These bio-based aromatic monomers can potentially lead to numerous polymers. The substitution of bisphenol A was studied in epoxy thermosets. Materials were prepared from the biobased epoxy monomers obtained from vanillin. Their thermo-mechanical properties were investigated and the effect of the monomer structure was discussed. High Tg phenol-free phenolic thermosets have been synthesized. Phenol and formaldehyde free phenolic thermosets were also prepared with high thermal stability. The properties of the materials prepared were found to be comparable to the current industrial references, indicating a potential replacement of fossil resources. The tunability of the final properties was achieved through the choice of monomer and through a well-controlled oligomerization reaction of these monomers.

10:55 AM SM10.02.02
Characterization of Fibril Hierarchical Self-Assembly of Sugar-Based Poly(D-glucose carbonate) Amphiphilic Block Copolymers in Solution Jee Young Lee[1], Yue Song[2], Michiel G. Wessels[1], Arthi Jayaraman[1,1], Karen L. Wooley[2] and Darrin J. Pochan[1]; [1]University of Delaware, United States; [2]Texas A&M

University, United States

Motivated by the recent drive to replace petrochemical plastics for more renewable source-based materials, our efforts focus on designing and characterizing a next generation biomolecular-based polymer for solution assembly applications. Sugar-derived poly(D-glucose carbonate) (PGC) molecules are synthesized, and their solution chain dynamics and assembly behavior are analyzed in the production of nanoparticles. Unlike conventional vinyl-based polymers with flexible coil-like chains, the PGC system is characterized by its entire backbone composed of semiflexible, hydrophobic glucose monomers where its chain rigidity and local amphiphilicity created by the backbone compared to added side chains are expected to significantly impact both local and global solution chain behavior. First, with a PGC-containing amphiphilic diblock copolymer system, we explored kinetically controlled assembly pathways by variation of solvent composition that lead to the hierarchical assembly of ribbon-like fibers with features that do not follow the traditional BCP micellar-like packing. We show that while the stiffness of the PGC backbone impacts the local BCP chain conformation and chain packing within the assembled nanostructure, the backbone hydrophobicity drives the unidirectional hierarchical fibril growth by the formation of soft patchy precursor particles. Second, to understand how the chain behavior affects the final assembly morphology, the hydrophilic block equivalent homopolymers were studied using small-angle neutron scattering techniques to obtain polymer chain solution properties for a better understanding of the PGC block copolymer chains in similar solvent conditions. These results suggest polymers with unconventional backbone chemistries, frequently found in natural carbohydrate-based molecules, can shed light on the effects of polymer backbone rigidity and hydrophobicity on the assembly pathway and final assembled structures while also presenting opportunities to better understand other bio-inspired green chemistries-based molecules can organize and assemble in various environment conditions.

11:10 AM SM10.02.03

Late News: Multifunctionality by Core/Shell Design of PLLA/PDLA Nanofibres Axel T. Neffe[1], Quanchao Zhang[1], Paul J. Hommes-Schattmann[1], Weiwei Wang[1], Xun Xu[1], Bilal S. Ahmad[2], Gareth Williams[2] and Andreas Lendlein[1]; [1]Helmholtz-Zentrum Geesthacht, Germany; [2]University College London, United Kingdom

Polymeric materials modulating regenerative processes in vivo need to fulfill multiple requirements that include handling, macroscopic performance after implantation, guiding of cellular behavior, as well as degradation creating space for new tissue to form. Adressing the individual requirements by macromolecular chemistry is likely to lead to highly complex polymer systems. In addition, biomaterials with novel chemistry face substantial hurdles in the regulatory process. For translation, use of components already established in the clinic would be highly beneficial, but requires the realization of multifunctionality [1] by material design. Electrospun polymer meshes are of interest as they allow a multiscale design by adjustment of fiber diameter and fiber organization in the mesh (orientation, density) in addition to the macroscopic shape. Furthermore, the porous structure allows facilitates cell migration. Polylactide (PLA) is – due to the histocompatibility with different tissues and its hydrolytic degradability - commonly applied in biomedicine. The rate of crystallization of PLA is however quite slow, and as crystallinity of the polymer matrix is of importance for its mechanical behavior, control over the crystallization would be advantageous. Interestingly, mixtures of isotactic Poly(L-lactide) (PLLA) and Poly(D-lactide) (PDLA) form stereocrystallites [2] that are formed faster than PLA homocrystallites, and moreover have higher thermal, mechanical, and hydrolytic resistance. Furthermore, lactide is considered a green polymer.

Here, we hypothesized that by forming coaxial nanofibers of PLLA and PDLA, it is possible to initiate the formation of stereocrystallites at the interface of the two layers and therefore have a temporal and spatial control over the crystallization of the matrix. In fact, electrospinning of coaxial fibers consisting of a lower M_w (= 47 kg mol^{-1}) PLLA core and a higher M_w (= 147 kg mol^{-1}) PDLA shell resulted in amorphous fibers. Annealing of the fibers above the glass transition temperature T_g led to stereocrystallization as shown by Wide Angle X-Ray Scattering. DSC studies could be used to quantify crystallization, but does not represent the situation after spinning as crystallization also happened during the heating phase. The crystallization led to changes in the mechanical behavior as determined in tensile tests at room and temperature in the dry state and under physiological conditions. Interestingly, the stereocrystal containing materials had lower Young's moduli E (9±1

MPa) compared to the as-spun materials (46±8 MPa), and were also softer than PDLA or PLLA, which can be rationalized by localization of the crystals and relaxation effects. In a second step, gelatin was added to the PDLA phase in order to generate fibers that display adhesion sites for cells on the surface, which was shown by labelling of gelatin on the fiber surface. Gelatin did not negatively influence the (stereo)crystallization of PLA and led to a slight reduction of the T_g. The overall morphology can therefore be understood as semiinterpenetrating polymer network with physical netpoints (crystallites). Altogether, a material system with crystallization controlled by design as well as with cell adhesion sites could be formed in one step based on components established in the clinics.

11:25 AM SM10.02.04
Late News: A Semi-Continuous Flow Platform for the Direct Preparation of Novel Cyclic Phosphate Monomers from Bulk Chemicals and Their Further Polymerization Toward Functional Polyphosphoesters Romain Morodo, Raphaël G. Riva, Christine Jerome and Jean-Christophe M. Monbaliu; University of Liège, Belgium

Polyphosphoesters have recently emerged as new materials for biomedical applications thanks to their biocompatibility and biodegradability properties that can be finely tuned by varying their functional side-chains linked to a pentavalent phosphorus. The preparation of polyphosphoesters frequently relies on the ring-opening polymerization of 5-membered cyclic phosphate monomers (CPMs), which are generally synthetized through a 3-step procedure. Starting from bulk chemicals the preparation of such monomers by a batch process is time-consuming, difficult to scale-up and involves safety concerns such as the uncontrolled generation of HCl by-product and the handling of sensitive and corrosive intermediates. To this end, we developed a semi-continuous flow platform allowing the direct preparation of CPMs starting from PCl_3 and a 1,2-diol derivative without isolation of the intermediates. The first step involved the preparation of cyclic chlorophosphite derivatives by reacting a neat diol with a highly concentrated organic solution of PCl_3 at room temperature with an associated residence time of 1 minute in a compact coil reactor. This procedure allowed to produce a wide range of novel cyclic chlorophosphites starting from various diols in moderate to high yields and with a daily productivity of up to ~500 g. The scope was also extended to thioalcohol, dithiol, aminoalcohol and diamine derivatives and the process was eventually adapted to a base-involving procedure allowing the conversion of more demanding substrates such as highly hindered pinacol-type diols. The next oxidation step toward cyclic chlorophosphates was directly concatenated with the upstream production of chlorophosphites in a single continuous flow system. A high pressure and an improved mixing capacity allowed to perform the oxidation using 4 equivalents of molecular oxygen in only 21 seconds of residence time at 65 °C toward a quantitative conversion while batch procedures usually require tens of hours or days of reaction time. A final functionalization of chlorophosphates toward various CPMs was subsequently integrated in a semi-continuous flow platform where the effluent coming from the oxidation step is directly reacted in a batch reactor. The system allowed to produce the CPMs directly from PCl_3 in an extremely shortened time by a single process without purification and isolation of the sensitive intermediates while mitigating the hazards linked the corrosive derivatives produced. Among the novel monomers prepared, a bifunctional derivative was successfully copolymerized by ring-opening polymerization allowing the introduction of a typical alkoxy pendant group linked to a pentavalent phosphorus and an additional convertible chloromethyl function directly linked to a main-chain carbon. The introduction of such functionalizations opens new opportunities for the preparation of novel materials with various properties which could be time-dependent through the quick (P-linked group) or slower (C-linked group) degradation of the polyphosphoester linkages.

Late News: Fabrication of Hemp Fiber Composites for Hydroponic Application via PVA-Assisted Crosslinking of Hemp Lignin Avinash Kumar Both, Mark A. Helle and Chin Li Cheung; University of Nebraska–Lincoln, United States

Lignin is an abundant, under-utilized, and cheaply available bioresource. It is a phenolic macromolecule which substantially differs depending on the plant species and the type of isolation process. In this presentation, we describe a green approach to make making chemically reactive lignins and lignin-containing composite materials. These composite materials were shown to be applicable as growing media for hydroponics. Our reaction scheme was to couple lignin with a bifunctional linker molecule comprising of an aromatic amine group and a protected vinyl sulfone group. The chemical process begins with the conversion of the aniline-amine group of this linker to an electrophilic diazonium salt to react with the electron-rich naphthalene rings of the lignin. The other functional end of the linker was then deprotected under basic conditions to yield the vinyl sulfone for forming covalent bonds to the hydroxyl groups of substrates via the Michael reaction. The only byproducts are harmless inorganic salts. Unlike common composite fabrication processed that require organic solvent, the process is performed in water and thus is eco-friendly.
The increase in hemp farming in the U.S. in recent years has resulted in a large supply of hemp fibers. We demonstrated the application of our green approach to fabricate hemp fiber composites for hydropnics. The lignin inside hemp fibers was functionalized by employing a bifunctional linkers to make chemically reactive hemp. The anchored vinyl sulfonate group of the linker was then used to cross-link hemp fibers with polyvinyl alcohol (PVA) to yield hemp fiber composites. These hemp composites were analyzed to have a Young's modulus of 5.4×10^{-3} GPa but were also found durable. Other properties of this composite such as water retention capacity values, C/N ratios, and salinity were evaluated to discern their suitability for hydroponic applications. The hemp fiber composites were applied as hydroponic growing media to grow model plant systems. Our results demonstrated that the hemp composites can be as effective growing media as other commercially available ones.

Carbon Dioxide for Producing Non-Isocyanate Polyurethane Foams, Adhesives, Hydrogels and—Much More! Christophe Detrembleur, Fabiana Siragusa, Thomas Habets, Florent Monie, Maxime Bourguignon, Christine Jerome and Bruno Grignard; CERM, University of Liege, Belgium

The recycling of carbon dioxide (CO_2) by transforming this waste into value has become a major goal in contemporary science. Strategies are emerging to turn this renewable carbon feedstock into valuable engineering plastics while diversifying renewable resources for the sustainable production of consumer materials.[1] Novel routes to efficiently turn CO_2 into polymers are expected to accelerate and facilitate the transition from existing fossil-based to future generations of more sustainable materials while trying to meet the requirements of a circular economy for consumer plastics.
In the first part of this talk, we will discuss how CO_2 can be converted into monomers[2] that are then involved in step-growth copolymerizations with diamines to produce non-isocyanate polyurethanes (NIPUs)[3], greener variants of conventional polyurethanes that are commonly prepared by the toxic isocyanate chemistry. These monomers can be easily and quantitatively produced at the multi-kg scale under solvent-free conditions in our lab. We will show how they can be exploited to design some representative high performance NIPUs materials. We will first discuss how adhesives and coatings can be produced under solvent-free conditions, with adhesion performances on various substrates (aluminum, wood, stainless steel, glass) that compete to those of commercial products, provided that appropriate curing is applied.[4] We will then report on an innovative robust and solvent-free process for the construction of flexible or rigid self-blown NIPU foams that offers the first realistic alternative to the traditional isocyanate route.[5] In this process, the CO_2-based monomer is not only exploited to construct the NIPU matrix but also for its self-blowing. If time permits, we will also show that NIPUs hydrogels can be produced in water at room temperature without any catalyst with impressive short gel times.[6] These hydrogels can be easily reinforced by introducing natural polymers or clay in the formulations prior to curing. All these technologies can be easily scaled-up and are highly versatile, opening new opportunities in the design of more sustainable materials while valorizing CO_2 as a renewable carbon feedstock.
In the second part of the talk, we will describe an innovative approach for the facile preparation of new regioregular functional NIPUs (e.g. poly(oxo-urethane)s and poly(oxazolidone)s) at room temperature by using a novel family of monomers prepared by the CO_2 chemistry.[7] The special reactivity of these monomers will be

discussed, and if time permits, we will show how they can be exploited for the facile construction of other relevant polymers (e.g. polycarbonates, sulfur-containing polymers) under mild operating conditions.[7,8]

New Exo-Vinylenecarbonates Based on CO_2 for the Synthesis of Polyurethanes and Polycarbonates

Thomas Schaub[1,2]; [1]BASF SE, Germany; [2]Catalysis Research Laboratory (CaRLa), Germany

Based on the bulk chemical 1,4-butynediol, readily available epoxides and carbon dioxide, a new series of unsubstituted exovinylene carbonates were synthesised. Chemoselective additions of diamines or diols to these cyclic carbonates allow the regiocontrolled synthesis of new functionalised polyurethanes and polycarbonates under mild conditions. This route to polyurethanes avoids the use of toxic isocyanates.
For the monomer synthesis, we also developed a straight-forward approach to separate the catalyst from the exo-vinylene carbonate (EVC) products of the carboxylative cyclisation of primary propargylic alcohols. The liquid-liquid phase synthesis utilises lipophilic silver(I) carboxylate salts and *N,N*-dioctyl modified phosphine (FatPhos) ligands to enhance catalyst solubility in non-polar solvents. Following simple liquid-liquid phase separation, EVCs relevant as monomers for poly(hydroxyurethane) and poly(carbonate) synthesis were isolated in the non-miscible polar phase in good yields and the catalyst was used in recycle experiments.

Late News: Biodegradable Aliphatic Polyphosphoester-Based Particles—Green Production by Batch and Flow Processes

Philippe J. Lecomte, Christine Jerome, Jean-Christophe M. Monbaliu, Raphaël G. Riva, Jérémie Caprasse and Romain Morodo; University of Liège (ULiege), Belgium

Nano- and microparticles are used as carriers for the controlled delivery of an active ingredient with a high potential for applications for, among others, the health care and personal care industry. Particles made up of aliphatic polylactones, typically, polylactide, polyglycolide and polycaprolactone are very well-known since many years. Aliphatic polyphosphoesters less popular even though they this class of polymers has witnessed a renewed interest. This communication aims at comparing the potential of aliphatic polylactones and aliphatic polyphophoesters with a special attention paid on particles, based on the recent developments carried out in the Center of Education and Research of Macromolecules of the University of Liège.
Ring-opening polymerization of 5-membered cyclic polyphosphoesters is very efficient for the synthesis of high molar mass aliphatic polyphosphoesters. As far as cyclic 5-memberd phosphates are concerned, their extremely high sensitivity to hydrolysis remains a strong limitation at the time being. In this context, efficient processes allowing the synthesis of a wide range of aliphatic polyphosphoesters, functionalized or not, will be reported based on: (1) flow technologies, (2) organocatalysis and (3) chemical modification of the polymers. Advantages and drawbacks of aliphatic polyphosphoesters compared to polyesters will be detailed with a special attention on both the synthesis of these polymers and their properties, to assess their potential for future applications. Particles made up of biodegradable poly(phospho)esters will be shown to be prepared by the self-assembly of amphiphilic polymers or by nanoprecipitation in batch or in flow reactors. Depending on the preparation process and the chemical structure of the polyesters, the size and size-dispersity of particles as well as the loading content, loading efficiency and release rate of a model active ingredient will be discussed.

Acknowlegements: Philippe Lecomte is research associate by the belgian FNRS. The authors thanks all the partners of the IN-Flow project *carried out under the Interreg V-A Euregio Meuse-Rhine Programme, with €2.1 million from the European Regional Development Fund (ERDF). By investing EU funds in Interreg projects, the European Union invests directly in economic development, innovation, territorial development, social inclusion, and education in the Euregio Meuse-Rhine.*

1:40 PM SM10.03.03
3D Printing Sustainable High-Performance Nanocellulose and Chitosan Composites Rigoberto C. Advincula[1,2,3]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]Case Western Reserve University, United States

The ecosystem of 3D printing to fabricate objects from polymeric nanocomposite materials is important for wide use and rapid scale development towards high-performance materials. Other materials based on metallic, ceramic, hydrogels, and other non-metallic do not have as wide a range of properties leading to new structure-composition-property relationships. Nanomaterials together with sustainable biobased polymers can be used to enhance performance in thermoplastics, thermosets, and elastomers and their thermo-mechanical properties. In this talk, we emphasize the use of sustainable cellulosic and non-cellulosic additives to improve the performance of composite polymer materials. This has been demonstrated in the choices of 3D printing methodologies (FDM, SLA, SLS, VSP) which can make use of blended or formulated compositions of these sustainable filler materials. By incorporating nanomaterials such as nanocellulose, nanosilica, nanoclays with 3D printing new designs of toughened materials on commodity polymers, the value chain of biobased materials can be extended to higher values. 4D Printing will be demonstrated based on stimuli-responsive properties as reported.

1:55 PM SM10.03.04
Late News: Recyclable Porous Ionic Liquid Catalysts from One-Pot Emulsion Templating Multicomponent Polymerization Pierre Stiernet, Abdelhafid Aqil and Antoine Debuigne; Uliège, Belgium

Porous poly(ionic liquid)s (PILs) combine the intrinsic features of ionic liquids (ILs) with properties of polymers and porous structures notably enlarged surface area, high ionic density, spatial structuration, and the tunability of their properties via counterions exchange. Over the years, they have become essential materials for many applications, i.e., gas separation, CO2 capture, energy storage, polymer electrolyte in Li-batteries, sensors and catalysis.[1] Amongst them, porous poly(imidazolium)s (PIMs) are of great interest for cutting edge

applications, especially for heterogenous catalysis. Their chemical composition catalyzes a wide range of reactions while their macrostructure allows easy recyclability without the need of advanced purification methods. However, structuring PIMs into porous materials is not trivial and requires multistep approaches based on the polymerization of preformed imidazolium monomers[2] or by post-modification of porous organic networks. Therefore, the search for simpler and straightforward synthesis of porous PILs is highly relevant. In this respect, the emergence of multicomponent reactions (MCR), in which three or more compounds react and form a product containing essentially all atoms of the starting reagents, offers new opportunities.[3] This communication aims at reporting a straightforward and atom economical approach for designing interconnected macroporous imidazolium-based networks. The latter combines for the first time the aqueous mediated Radziszewski MCR[4] under high internal phase emulsion (HIPE) conditions. The catalytic activity and recyclability of these materials are illustrated for transesterification and decarboxylation reactions.[5]

2:00 PM SM10.03.05
Late News: Full Circle Recycling of Silicones and Their Resins Joseph Furgal and Buddhima Rupasinghe; Bowling Green State University, United States

Siloxane based polymeric materials are widely used all over the world due to their chemical, mechanical, and thermal stability, and low-toxicity. Despite their usefulness, a critical issue has been the ability to recycle them effectively. The present methods used to recycle silicone-based materials, such as PDMS, involve high temperatures/pressures, and complicated setups. To address this issue, we have established an efficient room temperature technique for depolymerization of silicone-based polymers and resins in the presence of low catalytic amounts of fluoride in specific high swell organic solvents. The products primarily contain cyclic siloxane units (D4, D5, D6) as verified by GCMS and ^{29}Si NMR. Nearly any silicone resin can be depolymerized quite rapidly using our methods. Silicone rich systems result in the best conversions and the highest quantity of identifiable cyclics, while complex resins resulted in complicated products alongside discernable cyclics. We have also repolymerized the products from this process to reform silicones via acid, base and fluoride catalysis. Our discovery has the potential for large scale industrial processing due to the use of mild conditions and solvent recycling ability.

2:15 PM *SM10.03.06
Using Efficent Chemistries to Create Sustainable Materials Andrew P. Dove; University of Birmingham, United Kingdom

The global need to devise strategies that can provide applicable solutions to recycling plastics is clear and urgent. It is estimated that a total of 8300 million metric tonnes of plastics have been produced to date. Incredibly, more than 40 years after the launch of the recycling symbol, less than 10% of plastics that have been manufactured are recycled; the rest are either poured into landfill, burned to produce CO2 and other harmful gases or, worst of all, discarded into the environment. There are several potential approaches to solving the plastic problem, all of which have merit and will address a part of the problem in a different way. To ensure success, all approaches need to be followed. One of the best known is the creation of a circular economy, in which used plastic is recycled chemically to yield virgin grade materials. Our work has focussed on new methods to catalytically recycle polymers as well as develop new materials with interesting properties that can be fully recycled by chemical means. Efficency of the chemistry used is an important aspect to ensure that the energy requirements remain low and waste is limited. To this end, we have focussed on applying highly efficient click chemistries to create new materials, including those from sustainably sourced starting materials, that can be assembled and disassembled on demand. This presentation will cover some of the latest developments from our laboratory in these areas.

2:40 PM SM10.03.07
Late News: Degradation Kinetics of oligo(ε-caprolactone) Ultrathin Films—Influence of crystallinity
Shivam Saretia[1,2], Rainhard Machatschek[1] and Andreas Lendlein[1,2]; [1]Helmholtz Zentrum-Geesthacht, Germany; [2]University of Potsdam, Germany

Besides the hydrolysis rate of the ester bonds, the degradation behavior of polymers is also influenced by their crystallinity.[1] The tight assembly of polymer chains restricts the access of water/ions to cleavable chemical bonds. In bulk, it is often very difficult to quantify this effect. Degradation-induced crystallization can promote an increase in crystallinity during degradation, which cannot be distinguished from an increase in crystallinity simple because of faster degradation of amorphous segments. Polymers like oligo(ε-caprolactone) (OCL) exhibit hydrolytic degradation times even at acidic pH in the range of several days to months. During that time period other ageing phenomena can occur as well. In contrast, the degradation of OCL in ultrathin films takes only a few hours. Here, we hypothesize that we can determine the degradation rate of OCL segments in amorphous and crystalline domains via this approach, which can further be utilized to tailor the degradation of ultrathin OCL films in acidic environments.

We apply the Langmuir technique to generate ultrathin OCL films at the air-liquid interface with precisely adjusted semi-crystalline morphology, including crystal size, number density, thickness, and melting temperature.[2] Partially crystalline or highly crystalline films of hydroxy and methacrylate end capped linear oligomers are prepared by crystallization at different film areas and surface pressures. Both semi-crystalline films and amorphous films are hydrolytically degraded at pH ~1.5 both at room- and at elevated temperature, either at constant surface pressure at the air-water interface or as transferred films on silicon surfaces.
By comparing the data for highly crystalline with amorphous films using appropriate quantitative models, we are able to extract the degradation rate constants of OCL segments in amorphous and crystalline domains. The comparison between the polymers with two different end-groups enables further insights whether the chain packing at the crystal surfaces affects free volume within crystalline regions, thereby increasing the permeation of proteolytic ions for faster hydrolytic degradation. Amorphous ultrathin films of OCL diol degraded completely at pH 1.2 within ~16 h. Yet, highly crystalline ultrathin films of OCL diol degraded only by ~10 % after 14 h at the same pH, even at an elevated temperature of 46 °C.

The present work demonstrates the option to control the hydrolytic degradation of OCL in ultrathin films via crystallization. Besides for determination of degradation rate constants, thin layers with controlled crystallinity can be further investigated as degradable coatings. These coatings are thermoswitchable and the difference in degradation behavior between crystalline/amorphous films suggest a thermally induced acceleration of degradation.

Renewable Polymers via Precision Polymerization of Plant-Derived Vinyl Monomers Masami Kamigaito; Nagoya University, Japan

Renewable polymer is now indispensable for sustainable developments of modern materials. Vinyl polymers constitute one of the largest families among various synthetic polymers and are generally prepared from

petroleum-derived vinyl monomers. Nature also produces a variety of vinyl compounds with unique structures, which are often observed in terpenoids and phenylpropanoids. We found that these natural vinyl compounds can be classified into several families such as non-polar olefins, styrenes, and acrylates in a similar way to petroleum-derived vinyl monomers depending on the substituents attached to the vinyl groups. This suggests that they can be polymerized by designing suitable catalysts and initiating systems for the monomers. In addition, their unique natural structures will give specific properties and functions to the resulting bio-based polymers, which cannot be easily attained by polymerization of common simple vinyl monomers derived from petroleum.
From this viewpoint, we have been investigating polymerization of various unique bio-based vinyl compounds, which can be directly obtained from plants or indirectly derived from natural compounds via simple transformation reactions. In particular, we have been focusing on the controlled polymerizations because the controlled polymer structures will further bestow special properties and functions to the bio-based polymers. In this talk, I will discuss our recent results on controlled radical and cationic polymerizations of bio-based vinyl monomers derived from terpenoids and phenylpropanoids for high-performance and functional sustainable polymeric materials.

4:25 PM SM10.04.02
Directional Evaporative Crystallization of Poly(Lactic Acid) in Presence of Polyphenols Yejin Park and Jongwhi Lee; Chung-Ang University, Korea (the Republic of)

The biodegradable polymer, poly(lactic acid) (PLA), has become a material of high industrial value. However, the low toughness and low heat distortion temperature of PLA still limits its industrial use. Since controlling crystallinity is a convenient strategy to improve the heat distortion temperature, many studies have been conducted on PLA crystal engineering. The use of crystallization additives could accelerate the nucleation and growth behavior of PLA, but they should have environmentally friendly properties. Herein, natural polyphenols were employed to improve the crystallinity of PLA, which have strong antioxidant properties. Natural polyphenols can be obtained from various fruits and plants, and they are environmentally friendly and harmless to humans. Polyphenols were used as nucleants for the heterogeneous nucleation of PLA chains by adding in solutions for film casting. Polyphenols were prepared with controlling their sizes in two ways, a top-down ball milling method and a bottom-up precipitation method. PLA was dissolved into a volatile solvent at room temperature, and the biopolymer films were made by a solvent-casting technique. The cast film of solution was partially contacted with a hot plate and experienced directional evaporation under one-way air flow. As a nucleation agent, the existence of polyphenols improved the crystallinity of the PLA films. The polyphenols prepared by the ball milling and precipitation methods have smaller particle sizes than the corresponding raw polyphenols. The degree of PLA crystallinity reflects the size of the polyphenol particles: The smaller the particle size, the larger the surface area, and more nuclei could result. The one-way airflow at a proper temperature produced controlled moving of crystallization front, and as a result, uniform PLA films having polyphenol nuclei were produced. It is expected that natural polyphenols, which have biocompatibility and biodegradability, could serve as crystallization seeds in making PLA films by controlling the crystallinity of PLA, and this novel way to control the crystallinity of PLA could offer new solutions for the future replacement of plastics.

4:30 PM SM10.04.04
Large Thermal Conductivity Anisotropy of Orientated Cellulose-Clay Composite for Fire Retardancy
Guantong Wang[1], Jing Liu[1], Lilian Medina[2], Lengwan Li[2], Bin Xu[1], Lars Berglund[2] and Junichiro Shiomi[1]; [1]The University of Tokyo, Japan; [2]KTH Royal Institute of Technology, Sweden

Flame-retardant materials are widely used in various applications. Most of the flame-retardant materials contain Br and Cl that are reported to form toxins. Montmorillonite-clay/cellulose nanocomposite, a new green functional flame retardant material, shows excellent mechanical properties, gas barrier properties, biodegradability, and flame retardant properties. When the multilayered montmorillonite-clay/cellulose composites are subjected to fire, montmorillonite forms protective surface barriers of intaking oxygen and

volatiles, meanwhile, outside layers of dilative fire retardant composites form a char layer to protect further propagation and insulate the underlayer materials. Nano-cellulose is induced as for its high strength, and high crystalline stiffness to improve composites' mechanical properties, and it is considered as an excellent candidate in the use of thermal management with high thermal conductivity. This intrinsic high thermal conductivity of nano-fibrillated cellulose has brought a new concept for montmorillonite clay/cellulose flame retardant materials [1], reducing the highest temperature by modifying thermal degradation route with the help of high anisotropy ratio of thermal conductivity composites in in-plane direction to dissipate heat. However, the anisotropy of thermal conductivities of composites has not been fully investigated. In this work, we prepared CNF water suspension and clay suspension and mixed them for around five minutes. Next, clay-CNF co-suspension was filtered under vacuum conditions for several hours by using ultra-filtration membranes. The samples which obtained after filtration was finally dried in a dryer under 93 °C for 15 minutes[1]. we measured the anisotropy ratio of thermal conductivity as a function of montmorillonite-clay/cellulose content. We result shows that the cross-plane thermal conductivity depends on the clay content non-monotonically; as the clay content increases from 0% (pure cellulose), the thermal conductivity decreases until the content reaches 80% and then increases until 100%. The in-plane thermal conductivity also shows a non-monotonic dependence on the content; increasing until 50 % and then decreases. This gives rise to the largest anisotropy at clay content of 50 %, where in-plane thermal conductivity is 30 times larger than the cross-plane thermal conductivity. Furthermore, Raman spectroscopy was performed to investigate the orientation of cellulose nanofibrils in the composite, and the analysis reveals that the degree of alignment strongly depends on the clay content with the maximum achieved at 50 % content, revealing that the large anisotropy is originated from the alignment of the cellulose nanofibrils.

Lignin Fractionation and Valorization with Aqueous Renewable Solvents—Focusing on Higher-Value Applications Mark Thies[1], Amod A. Ogale[1] and Mojgan Nejad[2]; [1]Clemson University, United States; [2]Michigan State University, United States

By exploiting the novel liquid–liquid equilibrium (LLE) that exists between lignin and hot, one-phase solutions of aqueous renewable solvents, crude bulk lignins can be simultaneously fractionated, cleaned, and solvated for conversion to higher-value, high-quality bioproducts. This unusual LLE phase behavior forms the basis for a fractionation process that we refer to as Aqueous Lignin Purification with Hot Agents, or ALPHA. With this recently patented technology, simultaneous control of both lignin purity and molecular weight becomes possible. Furthermore, ALPHA has also been developed for continuous operation, so it can be commercially scaled-up. Finally, the technology has the added advantage of using renewable solvents that are produced within the biorefinery itself, including acetic acid and ethanol.
Lignin is like any other polymer in that the molecular weight can have a dramatic impact on its suitability for a given application. In addition, polymer purity can also be an important requirement if the desired materials properties are to be achieved. Two large and growing markets have been identified for our “ALPHA” lignins: (1) high-performance carbon fibers for automotive applications and (2) rigid polyurethane foams for building spray insulation. In both cases, we are showing how lignin fractions isolated by ALPHA with preferred molecular weights, purities, and chemical functionalities yield decidedly superior performance vs. the starting bulk feed lignins, whether they be Kraft lignins or agriculturally based lignins derived from hybrid poplar or corn stover. In particular, ALPHA lignins exhibit superior spinnability and result in carbon fibers having improved strength and modulus. Alternatively, other ALPHA lignins tuned to have a completely different set of properties are being used to make polyurethane foams at polyol substitution rates of up to 60%, with most foam properties showing improvement over the polyol-based control.

8:25 AM SM11.01.02
Bioinspired Lignocellulose Matrices for Tunable Sorption and Release—From Sustainable Agriculture to Environment Remediation Tahira Pirzada, Jacob John, Charles H. Opperman and Saad A. Khan; North Carolina State University, United States

Being significant components of woody and non-woody plants, lignocellulosic have recently found enormous applications in various fields ranging from biofuels and filtration to battery materials. We present an innovative approach to fabricate bioinspired lignocellulosic materials with tunable sorption and release profiles. We have prepared lignin-cellulose hybrid nanofibers and particles via respective electrospinning and anti-solvent precipitation of mixtures containing biodegradable cellulose and alkali lignin. We find an interesting correlation between the precursor mixture composition and the fiber/particle physical properties. When the sorption and release profile of these matrices is investigated, the matrix composition seems to monitor its capacity and kinetics to sorb and release various types of molecules. In particular, we have examined the scope of these matrices as sorbents for industrial contaminants using model dyes, while efficacy of these matrices as sustained-

release media for agrochemicals is analyzed by using abamectin as the model pesticide. We have also determined the bioavailability of abamectin from various matrices using *in-vitro* bioassays. We believe that by manipulating the composition of the matrices, we can fine-tune their sorption and release profiles, while flexibility in fabricating the matrices in different physical forms further enhance the scope of our approach to be applied in diverse applications.

8:40 AM SM11.01.03
Plant-Inspired Phenyl Chemistry to Engineer Electroconductive Hydrogel Ink for 3D Printing Technique
Mikyung Shin[1], Subin Jin[1] and Jason Burdick[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]University of Pennsylvania, United States

Electroconductive hydrogels are promising materials for mimicking electrophysiological environments of biological system towards cardiac/neural tissue engineering, therapeutic applications, and bioelectronics. Considering recent approaches of 3D printing technique to fabricate desirable objects for medical applications, injectability, biocompatibility and mechanical strength of those conductive hydrogels are necessarily required. However, current strategy of simple imbedding of conductive additives (e.g., carbon materials, metal nanoparticles, and conducting polymers) into the hydrogel network has challenges to achieve stable gelation, toughness, and high conductivity before and after 3D printing. Herein, we propose two types of plant-inspired phenyl chemistry, i) gallol oxidation and ii) biphenyl formation via Suzuki-miyaura coupling, for *in situ* fabrication of electroconductive hydrogel inks applicable to extrusion-based 3D printing. In the first topic, injectable and conductive microgels are developed for *in situ* deposition of silver nanoparticles on the surface of the hydrogels via redox activity of the gallol moieties - which is abundant polyphenol in plant kingdom, further applying to 3D printing and electrophysiological muscle tissue support. In the second topic, the phenylborate-triggered conductive hydrogels are formed by biphenyl coupling upon gold reduction, exhibiting high cytocompatibility and temporal injectability for printing of biotic-abiotic interfacing layers in bioelectronics. Our finding of the phenyl chemistry would provide an insight to a variety of applications where conductive materials are needed.

8:55 AM SM11.01.04
Design of Fluorescent and Encapsulating Particles from Biosourced Monomers— Shaping, Characterization, Degradation and Controlled Release Chaohe Hu[1,2] and Jacques Fattaccioli[1,2]; [1]École Normale Supérieure, France; [2]Institut Pierre-Gilles de Gennes, France

Since its beginning, in the early 1920's, polymeric industry relies heavily on fossil fuel resources. Approximately 4%-8% oil, gas and their derivatives are nowadays transformed into polymeric materials. Most of them are non-recyclable and non-degradable, hence leading to serious environmental issues, detrimental to wildlife and humans. In this context, there is a need for the development of alternative polymeric products, which, starting from renewable commodities, will share the same level of complexity than current ones derived from oil industry.

Among the various biosourced raw products used to make polymeric materials, vegetable oils are promising for their low cost and intrinsic degradability, but also because their production is already optimized for the food industry. Acrylated epoxidized soybean oil (AESO) is one example of the vegetable oil derivatives that are used as e.g. plastifying additives for the formulation of PVC. Alone, AESO can be readily and rapidly polymerized to give a thermoset polymer. However, as a consequence of its high intrinsic viscosity, most of the research on AESO-based polymer so far is only focused on the bulk, coating or film properties of this material, leaving the possibility to fabricate high added value materials a blind spot.

Herein, we present the development of a simple, "one-pot" approach to manufacture monodispersed AESO microparticles, based on a microfluidic chip with a flow-focusing structure for emulsification and the serpentine zone for UV-induced reticulation. We show that the size and shape of particles can be tailored easily by precisely tuning the nature and concentration of a co-solvent, used to decrease the viscosity of the dispersed

phase, and monitoring the hydrodynamics of the flow. Exploiting the presence of triglycerides structures within the thermoset, we show that the particles are degradable in alkaline conditions. In addition, we show that AESO particles are good at encapsulating model amphiphilic or hydrophobic fluorescent molecules, and at releasing them on long timescales in the external, continuous phase.

Our work is a first step towards the development of a full range of functional microspheres from biosourced raw materials.

9:10 AM SM11.01.05
Deformation Processing of Palm Leaf Materials for Eco-Friendly Food Packaging Debapriya Pinaki Mohanty[1], Anirudh Udupa[1], James B. Mann[2] and Srinivasan Chandrasekar[1]; [1]Purdue University, United States; [2]M4 Sciences Corporation, United States

The proliferation of single-use plastics (e.g., food packaging) has led to investigation of sustainable plant-based substitutes. We report on the immense potential of leaf-sheath from a palm tree—*Areca catechu*—for manufacturing of eco-friendly, single-use food ware, by direct single-step forming of the sheath material. Using microstructural analyses and different mechanical loading paths, we show that this sheath material can accommodate large forming strains of up to 200% prior to failure. The sheath's deformation response is highly sensitive to hydration, with up to 400% increase in forming strain, so that present manufacturing techniques, largely driven by empiricism and heuristics, are far from optimal. The embodied energy for the palm products is 4-5 orders of magnitude smaller than for equivalent plastic or paper products. Our results delineate product shapes that can be formed in a single step using this material, without intermediate pulping processes, thus demonstrating its versatility. The manufacturing approach demonstrated with the palm leaf has inherent advantages over other resource-intensive, multi-step processing methods commonly used with plant materials.

9:25 AM *SM11.01.06
Understanding Structure/Property Relationships of Lignocellulosic Biopolymer Assemblies Through Molecular Modeling and NMR Peter Ciesielski; National Renewable Energy Laboratory, United States

Plant cell walls are highly-evolved nanocomposite materials with impressive properties and useful functionality. The macromolecular assembly of cellulose, hemicellulose, and lignin, collectively termed lignocellulose, serves multiple functions to plants including structural support, transport of water and nutrients, and biological defense. This same material has also served humanity since the beginning of civilization in applications spanning construction materials, clothing, and fuel. Advances in our understanding of the molecular-level structure/property/function relationships of lignocellulose will enable us to use this natural, renewable material to meet the technological demands of modern society, and thereby displace incumbent materials and fuels derived from fossil carbon which are the cause of increasing environmental detriment. In this presentation, I will discuss modeling approaches to understand how molecular characteristics give rise the emergent properties that ultimately govern the bulk behavior of lignocellulosic composites. Specifically, I will present a study of how the molecular structure of xylan, a hemicellulose, impacts its binding affinity to cellulose nanofibrils. Our findings indicate that xylan of degree of polymerization (DP) less than 20 will detach from the surface of cellulose fibrils in an aqueous environment, while xylan polymers with DP greater than 20 remain strongly bound. Next, I will discuss the construction of simulations of a 3-component system including multiple cellulose nanofibrils, cellulose, and lignin. The starting configuration of the polymers is informed by NMR experiments. Simulations varying the monomeric composition of the lignin polymers show that monomers that contain more methoxy groups on the aromatic rings increase the mechanical integrity of the assembly. Finally, I will present recent progress towards development of a coarse-grained dynamics modeling framework that will enable investigations biopolymer assemblies several orders of magnitude larger than those accessible to molecular dynamics simulations.

11:45 AM *SM11.02.01

Thermal Enhancement of Bioinspired Catecholamine Coatings Kyueui Lee[1], Minok Park[1], Katerina Malollari[1], Peyman Delparastan[1], Costas Grigoropoulos[1] and Phillip B. Messersmith[1,1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

In nature, catecholamines play important and diverse roles, including neurotransmission, wet adhesion, pigmentation and photoprotection. The special combination of catechols and amines is a subject of high interest, not only for understanding the biological roles of catecholamines, but also as building blocks for synthetic materials. In the proteins that enable adhesion of marine mussels to wet surfaces, the intimate association of catechols and amines is believed to be essential to interfacial adhesion. As a result, combinations of catechols and amines have featured prominently in the design of synthetic adhesive polymers and in multifunctional 'polydopamine' coatings. Polydopamine coatings derived from polymerization of catecholamines can be exploited for a variety of practical applications. In this talk we will describe our recent elucidation of the macromolecular nature of polydopamine and describe our attempts to improve the mechanical performance of these coatings. In particular, we recently showed that laser thermal annealing of pDA produced further polymerization of monomeric and oligomeric species leading to fundamental changes in molecular and bulk mechanical behavior, including vast improvement in scratch resistance. Laser-annealed pDA has better scratch resistance than titania and silica, while preserving the multifunctional properties of pDA that are attractive in a variety of contexts. The results of this work suggest new opportunities for the use of PDA in mechanically demanding applications.

12:10 PM SM11.02.03

Diatoms Microalgae as Living Platforms for Optoelectronics Gianluca M. Farinola[1], Stefania R. Cicco[2], Roberta Ragni[1], Danilo Vona[1], Gabriella Buscemi[1] and Gabriella Leone[1]; [1]Università degli Studi di Bari Aldo Moro, Italy; [2]CNR-ICCOM, Italy

Diatoms are single celled microalgae which couple photosynthetic activity with the biomineralization process of conversion of inorganic silicate into complex and nanostructured biosilica. Biosilica shells (frustules) exhibit high surface area, periodic porosity, transparency and mechanical resistance. All these features of their silica shells make diatoms appealing living sources of sustainable smart materials for applications in photonics, optoelectronics, sensing and biomedicine [1].
Recently, we demonstrated an *in vivo* protocol which enables frustules' silica modification by simple introduction of functional molecules into the colture medium. Many functional molecules can be introduced into the biosilica by this approach, including organic [2] and organometallic emitters [3] and also compounds of pharmacological interest [4].
We recently demonstrated that a surface adherent diatom species, *Phaeodactylum tricornutum*, can self-populate and propagate on transparent conductive ITO electrodes, producing photocurrents. In addition, these diatoms can uptake luminescent and optoelectronically active organometallic complexes during their growth and adhesion process. The combination of these features enables to envision microalgae as a platform which can self-assemble in optoelectronically active layers, suitable for producing living micro-devices.

12:25 PM SM11.02.04

Late News: Robust Biocompatible Composites Inspired from Marine Shell Nacre Hemant K. Raut and Javier G. Fernandez; Singapore University of Technology and Design, Singapore

Addressing the global challenges of sustainability calls for the development of materials using bio-based constituents that can outperform conventional materials. An example of one such bio-based material is chitosan (that is derived from marine shells). However, the use of chitosan in load-bearing structural and industrial applications is limited due to its inferior mechanical properties in comparison to a variety of engineered materials such as ceramics and metals.
Interestingly, the shells of marine species – nacre, from which chitosan is extracted, is one of the strongest known natural materials. This is possible because in nacre the chitin (from which chitosan is derived) is embedded with mineral platelets of calcium carbonate, forming a brick-mortar architecture.
Based on this bio-inspiration, a nacre-mimetic composite comprising bio-based constituents (chitosan and silk) and calcium carbonate minerals is manufactured by a green bio-mineralization approach. The approach enables synthesis of mineralized (calcium carbonate) films with teeth-like patterned microstructures. The films comprising the patterned minerals are then stacked with the patterned sides facing each other and infused with silk fibroin. Subsequent drying consolidates the mineralized films into a nacre-mimetic composite where across successive layers, the films are laterally interlocked due to their patterned topography. The resultant composite exhibits nearly 85% higher tensile strength and elastic modulus at least 10 times higher than that of chitosan owing to the distinctive micro-level interlocking between the mineralized films.
Owing to its bio-based constitution, the nacre-mimetic composite also exhibits biocompatibility and mechanical properties similar to that of mammalian bone, making it potentially useful for hard-tissue regeneration applications.

12:40 PM SM11.02.05

Late News: Micro- and Nano-Structured Camouflage Surfaces Inspired by Cephalopods Yinuan Liu, Zhijing Feng, Chengyi Xu and Alon Gorodetsky; University of California, Irvine, United States

Wrinkled surfaces and materials are widespread throughout the natural world and underpin the functionality of a variety of emerging modern technologies. Indeed, the implementation of wrinkles can improve the performance of controllably-wettable surfaces, conductive electrodes, photovoltaics, and dielectric elastomer actuators. However, despite tremendous progress to date, the reversible post-fabrication tuning of wrinkle sizes across multiple length scales has remained quite challenging, and the development of comprehensive relationships between structure and function for optically-active wrinkled surfaces has often been fraught with difficulties. Herein, by drawing inspiration from natural micro- or nano-structured cephalopod skin components and leveraging methodologies established for artificial adaptive infrared-reflecting and infrared-transmitting soft actuators, we engineer camouflage surfaces with dynamically-reconfigurable morphologies and concomitant tunable visible-to-infrared spectroscopic properties, while also developing an enhanced understanding of the relationship between their local surface structures and global functionalities. When mechanically actuated, our systems can reconfigure their height frequency distributions by ≈ 180-fold and root-mean-square roughnesses by ≈ 215-fold; alter their visible to near-infrared total reflectances, transmittances, and absorptances by ≈ 10 %, ≈ 20 %, and ≈ 30 % and their mid- to long-wavelength infrared total reflectances, transmittances, and absorptances by ≈ 26 %, ≈ 27 %, and ≈ 36 %; and modulate their specular-to-diffuse reflectance and transmittance ratios by ≈ 18-fold and ≈ 60-fold within the visible to near-infrared and by ≈ 5-fold and ≈ 38-fold within the mid- to long-wavelength infrared. When electrically actuated, our systems maintain their highly-desirable visible and thermal functionalities and feature competitive figures of merit, e.g., reasonable maximum areal strains of ≈ 60 %, rapid response times of ≈0.7 s, and good stabilities upon repeated actuation Overall, our findings constitute another step forward in the continued development of cephalopod-inspired light- and heat-manipulating architectures and appear well-positioned to facilitate new opportunities in

areas as varied as sensing, electronics, optics, soft robotics, and thermal management.

SESSION SM11.03: Cellulose-Based Materials I

Tuesday Afternoon, April 20, 2021
SM11

2:15 PM *SM11.03.01
New Photonic Materials from Cellulose Nanocrystals Mark Maclachlan; The University of British Columbia, Canada

In nature, structural organization of biopolymers at the nanoscale leads to iridescent coloration, as observed in beetle shells and bird feathers. These structural colors can be mimicked in synthetic materials derived from cellulose nanocrystals (CNCs) because CNCs organize into a helical structure (known as a chiral nematic liquid crystal). When a suspension of CNCs is dried, the resulting film has a chiral nematic structure and, if the pitch of the helical structure matches the wavelength of visible light, the film will appear iridescent.[1]

Over the past decade, we have been developing new materials derived from CNCs, with a particular emphasis on creating new photonic materials. For example, we have exploited CNCs as a template to construct novel chiral nematic mesoporous materials with photonic properties.[2] We have succeeded in preparing silica,[3] organosilica,[4] and polymeric materials[5] through self-assembly or templating methods.

In this presentation, I will discuss our recent progress using CNCs to create flexible photonic materials that respond to stimuli.[6,7]

Wood Nanotechnologies Liangbing Hu; University of Maryland, United States

I will give an overview of our published work on nanotechnologies using cellulose nanomaterials, with a focus on assembly and functionalization strategies of **wood nanocellulose** aimed at specific properties, with an eye toward high impact applications including energy, electronics, building materials and water treatment, including nanomanufacturing and light management in transparent nanopaper for optoelectronics (as a replacement of plastics); mechanical properties of densely packed nanocellulose for lightweight structural materials (replacement of steel, **Nature** 2018); artificial tree for high-performance water desalination and solar steam generations; mesoporous, three-dimensional carbon derived from wood for advanced batteries (replacement of metal current collectors for beyond Li-ion batteries); nano-ionic thermoelectrics (**Nature Materials**, 2019); radiation cooling (**Science**, 2019).

3:05 PM *SM11.03.03
Renewable Nanoparticles in Superstructured Materials Rojas Orlando[1,2]; [1]Aalto University, Finland; [2]The

University of British Columbia, Canada

Superstructured colloidal materials are proposed to endow new functions to renewable nanoparticles, including chitin and cellulose which can be isolated as large axial aspect nanofibrils or shorter nanorods. Interparticle interactions and ensuing adhesive forces are used for building macroscale assemblies displaying networks with tailorable strength, cohesion, porosity and with opto-mechanical response. Here, we demonstrate that the topology of nanonetworks formed from the respective system enables robust superstructuring of diverse particles, including mineral and organic, representing a generic pathway for the fabrication of a new class of constructs. An intermixed network of fibrils with particles increases the toughness of the assemblies by up to three orders of magnitude compared, for instance, to sintering. Supramolecular cohesion is transferred from the fibrils to the constructs following a power law, with a constant decay factor. Our results are expected to expand the development of functional colloids from laboratory-scale towards their implementation in nanomanufacturing of bulk materials.

3:30 PM SM11.03.04
Super Thermal Insulating Cellulose Aerogel with Quasi-Closed Micropores via Emulsion Templating
Mingyao Song, Jungang Jiang and Feng Jiang; The University of British Columbia, Canada

Due to its lightweight and high porosity, aerogel has been considered a promising material with great potential in thermal insulation application. Although silica aerogel demonstrates ultralow thermal conductivity of less than 15 mW/(m K), its brittleness has limited its wide application. Therefore, flexible and durable aerogel with low thermal conductivity has been actively pursued, especially those derived from natural polymers. In this presentation, we report a cellulose nanofibrils (CNF)/Pickering emulsion composite aerogel with quasi-closed internal pores with extremely low thermal conductivity. The composite CNF/emulsion aerogel was fabricated by Pickering emulsion templating and solvent exchange methods. By removing the oil phase from the emulsion, quasi-closed pores could be generated inside the aerogel, which can reduce the thermal conductivity to 15.5 mW/(m K). The presence of quasi-closed pore from emulsion templating is verified from both confocal microscopy and scanning electron microscopy images. The composite aerogel showed very low density of 11.4 mg/cm^3, high mesoporosity, high specific modulus of 18.2 kPa/(mg cm^3), and specific yield strength of 1.6 kPa/(mg cm^3). The CNF/emulsion composite aerogel also demonstrates superb flexibility and infrared shielding performance. It is expected such all-cellulose aerogel can be used in textile and clothing, as well as building and construction for thermal insulation and management.

3:45 PM SM11.03.05
Nanocellulose-Enhanced High Performance Ionic Conductive Organohydrogels—A Versatile and Adaptive Platform for Multi-Functional Sensors Yuhang Ye, Yifan Zhang, Yuan Chen, Xiaoshuai Han and Feng Jiang; The University of British Columbia, Canada

To date, ionic conducting hydrogel has attracted tremendous focus as an alternative to the conventional rigid metallic conductors in fabricating flexible and soft electronics, owing to their intrinsic characteristics of high stretchablility, transparency, tunable mechanical property, consistent conductive phase, and biocompatibility. However, the current ionic conductive hydrogels still suffer from two long-standing dilemmas, which is between the strength and toughness, as well as between the mechanical strength and ionic conductivity. In addition, ionic conductive (organo)hydrogel with freezing tolerance has not been widely reported, and the current anti-freezing ionic conductive (organo)hydrogel showed unsatisfactorily low ionic conductivity at subzero temperature. Therefore, simultaneous realization of high strength, stretchability, toughness, ionic conductivity, and freezing tolerance through a simple approach is still a challenge.

In this work, a novel polyvinyl alcohol (PVA)- cellulose nanofibrils (CNF) ionic conducting organohydrogel with integrated characteristics, including superb mechanical performance (stress up to 2.1MPa, strain up to 660%), high conductivity (3.2 S/m at room temperature), transparency (90%), freezing tolerance (-70 °C), and long-term solvent retention, was facilely fabricated through a simple sol-gel transition method. Owing to the

existence of DMSO/H2O binary solvent system, the organohydrogel maintains flexible and conductive (1.1 S/m) even at -70 °C. This material design verifies the synergistic effect of CNF in enhancing both mechanical properties and ionic conductivity, providing a facile solution to address the long-standing dilemma among strength, toughness, and ionic conductivity for the ionic conducting hydrogel. In addition, the ionic conductive organohydrogel exhibits excellent sensing performance and can be rationally assembled into multi-functional sensors to detect full-range human body movement with high sensitivity, stability, and durability. Attributed to these characteristics, this PVA-CNF ionic conducting organohydrogel is believed to function as a versatile and adaptive platform for future manufacturing of multi-functional sensors in extensive applications such as health monitoring, electronic skin, and wearable electronics.

4:00 PM SM11.03.06
Nanocellulose Alignment and Its Application Zhangkang Li and Jinguang Hu; University of Calgary, Canada

Nanocellulose research has addressed increased attention in the bioprocessing community, especially the utility of these materials in different fields including biomedical and materials applications. However, the major concern in today's nanocellulose research is not about production but matters a lot to find a better application where its structural characteristics could be tailored by different methods. In this presentation, a scalable method for the assembly of oriented bacterial nanocellulose (BC) films is presented, based on using wrinkled thin silicone substrates of meter square size as templates during BC biotechnological synthesis. Control samples, including flat templated and template-free oriented bacterial cellulose, along with the oriented BC, are morphologically characterized using scanning electron microscopy (SEM). Multiple functional properties including wettability, birefringence, mechanical strength, crystallinity, water retention, thermal stability, etc., are being characterized for the BC samples, where the wrinkling induced in-situ BC alignment not only significantly improved material mechanical properties (both strength and toughness) but also endowed unique material surface characteristics such as wettability, crystallinity and thermal stability. Owing to the enhanced properties observed, potential applications of wrinkle templated BC in printing and cell culture is being demonstrated as a proof of concept. The excellent improved mechanical properties and respectable printability of wrinkle templated BC also opens the door for various cellulose-based wearable and printable electronic devices and sensors application.

5:15 PM DISCUSSION

5:40 PM *SM11.04.02
Programming Self-Assembling Protein Engineered Biomaterials Michael Meleties, Priya Katyal, Kamia Punia, Yao Wang and Jin Montclare; NYU Tandon School of Engineering, United States

Inspired by nature's biopolymers, we engineer artificial protein materials on the genetic and chemical level leading to new properties and function. We employ synthetic and chemical biology to construct our materials and endow them with stimuli-responsiveness. In particular, we have fabricated protein-derived nanomaterials: coiled-coil fibers and helix-elastin block polymers. We investigate the fundamental self-assembly and molecular recognition capabilities of these systems. More importantly, we are able to harness these structure as well as others to interface with small molecule therapeutics and cells. Our studies lead to insights in how we can program self-assembling protein biomaterials to be sensed and respond to external stimuli.

6:05 PM SM11.04.03

Experimental Synthesis and Computational Modeling of Silk-Mimetic Polymers Amrita Sarkar, Tanner Fink, Yanming Zhang, Yunfeng Shi and Runye H. Zha; Rensselaer Polytechnic Institute, United States

Silk fibroins are naturally occurring proteins that can exhibit a combination of strength and toughness far exceeding those achieved by man-made polymers. For example, the dragline silk of the European garden spider has higher tensile strength and stiffness than nylon 6/6, with three times the toughness of Kevlar. The exemplary properties of silk fibroins arise from their chemical architecture, in which rigid hydrophobic and flexible hydrophilic peptide segments linearly alternate. Supramolecular assembly of silk fibroins yield a nanostructured material with crystalline beta-sheet domains, which provide strength and stiffness, dispersed in an amorphous matrix, which provides toughness. Interestingly, silk fibroins bear structural resemblance to synthetic segmented copolymers such as poly(ether-block-amide) (PEBA), yet man-made PEBA are vastly inferior in mechanical properties compared to many natural silk fibroins. Thus, mimicking silk fibroin architecture in synthetic polymers can unlock the path to synthesizing exceptionally strong and robust next-generation polymers. Unfortunately, rational design of silk-mimetic polymers is hindered by: 1) the challenges faced in rapid synthesis of well-defined segmented polymers bearing multiple aggregation-prone "blocks", and 2) the lack of knowledge in predicting how chemical structure and sequence dictates supramolecular structure and mechanical properties. This talk will present our recent work in developing a new route towards efficient synthesis of silk-mimetic polymers. In particular, we discuss a two-stage modular approach based on microwave-assisted chemistry that is capable of generating silk-mimetic polymers with well-defined beta-sheet forming peptide segments and improved molecular weights. This work is the first to demonstrate Cu(I)-mediated click chemistry as a new approach toward efficient step-growth polymerization of silk-mimetic polymers. Notably, this synthetic approach can reach molecular weights within 20 min that far surpass those obtained by traditional peptide coupling reagents, and the resulting polymers readily form silk-like supramolecular structures. The speed and modularity of this synthetic approach offers possibility for creating libraries of silk-mimetic polymers for systematic study of structure-property relationships. Furthermore, this talk will also briefly discuss a new computational model for predicting materials properties based on chemical structure in silk-mimetic polymers. This computational model can reveal fundamental mechanisms in the mechanical behavior of silk-mimetic polymers in relation to molecular and supramolecular structure. Thus, these experimental and computational tools are crucial steps towards enabling rational design and synthesis of silk-mimetic polymers.

6:20 PM SM11.04.04

Programming *Bombyx Mori* Silk's Water-Responsive Actuation Using Silica Nanoparticles Yeojin Jung[1,2], Raymond S. Tu[1,2] and Xi Chen[1,2]; [1]The City College of New York, United States; [2]Advanced Science Research Center at City University of New York, United States

Spider silk that mechanically swells and shrinks in response to changes in relative humidity or water gradient has shown capability to exert higher energy than conventional actuators and artificial muscles, and thus holds potential to be used as high-energy actuating components for various engineering applications, including robotics, shape morphing, and smart structures. However, spider silk's low availability largely limits these potential applications. We found that water-responsiveness of *Bombyx (B.) mori* silk, which possesses a similar supramolecular structure to that of spider silk, could be dramatically increased, and even surpasses that of spider silk, by simply adding silica nanoparticles. Mechanical and microstructural analyses using FTIR and AFM, together with our previous studies on water-responsiveness of regenerated silk with various β-sheet crystallinity, suggest that stiff silica nanoparticles could dramatically reduce energy dissipation within silk's supramolecular network, and increase energy conversion efficiency during silk's water-responsive actuation. We also demonstrate that a large-scale actuator of *B. mori* silk/silica nanoparticles composites that reversibly lift a weight powered by humidity changes, showing the possibility of using silk with lower-cost and wider availability as building blocks for high-energy water-responsive structures.

6:35 PM SM11.04.05
Photo-Crosslinking Silks Under Stretches for Boosting Strength Chang Liu and Bin Fei; The Hong Kong Polytechnic University, Hong Kong

Silk fibroin fibers (FFs), produced from natural silk by removing their sericin coating layer, have been used as a biomedical suture material for centuries. Both physical and chemical methods have been used to enhance the strength of silk fibroin. However, the current methods have limitations. For example, the physical methods lead to the brittle nature of silk fibroin due to the increasing of β-sheet content. The chemical crosslink methods show better nature, but they may be time-consuming or lead to cytotoxicity under certain conditions, limiting the fields, especially in biomedical. Therefore, a rapid and mild chemical crosslink method is necessary to develop.

In this study, silk fibroin fibers were crosslinked by employing photoredox catalysis. The chemical crosslink through dityrosine connection was confirmed, and further evaluated by the crosslink density. Further applying tension stretch to the fibers, the break stress and modulus of stretched photo-crosslinked FFs increased by nearly 70% and 50% than that of original FFs. This approach constitutes an easy and straightforward strategy for the strengthening of FFs, promotes the FF applications in broad engineering fields.

6:50 PM SM11.04.06
Dry Cell-Free Protein Synthesis Formulations are Compatible with Polymer Casting Techniques Marilyn Lee[1], Rebecca Raig[2,3], Danielle Kuhn[1], Matthew Lux[1] and Maneesh Gupta[3]; [1]U.S. Army CCDC Chemical Biological Center, United States; [2]UES, Inc., United States; [3]Air Force Research Laboratory, United States

Cell-free systems have growing importance as a way to use synthetic biology tools in resource-poor environments. Lysates may be dried for storage, delivering biochemical activity for sensing or producing molecules on-demand upon rehydration at the point of need. Up to now, cell-free protein synthesis (CFPS) reactions have been studied as aqueous solutions in test tubes or absorbed onto paper or cloth. Embedding biological functionality into broadly-used materials, such as plastic polymers, has long been an attractive goal. Unfortunately, this goal has for the most part remained out of reach, often due to the fragility of biological systems outside of aqueous environments. In this work, we describe and utilize a surprising and useful feature of lyophilized cell-free lysate systems: tolerance to casting methods involving exposure to organic solvents or heat up to 90°C. To explore this newly discovered feature, a variety of solvents were tested and CFPS reaction components were screened for protective properties. CFPS is compatible with several polymer types. Tolerance to polymer casting enables the delivery of dry cell-free reactions in the form of coatings or fibers, among other processing possibilities.

SESSION SM11.05: Cellulose-Based Materials II

Structured Materials from Cellulose Nanofibrils Lars Wagberg, Tobias Benselfelt and Daniel Söderberg; KTH Royal Institute of Technology, Sweden

Biobased Cellulose NanoFibrils (CNFs) constitute a highly anisotropic nanomaterial with excellent mechanical properties with a well defined surface chemistry and outstanding durability in harsh environments. During the last two decades CNFs have been used in numerous applications ranging from antibacterial, composite, energy storage, display and fire proofing applications , to mention a few, where different aspects of their inherent

apllications have been utilized. The Youngs modulus of the fibrils is around 130 GPa and it should hence be possible to create outstandig materials of these materials provided that the nanostructure of the prepared materials could be controlled. Since materials from CNFs are almost exclusively formed from water it is essential to control their colloidal interactions in dispersion to create an ideal structure for a certain end-purpose. In the present contribution two different strategies will be handled in detail. In the first appoach anionically modified CNFs were well dispersed at low concentrations together with small amounts of high molecular mass sodium alginate before dewatering of the dispersion to a solid gel before drying. The so prepared materials were then re-swollen in aqueous solutions containing different di-valent or tri-valent counterions resulting in wet films with excellent mechanical properties. A wet film of these materials with 50 % water was shown to have modulus, strength and stress at break comparabel and even better than HD polyethylene. The reason to this extraordinary behaviour is that the fibrils form a volume spanning arrested state (VAS) as the concentration is increased during dewatering and this creates a lamellar structure in the concentrated wet film with an intertwined network of alginate polymers. As the dry films are re-swollen this network basically expands in one direction and by using multivalent ions the alginate molecules are able to lock the structure creating a type of interpenetrated network of CNF and alginate. In the second approach the CNFs are converted to end-less filaments using a flow-focusing methodology. In this approach the well dispersed fibrils are oriented in an elongational flow in a flow-focusing device and by using an acidic solution to create this flow the fibrils are locked in an oriented structure where their excellent mechanical properties can be fully utilized to create strong and thin filaments. This concept can also be developed by using coaxial arrangements where different types of interactive filaments can be prepared.

8:50 AM *SM11.05.03
Multifunctional Cellulose Biocomposites of High Strength and Optical Transmittance Lars Berglund; KTH Royal Institute of Technology, Sweden

Polymer matrix cellulose biocomposites are widely used in the form of molded components in industry exemplified by automotive applications. Improved control of the nanostructure makes it possible to significantly widen the range of properties and potential applications. Top-down approaches are particularly interesting, since the nanostructure can be controlled both in terms of spatial nanocellulose fibril distribution and its orientation. One can also prepare optically transparent materials by selection of an appropriate polymer matrix. By the addition of functional components in the form of nanoparticles or dyes, the photonics functionality can be extended further for applications such as smart windows, wood for solid state lasing and heat storage. Molecular and nanoscale understanding of processing for nanostructural control is essential, as well as the effect of nanostructure on physical properties. Materials design in terms of wood substrate modification, chemical treatment and polymer impregnation strategies will be discussed. This includes methods for nanostructural characterization, mechanisms for light transmission, reduction of moisture sensitivity and effects from refractive index matching between the polymer and the wood substrate.
An important argument for cellulosic materials is their role in sustainable development, and this topic will be analyzed. There is a tendency to emphasize the renewable resource origin of cellulose, but this may not always be sufficient to justify the replacement of established materials.

9:15 AM SM11.05.04
Bacteria Cellulose Derived Functionalized Separator for Lithium Sulfur Batteries Wenyue Li and Zhaoyang Fan; Arizona State University, United States

Other than its superior mechanical strength and thermal stability, bacterial cellulose (BC)-derived thin sheet could also provide other crucial functions as an excellent separator candidate used in emerging battery technologies. Particularly, for lithium sulfur batteries (LSBs), polysulfide shuttling effect and lithium dendrites are two tough issues that cause numerous problems including low cell efficiencies, fast battery decay and safety concerns. To attack these two problems simultaneously, this study presents a functionalized BC separator by manipulating its oxygen-containing functional groups. With enhanced repulsive force between polysulfides and the carboxyl-altered BC film, the polysulfide shuttling can be effectively suppressed on the cathode side.

Correspondingly, the tendence of lithium ion absorption to the oxygen functional groups is capable of generating uniform lithium ion diffusion at the interface of the lithium anode and the BC separator, resulting in stable lithium stripping/plating processes by inhibiting lithium dendrite growth. As a result, the LSB cell with a BC separator, at a sulfur load of 4 mg cm^{-2}, delivers a specific capacity of 1450 mAh g^{-1} at 0.1C, or 1000 mAh g^{-1} at 0.3C over 100 cycles, suggesting the superior performance of BC separators in LSB.

9:30 AM SM11.05.05
Optimization of Spray-Drying Cellulose Nanofibrils for Biocomposites Xianhui Zhao[1], Lu Wang[2], Kai Li[1], Katie Copenhaver[1], Halil L. Tekinalp[1], Douglas Gardner[2] and Soydan Ozcan[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Maine, United States

Growing interest in using cellulose nanofibrils (CNFs) to reinforce polymers is attributable to CNFs' unique properties such as high aspect ratio, high specific strength, light weight, low cost, and renewability. However, drying CNFs effectively with less agglomeration at low cost is a main challenge for enabling use of CNFs in biocomposites. In the present study, CNFs derived from bleached pulps were spray-dried at six different conditions: two temperatures (~125 °C and ~110 °C) and three feed concentrations (1.3%, 1.5%, and 1.8%). The spray-dried CNFs were compounded with polylactic acid (PLA) (at 5 wt% CNF level) to form CNF/PLA biocomposites. The biocomposites obtained were characterized using techniques including tensile testing, rheological analyses, dynamic mechanical analysis (DMA), differential scanning calorimetry (DSC), thermogravimetric analysis (TGA), and scanning electron microscopy (SEM). The tensile strengths of the CNF/PLA biocomposites varied largely from 32 to 54 MPa (69% change). When the CNFs were spray-dried at the higher temperature (~125 °C) with a feed concentration of 1.3%, the CNF/PLA biocomposite had the highest tensile strength among all composites. This indicates that the CNF spray-drying condition has a significant effect on the mechanical properties of the CNF/PLA composites. Some physicochemical treatments on CNFs will be utilized in the future to further improve the properties of CNF/PLA composites.

SESSION SM11.06: Protein and Peptide Based Materials II

2:15 PM SM11.06.01
Biomimetic Tooth Repair—Peptide-Guided Remineralization of Functional Dental Tissues Deniz T. Yucesoy[1,2,2], Hanson D. Fong[2,2], Jacob Rodriguez[2,2], John Hamann[2,2], Sami Dogan[2] and Mehmet Sarikaya[2,2,2]; [1]Izmir Institute of Technology, Turkey; [2]University of Washington, United States

Dental diseases are a global health problem affecting large populations despite the widespread use of fluoride and other preventive treatments. Primarily as result of demineralization, i.e., loss of mineral from teeth, these ailments are associated with incipient caries, gum recession, hypersensitivity, and gingivitis. Current dental therapies mostly rely on replacement defective or lost tissue with synthetic restorative dental materials with limited long-term success, often causing post-therapeutic problems, e.g., gingival inflammation, secondary caries, and even tooth loss. Incorporating a functional mineral layer that can be fully integrated into underlying molecular tooth structure in repairing the tissue has been a long-standing challenge. Following lessons from biology where proteins guide tissue formation, we develop a peptide-based biomimetic remineralization methodology to restore demineralized dental hard tissues in enamel, dentin and cementum using peptides derived from biomineralizing proteins, such as amelogenin, the key protein in enamel. Dubbed as amelogenin-derived peptides, ADPs are designed through a multipronged approach including biocombinatorial selection, bioinformatics, molecular simulations, and by iteratively testing via binding and mineralization assays. The ADPs are used in guiding remineralization *in vitro* on artificially demineralized teeth of extracted human, rat,

and porcine teeth as under simulated physiological conditions and in vivo rat model. In a variety of treatment modalities, the peptide treated test groups displayed structure and morphology with well-integrated interfaces exhibiting local mechanical properties mimicking the restored tissues, e.g., similar to dentin-enamel junction (DEJ) and dentin-cementum junction (DCJ). The highly potent materials and methods developed in this work pose to drastically alter the current dental health care by highly effective practical products and procedures in restorative and cosmetic dentistry as well as in preventive daily oral care.

2:30 PM SM11.06.02

Late News: Functionalization of Supramolecular Ureidopyrimidinone-Materials by Photo-Induced Oxygen-Tolerant Polymerization Muhabbat Komil[1], Bastiaan Ippel[1], Paul Bartels[1], Serge Söntjens[2], Maarten Pouderoijen[2] and Patricia Dankers[1]; [1]Technische Universiteit Eindhoven, Netherlands; [2]SyMo-Chem, Netherlands

An elegant way of biomaterial synthesis is through supramolecular chemistry, where functional moieties are held together via dynamic and reversible bonds. An example of such a supramolecular moiety is the ureidopyrimidinone (UPy), which dimerizes by four-fold hydrogen bonding and distinctly self-assembles into nanofibrous structures. Various polymers, functionalized with multiple UPy-motifs, can be processed into films and scaffolds, giving a wide choice of materials characteristics for numerous biomedical applications. Furthermore, because of the supramolecular nature, countless different additives modified with a UPy-motif are easily incorporated into the supramolecular materials to achieve the desired functionality for potential applications as biomedical materials.
Previously, we demonstrated the design of a UPy-functional alkyl halide initiator, including its incorporation into the UPy-functional polycaprolactone (UPy-PCL) films at different concentrations by solvent casting. Grafting of antifouling polymers by atom transfer radical polymerization (ATRP) in form of polyzwitterions in a fully aqueous medium at room temperature was described. Furthermore, we were able to successfully functionalize microporous supramolecular electrospun scaffolds prepared from telechelic UPy-PCL with polyzwitterions. Post-polymerization surface elemental composition measurements, revealed presence of two distinct signals that reflected the charged atoms of the polyzwitterions. The charges strongly affected the wettability of the grafted materials. Additionally, presence of the new polymer layer on the surfaces was characterized by differences in surface morphology and cellular adhesion pre- and post-polymerization. The amount of polymer was dependent on the concentrations of UPy-initiator incorporated into the supramolecular films, as well as polymerization times.
We have now further improved our approach by utilizing photo-induced ATRP to gain temporal control over the polymerization. Photo-induced ATRP allows us to pattern our supramolecular material surfaces with functional polymers. With recent developments in the field of radical polymerization, we now utilize enzymatically degassed ATRP, which is oxygen-tolerant and has alleviated the need for inert atmosphere. Thus, we can perform open-to-air polymerization and effortlessly upscale supramolecular material functionalization to multiple materials at a time. With catalytic amounts of glucose oxidase enzyme, we have observed excellent control over the polymerization in a fully aqueous medium at room temperature, by means of linear first-order kinetic behaviour and narrow molecular weight distributions. We have successfully synthetized hydrophilic oligo(ethylene glycol) (OEG) polymer brushes with varying brush lengths, which resulted in thermoresponsive materials. Additionally, functional OEG copolymer brushes were prepared with multiple pendant amine moieties, which were positively charged at physiological conditions. Amine moieties can act as anchors to conjugate various peptides, dyes and bioactive motifs, post-polymerization. Currently, we are continuing implementation of photo-induced oxygen-tolerant ATRP for the design of bioactive materials with carbohydrate moieties. Materials functionalized with carbohydrate moieties serve as excellent candidates for extracellular matrix mimics. We are excited to further investigate a plethora of possible applications of our functional supramolecular materials in the field of tissue engineering and regenerative medicine.

2:45 PM SM11.06.03

Biologically Engineered Living Bacterial Thin Film with Tunable Stiffness and Self-regeneration Capability Dong Li[1], Victor Mann[1], Marimikel Charrier[2], Caroline Ajo-Franklin[3] and Paul Ashby[1]; [1]Lawrence

Berkeley National Laboratory, United States; [2]Colorado University, United States; [3]Rice University, United States

Natural biological materials often demonstrate intriguing properties that are difficult to replicate in man-made materials, such as self-repairing/-regeneration, adaptable morphological and mechanical switch, sensing and responding. One promising strategy of incorporating these living aspects into creating new materials is to genetically program microbes and use them as the major building blocks. Here we report a new Engineered Living Material (ELM) that harnesses the active properties of bacterial cells to create an ultra-stiff, regenerable, and responsive film. The material is assembled from tightly packed cells whose solid surfaces are densely crosslinked. The surface layer (S-layer) protein of *C. crescentus* was engineered to display SpyTag over the entire cell body. These functionalized bacterial cells crosslink into tight assemblies with close cell-cell contact mediated by nanoparticles displaying SpyCatcher and the formation of SpyCatcher-SpyTag iso-peptide bonds. We found (1) A layer of densely packed Qdots can be displayed on living bacterial surface. (2) Stiffness of the crosslinked bacterial film increases over 30 times compared to non-crosslinked biofilms. Cleavage of a disulfide bond inserted between SpyCatcher and the nanoparticles melts the crosslinked film, confirming the specific covalent linkage is responsible for the enhanced mechanical properties. (3) The engineered ultra-stiff bacterial film can harvest nutrients to both continue to manufacture new material and regenerate damaged regions due to the continuous growth of *C. crescentus* cells and the expression of new S-layer proteins in the presence of crosslinking agent. (4) The crosslinked living bacterial film exhibits dynamic morphological and mechanical response to environmental osmotic stressing caused by a neutral polymer macromolecule polyethylene glycol 8000. With these materials we introduce a new design principle for creating high stiffness in liquid content materials.

3:00 PM SM11.06.04
Decellularized Extracellular Matrix Bioinks for Cancers-on-Chips Hee-Gyeong Yi; Chonnam National University, Korea (the Republic of)

Microphysiological cancer systems (Cancers-on-Chips) are emerging cancer models for better cancer research. Conventional cancer models have failed in capturing the underlying mechanisms of how cancer reacts to the current anti-cancer approaches due to the lack of similarities with the original cancer of patients. The challenge is modeling a complex and heterogeneous cancer environment where every element contributes to cancer hallmarks development. Recently, biofabrication technologies have been advanced to spatially control multiple types of cells and biomaterials to mimic the native physiology of human tissue and organs. In particular, 3D cell-printing has beauty in manipulating the 3D anatomical structure of cancerous tissue through a layer-by-layer process that stacks up cells and bioinks following a precisely designed sequence. The decellularized extracellular matrix bioinks that mimic the tissue-specific environment has recapitulated the pathology and aggressiveness of cancer. In addition, 3D cell-printing has shown the possibilities in modeling various types of cancers for future cancer research.

3:15 PM SM11.06.05
A Novel Supramolecular Cryopreservation Nanoagent Based on Self-Assembly of Peptide Hayeon Kim and Eunji Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

Cryopreservation is very important in biotechnological, pharmaceutical, biochemical or food industries as the purpose of storage of protein drugs, cells, tissues and food, and ice slurries for refrigeration systems. Antifreeze protein (AFP) have been received attention with their potential as a cryopreservation agent by their ability to prevent the organisms from freezing at the subzero environment through antifreeze activity such as ice recrystallization inhibition or thermal hysteresis effect. However, it is struggling to apply the natural AFP in practical industries as cryopreservation agent because of their irreversible denaturation and the difficulty in extraction from nature. These challenges have led to developing artificial cryopreservation agents like dimethyl sulfoxide and sodium phosphates but due to the cytotoxicity and less biocompatible of them, the recovery rate of the target matter is too low when they are added. Here, the natural AFP mimetic short peptides conjugated

with specific amino acids showing antifreeze activity and fibrous assembly with enhanced π-π stacking are prepared by supramolecular chemistry to increase both antifreeze activity and biocompatibility. This research might provide a useful strategy to fabricate the cryopreservation agent through the supramolecular nanomaterials and to figure out the mechanism of ice binding to antifreeze protein.

SM11

5:15 PM INTRODUCTION

5:20 PM SM11.07.03
Near-Field Electrospun Hybrid Biodegradable Polymer/M13-Bacteriophage Whispering Gallery Mode Biosensors Stephen T. Hsieh, Joseph E. Cheeney, Xi Ding, Nosang V. Myung and Elaine D. Haberer; University of California, Riverside, United States

Polymer/virus based biosensors are a compelling system for medical diagnostics, environmental monitoring, and food security. The hybrid system of a biocompatible polymer with a virus bio-recognition element, results in a bio-friendly device that is solution processable. Typically, antibodies or aptamers are used as the bio-recognition element, however they can be costly and time consuming to produce, lack stability under sensing or surface functionalization conditions, and be poorly oriented during functionalization rendering a fraction of receptor sites useless. In contrast, the M13 virus, a harmless and non-toxic filamentous bacteriophage, can be manufactured in large quantities through inexpensive infection of a bacterial host and can withstand a large range of temperatures and pHs. Moreover, this combinatorial phage display workhorse can be genetically modified to display thousands of well-ordered, densely packed affinity peptide fusions with controlled orientation along its less than one micron length.
Recent work has demonstrated that electrospun polymer fibers can be utilized as optical resonator whispering gallery mode (WGM) sensors. These WGM sensors have potential as highly sensitive, label-free sensors. The high quality (Q) cavities are of particular interest as they enable light to recirculate hundreds to millions of times or more, significantly increasing interaction with an analyte and improving device sensitivity. Light propagating at the periphery of these radially symmetric resonators is confined by total internal reflection such that its evanescent field serves as a probe for analyte binding events on the resonator surface. A promising biosensor device would combine the polymer/virus bio-recognition with the WGM sensing mechanism. An ideal method would be to electrospinning polymer/M13 fibers capable of supporting WGM while still maintaining the M13 bio-recognition properties
Here, we used near-field electrospinning, a direct write fabrication method utilizing a low strength electric field, to create polyvinyl alcohol (PVA) WGM fiber resonators with incorporated M13 biorecognition elements. A streptavidin-binding phage functioned as a model bioreceptor to demonstrate the utility of the sensing platform. The surface concentration of M13 was evaluated via streptavidin-conjugated gold nanoparticle binding and x-ray photospectroscopy (XPS). Rhodamine 6G (R6G) was then incorporated into the fiber as an emitter. Sharp peaks associated with WGMs decorated the broad dye fluorescence. The resonant modes were identified using Mie theory, and Q values and free spectral range were measured. Subsequently, the fibers were used to detect streptavidin and the sensitivity of these novel PVA/M13 biosensors was determined. These studies demonstrate the potential of electrospun WGM resonators with incorporated phage-based bioreceptors as a robust platform for highly sensitive biosensing.

5:35 PM SM11.07.04
Bioinspired Interphase Engineering for 1D and 2D Nanocarbon-Included Functional Composites

Weiheng Xu, Sayli Jambhulkar, Dharneedar Ravichandran, Yuxiang Zhu and Kenan Song; Arizona State University, United States

Layer-structured composites have broad applications in the biomedical device, tissue scaffolds, skin membranes, solar cell devices, battery and supercapacitor devices, sensors, and actuators. Here we report the biosystem-mimicking structure of layers along the thickness or radial directions. These polymer/nanoparticle composites display in different material forms, such as fibers, thin films, or laminates. The combination of the soft micromoles and hard nanoparticles have synergistic effects in mechanical robustness and functional versatility. We demonstrate via a few polymers of polyvinyl alcohol (PVA), polyacrylonitrile (PAN), and thermoplastic polyurethane (TPU). Different nanoparticles in one-dimension and two-dimension are incorporated in these polymers, for example, carbon nanotubes (CNTs), carbon nanofibers (CNFs), and graphene nanoplatelets (GNPs). The composites' compositions and structures in each layer can be tuned via manufacturing customization and material modification. We will demonstrate how uniquely designed structures benefit mechanical enhancement, electrical conductivity, and gas sensitivity.

5:50 PM SM11.07.05
Late News: Blends of Beeswax and Soy Wax as Encapsulating Materials for Soil-Biodegradable Electronics Madhur Atreya, Gabrielle Marinick, Karan Dikshit, Charlotte Bellerjeau, Yongkun Sui, Carson Bruns and Gregory Whiting; University of Colorado Boulder, United States

The growing field of printed biodegradable electronics provides the opportunity to monitor soils at a high spatial density without the risk of increased waste. A tunably degradable encapsulant is a critical component of soil-degradable electronics, as it acts to delay the ingress of water, microbes, and other agents responsible for degradation. Existing biodegradable polymers such as poly(lactic acid) tend to have limited utility due to their uptake of water which could in turn expose components underneath. Candelilla wax has been shown to be an effective encapsulating material in biomedical applications [1]. We have recently demonstrated that a blend of beeswax and soy wax is an effective encapsulant for printed biodegradable soil moisture sensors [2]. In this presentation, we elaborate on the thermal/mechanical properties of beeswax-soy wax blends to explore the conditions required for melt processing and coating substrates. In addition, we explore the tunability of degradation and introduce a novel wax-based soil degradation sensor, where time to sensor failure can be correlated to microbial or enzymatic activity.

6:05 PM SM11.07.06
Late News: Sub-Micron Topography Modulates Strain-Stiffening Behavior in Fibrous Hydrogels Sara Heedy, Juviarelli Pineda and Albert Yee; University of California, Irvine, United States

Nature provides soft materials, such as gels, capable of complex mechanical responses that vary with hydration level and other environmental factors such as pH and salinity. Such biological "soft" polymers often consist of nanofibers capable of aggregating further into microbundles. These biopolymers contain relatively rigid building blocks along the chain backbone, which is necessary to form hierarchical structures characteristic of fibers. The fiber forming hierarchical biopolymers exhibit a nonlinear stress-strain response – typically a 'J-shape' stress-strain curve that demonstrates strain-stiffening behavior. Being able to replicate this strain-stiffening behavior is critical for the success of future bio-electronic interfaces and medical devices. Systems designed to exhibit strain-stiffening responses demonstrate unfolding, deformation, and straightening of the network. Recent designs include wavy-textures induced by pre-straining, self-assembled elastomers, and kiragami-inspired systems. Yet, it remains a worthwhile goal to develop tunable strain-stiffening systems,

particularly from biocompatible polymers. Here, we demonstrate a new approach to modulating the strain-stiffening response of monolithic fibrous hydrogels through application of a physical surface topography.

We fabricated periodic pillar nanostructures on a fibrous chitosan hydrogel using solvent dropcast lithography. We produced a range of regularly spaced nanopillars with periodicities of approximately 200 nm, 300 nm, and 500 nm, which is comparable to the biopolymer radius of gyration (~250 nm). We performed tensile testing in the plane of the hydrated films with and without nanopatterns to determine the effect of surface nanostructures on film stiffness. We found, surprisingly, that the elastic moduli increased in the films with nanopillar topography, and that the amount of increase was correlated to the increasing feature size of the films. Furthermore, the nanopillar topography strongly modulated the strain-stiffening response.

To determine the origin of the processing-structure-mechanical property relation, we systematically investigated the nanoscale topography deformation utilizing atomic force microscopy, and observed significant alignment of the nanofibers at deformations above the nonlinear stress-strain transition point. In this presentation, we report on our study to examine the role of interactions and ionic linkages in the hydrogels and to determine if there is a limit to the tunable mechanical properties. The simple method to fabricate a monolithic strain-stiffening system from fibrous hydrogels could be translated towards other biopolymer-based devices and materials including electronically active biopolymers.

6:20 PM SM11.07.07
Muscle-Inspired Hydrogels of High Toughness and High Contractile Force Ximin He, Mutian Hua and Shuwang Wu; University of California, Los Angeles, United States

Hydrogels are a class of water-laid crosslinked polymers with tissue-like microstructure and unique stimuli-responsive deformability, with great potential for tissue engineering, humane-machine interface, and artificial muscle for soft robots and wearable electronics. However, due to the high porosity their intrinsic mechanical weakness and low deliverable actuation force limit their applications. We have recently made progresses on developing a new generic method to construct hydrogels of (1) ultra-toughness and (2) high deliverable force and power density during actuation. First, Natural load-bearing materials like tendons are strong and tough, owing to the hierarchically assembly of anisotropic structures across multi-length-scales. We have developed a strategy to produce polymers with tendon-like hierarchical architecture. Multiple mechanisms originating from these structures at different length-scales were integrated in the water-rich polymer (70-95% water) to feature both ultra-high ultimate stress (23.5 MPa) and strain (2900%), which yields giant toughness (210 MJ/m^3, 170 kJ/m^2) and remarkable fatigue resistance, 10-time tougher than natural tendon, Kevlar and rubber. This research may make hydrogels capable of practical applications that requires long-term services with high-loads and abrupt-impacts, and extend to the optimization of various polymeric materials. Second, inspired by the energy conversion mechanism of many creatures during jumping, we designed an elastic-driven strong contractile hydrogel through storing and releasing elastic potential energy in polymer network. It can generate high contractile force (40 KPa) rapidly at ultra-high work density (15.3 KJ/m^3), outperforming current hydrogels (~0.01 KJ/m^3) and even biological muscles (~8 KJ/m^3). This demonstrated elastic-energy storing and releasing method endows hydrogels with elasticity-plasticity switchability, multi-stable deformability in fully reversible and programmable manners, and anisotropic or isotropic deformation. With the high power density and programmability via this customizable modular design, these hydrogels demonstrated potential for broad applications in artificial muscles, contractile wound dressing, and high-power actuators.

6:35 PM SM11.07.08
Plant-Inspired hydrogels for Phototropic Energy Harvesting and Flexible Storage Devices Ximin He and Yusen Zhao; University of California, Los Angeles, United States

Nature with the 3.8 billion years of research and development experiences can always provide us with out-of-the-box ideas for man-made materials from their superior design and functionality. Recent progresses by our group on energy harvesting (Nat. Nanotech. 2019) and energy storage (Adv. Funct. Mater. 2019; Matter 2020)

materials will be presented. First, plant can turn its head following the sun, known as phototropism, to maximize the photo(thermal) energy harvesting. Engineering such a self-adaptive actuation ability in synthetic materials would be highly advantageous for advancing intelligent energy-efficient systems and enhancing the performance of optical or optoelectronic devices, avoiding computer programming or electromechanical control and external power supply. We have an artificial phototropic system based on nanostructured stimuli-responsive polymers that can aim and align to the incident light direction in the three-dimensions over a broad temperature range. Such adaptive reconfiguration is realized through a built-in feedback loop rooted in the photothermal and mechanical properties of the material. This system is termed a sunflower-like biomimetic omnidirectional tracker (SunBOT). We show that an array of SunBOTs can, in principle, be used in solar vapour generation devices, as it achieves up to a 400% solar energy-harvesting enhancement over non-tropistic materials at oblique illumination angles. The principle behind our SunBOTs is universal and can be extended to many responsive materials and a broad range of stimuli. Second, wood in nature has well-defined vertical structure with low tortuosity to facilitate the mass transport. Inspired from the wood structure, we designed anisotropic hydrogels with alignment to increase the ionic conductivity of materials. The pore size can be rationalized and reduced even smaller than natural wood to increase the specific area, while maintaining the alignment. Conducting polymer, owing to its mesoporous structure and high electrical conductivity has been widely used for supercapcitors. By incorporating the conducting polymer in hydrogel-based matrix, the all-solid-state supercapacitor with high electrochemical performance can be fabricated. Such conducting polymer-hydrogel composites exhibit unprecedented ionic conductivity, areal supercapacitance, power density, energy density, capacitance retention and cyclic stability. Besides, the hydrogel matrix also provides excellent flexibility under cyclic bending, making it possible for flexible electronics.

SM11.08.02
BioInspired Fish Scales—A Kinematic and Numerical Approach for Flexible Armor Design Ailin Chen, Komal Thind, Kahraman Demir and Grace X. Gu; University of California, Berkeley, United States

Fish scales serve as a natural dermal armor with remarkable flexibility and puncture resistance. Through biomimetic scales, researchers are able to acquire these properties and tune them by adjusting their design parameters. Overlapping scales, as seen in elasmoid scales, can lead to complex interactions between each scale. These interactions are able to maintain stiffness while improving flexibility. Hence, it is important to understand these interactions in order to design biomimetic fish scales. As the scaled substrate deforms and the scales start to engage, modeling the flexibility requires accounting for nonlinear relations. Current studies focus on characterizing these kinematic linear and nonlinear regions but fall short in modeling the kinematic phase shift. Here we propose an approach that will predict when the transition from linear to nonlinear will occur, allowing for more control of the substrate's overall behavior. Using a kinematic analysis of the interacting scales, we can model the flexibility at the transition point where the scales start to engage in a nonlinear manner. The validity of these kinematic predictions will be investigated through finite element analysis. The results of this investigation could allow for an efficient optimization method for scale-like designs that can be applied to various applications.

SM11.08.03
Hierarchical Alginate Hydrogel Architectures and Multi-Layered Encapsulation Yoon Jeong and Joseph

Irudayaraj; University of Illinois at Urbana-Champaign, United States

Hierarchically ordered structures can be found in a variety of biological systems ranging from microscopic to the macroscopic scale in nature. Not surprisingly, inspiration from nature has provided cues to stimulate research in materials preparation to obtain functional hierarchy. For instance, hierarchical and ordered biological structures, in many tissues such as cartilage, and cornea, are well exemplified. Extensive efforts have been made to mimic the native biological structures of a tissue on cell layers and stratification. We attempt to develop hierarchical and layered hydrogel architectures with robust design necessary for cellular encapsulation.

Research on hierarchical structured hydrogels is still in its infancy. More recently, new hierarchical hydrogel architectures have been pioneered to create multi-layered chitosan hydrogels in a concentric fashion. Pioneering efforts to develop hierarchical architectures with hydrogel have provided fundamental insights at the molecular level. Yet the strategies might not be standardized because substantial different design considerations is required due to a wide range of biochemical processes involved. In some cases, cytotoxic processes and/or chemicals to form a gel structure are utilized which results in an inevitable cell damage. Furthermore, at small scales, the fabrication of micro-size architectures requires higher reaction rates than that of macroscopic objects, which causes agglomeration between gels in a reaction bath. Due to the agglomeration issue, there has been an absence of reliably scale-down models for mass production. Only a few methods have been introduced to produce a single multi-layered capsule with diameters between 4 and 20 mm. Even with predictive mechanisms in various hydrogels, challenges exist in both mass production and scaling-down of the size of hydrogel architectures, and multi-layered techniques for cell encapsulation studies are even sparse.

We propose the fabrication of multi-layered alginate capsules to resolve the technical bottlenecks through precise control of hydrogel modalities and shell thickness at micron scale enabling scaleup for mass production. The multi-layered capsules comprise of natural alginate polymer crosslinked with Ca^{2+} ions without auxiliary crosslinking agents. To the best of our knowledge, no theoretical or empirical formulation has been suggested to describe the process underlying our hierarchical alginate structures. In addition to the materials we also suggest a hypothetical mechanism to explain how different alginate hierarchical structures can be fabricated and demonstrate its encapsulant application for heterogenous microbial spatial distribution. We believe our proposed encapsulation methodology with alginate hydrogels will be an effective avenue to organize cells into sophisticated and stratified structures to study intra and multi-cellular communication.

SM11.08.04
***In Situ* Investigations of Biochar as a Tunable Platform for Aqueous Malathion Adsorption** John Kirtley, Daniel Goettlich, Abdul Hadi and Kelsi McEnaney; Montana Technological University, United States

Biochar, a highly porous carbonaceous product of biomass pyrolysis, offers a wide array of surface functional groups and structural modalities that depend on biomass properties and pyrolysis conditions. This tunable platform promises versatility in capturing aqueous organophosphates, including malathion, a hazardous pesticide and chemical warfare agent surrogate. While some studies have elucidated the general mechanisms associated with biomass pyrolysis, the relationship between material evolution and efficacy toward a variety of emerging applications is largely unknown. In this work, we use Raman spectroscopy and Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS) to probe *in situ* the molecular and structural changes of coir biochar at various temperatures up to 850 °C. Raman signatures from biochar reflect the complex structural changes of the amorphous carbon as it gradually transforms to larger aromatic structures, during a slow temperature ramp and subsequent 2-hr dwell. DRIFTS similarly indicates increasing aromatic character and fewer aliphatic groups as pyrolysis temperature increases, while some oxygen-containing functional groups (hydroxyl, carbonyl) are largely eliminated by 500 °C. These tunable chemical groups/carbon structures are expected to significantly impact the adsorption of aqueous malathion onto the meso and micro pore surfaces of biochar due to various non-covalent interactions. To test this hypothesis, we use high-performance liquid chromatography (HPLC) to record the concentrations of aqueous malathion containing biochar suspensions, over time. Initial work suggests that biochar is effective in adsorbing malathion, and continued studies elucidate

the nature of the biochar-malathion interactions. In particular, during the course of an adsorption experiment, biochar suspensions are removed and analyzed using attenuated-reflectance FTIR. Spectra from suspensions containing the highest concentrations of malathion near equilibrium suggest the highest density of surface-adsorbed malathion, and that the malathion carbonyl groups may be responsible for this interaction.

SM11.08.05
Polydopamine-Coated Silica Aerogels with Enhanced UV-Absorption Gabrielle S. Rey[1], Stephanie L. Vivod[2], Saranshu Singla[1], Theresa Benyo[2] and Ali Dhinojwala[1]; [1]The University of Akron, United States; [2]NASA Glenn Research Center, United States

Silica aerogels are lightweight, open-celled, porous structures that have advantageous properties such as low density and high surface area. Due to these characteristics, silica aerogels would be great candidates for aeronautical applications. Recently, there has been considerable interest in functionalizing substrates with polydopamine (PDA), a polymeric, bio-inspired synthetic analogue of melanin. Due to the catechol functionalities in PDA, PDA can easily adhere to a variety of substrates. While many studies coat two-dimensional substrates easily, very few studies exist that coat three-dimensional scaffolds with PDA while maintaining the scaffold's original properties. Here we demonstrate an in-situ coating method for depositing PDA on silica aerogel by utilizing the amine functionalities within the aerogel. The coated PDA-aerogel maintain high porosity (> 90%) and high surface areas (around 600 m^2/g). It also exhibits strong absorption of UV-light in comparison to the uncoated aerogel monolith due to UV-absorption ability of PDA. PDA- coated aerogels have promising potential to serve as radiation-mitigating materials for space exploration.

Bioinspired Nano and Macro Composite Structures as Thermoelectric Devices Yuxiang Zhu, Weiheng Xu, Dharneedar Ravichandran, Sayli Jambhulkar and Kenan Song; Arizona State University, United States

Thermoelectric devices can collect heat and convert them as electricity; thus, fabrication of composites with programmable electrical conductivity, thermal conductivity, and Seebeck coefficient parameters can enable highly efficient energy generation and storage. Our research reported the processing of polymer and nanoparticles from a molecular scale via the in-situ polymerization method. The nanoscale polymer/nanoparticle hybrid mimicked biosystems such as blood vessels or cellular structures in plants. Via the interphase formation, the thermal and electrical conductivity of the macroscale composites showed optimized properties. As compared to the simple blending of the polymer and the nanoparticles, our in-situ polymerized composites exhibited much enhanced thermoelectrical performance and shed light on manufacturing that transfer the nanoscale properties to the macroscale device performance.

Late News: Direct Laser Written Microstructures Displaying Reversible Sugar-Induced Actuation Alexa Ennis, Deanna Nicdao, Colm B. Delaney and Larisa Florea; Trinity College Dublin and The University of Dublin, Ireland

The reversible binding of phenyl boronic acids (PBA) to 1,2 or 1,3 diols has been explored for over 20 years.[1] Solution based studies have used these molecules to generate measurable colorimetric, fluorescent, or electrochemical change in response to common saccharides, such as glucose and fructose. As the nature of their reversible bond formation remains relatively unspecific to the nature of the sugar present, their application has struggled to ever compete with the accuracy of enzymatic systems based on glucose oxidase. However, the potential to incorporate these materials, in a facile manner, into soft polymeric matrices can offer significant advantage in the generation of passive sampling and even self-regulating systems.
To this end, sensors and actuators based on the PBA-containing hydrogels have found application in optically, electrically, and even mechanically responsive materials. A large proportion of the research which generates binding-induced shape changes, relies on swelling or shrinkage of PBA materials, caused by modulating osmotic pressure upon bond formation with the sugar molecule, a phenomenon first exploited by Matsumoto et

al. in 2004.[2] Volume change of PBA in hydrogel structures can be hampered by slow response times as the speed of the response relies on the volume-dependent diffusion times of analytes to receptor sites. To date, such systems have primarily been implemented in macro-sized gels which have contributed to this effect. As the kinetics of hydration process are typically proportional to the square of the linear dimension[3], a reduction in hydrogel size from mm to μm (as presented herein) reduces the response time by a factor of 1 million. We present a system compatible with two photon polymerization (2PP) which allows for the fabrication of structures on the micron and sub-micron scale. The advantage of having such small structures is that the traditionally slow responses times associated with PBA based hydrogels are overcome by the fast diffusion of the analyte throughout the structure.
To study the actuation of microstructures fabricated using our novel photoresist, arrays of pillars with 20 μm diameter and 30 μm height were fabricated. When exposed to a D-fructose solution, the pillars underwent a significant swelling response. Up to a 90 % increase in area of the pillars was observed within 30 seconds of the addition of 100 mM fructose solution. It was demonstrated that this response was reversible and reproducible over multiple cycles.
Interestingly, the degree of actuation can be tailored by adjusting the laser dosage used to fabricate the structures. As expected, structures fabricated using higher laser powers were more densely crosslinked and therefore exhibit a reduced swelling response when compared to structures fabricated at lower laser powers. For example, the area of structures fabricated at a 20 mW laser power increased by almost 90 %, while structures fabricated at a 40 mW laser power only underwent a 40 % increase in area.
This work enables the realization of soft complex 3D microstructures and actuators with programmable response and fast response-time.

SM11.08.10
Late News: Teroligomers from Morpholine-2,5-Diones Providing a Large Variety of Repeating Unit Sequences Xiao Liang[1], Marc Behl[1] and Andreas Lendlein[1,2]; [1]Institute of Active Polymers Helmholtz-Zentrum Geesthacht Centre for Materials and Coastal Research, Germany; [2]University of Potsdam, Germany

The structural variation of functional side groups and sequence structures of repeating units in oligodepsipeptides (ODPs) allows the design of matrix materials exhibiting strong physical interactions with specific drug molecules[1,2]. In this way high drug loading can be achieved. Here teroligomers are prepared by a ring-opening polymerization of three different morpholine-2,5-diones. Dibutyl tin(II) oxide were reacted with 2-hydroxyethyl disulfide forming the catalyst / initiator system for the library of teroligomers[3]. It was designed to potentially introduce redox sensitivity to the ter-ODPs. The optimized synthetic route enabled the presence of dihydroxy terminal groups on the ter-ODPs, and minimized the formation of macrocycles as a potential side reaction. The systematical variation of repeating units composition in ter-ODPs samples was quantitatively calculated by ^{1}H-NMR according to the intensity variation of the methyl/methylene signals from the different repeating units, and it was in line with the variation of comonomer ratio of the feed composition for the ROP reactions. As the repeating units in ter-ODPs have different molecular weight, the composition variation in different ter-ODPs was also reflected by MALDI-TOF-MS results. The intensity of m/z^+ peaks assigned to telechelic ter-ODPs with high methyl-modified MD units (MMD_{units}) content increased accordingly as the composition of the MMD_{units} increased, and thus a shift of m/z^+ peaks of telechelic structures was observed. In addition, the intensity change of the $\delta_s(CH_3)$ band at 1375 cm^{-1} in the fingerprint area of the FT-IR spectra of different ter-ODPs samples, attributed to the iso-butyl modified MD units could be an additional hint for the composition variation of ter-ODPs. The good end group functionality of ter-ODPs was reflected by the further

linkage with isophorone diisocyanate (IPDI) via the coupling of hydroxy ends of ter-ODPs and one of the isocyanate group of IPDI. In future, these ter-ODPs could be used as interesting candidate matrix materials for drug releasing implants such as particulate dosage forms.

SM11.08.11

Late News: Microbe-Assisted Titanium Oxide Composite Development for Lithium-Ion Battery (LIB) Anodes with Super-Concentrated Aqueous Electrolytes Pei-en Weng[1], Alexander Gooyandeh[1], Avinash Godara[2], Tianyu Li[3], Jocelyn Vanlenzuela[1], Steven Mancini[1], Samuel Ming Tuk Yeung[1], Katy Kao[1] and Dahyun Oh[1]; [1]SJSU, United States; [2]Texas A&M University, United States; [3]North Carolina State University, United States

Unique structural and intermolecular properties found in nature for generations have inspired humanity to engineer more efficient products. Biomaterials-driven nanostructures have also shown remarkable performance improvements in electronics. The recent development of carbon-coated TiO_2 has been proved to improve the performance of TiO_2 as an anode material in Li-ion batteries (LIBs). Microbes, such as E. coli, contain a high amount of carbon, making them a promising precursor for the formation of carbon layers. In this presentation, we report a bioinspired synthesis method to fabricate a composite using microbes and anatase TiO_2 to improve the energy density and cycle life of aqueous LIBs with the water-in-salt electrolyte (WiSE), (aqueous electrolyte composed of 21m LiTFSI (lithium-bis(trifluoromethanesulfonyl)-imide)). Anatase TiO_2 synthesized by the sol-gel method can reach a high theoretical capacity (167 mAh/g) and increase batteries' energy density. The volumetric changes in its crystalline structure during the lithiation/delithiation is less than 4%, making the anatase TiO_2 a possible anode material for stable batteries. By using two different strains at different growth stages, we were able to control the microstructure of the microbe-assisted TiO_2 (m-TiO_2) composite based on the variability of the shape of the microbes. The synthesis process involved subsequent mixing and dehydration of the microbe and TiO_2 mixture, followed by an annealing process. The microbes acted as carbon precursors and formed a carbonaceous layer on the anatase TiO_2. These carbonaceous biofilms are expected to improve the composite's conductivity and prevent direct contact between the anode and water molecules in WiSE. With m-TiO_2 anodes, we achieved 37.2% higher specific capacity at the fortieth cycle at the C/5 rate and 49.2% higher at the C/2 rate compared to the performance of bare TiO_2 anodes.

Assemblies of Ordered Nano-Hybrids Obtained by Biomineralization-Inspired Processes Takashi Kato; The University of Tokyo, Japan

Biomineralization processes are controlled by organic templates such as peptides and polysaccharides. Acidic peptides and proteins exert effects on morphologies of biominerals, which are organic/inorganic hybrids [1-3]. Inspired by these processes, we have obtained a variety of synthetic organic/inorganic hybrids. Here we show recent developments of nanorod and nanodisk hybrid materials based on calcium carbonate [4] and hydroxyapatites (HAP) [5-8]. These hybrid materials are obtained in the presence of an acidic synthetic polymer, poly(acrylic acid). These nano-hybrids form colloidal liquid-crystalline states due to their anisotoropc shapes. The dynamic and alignment behavior has been examined for these nano-hybrids by x-ray and neutron scattering [6,7]. Biofunctions of these materials have been studied for HAP nanomaterials [8].

8:25 AM *SM12.01.02
Diverse and Unique Colloidal Particles Assembled from Polydisperse Liquid Crystalline Oligomers Shu Yang; University of Pennsylvania, United States

Polymeric colloidal particles play important roles in applications including coatings, adhesives, paintings, drug delivery, and personal cares. Often they are prepared from emulsion polymerization with well-controlled chemical compositions of surfactants and monomers. Polydispersity tends to impede self-assembly processes and the control of particle morphologies. In contrast, nature provided us diverse examples of microparticles that have unique surface textures from mixtures of polypeptides. Further, shape transformation from one state to another is not uncommon in biology.

Here, I will present two examples of self-assembled colloidal particles polymerized from nematic liquid crystal

oligomers (LCOs), where oligomerization and polydispersity of the chain lengths is a feature. In the first example, we synthesize microparticles using a microfluidic device, followed by solvent evaporation and photopolymerization, leading to with robust, tunable surface patterns. Phase separation of LCOs occurs at the interface of the oil-in-water droplet upon organic solvent evaporation, which is facilitated by the mechanical coupling of LCOs of different chain lengths at the droplet interface. In the second example, we show dramatic shape transition of nematic LCO drops to a rich variety of non-spherical morphologies with unique internal structures upon cooling from the isotropic state to the nematic state. Here, molecular heterogeneity *promotes* and stabilize the reversible transitions. These studies suggest that heterogeneity and anisotropy together with shape control will offer new exciting routes to create a wide variety of bioinspired materials.

8:50 AM SM12.01.03
The Dynamics of Chemical Interactions in a Fluid Medium as Revealed by Turing Patterns—A Model Study for Exoskeletal Patterns in Morphogenesis Renuka Rajasekaran; Luella High School, United States

Allen Turing suggested that a system of chemicals reacting with each other and diffusing across space, termed a reaction-diffusion system, could account for the chief phenomena producing exoskeletal patterns in morphogenesis. Turing Patterns remained dormant for some time due to Turing's untimely death and the dominance of the Second Law of Thermodynamics in the scientific world. Some alternatives to the reaction-diffusion theory have also been proposed now. For instance the mechanochemical theory of morphogenesis. However, there are several puzzles to be solved in Turing Patterns. Chief among such puzzles is: which chemicals are the most fundamental of biological patterns? Neither Turing, nor the latter researchers have addressed this question. The present work is an effort to seek answer to this question through a simplistic approach.
The study's focus started with melanin, which is the chief pigment of exoskeleton color and pattern prints. Evidence shows that in the complex genetic expression of melanin, casein is involved through an enzyme called casein kinase. Therefore, it was realized that exploration of caesin's Turing patterns in a physiological fluid model deserves a study. In the simplified model of the physiolgical fluid chosen for this study, certain key ingredients were incorporated into cow's milk; they are: sucrose, collagen, and sodium chloride. The rationalel for the choice of these ingredients is given below.
Sucrose is involved in embryonic development as the energy source and it also serves as the signaling material for gene expression. Collagen is a fibrous protein and constitutes nearly 50% of body protein in mammals. Collagen also comes to the central stage from the osteogenesis (bone development) phase in embryonic development. Given that casein, collagen, and sucrose are macromolecules, they serve a major role as the basic building blocks of embryonic development. The importance of sodium chloride comes from the fact that it is the dominant physiological electrolyte.
Casein is a popular globular protein; as is well known, globular proteins have complex structures (conformation) and have a far greater variety of biological functions. They are thus very dynamic rather than static in their activities. Notably, casein is involved from the start in the embryonic development both in vertebrate and invertebrate animals as well as in plants.
In consideration of the relevance to morphogenesis, Turing patterns of the interaction between casein, sucrose, collagen, and sodium chloride in aqueous medium were investigated in the present study. The stains used are the dye/pigment components of common food coloring agents. The present investigation provides a strong support to casein being the most fundamental macromolecule, which initiates, controls, and guides pattern formation. Salt helps in the polarization of casein and loosens the micelles to different patterns depending on the degree of polarization determined by salt concentration. Sucrose cross links casein strands in unique ways to produce different patterns, guided by its concentration. As revealed by the Turing patterns, sucrose's effect is so magical and seemingly different unique conformational structures are created by casein-sucrose interaction. The Turing patterns also indicate that the effects of these substances are synergistic. Furthermore, some of the patterns revealed by casein and collagen are similar to that of the embryo in gastrulation and neurulation. The present investigation also leads to an understanding that stripes of alternative colors we see on the animal skins (such as zebras) do not seem to come from two different pigments; but they seem to be different tones of the same color. The tone is determined by the kinetics of the underlying physicochemical phenomena.

9:05 AM *SM12.01.04
Light-Responsive Shape-Shifting Nanoparticle Superstructures Nathaniel Rosi and Yicheng Zhou; University of Pittsburgh, United States

We have developed a peptide-based approach for designing and constructing structurally complex nanoparticle superstructures. In this approach, peptide conjugate molecules bind to inorganic nanoparticles and direct their assembly. This presentation will detail first generation 'static' superstructures, including 1-D assemblies such as gold nanoparticle helices and discrete 0-D assemblies such as hollow spherical superstructures. We will discuss the subtle differences between the peptide conjugates which direct the assembly of these morphologically distinct superstructures and suggest design criteria for conjugates that can be used to construct second generation 'dynamic' superstructures. As a proof of principle, we design a family of photoresponsive peptide conjugates to control the reversible assembly of gold nanoparticles. The conjugates have different responses to input of UV radiation. We demonstrate that the nanoparticle superstructures constructed from these conjugates can undergo morphological shifts from spheres to 1-D assemblies. These results point toward new methods for dynamically controlling nanoparticle assembly via photo stimulus and new families of structurally complex dynamic nanoparticle superstructures.

9:30 AM SM12.01.06
Doping Silicon, Using DNA Ruobing Bai and Haitao Liu; University of Pittsburgh, United States

This talk will present our recent effort towards achieving nanoscale site-specific doping of Si wafer using DNA as both the template and the dopant carrier. Upon thermal treatment, the phosphorous atoms in the DNA diffuse into Si wafer, resulting in doping within the defined region right below the DNA template. A doping depth of 30 nm is achieved for 10s of thermal treatment. We have fabricated prototype field effect transistors using the DNA-doped Si substrate. By using DNA nanostructures to pattern self-assembled monolayers, we are able to achieve both *n*-type and *p*-type site-specific doping of Si. This work shows that DNA nanostructure template is a dual-use template that can both pattern Si and deliver dopants.

10:30 AM *SM12.02.01
Designing Self-Assembling and Gradient Materials for Regenerative Medicine Molly Stevens; Imperial College London, United Kingdom

This talk will provide an overview of our recent developments in self-assembling and gradient materials for regenerative medicine. We are using remote fields to engineer complex 3D architectures that mimic anisotropic and multiscale tissue structures and produce spatially arranged bioinstructive biochemical cues. We have used acoustic stimulation to produce engineered muscle with bundles of aligned fibres [1], and magnetic fields and buoyancy to achieve biochemical gradients in osteochondral scaffolds [2]. These versatile technologies can be applied to wide range of tissue engineering and drug delivery. We also use light stimulation on our photocaging gRNA strategy for spatiotemporally resolved CRISPR-Cas gene editing [3]. Using this system, we have achieved *in vivo* spatiotemporally controlled gene editing in living zebra fish embryos upon brief exposure to UV light. Finally, we will discuss recent developments in our tunable nanoneedle arrays for multiplexed intracellular biosensing at sub-cellular resolution and modulation of biological processes [4].

10:55 AM *SM12.02.02
Self-Assembling Peptides for Regenerative Medicine Applications Fabrizio Gelain; IRCCS Casa Sollievo della Sofferenza, Italy

Peptidic biomaterials have been receiving great interest because of their easiness of scale-up production, absence of pathogen-transfer risk, biomimetic properties, nanostructured morphology and customization potential for the specific tissue engineering application. However, their proper usage requires the understanding of multiple phenomena taking place at different scale levels during self-assembling. In this presentation, focused on the nanotech advancements in the field of regenerative medicine, we will see some multi-disciplinary researches and advances toward the regeneration of nervous tissues and pancreatic islets transplantation. This will bring us from molecular dynamics to cross-linking and electro-spinning of self-assembling peptides, from high-density 3D cells cultures to in vivo testing.

11:20 AM SM12.02.03
Biomimetic Self-Templating Fibrillogenesis Seungwook Ji[1,2], JuHun Lee[1,2] and Seung-Wuk Lee[1,1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

In nature, many filamentous macromolecules self-assemble into complex, hierarchically ordered fiber structures. The formation of fibers proceeds as cells secrete the macromolecules into a confined extracellular space. The filamentous macromolecules stabilize into diverse non-equilibrium structures that exhibit exquisite optical, mechanical and biological functions. To explain the mechanism of fiber formation in nature, biophysicists have constructed a variety of theoretical and experimental models. These models could not propose real-time processes of fiber formation and assume no interaction between macromolecules in general. Because it is not trivial to design an interaction-controllable system; this basic limitation and assumption, however, is highly simplified and does not represent the reality of nature. We demonstrate our recent efforts to design a biomimetic self-templating fiber formation process under the interaction-controllable system. M13 bacteriophage possesses a long filamentous shape with a helically-arranged protein surface, analogous to naturally existing basic building blocks. As a result of amplification through bacterial infection, M13 bacteriophage is identical, homogenous, and can be easily genetically engineered to make M13 bacteriophage a promising biomaterial in designing a biomimetic system. In this study, we genetically engineer M13 bacteriophage to install a functional peptide motif (VGVPGVG (V: Valine, P: Proline, G: Glycine)) at the end of the major capsid protein p8 to tune interactions between biomolecules during assembly. The introduced functional peptide motif possesses hydrophobic residue which can trigger hydrophobic interaction between phages. In addition, we applied depletion attraction force to manipulate interaction more precisely. We demonstrate that by controlling thermodynamic factors (e.g. concentration of phage and depletant, ionic strength and temperature, etc) we could investigate real-time evolution process of fibrous structure formation and understand how the molecular level interaction acts to the process. Engineered phages go through loosely assembled tactoids, densely packed domains, stacking of domains to fibrils formation and further hierarchical structures. Our approach provides the understanding how the formation of each ordered structure could be the

basis of the next hierarchical structure formation. To investigate the time dependent evolution process of fibrous hierarchical structures, we employed polarized optical microscopy (POM). Other microscopic and nanoscopic structure characterization were carried out by atomic force microscopy (AFM) and scanning electron microscopy (SEM).

11:35 AM SM12.02.04
Pyroelectricity of M13 Bacteriophages Han Kim[1], Seungwook Ji[1], Inseok Chae[1], Kento Okada[1,1] and Seung-Wuk Lee[1,1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Pyroelectricity is a physical phenomenon of polarization change under temperature fluctuation in the environment. Biological building blocks such as amino acids, deoxyribonucleic acid (DNA), ribonucleic acid (RNA), proteins, and biomaterials such as soft and hard and tissues with hierarchical structures are composed of polar molecules and also known to induce pyroelectric property. However, the molecular mechanism of the pyroelectric effect in biological materials is still elusive. Here we report M13 bacteriophage (phage) as a programmable biomacromolecule building block to study the structure and function relationship of the pyroelectric biomaterials. M13 phage is a benign and non-harmful virus to infect only bacterial host cells. It has a filamentous shape with 880 nm in length and 6.6 nm in diameter. The M13 phage is assembled with 2700 copies of major pVIII coat protein hierarchically with spontaneous polarization. Through genetic modification, we can precisely control the chemical and physical structures of the phage proteins and investigate how the polarization changes under heat application. We can further easily amplify to produce identical copies of the phage on a large scale and self-assemble the phage into highly ordered arrangements. Here we developed a novel pyroelectric material and device using M13 phage. We first created a unidirectionally polarized monolayer phage film and characterized its pyroelectric characteristics. To determine how the heat can manifest polarization of the phage, we used piezoresponse force microscopy and Kelvin probe force microscopy and observed the polarization changes by visualizing the changes in the amplitude, phase, and surface potential under temperature changes. We then modified the polarization of the phage protein by inserting a variable number of negatively charged amino acids to demonstrate the origin of the pyroelectricity of the phage and to suggest the controllability of the pyroelectricity in biomaterials. We finally fabricated phage-based pyroelectric devices that can be used for thermosensor and energy harvester to show the feasibility of future applications. Our approach shows how the hierarchical assembled polar molecules contribute to the pyroelectricity in a biological system in a molecular level and how we can utilize the pyroelectric biological materials for future self-powered system and biomedical applications.

11:50 AM SM12.02.05
Self-Assembly of Aramid Amphiphiles into Ultra-Stable Nanoribbons and Aligned Nanoribbon Threads
Ty Christoff-Tempesta and Julia Ortony; Massachusetts Institute of Technology, United States

Small molecule assemblies in biological systems, such as cell membranes, benefit from high-surface-areas, tunable surface decoration, and responsiveness for interaction with their environments. In these systems and the synthetic analogues inspired by them (e.g. those derived from peptides), molecular migration, molecular exchange, and other dynamic instabilities are pervasive. These dynamic processes can be beneficial in applying supramolecular assemblies in biological environments, but increasing nanostructure stability may provide a route to their use in non-biological contexts. Here, we introduce the design of the aramid amphiphile (AA) motif to form microns-long nanoribbons with a dense, percolated hydrogen bonding network. These nanoribbons exhibit suppressed molecular exchange dynamics, mechanical properties on par with silk, and morphological stability outside of water. We utilize this stability to, for the first time, produce dried macroscopic threads of small molecule amphiphiles and demonstrate tunability of their mechanical properties. Finally, we incorporate photoswitchable moieties into the amphiphile design and show their triggerable, reversible morphological transitions between nanoribbon and nanotube states. Both morphologies exhibit months-long stability, persistence in air, and convert fully upon triggering. The AA platform overcomes dynamic limitations of conventional supramolecular systems to provide a novel route to solid-state

nanostructured molecular materials.

Bio-Inspired Photosynthetic and Bioactive Hydrogels Samuel I. Stupp; Northwestern University, United States

Our laboratory is focused on the design of synthetic functional systems that can emulate the most intelligent processes in supramolecular structures of plantea and animalia kingdoms. Two functional hallmarks of naturally occurring chemical systems are the photosynthetic machinery of green plants, which "safely" sustains life on the planet, and the amazing signaling pathways that rule the behavior of cells. Both use hydrogels as the "material" environment in which evolutionary events have optimized their respective functions. In this lecture we describe bio-inspired synthetic hydrogels inspired by green leaves that are based on light harvesting supramolecular polymers and enzymes. These systems synthesize molecules such as hydrogen peroxide, potentially useful as liquid fuels in sustainable energy systems. The lecture will also describe highly dynamic supramolecular polymer hydrogels that mimic extracellular matrices and effectively signal cells to promote regenerative signaling pathways. This particular work will highlight the use of hydrogels in promoting regeneration in the central nervous system, a goal that for many reasons has great societal impact to be explained in the lecture.

Metal-Binding Peptoids as a New Platform for the Development of Functional Bio-Inspired Materials and Supramolecular Peptoid Architectures Galia Maayan; Technion–Israel Institute of Technology, Israel

Peptoids, N-substituted glycine oligomers, are an important class of peptide mimics that are generated from primary amines rather than from amino acids. Their facile and efficient synthesis on solid phase support enables the incorporation of various functional groups at specified *N*-positions along their spine including metal-binding ligands and catalysts.[1] Peptoids can adopt polyproline type helices if the majority of their sequence consists of chiral bulky pendent groups.[2] Such side-chains are structure inducers but they have no functional value. In my talk I will present the inclusion of metal-binding ligands within peptoid sequences as a new platform for the development of functional bio-inspired materials and supramolecular peptoid architectures. Thus, I will describe: (i) Controlled aggregation of Ag(0) NPs at room temperature in water near neutral pH mediated by peptoids, where tuning the sequence or of the peptoid or changing the metal-binding ligand impact the morphology of the Ag(0) NPs assemblies.[3] (ii) Cu(II) mediated self-assembly of short peptoids to form double-stranded peptoid helicates,[4] and distinct copper-peptoid duplexes, where changing only one non-coordinating side-chain leads to different supramolecular structures including tightly packed helical rods or nano-channels, and to different the pore sizes of the nano-channels.[5] The selective recognition abilities of the nano-channels towards biologically relevant small molecules and anions will be also demonstrated. (iii) The direct correlation between the structure of short metal-binding peptoids varied in their monomer sequence, and the photoluminescence of their Ru(II) complexes, where .helical peptoids do not affect the fluorescence of the embedded Ru(II) chromophore, while unstructured peptoids lead to its significant decay.[6]

1:25 PM *SM12.03.02
Expanding Hydrogel Functionality using Hierarchical Structure in Precision Polymers Adrianne M. Rosales; The University of Texas at Austin, United States

Tissue engineering offers great promise as a therapy for damaged tissues, a replacement for whole organs, or a platform for drug screening; however, many biomaterial scaffolds fall short on yielding reproducible and functional constructs. Hydrogels in particular have garnered intense interest as tissue engineering scaffolds due to their tailorable permeability, mechanics, and degradability. Synthetic materials are attractive due to their known chemical compositions and reproducibility, but the challenge with their use lies in the lack of complexity as compared to biological systems, especially with regard to sequence-specific bioactivity and hierarchical structure. Hence, our work aims to expand the toolbox for building complexity and functionality into synthetic hydrogel biomaterials by using precise polymer architectures, specifically those of polypeptoids. Using non-natural polypeptoid crosslinkers, we achieved control over the mechanics of poly(ethylene glycol) (PEG) hydrogel platforms by varying monomer sequence and chain structure. Unlike traditional crosslinking methods, our polypeptoid crosslinkers enabled control over hydrogel mechanics without altering network connectivity. Due to their biomimetic backbone, the polypeptoid crosslinkers also conferred stability to cellularly-secreted proteases, as compared to biological substrates. Furthermore, we examined the ability of non-natural peptoid monomers to tune proteolytic degradation rate using hybrid peptide-peptoid structures. Overall, our results suggest that sequence control of synthetic polymers may be a general strategy for expanding the functionality of biomaterial scaffolds for tissue engineering, particularly with respect to mechanics and degradation in complex biological environments.

1:50 PM SM12.03.03
Peptoid-Directed Assembly of CdSe Nanoparticles Madison Monahan[1], Bin Cai[2], Tengyue Jian[2], Shuai Zhang[2,1], Guomin Zhu[2,1], Chun-Long Chen[2,1], James J. De Yoreo[1,2,1] and Brandi Cossairt[1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

The high information content of proteins drives their hierarchical assembly and complex function, including the organization of inorganic nanomaterials. Peptoids offer an organic scaffold very similar to proteins, but with a wider solubility range and easily tunable side chains and functional groups to create a variety of self-assembling architectures with atomic precision. If we could harness this paradigm and understand the factors that govern how they direct nucleation and assembly of inorganic materials to design order within such materials, new dimensions of function and fundamental science would emerge. In this work, peptoid tubes and sheets were explored as platforms to assemble colloidal quantum dots (QDs) and clusters. We have successfully synthesized CdSe QDs with difunctionalized capping ligands containing both carboxylic acid and thiol groups and mixed them with maleimide containing peptoids, to create an assembly of the QDs on the peptoid surface via a covalent linkage. This conjugation was seen to be successful with peptoid tubes, sheets and CdSe QDs and clusters. Particle identity was confirmed on the peptoid surface using EDX and high-resolution TEM. The particles were seen to have a high preference for the peptoid surface but non-specific interactions with carboxylic acid groups on the peptoids limited control over QD density via the maleimide conjugation. Replacing the carboxylic acid groups with methoxy ethers allowed for control over QD density as a function of maleimide concentration. ^{1}H NMR analysis demonstrated that binding of QDs to peptoids involved a subset of surface ligands bound via the carboxylate functional group, allowing sulfur to bind via covalent linkage to the maleimide. Overall, we have shown the compatibility and control of CdSe-peptoid interactions via a covalent

linkage with varying peptoid structures and CdSe particles to create complex hybrid structures. Future work looks to expand the library of compatible nanoparticles to tune the properties of the hybrid materials and pattern complimentary nanoparticles onto a single peptoid surface and to investigate the assembly of peptoid nanostructures after conjugation with nanoparticles

2:05 PM *SM12.03.04
Protein-Mimetic Materials from Sequence-Defined Peptoid Polymers Ronald N. Zuckermann; Lawrence Berkeley National Laboratory, United States

A fundamental challenge in materials science is to create synthetic, organic nanostructures with the same architectural sophistication as proteins. One of the most exciting ways to do this is to mimic nature, and synthesize sequence-defined, non-natural polymer chains that spontaneously fold and assemble into precise three-dimensional structures. Peptoid polymers offer a unique platform to advance this general approach. We developed an automated synthesis method, the solid-phase submonomer method, which can efficiently synthesize high-purity, sequence-defined peptoid polymers up to 50 monomers in length. The method uses readily available primary amine synthons, allowing hundreds of chemically diverse sidechains to be cheaply introduced. We use this method, along with computational modeling, to design, synthesize, assemble and engineer a variety of protein-mimetic nanostructures, and to probe fundamental questions in self-assembly and polymer physics. Here, we show by NMR, direct imaging using cryo-TEM, X-ray scattering, and MD sumulations, that all known crystalline peptoid assemblies share a fundamental secondary structure motif based on a backbone fold containing all *cis*-amide bonds. This unexpected universality of peptoid backbone folding offers a unique opportunity to rationally design and engineer these materials to create robust, atomically-defined nanomaterials capable of protein-like functions.

2:30 PM SM12.03.05
Designing and Building Hierarchical Heterostructures through Solid-Binding Proteins Functionalized Peptoid Nanosheets Jinrong Ma[1], Bin Cai[2], Shuai Zhang[1,1], Tengyue Jian[2], James J. De Yoreo[2], Chun-Long Chen[2] and Francois Baneyx[1,1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Despite their technological potential and decades of advances in synthetic and biological chemistry, the construction of hierarchical architectures that intimately integrate synthetic polymer, natural biomolecules and inorganic components remains difficult. Two promising building blocks to tackle this challenge are peptoids, a class of peptide mimics that can be designed for self-assembly into well-defined structures, and solid-binding peptides (SBPs), which offer a biological path to controlled inorganic assembly and mineralization. Here, we report on the synthesis of ~3.3 nm-thick, thiol-reactive peptoid nanosheets assembled from equimolar mixtures of unmodified and maleimide-derivatized version of the $Nbpe_6Nce_6$ oligomer, optimize the location of cysteine residues in silica-binding derivatives of superfolder green fluorescent protein (sfGFP) for maleimide conjugation, react the two components to form peptoid-protein hybrids that exhibit partial or uniform protein coverage on both of their surfaces, and use 10 nm silica nanoparticles to trigger the stacking of these 2D structures into a multi-layer material comprised of alternating peptoid, protein and inorganic layers. We also exploit the display of solid-binding proteins on peptoid nanosheets and nanotubes to template the organization and control the precipitation of various inorganic materials, establishing peptoid-protein hybrids as a promising platform for materials science.

2:45 PM SM12.03.06
Multi-Phase Assembly of Short-Sequence Peptoid on MoS2 Shuai Zhang[1,2], Peng Mu[2], Chun-Long Chen[2,1] and James J. De Yoreo[2,1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Inspired by Nature, numerous biomolecules with complementary binding affinity to inorganic surfaces have been designed. These biomimetic molecules, including peptides, proteins, and peptoids, have convincing

applications in molecular recognition, fabrication of bio-hybrid materials, (bio)mineralization, energy conversion, storage, and transportation of matter and information, etc.
Peptoid is a class of biomimetic polymer with compatible bio-functions to peptide but has better thermal and chemical stabilities. It offers unique advantages for creating hierarchical assemblies at solid-liquid interfaces, serving as templates with outstanding spatial order for further functionalization. In this talk, I will present the most recent achievements of assembling short peptoid oligomers on MoS_2. By adjusting the pH of the assembly solution and the size of peptoid hydrophobic side chains, we demonstrated that peptoid assembly on MoS2 could have diversity phases, including the homogeneous film with high crystallinity, disk-like single-layer domains, and lamella patterns. We further found that these phases can co-exist with each other, and the homogeneous film is the template for the growths of the other two phases. After comparing the results to the simulations, it is clear that the peptoid-peptoid interaction and peptoid-MoS_2 interaction, mediated by pH, both play crucial roles in this multi-phase assembly. These results improve the knowledge of designing hierarchical architectures with biomolecules at solid-liquid interfaces. It also provides opportunities to optimize the performance of semiconductor devices in the future.

4:00 PM *SM12.04.01
Bio-Inspired Approaches for Assembly—Insights for Graphene and *h*-BN Marc R. Knecht; University of Miami, United States

Controllable assembly of materials with regiospatial precision remains a grand challenge where complex arrangements are required to achieve emergent properties. Such structures are required for a wide range of applications, including metamaterials, optical limiting, catalysis, biosensing, etc. Bio-inspired approaches represent unique avenues to achieve such organized structures based upon the precision achieved through biorecognition. Such assembly capabilities are well known in biological systems; however, translation of these approaches to non-natural materials remains difficult to achieve due to the lack of fundamental information concerning the interactions between biomolecules and material surfaces, especially for material compositions not typically observed in nature. In this talk, initial steps to access bio-based approaches for the assembly of two dimensional nanosheets of graphene and hexagonal boron nitride (*h*-BN) in three dimensions will be discussed. Our research has demonstrated that peptides can be used to drive graphene exfoliation from bulk graphite where modification of the peptides with fatty acid domains can be exploited to minimize defect incorporation in the final materials. Through a combination of experimental analyses and computational modeling, we have identified key parameters to control both the binding at the nanosheet surface for both graphene and *h*-BN, as well as the selectivity between the two different materials. Interestingly, the length of fatty acid modifications to the peptide sequence plays an important role in controlling the final bound structure, including achieving highly viscoelastic biointerfaces. Such capabilities are key for the design of new biomolecules with multiple materials binding domains, which could eventually be exploited to drive nanosheet heterostructure formation.

4:25 PM SM12.04.02
Periodic Phosphorylation and Disordered Domain in Amyloid Nanoribbons Impact Nucleation and Growth of Amorphous Mineral Susrut Akkineni[1,2], Cheng Zhu[3], Jiajun Chen[4], Miao Song[2], Samuel Hoff[3], Johan S. Bonde[5], Jinhui Tao[2], Stefan Habelitz[6], Hendrik Heinz[3] and James J. De Yoreo[2,1]; [1]Univeristy of Washington, United States; [2]Pacific Northwest National Laboratory, United States; [3]University of Colorado Boulder, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]Lund University, Sweden; [6]University of California, San Francisco, United States

Protein nanoribbons are believed to direct the organization of soft, amorphous mineral into tough, crystalline composites, however, how these ribbons scaffold an amorphous layer remains elusive. Inspired by tooth enamel, wherein amyloid-like amelogenin protein guides apatite mineralization, we investigated the impact of protein and peptide nanoribbon structure on thermodynamics and kinetics of heterogenous calcium phosphate nucleation and growth. Using *in situ* atomic force microscopy, supported by X-ray diffraction and molecular dynamics simulations, the molecular self-assembly, structure and function of nanoribbons arrays on graphite were resolved. We find that the nanoribbons lowered the barrier for formation of an amorphous phase, likely due to the hydrophilic side groups that protrude into solution with periodicity. Modification of the periodic domain with phosphorylation enhanced nucleation rates, whereas addition of a hydrophilic, disordered domain at C terminus promoted growth rates. These relationships provide empirical evidence for mineralization scaffolded by amelogenin nanoribbons and fundamentals for synthesis of hierarchical hybrid composites controlled by functional domains in nanoribbons.

From Nanoscale Interfacial Control to Bioinspired, Macroscale Thermoelectric Devices in Polyaniline/Nanocarbon Composites Yuxiang Zhu, Weiheng Xu, Dharneedar Ravichandran, Sayli Jambhulkar and Kenan Song; Arizona State University, United States

A thermoelectric generator is a promising approach to recovering this low-grade energy and provides a circular economy method for energy sustainability. So far, only 70% of humanity's total energy dissipates as waste heat, further exacerbating the energy crisis and global warming. This study will demonstrate the scalability of coating polyaniline (PANi) on carbon nanotubes (CNTs) for efficient thermoelectrical energy conversions. We start from the in-situ polymerization of aniline with mixed CNTs, and found that the coating of PANi on CNTs showed distinct phases as compared to mixed PANi/CNTs blends. A further examination of their properties showed higher thermal stability and mechanical robustness. More importantly, with different CNT concentrations, the thermoelectric performance was optimized in bioinspired gill structures. We demonstrated the uses of this structure in current/voltage measurement and showed efficiency in powering in-house designed sensors. Our manufacturing is applicable in conjugating polymers for thermoelectric devices.

4:55 PM SM12.04.04
Symbiotic Binary Assembly of Peptide Nano-Mosaics at Graphite Interfaces Tyler D. Jorgenson, You-Hsin Chen, Hadi Zareie, Mehmet Sarikaya and Rene Overney; University of Washington, United States

Control over the self-assembled hierarchical structure of functional biomolecules at solid interfaces is essential for the fabrication of micron-scale bio-nanodevices. Promising candidates are solid-binding peptides selected for specific inorganic solids by directed evolution techniques. Many of these selected peptides exhibit spontaneously long-range ordering at two-dimensional atomically flat solid surfaces. Advanced bio-nanotechnologies, such as multi-enzymatic bioreactors, require multiple, independently tunable functionalization of two or more different peptides to tailor interfacial molecular structures and functions. However, the current understanding of miscibility and binary assembly of peptides at interfaces is lacking. Here we present our findings on binary peptide assemblies at cleaved graphite surfaces with extraordinarily well behaved immiscible long-range ordered structures. We show that nucleation rates of the binary assembled system exceed those of the constituent peptide systems and are tunable by blending ratio and total peptide concentration. Molecular dynamics simulations and nanoscale atomic force microscopy attribute peptide immiscibility to peptide specific substrate recognition and self-assembly directions. Collectively, these findings lead to model predictions of the binary assembly structures of immiscible peptides based on 2D nucleation parameters of the single peptide assemblies. Our findings facilitate the molecular scale engineering of structured bio-nano interfaces through a multi-species self-assembly process and advance the fabrication of high-density patterning of biomolecules for biomimetic technologies, e.g., in multienzyme bioreactors and multiplexed biosensors. The research was supported by NSF-DMREF program through the grant DMR-1629071, 1848911, and 1922020 as part of the Materials Genome Initiative.

5:10 PM *SM12.04.05

Balancing Interactions Over Multiple Length Scales to Direct Assembly of Engineered Proteins at Mineral Surfaces James J. De Yoreo[1,2], Shuai Zhang[2,1], Robert Alberstein[3], Harley Pyles[2], Jiajun Chen[4,2,1], Faik A. Tezcan[3] and David Baker[2,2,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States; [3]University of California, San Diego, United States; [4]Lawrence Berkeley National Laboratory, United States

Self-assembly of particles to form superlattices and other ordered structures is typically thought of in terms of colloidal forces and liquid crystal ordering. Considerations of shape and solvent entropy dominate the controls on organization while atomic-scale details are of lesser importance due to the fairly homogeneous nature of the building blocks. Proteins offer unique advantages over inorganic particles as nanoscale building blocks, including monodisperse structures and specific interactions that are both atomically precise in their location on the protein and tuneable in their strenghts. For this reason, ordered assemblies of protein building blocks exhibit a wide range of structural motifs including 1D nanofibers and tubes, 2D lattices and 3D capsids and frameworks. Protein-based systems have the further advantage that they are readily assembled in interrogated in mild aqueous conditions, making them amenable to molecular resolution imaging techniques that provide a unique window into the assembly process. Here we report on two systems of engineered proteins. The first consists of a highly patchy 4-fold symmetric protein building block (L-rhamnulose-1-phosphate aldolase; RhuA), whose self-assembly is driven at the shortest length scale by disulphide bonds designed into four corners of the protein. By introducing a charged, atomically patterned substrate and varying charge states via solution ionic strength, we achieve simultaneous control of four different classes of interactions (covalent bonding, electrostatic surface templating, dipole-dipole interactions and desolvation-induced complexation) to yield four distinct, precisely patterned 2D crystals. The second system consists of a de novo designed rod-shaped helical repeat protein, DHR MicaN whose length can be set arbitrarily to N units of one repeat. These MicaN proteins are designed to interact in an epitaxial manner with the K^+-sublattice of muscovite mica. Variation of the design created an end-to-end hydrophobic interactions that were either dimeric at both ends or trimeric interface at one end and dimeric at the other. As with RhuA, we show that the interplay of the specific intermolecular interactions, regional electrostatic interactions and global colloidal forces lead to a variety of distinct ordered phases that are not expected for uniform or non-interacting colloids. In all cases, in situ AFM reveals the development of order and its relationship to protein design and surface and solution interactions. The results provide a mechanistic picture of assembly by protein building blocks that links pathways and outcomes to the influence of interactions over many length scales.

5:35 PM *SM12.04.06

Biological Synthesis and Structural Developments in Ultrahard Teeth of Chiton Taifeng Wang[1], Anna Pohl[1], Steven Herrera[1], Y. Narahara[1], M. Nemoto[1] and David Kisailus[1,2]; [1]University of California, Riverside, United States; [2]University of California, Irvine, United States

There is an increasing need for the development of multifunctional lightweight materials with high strength and toughness. Natural systems have evolved efficient strategies, exemplified in the biological tissues of numerous animal and plant species, to synthesize and construct composites from a limited selection of available starting materials that often exhibit exceptional mechanical properties that are similar, and frequently superior to, mechanical properties exhibited by many engineering materials. These biological systems have accomplished this feat by establishing controlled synthesis and hierarchical assembly of nano- to micro-scaled building blocks. This controlled synthesis and assembly require organic that is used to transport mineral precursors to organic scaffolds, which not only precisely guide the formation and phase development of minerals, but also significantly improve the mechanical performance of otherwise brittle materials.

Here, we investigate an organism that have taken advantage of hundreds of millions of years of evolutionary changes to derive structures, which are not only strong and tough, but also demonstrate abrasion resistance. All of this is controlled by the underlying organic-inorganic components. Specifically, we discuss the formation of heavily crystallized radular teeth the chitons, a group of elongated mollusks that graze on hard substrates for

algae.

Our investigation of the formation of a fully mature radular tooth from *Cryptochiton stelleri* found in the eastern Pacific, occurs over a series of more than 40 teeth. The initial stage of tooth formation begins with the synthesis of a three-dimensional fibrous α-chitin organic matrix, prior to the onset of crystallization. Microscope analysis of early stage teeth shows ferrihydrite mineral particles growing on α-chitin fibers. Synchrotron x-ray, combined with TEM analyses show that ferrihydrite exists as randomly oriented aggregates, but undergoes a phase transformation to magnetite within a few rows of teeth. We discuss potential mechanisms of nucleation of ferrihydrite, its transformation to magnetite as well as its subsequent mesoscale ordering, crystal growth and the resulting mechanical properties. From the investigation of synthesis-structure-property relationships in these unique organisms, we are now developing and fabricating multifunctional engineering materials for energy and water purification based applications.

SESSION SM12.05: Bio-Inspired Hybrid Materials III and Poster Session
Session Chairs: Chun-Long Chen and Ki Tae Nam

SM12

8:15 PM SM12.05.01
Particle Analogs of Electrons in Colloidal Crystals Martin Girard[1], Shunzhi Wang[1,2], Jingshan S. Du[1], Anindita Das[1], Chad Mirkin[1] and Monica Olvera de la Cruz[1]; [1]Northwestern University, United States; [2]University of Washington, United States

A versatile method for the design of colloidal crystals involves the use of DNA as a particle-directing ligand. With such systems, DNA-nanoparticle conjugates are considered programmable atom equivalents (PAEs), and design rules have been devised to engineer crystallization outcomes. This work shows that when reduced in size and DNA grafting density, PAEs behave as electron equivalents (EEs), roaming through and stabilizing the lattices defined by larger PAEs, as electrons do in metals in the classical picture. This discovery defines a new property of colloidal crystals—metallicity—that is characterized by the extent of EE delocalization and diffusion. As the number of strands increases or the temperature decreases, the EEs localize, which is structurally reminiscent of a metal-insulator transition. Colloidal crystal metallicity, therefore, provides new routes to metallic, intermetallic, and compound phases.

8:30 PM SM12.05.02
***In Situ* Generated Silver Nanodot FRET Pair Reveals Nanocage Size** Junhua Yu and Sungmoon Choi; Seoul National University, Korea (the Republic of)

Deciphering the structure and function of nanocages in macromolecules is essential to understand how the confined and finely tuned nanostructure assists and catalyzes reactions. Furthermore, we have been able to develop new strategies to employ unique functionalities of these nanocages unavailable by conventional methods. However, the identification and characterization of nanocages in macromolecules are always challenging; particularly, a fast and straightforward detection of the nanocage size is still missing. FRET can sense nanometer-scale dimensions while keeping the target intact. We have applied the silver nanodot FRET pair to the measurement of nanocages in reverse micelles successfully. Our results also clearly demonstrate that the water nanocage size of the Triton X-100/1-hexanol/cyclohexane-based reverse micelles expanded as more water was added into the system, clarifying long-term confusion regarding the size of the nonionic surfactant-based reverse micelles. The diameter of the nanocage obtained from the FRET of the nanodots was consistent with the size of the nanocage revealed by the cryo-TEM, suggesting that the FRET of silver nanodots to detect nanocage size is an easy and accurate tool. Our approach can be further applied to the measurement of

nanocages in proteins in the future.

Electrostatically Driven Assembly of Gold Nanorods Using *De-Novo* Designed Protein Fiber Muammer Y. Yaman[1], Kathryn N. Guye[1], Hao Shen[1], Maxim Ziatdinov[2], Sergei Kalinin[2], David Baker[1] and David Ginger[1]; [1]University of Washington, United States; [2]Oak Ridge National Laboratory, United States

Hierarchical inorganic materials are highly desirable for the development new advanced technologies[1]. Using programmable macromolecular building blocks such as protein[2], peptoid[3] and polymers[3] as templating agent is an effective approach to achieve the hierarchy of inorganic materials. Inducing the successful preparation of functional inorganic materials, these programmable building blocks allow us to control their optical and electronic properties. Due to theie outstanding properties, these materials can be applied in a wide range of applications, such as plasmonics[1] and quantum optics[1]. However, there still lack of a conclusive guiding rule for the successful synthesis of hierarchical inorganic materials with desired properties via designing macromolecular building blocks. Here, we studied the assembly behavior in a simple system, where *de-novo* designed protein nanofibers[4] act as the building block, and Au nanoparticles as the inorganic units, towards a general rule for the effect of ionic strength on macromolecule templated assembly of inorganic materials. The protein fibers were designed to be negatively charged and the Au nanorods were synthesized to be positively charged; the electrostatic force were assumed to be the driving force of the hybrid assembly. After electrostatic assembly of Au nanorods along the protein fibers were achieved, we conducted a series of experiments to study the influence of external parameters, such as the aspect ratio of Au nanorods and salt concentration (ionic strength) on the assembly of Au nanoparticles on protein fibers. Moreover, we have developed an automated image analysis tool to help understand the as-obtained experimental data including scanning electron microscope images. With the new image analysis tool, we were able to calculate and analyze the attachment angle of Au nanorods with respect to protein fibers. Our results demonstrate that the average attachment angle varies depending on the ionic strength of the solution. This work is a promising step to the successful synthesis of functional inorganic materials and provides a guiding rule of ionic strength on the orientation of inorganic building blocks in electrostatically-driven hierarchical assembly.

9:30 PM SM12.05.06
Biodegradable Poly-L-lactic acid/Glycine Core/Shell Nanofibers with High Piezoelectricity via Self-Assembly Technology Tong Li, Jun Li, Long Gu and Xudong Wang; University of Wisconsin-Madison, United States

Soft piezoelectric materials are an important group of functional material for state-of-the-art energy harvesting, energy conversion and sensing technologies. Since piezoelectric materials can couple mechanical energy and electric polarization, they can serve as appealing sensing materials, alternative to the described passive semiconductors and capacitive polymers, for self-powered force sensors. While polyvinylidene difluoride has been a well-known and broadly used soft piezoelectric polymer material over years, non-degradability raises a significant concern in terms of safety issues and often requires an invasive removal surgery, which can damage directly interfaced tissues/organs. Poly-L-lactic acid (PLLA), a biodegradable medical polymer, has been shown to exhibit piezoelectricity when appropriately processed, thereby offering an excellent platform to construct safer, biodegradable piezoelectric implants, which can avoid problematic removal surgeries. However, unlike ceramic-based piezoelectric materials, to reach desired high piezoelectric property and long-term stability in biological environment still stand as a big challenge in PLLA soft biodegradable nanomaterial development.
In our work, we report a one-step strategy for fabricating core/shell PLLA/Glycine (Gly) NFs with a very high crystalline content and orientation of the polymer chains. The self-assembled core/shell structure is believed essential for the formation of crystalline phase and alignment of polymer chains, where strong intermolecular interaction between the -NH_2 groups on Gly and –C=O groups on PLLA is responsible for aligning the PLLA chains and promoting crystalline nucleation. The orientation of polymer chains in the PLLA/Gly NFs along their axes is up to 0.88 observed at atomic scale through high resolution transmission electron microscopy, and the crystallinity ratio is found to be 0.73. The as-obtained PLLA/Gly NFs exhibit significantly enhanced piezoelectric performance and excellent stability and biocompatibility. We also verify that PLLA/Gly NFs functioned well in its predefined lifetime and eventually self-degraded. In addition, the successful formation of high crystallinity ratio with a well-oriented polymer chains offers a structural-assisted design strategy, as opposite to traditional stretching and thermal process, to fabricate high-performance soft biodegradable piezoelectric materials at molecular level.

Oriented Crystal Growth of Phenylalanine and Dipeptide by Solution Shearing Kazunori Motai and Yuhei Hayamizu; Tokyo Institute of Technology, Japan

Crystallization of biomolecule offers to form long-range ordered molecular structures in an energy efficient manner under aqueous conditions[1]. Peptide sequences can be designed to establish desired crystal structures. These structured biomaterials will give rise to new functional devices which can be used for various applications. However, the method to form aligned peptide crystalline structures on substrates with a controlled manner is still limited. In this research, we aimed at developing a solution process to align crystals on a substrate in a thin film form. Solution shearing is a promising method to fabricate aligned molecular thin films, which has been studied with synthetic organic molecules, especially for organic semiconductor [2]. In this process, the solution is sandwiched between a blade and substrate. Evaporation of solution occurs at the meniscus formed at the edge of a blade. As the solution evaporates, molecules form thin film with a certain molecular orientation on the substrate. To the best of our knowledge, there is no report applying this method for biomolecules to form their oriented films. Biomolecules have different features from organic semiconductors for the solution shearing process. (1) while synthetic semiconductor organics are dissolved in organic solvents, biomolecules are dissolved in water. Water has a relatively higher boiling temperature than usual organic solvents. (2) while semiconductor organics have planar conformation which is advantageous for the crystallization, peptides or amino-acids are relatively flexible and hard to form a crystal. Thus, optimization of the sweeping speed and temperature of the substrate in the solution shearing is important for the formation of uniform and large-area thin film.
In this study, we developed a fabrication technique of oriented biomolecular thin film based on the solution shearing method. To achieve this goal, we developed a hand-made system for the solution shearing with biomolecules in aqueous solutions, and optimized the sweeping speed and temperature in the process. We utilized amino acids and peptides to test the ability of our system, and we analyzed the structures of deposited thin films of amino acids and peptides by X-ray diffraction (XRD) and angle dependent polarized Raman spectroscopy [3]. As a result of the parameter optimization, we succeeded in fabricating 300 nm-thick oriented films with a size of more than 500 μm square. We have characterized thin films using polarized Raman

spectroscopy and X-ray diffraction (XRD) measurements. Raman spectra revealed that the solution shearing allows us to form crystalline amino acids and dipeptides on Si wafers. These experiments exhibited that the crystal orientations were along the direction of shearing. Furthermore, XRD spectra also revealed a formation of polymorph. It was found that we can suppress the polymorph formation by optimizing the condition of the solution shearing.

Influence of Surface Charge on Protein-Directed Electrostatic Assembly of Metal Nanoparticles Kathryn N. Guye, Hao Shen, Muammer Y. Yaman, Gerald Liao, David Baker and David Ginger; University of Washington, United States

Achieving controlled assembly of functional inorganic nanoparticles is a requirement for developing new applications in areas such as optoelectronics, sensing, and photocatalysis. Traditional methods, however, are often diffraction-limited or confined to small scale assemblies. Bioorganic templating of inorganic nanomaterials capitalizes on nature's evolutionary design to achieve highly ordered nanostructures, often otherwise inaccessible through conventional ligand-mediated or nanofabrication methods. To efficiently design biological scaffolds for the controlled ordering of nanoparticles, we must first identify and characterize the intersurface interactions governing the assembly process. Here, we study the protein-directed electrostatic assembly of spherical gold nanoparticles along high aspect ratio, *de novo*-designed protein nanofibers anchored to an ITO substrate. We achieve these structures via a layer-by-layer assembly process, in which alternating surface charges of each component drive the highly specific attachment of gold nanoparticles to the anchored protein nanofibers. We then characterize the composite structures by scanning electron microscopy. To probe the charge-dependent particle-substrate and particle-fiber intersurface interactions, we vary particle diameter and pH of the nanoparticle solution and measure particle density and specific binding efficiency to benchmark these interactions. We find an inverse correlation between nanoparticle diameter and particle density. We attribute this trend to more effective screening of the like-charge repulsion between the nanoparticle and substrate by the oppositely-charged protein nanofiber. We then explore how varying pH can tune the local interactions to adjust particle density and the specific binding efficiency. We observe the maximum attachment density at neutral pH at which the layers of the assembly have alternating charges. Furthermore, we note a significant decrease in particle density at low pH at which all surface moieties are protonated and prohibit electrostatic attachment. However, only a slight decrease at high pH is observed as the result of a monotonic decrease of specific binding efficiency with increasing pH due to the neutralization of the substrate surface charge. Finally, we predict optical properties of these composite structures by finite-difference time-domain simulations. These results demonstrate the importance of understanding intersurface interactions for electrostatic assemblies and will guide the design of future bio-templates for the ordering of inorganic nanoparticles.

9:45 PM SM12.05.09

***De Novo* Designed Protein Templates for Directing TiO_2 Mineralization** Amy E. Stegmann[1,2,3], Brittney Hellner[1], Harley Pyles[1,2,3], Fatima Davila[1,3,2], Francois Baneyx[1,3], David Baker[1,2,3] and James J. De Yoreo[3,1,1]; [1]University of Washington, United States; [2]Institute for Protein Design, United States; [3]CSASS, United States

De novo designed proteins enable the precise placement of functional groups in three-dimensional space, which can be leveraged to guide the precise nucleation and growth of inorganic phases to form complex hierarchical nanostructures. Proteins have diverse functional groups which enable them to access an array of applications.

Utilizing a strict control of chemical moieties in building blocks and designing repetitive interfaces enables precisely arranged structures to bridge scales. This control is shown to direct nucleation of precursors in solution at room temperature. Investigating the effect that organic molecules can have on nucleation by confining nucleation sites to specific geometries can lead to the formation of hierarchical materials with controlled microstructure. Understanding the effects that spatial presentation of different amino acid moieties has on the nucleated crystal phase and structure will facilitate the intentional design of self-assembled inorganic materials. Herein we demonstrate the influence that sequence can have on the phase of nucleated titania as well as the spatial control over nucleation that we can leverage using homo oligomeric *de novo* protein assemblies. We show that point mutations of different positively charged amino acids can favor anatase or beta phase titania. The templates shown here include small protein oligomers that display a favorable surface for nucleation, and large assemblies of protein fiber with mineralization directing moieties presented in the confined interior.

9:50 PM SM12.05.12
Forced Assembly of Polymer and Nanoparticles for Sensing Applications Weiheng Xu, Sayli Jambhulkar, Dharneedar Ravichandran, Yuxiang Zhu and Kenan Song; Arizona State University, United States

In fabricating polymer and nanoparticle composite or hybrid materials, the soft macromolecules' selective arrangement and the rigid nanoparticles's orders have been a bottleneck to overcome. We will use the bioinspired design of the composite structure to demonstrate the interface and interphase effects in stress transfer, energy transport, stabilization of dispersant, degree of confinement or bonding, and, other new property generations. This poster will introduce the polymer and nanolayered structures in fiber forms. Different polymers and different nanoparticles will be spun via in-house designed fiber spinning techniques. These fibers possess different layer thickness, nanoparticle concentration, and particle morphologies. As a result, these composite fibers display controllable mechanics and conductivity. We leveraged these properties for versatile sensors that are responsive to mechanical strain and gaseous analytes. Our manufacturing of the fibers has not been reported anywhere else and sheds light on a new sensor fabrication for environmental or human health monitoring.

9:55 PM SM12.05.13
Late News: Large-Scale Simulations of Nanostructures Formed During the Selective Binding of a M13 Biological Template to a Nanoscale Architecture Lunna Li[1,2], Angela Belcher[1] and Desmond Loke[2]; [1]Massachusetts Institute of Technology, United States; [2]Singapore University of Technology and Design, Singapore

Biological templates that can facilitate nanostructure assembly are widely used in next-generation remediation, electrochemical, photovoltaic, catalytic, sensing and electronic memory devices, but the fundamental features that control their dynamics have yet to be elucidated. By using large-scale molecular dynamics simulations, we reveal, in atomistic detail, the M13-biotemplating kinetics. We observe the assembly of gold nanoparticles on two experimentally-based M13 phage types using full M13-capsid structural models and with polarizable gold nanoparticles in explicit solvent. Moreover, mechanistic and structural insight into the selective binding affinity of the M13 phage to gold nanoparticles are obtained based on a previously unconsidered clamp-based binding-pocket-favored N-terminal-domain assembly and also on surface-peptide flexibility. Our results may open the route for the prospects of utilizing computational tools for genetically engineering a wide range of 3D electrodes for high density low-cost device technologies.

10:00 PM SM12.05.14
Late News: Associate Polymer Theory-Inspired Modelling of Intrinsically Disordered Protein-Mimicking Polymer-Oligopeptide Hybrids for the Formation of Artificial Membraneless Organelles Kalindu S. Fernando, Ghodshiehsadat Jahanmir, Ilona Christy Unarta, Jianhui Liu and Ying Chau; The Hong Kong University of Science and Technology, Hong Kong

Membraneless organelles (MOs) formation via liquid-liquid phase separation (LLPS) is a versatile spatiotemporal organizing mechanism in biological cells. They control biochemical reactions efficiently while being molecule enhancing hubs. Due to these diversified functionalities of MOs, there has been an increasing interest to develop novel bio-active materials and drug delivery systems to imitate MOs in recent years. Intrinsically disordered proteins (IDPs) are found to be one of the significant constitutes in MOs and our lab has been inspired to synthesize a new class of polymer-peptide conjugate known as **I**ntrinsically disordered protein mimicking **P**olymer-oligopeptide **H**ybrid (IPH) to mimic Fused in Sarcoma (FUS) protein. Liquid droplets reminiscent of MOs have been formed by IPHs under physiological conditions in-vitro.

We develop a computational method to describe the phase separation of IPHs. To describe IPH in a minimalist model, we consider an IPH of having a stickers-spacers architecture, leveraging on classical associative polymer theory. We employ molecular dynamics simulations to estimate the driving forces from the interactive oligopeptide segments (as stickers). The favorable enthalpy between oligopeptide segments provides the driving force for reversible binding between IPHs. We estimated the average binding energy between a pair of stickers as 96 kJ/mol using the Molecular Mechanics Poisson-Boltzmann Surface Area (MMPBSA) method.

Next, we adopt Monte Carlo simulations to describe the stochastic movement of IPHs under physiological conditions. IPHs are structured as strings of stickers and spacers and randomly placed in a three-dimensional simple cubic lattice (200×200×200) as a canonical ensemble. We perform 10^5 order of hypothetical Monte Carlo movements as self-avoiding walks on the lattice to obtain energy minimized configuration using the Metropolis-Hastings algorithm as movement acceptance/rejection criteria. Then the radial distribution function is used to identify the phase boundaries of the system. The results provide insights about the propensity of the IPHs to phase separate.

In summary, the research will provide a theoretical framework for understanding the material requirement on the molecular and macromolecular level for the IPHs to form MO-like structures. It provides a fast and economical means to guide the design of synthetic materials for mimicking intrinsically disordered proteins.

10:05 PM SM12.05.15
Late News: Excited-State Dynamics in DNA-Templated Molecular Dye Aggregates Jonathan S. Huff, Daniel B. Turner, Olga A. Mass, Matthew S. Barclay, Bernard Yurke, William B. Knowlton, Paul Davis and Ryan D. Pensack; Boise State University, United States

Molecular assemblies of dye molecules, known as dye aggregates, are of great interest for applications in light harvesting, nanoscale computing, and energy conversion, to name a few. When dye molecules are situated in close (few nm) proximity, short-range interactions modify their electronic structure, which is observed via dramatic changes in their optical properties. Recently, researchers have used DNA as a scaffold to template dye aggregates, raising the prospect that DNA nanotechnology may facilitate the development of aggregates with tunable optical properties. While the electronic structure (i.e., optical properties) of a variety of DNA-templated aggregates has been investigated via steady-state spectroscopic methods, their excited state dynamics, which are critical to their application, remain largely unexplored. In this contribution, we present time-resolved measurements of the excited-state lifetimes of a series of DNA-templated dye aggregates containing a prototypical cyanine dye, Cy5. We demonstrate that for all of the aggregate structures studied, the excited-state lifetimes are considerably shortened relative to that of the Cy5 monomer, exhibiting up to 20-fold lifetime reductions. We attribute the reduced lifetimes to enhanced nonradiative decay. Additionally, we discuss possible mechanisms of the enhanced nonradiative decay and ways that the nonradiative decay process might either be enhanced further or suppressed in order to meet the demands of various applications.

10:10 PM SM12.05.16
Late News: Artificial Membraneless Organelle-Based Therapeutic System for Regulation of RNAzyme Directed Gene Therapy Fariza Zhorabek and Jianhui Liu; The Hong Kong University of Science and Technology, Hong Kong

Stability and efficiency remain as a critical hurdle limiting clinical application of gene therapeutics, where development of protective gene carrier system has a potential to solve existing problems. In cells, nucleic acid molecules together with intrinsically disordered proteins (IDP) are actively localized in specialized compartments known as membraneless organelles (MO), that serve to stabilize, protect, and regulate corresponding reactions of molecules inside. Inspired by following beneficial aspects of MOs, here we report a new method for encapsulation and enhancement of functional activity of RNA therapeutics using membraneless organelle biomimetic system, reconstructed from IDP-mimicking polymer-oligopeptide hybrid (IPH). IPH, designed to display weak molecular attractions and RNA-binding capability, forms membraneless droplets under physiological mimicking conditions and demonstrates range of biomimetic properties. A model gene therapeutic, hammerhead RNAzyme against TNF-α cytokine mRNA, was preferentially recruited into IPH-droplets, along with target mRNA, with up to 30-folds enrichment. Owing to the liquid-like nature of the droplet interior, both recruited nucleic acid molecules exhibited free diffusion within the droplet environment as indicated by FRAP. Notably, RNAzyme catalytic activity was enhanced in the presence of the artificial MOs, demonstrated by gel electrophoresis and confocal fluorescence microscopy, presumably owing to localized increase of RNAzyme concentration and distinct droplet interior. This result also seems to indicate that localization within the IPH-droplet supports RNA folding, essential for its reactivity. Furthermore, methods for delivering RNAzyme loaded IPH-droplets into a macrophage cell line will be explored, where upon successful delivery, biocompatibility, stability, and suppression level of TNF-α production will be investigated. Overall, IPH-based MO biomimetics investigated here offers a potential as a gene carrier and bioreactor module, which may be useful for a range of gene therapeutic strategies.

SESSION SM12.06: Bio-Inspired Macromolecular Self-Assembly

8:00 AM *SM12.06.01
Functional Bioinspired Polypeptoids Jing Sun; Qingdao University of Science and Technology, China

Bioinspired polymeric materials receive considerable attention due to significant advantages over their natural counterparts: the ability to tune their structures over a broad range of chemical and physical properties, increased stability and improved processability. In particular, polypeptoids, or poly N-substituted glycines, are a promising class of peptidomimetic polymers, which offer great unique properties for both fundamental research and applications in biotechnology. The polypeptoid possess identical backbones to the polypeptide, but the side chain is attached to the nitrogen instead of a-carbon. It thus eliminates the inter- and intrachain hydrogen bonding and the chirality in the main chain. The peptoid polymers with high molecular weights and large scale yields can be obtained by ring-opening polymerization technique. Many polypeptoid-based block copolymers have therefore been synthesized and studied. We synthesized a series of functional polypolypeptoids with stimuli responsive properties by a combination of ring-opening polymerization and thiol-yne click chemistry. The obtained polymers show either LCST-type or UCST-type behaviour depending on the side-chain functionalities. We further reported a facile approach to prepare functional nanostructures such as highly flexible 2D crystalline nanosheets and superbrushes. The obtained bioinspired nanostructures are potential candidates for applications in nanoscience and biomedicine.

8:25 AM SM12.06.02
"Functional Fouling" of Surfaces by Interfacial Silk Fibroin Self-Assembly Tanner Fink, Caleb Wigham, Jeongae Kim and Runye H. Zha; Rensselaer Polytechnic Institute, United States

Silk fibroins are a class of proteins produced by a variety of insects and arachnids that can surpass man-made materials in specific strength and toughness. From a macromolecular perspective, silk fibroins have a linear architecture predominantly consisting of regularly alternating beta-sheet forming peptide segments and flexible peptide segments, resulting in a supramolecular network structure with stiff crystalline domains reinforcing an amorphous matrix. In nature, silk fibroins undergo a complex self-assembly process during spinning, rapidly transitioning from a soluble protein to an insoluble, highly robust material. Our work leverages the self-assembly of silk fibroin and silk-like macromolecules as a bottom-up method to form functional biomedical coatings. In particular, we have observed that non-specific interactions of silk fibroin with surfaces during supramolecular self-assembly can lead to the formation of stable and adherent thin-film coatings. These coatings provide complete surface coverage and can grow to tens of nanometers thick, completely transforming the physicochemical properties of a surface without requiring covalent chemistry or substrate pre-activation. Our studies also demonstrate that silk fibroin coatings can be generated on a variety of substrates ranging from hydrophobic Teflon to hydrophilic TiO_2. Furthermore, these coatings can readily exhibit beneficial biomedical properties, such as decreasing bacterial attachment and increasing neurite extension. Our research moreover delves into the complex interplay of surface-protein and protein-protein interactions underlying coating formation to establish methods by which we can tune the coating process. Through these investigations, we reveal a novel mechanism of protein adsorption that enables continuous, indefinite growth of robust protein layers on a variety of surfaces, which forms the foundation of a new approach towards modifying biomedical surfaces.

8:40 AM SM12.06.03
Computational Reverse-Engineering Analysis for Scattering Experiments (CREASE) on the Self-Assembly of Amphiphilic Polymer-Peptide Conjugates Ziyu Ye and Arthi Jayaraman; University of Delaware, United States

Peptide-based amphiphilic biomaterials that self-assemble into nanostructures provide a path for designing materials such as hydrogels and drug delivery vehicles. The engineering of these materials hinges upon the precise characterization of the self-assembled structures such as those obtained through small angle scattering techniques. The interpretation of these scattering profiles typically relies on analytical models for conventional shapes that may not capture the system geometry at hand. This calls for a method that is able to tie scattering profile features directly to the molecular level details in complex nanostructures without needing off-the-shelf scattering models. To address this need, we present recent developments in extending Computational Reverse-Engineering Analysis for Scattering Experiments (CREASE) to a system of polymer-peptide conjugates that self-assemble into bilayer and vesicle structures. Taking in scattering intensity profiles and polymer chemistries as inputs, CREASE combines genetic algorithm and molecular reconstruction simulations to determine the peptide amphiphile bilayer composition and vesicle dimensions (e.g. core diameter, layer thicknesses) and molecular level packing within the nanostructure.

8:55 AM SM12.06.04
Development of a Coarse-Grained Model to Simulate Assembly within Solutions of Cellulose and Cellulose Derivatives Zijie Wu and Arthi Jayaraman; University of Delaware, United States

In this talk we present a new coarse-grained (CG) model for cellulose and cellulose derivatives (e.g., methylcellulose) that enables simulations of their assembly in experimentally relevant solution conditions. This model balances the incorporation of chemical details at the monomer level (e.g., β, 1-4 linkage, relevant placement of groups that can/cannot form hydrogen bonds, directional hydrogen bonding interactions) as well as the reduction in degrees of freedom needed to simulate experimentally relevant length scales and time scales associated with assembly of multiple cellulose or methylcellulose chains in solution at finite concentration. We will first validate this CG model by comparing the cellulose single chain structure observed with the CG molecular dynamics (MD) simulations to that seen in atomistic MD simulations. We also compare the hydrogen bonding pattern, interchain distance and interchain orientation seen in multi-chain CG MD simulations with those observed in experimental crystallographic studies. After validation of cellulose CG model, we extend the

CG model to study impact of 'silenced' hydrogen bonding sites in order to simulate cellulose derivatives synthesized by substituting some of the hydrogen bonding -OH groups in cellulose with other non-hydrogen bonding groups (e.g., -OMe in methyl cellulose). We expect this type of CG model to be useful in predicting morphology of cellulose and its derivatives under a wide range of solution conditions and chemical modifications to the chains.

9:10 AM SM12.06.06
Late News: Antibacterial Alumochitin Thin Films Grown by Molecular Layer Deposition Karina Ashurbekova[1], Kristina Ashurbekova[2], Arbresha Muriqi[3], Leire B. Larrea[1], Borja A. Lerma[1], Iva Šarić[4], Evgenii Modin[1], Raul Perez-Jimenez[1,5], Mladen Petravić[4], Michael Nolan[3] and Mato Knez[1,5]; [1]CIC nanoGUNE, Spain; [2]Dagestan State University, Russian Federation; [3]Tyndall National Institute, Ireland; [4]University of Rijeka, Croatia; [5]IKERBASQUE, Basque Foundation for Science, Spain

Natural chitin and chitinoid materials have outstanding physical and biological properties, which inspired us to develop a process for biomimetic chitinoid organic and hybrid organic-inorganic thin film growth by Molecular Layer Deposition (MLD).
Here, we present a new class of organic–inorganic hybrid polymers called "metallosaccharides", based on sugar-type precursors. For a controlled MLD growth, the hexosamine monosaccharide N-Acetyl-D-mannosamine (ManNAc) was coupled with trimethylaluminum (TMA) repetitively in a cyclic manner for the growth of the hybrid organic-inorganic alumochitin thin films.
The self-limiting behavior of the surface reactions and the growth rate were determined by in-situ quartz crystal microbalance (QCM) and X-ray reflectivity (XRR) studies. The QCM measurements revealed a linear mass increase with the number of MLD cycles, and a film growth rate of ~20 ng/cm^2/cycle at 115 °C. XRR studies showed a growth rate of ~1.3 Å/cycle and a constant film density of ~2.5 g/cm^3. The chemical structures of the coatings were studied with e*x-situ* X-ray photoelectron spectroscopy (XPS) and attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR). Characterization of the film structure, morphology, and conformality were performed by High-resolution transmission electron microscopy (HR-TEM), showing uniform and conformal alumochitin films wrapping ZrO_2 nanoparticles (NPs).
The chemical interaction between ManNAc and TMA, and the possibility of hybrid alumochitin film formation were modeled by density functional theory (DFT). The computed interaction energies between TMA and ManNAc are negative, meaning that there's a strong interaction between these precursors. Theoretical modeling revealed that the proposed reaction mechanism for the ManNAc/TMA MLD process is energetically favorable.
The evaluation of the antimicrobial activity of the alumochitin thin film against Gram-positive (*Staphylococcus aureus*) and Gram-negative (*Escherichia coli*) bacteria was assessed. Bacteria attachment and proliferation on glass substrates, covered with MLD film, were analyzed by confocal microscopy. Both types of bacteria grow and proliferate on positive control samples, while neither *Staphylococcus aureus* nor *E. coli* bacteria attached to the surface of the alumochitin film. These results show a great antimicrobial activity of alumochitin against gram-positive and gram-negative bacteria, as well as its enormous application potential as bioactive surfaces.

This project has received funding from the European Unions Horizon 2020 research and innovation programme under the Marie Sklodowska -Curie grant agreement No 765378.

9:25 AM SM12.06.07
Late News: Structure, Tunable Self-Assembly and Optical Properties of a Model Cephalopod Protein Preeta Pratakshya[1], Gregor Ilc[2], Matic Kovačič[2], Atrouli Chatterjee[1], Janez Plavec[2] and Alon Gorodetsky[1]; [1]University of California, Irvine, United States; [2]Slovenian NMR Centre, Slovenia

The study of natural and designer protein-based materials has enabled the development of ubiquitous modern technologies for applications in optics, electronics, bioengineering and even medicine. Within this context, unique cephalopod structural proteins called reflectins have garnered attention due to their technological potential for the development of biophotonic and bioelectronic devices. However, the development of reflectin-based materials has been impeded by an incomplete understanding of their structures and properties. Here we

highlight the proteins' structure, assembly and multi-faceted material properties within the context of biophotonic platforms. Specifically, we present the molecular-level structure of a model cephalopod protein, its tunable self-assembly, and the correlation between its structural characteristics and optical properties. Our findings not only provide useful insights into the structure-function relationships of reflectins but also underscore their potential as functional biomaterials and hold relevance for the development of cephalopod-inspired optical technologies.

5:15 PM *SM12.07/SM09.04.01
Biomolecules for Non-Biological Things—Materials Construction Through Peptide 'Bundlemer' Design and Solution Assembly Darrin J. Pochan; University of Delaware, United States

Self-assembly of molecules is an attractive materials construction strategy due to its simplicity in application. By considering peptidic molecules in the bottom-up materials self-assembly design process, one can take advantage of inherently biomolecular attributes; intramolecular folding events, secondary structure, and electrostatic interactions; in addition to more traditional self-assembling molecular attributes such as amphiphilicty, to define hierarchical material structure and consequent properties. A new solution assembled system comprised of theoretically designed coiled coil bundle motifs, also known as 'bundlemers' will be introduced. The molecules and nanostructures are not natural sequences and provide opportunity for arbitrary nanostructure creation with peptides. With control of the display of all amino acid side chains (both natural and non-natural) throughout the peptide bundles, desired physical and covalent (through appropriate 'click' chemistry) interactions have been designed to produce one and two-dimensional nanostructures. One-dimensional nanostructures span exotically rigid rod molecules that produce a wide variety of liquid crystal phases to semi-flexible chains, the flexibility of which are controlled by the interbundle linking chemistry. The two dimensional nanostructure is formed by physical and covalent interactions and are also nanostructures not observed in nature. All of the assemblies are responsive to temperature since the individual bundle building blocks are physically stabilized coiled coil bundles that can be melted and reformed with temperature. Additional, novel nanostructures to be discussed include uniform nanotubes as well as the templated growth of metallic phases. Included in the discussion will be molecule design, hierarchical assembly pathway design and control, click chemistry reactions, and the characterization of nanostructure via electron microscopy, neutron and x-ray scattering, and rheological measurements, as well as inherent material properties (e.g. extreme stiffness, responsiveness to temperature and pH, stability in aqueous and organic solvents).

5:40 PM *SM12.07/SM09.04.02
De Novo Design of Protein-Based Materials and Machines David Baker; University of Washington, United States

We are exploring the de novo design of proteins that self-assemble into 1D (fiber), 2D (array), or 3D (crystal) architectures. We have designed, with near-atomic accuracy, 1D helical filaments with a wide range of diameters that assemble into precisely ordered micron-scale fibers, as well as 2D hexagonal arrays that assemble rapidly upon mixing the two designed protein components. The arrays span multiple microns and are robust to fusion of a wide range of functional groups enabling. We have also extended these approaches to the design of protein-inorganic hybrid materials. Finally, we are pursuing the computational design of new mechanical systems made of proteins. With this work, we seek to create custom devices that can perform useful work at the nanoscale.

6:05 PM *SM12.07/SM09.04.03
Dynamic and Adaptive Protein Assemblies by Chemical Design Faik A. Tezcan; University of California, San Diego, United States

Proteins represent the most versatile building blocks available to living organisms or the laboratory scientist for constructing functional materials and molecular devices. Underlying this versatility is an immense structural and chemical heterogeneity that renders the programmable self-assembly of proteins a challenging design task. To circumvent the challenge of designing extensive non-covalent interfaces for controlling protein self-assembly, we have endeavoured to use bonding strategies based on fundamental principles of inorganic, supramolecular and polymer chemistry. These strategies have resulted in 0, 1, 2, and 3D protein assemblies that display high structural order over many length scales and possess emergent chemical, physical, functional and dynamic properties. In this talk, I will present some of the recent protein-based assemblies and materials constructed in our laboratory.

6:30 PM SM12.07/SM09.04.04
Late News: Nucleic Acids Modulate Stiffness of Artificial Membraneless Organelles Jianhui Liu, Fariza Zhorabek and Ying Chau; The Hong Kong University of Science and Technology, Hong Kong

Driven by liquid-liquid phase separation (LLPS), an emerging universal intracellular organization mechanism, membraneless organelles (MOs) generally harbor intrinsically disordered proteins (IDPs) and RNAs. As a minimalist biomimetic synthetic pathway, we synthesized IDP-mimicking polymer-oligopeptide hybrid (IPH) by conjugating cysteine-terminated peptides to vinylsulfone-modified dextran *via* facile click chemistry pathway through Michael addition between thiol and vinylsulfone. Two peptide sequences, namely, cysteine-terminated low complexity domain-like peptide (CLCDP) and cysteine-terminated arginine-glycine-glycine-containing peptide (CRP), were designed to impart weak molecular attraction and RNA-binding capacity to IPH, respectively. Most intriguingly, IPH underwent LLPS under physiology-mimicking conditions *in vitro*, resulting in micron-sized compartmentalized droplets, which could recruit RNA to generate complexed coacervate, namely, artificial MOs (AMOs). Stoichiometry of RNA, represented by N/P ratio between IPH and RNA, could exert effect on viscoelastic properties (storage modulus, G', as an indicator of stiffness) of AMOs in a dose-dependent fashion, as will be quantified by microrheology, whilst no appreciable change of sphericity of AMOs was observed even for long RNAs (up to *ca*. 2.78 kbs) with high incorporation (up to N/P=1/25). Moreover, mobility, indicated by diffusion coefficient (D) measured by fluorescence recovery after photobleaching (FRAP), was also significantly affected by incorporation of RNAs. As an intracellular structural analogue which has also been shown implication in MO formation, (single/double stranded) DNA-based AMOs were also constructed and investigated. In stark contrast to RNA-based MOs, DNA modulates stiffness of AMO much more drastically, as is indicated by significant decrease of sphericity even at low incorporation (as low as N/P=1/0.1, similar length as RNA counterpart), as well as with very short DNA (*ca*. 36 bp, N/P=1/10), which will be further quantified by microrheology. Additionally, FRAP will be leveraged to quantify D of DNA-based AMO, which is expected to be drastically different from RNA-based AMO owing to occurrence of irregular-shaped assemblies. We reason the disparity between effect of RNA and DNA (single/double stranded) originates from the difference of intrinsic rigidity, as well as their non-specific interactions with IPH, which will be further elucidated *via* a biophysical model.

8:15 PM SM12.08.01
Late News: Developing Complex Structures—A Micron-Scale Tree Trunk with Its Annual Rings Arash Momeni[1], Christopher Walters[1], Yi-Tao Xu[1], Wadood Hamad[2] and Mark Maclachlan[1,3,4]; [1]The University of British Columbia, Canada; [2]FPInnovations, Canada; [3]Stewart Blusson Quantum Matter Institute, Canada; [4]Kanazawa University, Japan

Hierarchical biological materials, such as osteons and plant cell walls, are highly complex structures that are difficult to mimic. Here, we demonstrate that liquid crystal systems combined with polymerization techniques could be applied in confined spaces to develop complex structures. We report development of a highly ordered concentric chiral nematic polymeric fibers based on cellulose nanocrystals (CNCs).

CNCs are nano-sized needle-shaped crystalline cellulose particles obtained by treatment of cellulosic biomass with acids. CNC aqueous suspensions spontaneously form chiral nematic liquid crystalline structures above a critical concentration in water. Organization of CNC particles could be manipulated through confinement. In our experiments, CNC suspensions were mixed with polymeric precursors and confined within a glass capillary tube. The tube was aged for several days for the liquid crystalline structure to form, followed by UV-initiated polymerization to lock the structure. The resulting CNC/polymeric fiber could then be removed from the tube and shows a highly ordered single domain liquid crystalline structure throughout its length.

Polarized optical microscopy, electron microscopy, confocal microscopy and 2D X-ray diffraction showed highly uniform concentric rings throughout the length of the fiber. The concentric rings are formed by CNC particles arranging in a chiral nematic liquid crystalline order where the CNC particles' director rotates along the fiber diameter. A good analogy to describe the fiber structure is a tree trunk with its annual rings. The distance between the concentric rings of the fiber is equal to half of the pitch of the chiral nematic CNC liquid crystal. We tracked the formation of this highly ordered structure over time and under different conditions in which we varied the tube orientation, CNC concentration, CNC type, and capillary tube size.

Tube orientation during liquid crystalline phase formation was important because gravity causes sedimentation of tactoids, a predecessor to the long-range ordered phase. Tactoids are liquid crystalline anisotropic droplets that spontaneously nucleate above a critical CNC concentration and are the intermediate state bridging the isotropic phase and the macroscopic liquid crystalline phase with longer range order. CNC concentration and type were shown to determine the distance between concentric rings of the fiber. The capillary tube inner diameter was also important, and a single-domain structure was only obtained inside small-diameter tubes, not large ones. Mechanical tests showed similar properties for the chiral nematic and a pseudo-nematic CNC/polymeric fiber, both of which had superior mechanical properties compared to a polymer-alone fiber.

The structure of the single-domain chiral nematic concentric CNC/polymeric fiber is very similar to biological hierarchical structures, such as twisted plywood architecture of collagen fibers in cortical bone or twisting cellulose microfibrils of wood cell units. Indeed, liquid crystal systems, confined spaces, and polymerization techniques could be combined to achieve complex structures. These highly ordered CNC/polymeric fibers could become a platform for many applications from photonics to developing complex hierarchical materials.

Late News: Lipophilic Modification of Silica Coated Gold Nanorods Generates Enhanced Photoacoustic Signal Nonlinear with Laser Fluence Evan Mueller[1], Maju Kuriakose[1], Ke Ma[2], Marco Inzunza[1], Jennifer Cha[1], Todd Murray[1] and Andrew Goodwin[1]; [1]University of Colorado Boulder, United States; [2]Purdue University, United States

In this paper, lipophilically modified silica coated gold nanorods were developed to enhance the photoacoustic response of contrast agents. Photoacoustic imaging become a popular technique in the diagnostic imaging because it can utilize light at larger penetration depths and better resolution than optical coherence tomography or fluorescence imaging. In addition, photoacoustic imaging can augment optical microscopy to image in high

scattering tissue. To boost signal, many exogenous contrast agents have been synthesized. However, these agents are still limited to a linear dependence of signal on laser fluence, which limits the benefits for imaging in scattering media. The ability of agents to induce cavitation events in response to laser irradiation would both increase signal and promote nonlinearity. In this work, silica coated gold nanorods with a longitudinal plasmon peak of 750-800 nm were lipophilically modified to facilitate the formation of cavitation nuclei on the rod's surface. It was found that the lipophilically modified silica coated gold nanorods were able to achieve nonlinearity at pulse radiant exposures greater than 8 mJ/cm^2. At radiant exposures of 21 mJ/cm^2, the photoacoustic response was 13-15 times higher than unfunctionalized gold nanorods. The concentration of the samples was also investigated, and it was found that the photoacoustic response was greater for samples with higher concentrations than ones that were lower. Finally, the lipohilically modified silica coated gold nanorods were more resistant to etching in aqueous media, showing stability for more than one month in PBS.

Late News: Statistical Studies of Meniscus Splitting Using an Aqueous Mixture of Polysaccharides for Preparation of Bioinspired Functional Materials Isamu Saito, Koji Ogura, Yuiming Wu, Yoshiya Tonomura and Kosuke Okeyoshi; Japan Advanced Institute of Science and Technology, Japan

Influx and efflux of water is important for polysaccharides in living organisms, *e.g.* directional control of water diffusion on vascular bundle and water retention on fruits. While, it is possible to artificially create spatial patterns through water evaporation under physicochemically controlled environments. In fact, based on fingering phenomena, we could successfully obtain spatio-temporal patterns by drying aqueous mixture of polysaccharides.[1] The pattern formation has been demonstrated using several kinds of viscous aqueous mixtures of polysaccharides. The spatial pattern is formed by meniscus splitting with ordered depositions of polysaccharide self-assembly, from one space into multiple spaces. Differing from previous dissipative structures transiently showing spatial patterns, we successfully immobilized the structure as polymer deposition with uniaxial orientation. In this study, to clarify the factors on specific deposition nucleation, the nucleus position is statistically analyzed by changing the initial polymer concentration and drying temperature. Furthermore, by introducing crosslinking points into the membrane, the swelling characteristics as an anisotropic hydrogel were investigated. Reference 1. *Sci. 9:00 PM SM12.08.04
Late News: Iridescent Cellulose Nanocrystal Films Modified with Hydroxypropyl Cellulose Christopher Walters[1], Charlotte Bootte[1], Thanh Nguyen[1], Wadood Hamad[2] and Mark Maclachlan[1]; [1]University of British Columbia, Canada; [2]FPInnovations, Canada

Cellulose nanocrystals (CNCs) are an abundant biorenewable resource that spontaneously organize into chiral nematic liquid crystals with hierarchical structure. This chiral nematic organization is retained in dried films of CNCs, giving films with brilliant iridescent colors.[1] The introduction of polymers into a chiral nematic cellulose nanocrystal (CNC) matrix allows for the tuning of optical and mechanical properties, enabling the development of responsive photonic materials.[2] Previously, researchers have investigated CNCs added to hydroxypropyl cellulose (HPC), but not the effects of small amounts of HPC on CNC.[3, 4] In this study,[5] we explored the incorporation of HPC into a CNC film prepared by slow evaporation. In the composite CNC/HPC thin films, the CNCs adopt a chiral nematic structure, which can selectively reflect certain wavelengths of light to yield a colored film. The color could be tuned across the visible spectrum by changing concentration or molecular weight of the HPC. Importantly, the composite films were more flexible than pure CNC films with up to a ten-fold increase in elasticity and a decrease in stiffness and tensile strength of up to six-times and four-times, respectively. Surface modification of the films with methacrylate groups increased the hydrophobicity of the films and therefore the water stability of these materials was also improved.

Recombinant Spidroins for Fibrous Materials Applications Jinlian Hu; City University of Hong Kong, Hong Kong

Spiders can produce up to seven different types of silk fibers with varying mechanical properties and functions to support their survival. Some of their most characteristic properties that do not exist in other natural fibers are flat-stress strain behavior (tubuliform silk), supercontraction (dragline), and water collection (capture silk). These interesting properties can serve the requirements for smart functionality of materials for various applications. However, unlike silkworm silk spiders cannot be farmed due to their cannibalistic nature. This limits utilization of spider silks in their natural form for real world applications. The understanding of molecular structure of silks has inspired research by utilizing the repeating modules of spider silks with different gene sequence motifs to develop biomimic, novel and high performance materials. There are so far a range of recombinant spider silk proteins, namely, spidrions, being genetically produced by a variety of host organisms. Although such produced spidroins have been shown to be versatile proteins with the capability to be processed into diffeent morphologies, fibrous materials are still one of the most attractive incentives since its natural counerparts due to the above reasons. This talk will present several examples of biomimetic fibrous materials with different properties including shape memory/supercontraction, mechanical toughness and directional water collection by using spidroins made from different gene motifs expressed in E. Coli.

Tubuliform spidroin 1, from a black widow spider-Lactrodectus Mactans, was first genetically engineered by using the single repeat unit and abbreviated as eTuSp1 for flat-stress-strain mechanical properties. In this work, in good agreement with previous studies, spherical aggregates were considered as intermediates and could be induced into β-sheet-rich silk fibers by the shear and elongation. The underlying mechanism for the assembly of silk spheres and fibers were demonstrated by the micelle theory. To investigate mechanical properties, individual spheres were subjected to the AFM indentation and the corresponding compressive modulus was determined by using Hertz model. In the tensile test, the modulus of silk fibers could be flexibly regulated in accordance to different post-spin drawing ratios. We also prepared an engineered major ampullate spidroin 2 (eMaSp2) by using N & C terminal domains from spidroins MaSp1 of Euprosthenops australis and MiSp1 (minor ampullate spidroin) of Araneus ventricosus respectively for shape and stress memory fibers. Revealed by CD spectrum, eMaSp2 formed a dimer in the solution and predominantly obtained a α-helix structure. Upon exposure to the elevated temperature from 25 oC to 70 oC, a permanent transition from α-helix to β-sheet was observed. Followed by a biomimetic wet-spinning approach, eMaSp2 fiber was prepared and later displayed β-sheet-rich structure similar to natural counterpart.

Moreover, to obtain fibers to perform as a spider capture silk in spider web to collect water for recovering the daytime-distorted shape during night through water-sensitive shape memory effect. Different from using synthetic materials, an all silk-protein fiber (ASPF) with periodic knots to endow extremely high volume-to-mass water collection capability. This fiber has a main body of B. mori degummed silk coated with recombinant eMaSp2 of spider dragline silk. It is 252 times lighter than synthetic polymer coated nylon fibers that once was reported to have the highest water collection performance. The ASPF collected a volume of 6.6 μL of water and

has 100 times higher water collection efficiency compared to existing best water collection artificial fibers in terms of volume-to-mass index (VTMI) at the shortest length (0.8 mm) of three phase contact line (TCL). Since silkworm silks are available abundantly, effective use of recombinant spidroins tandemly shows great potential for scalability.

Adsorption of Soy Protein Globulins at the Water/Oil Interface: Viscoelastic Effects Farshad Nazari[1,2] and Mohammad Reza Rahimpour[2]; [1]Florida State University, United States; [2]Shiraz University, Iran (the Islamic Republic of)

Possessing an amphiphilic character, proteins are commonly used to stabilize the oil-water interface of the food-grade emulsions. Soybeans are a particularly good source of edible proteins because of their relative abundance, sustainable supply, and low cost. Soy proteins can be isolated from other components of the beans and converted into functional ingredients using commercially viable extraction and purification methods. The major fractions in soy protein are globulins, namely β-conglycinin (a 7S globulin) and glycinin (an 11S globulin). These protein globulins are one of the most commonly used plant proteins for the fabrication of food-grade particles as Pickering emulsion stabilizers. As the use of soy protein isolates in complex food systems such as emulsions and suspensions, gains more momentum, it is important to fully understand the amphiphilic properties of these protein globulins and study their adsorbance at the oil-water interface.
Diffusing away from the aqueous phase, soy protein (SPI) globulins adsorbed at the water/oil interface. For this film of adsorbed SPI, the viscoelastic effects were investigated using a rotational rheometer equipped with the double-wall ring geometry (DWR). Steady-shear time sweeps using DWR revealed an increase in the interfacial viscosity similar to the Kelvin-Voigt model. The relaxation time (as a measure of the initial adsorbance rate) scaled linearly with the SPI bulk concentration (E/eta~c^1.0). It was concluded that perhaps, at the early stages of SPI adsorbance, the transport mechanism is driven by the concentration gradient between the layer adjacent to the interface and the interface itself (c/2*Rh, with Rh being the hydrodynamic radius of the SPI globulins). Moreover, frequency sweeps (at 0.01-100 rad/s) from the DWR indicated a highly entangled layer of SPI globulins at the interface. However, pressure-driven flow through a pipe at high shear rates (steady flow at ~10-1000 1/s with zero interface) showed Newtonian flow behavior (n~1.0). This was attributed to the difference in conformation for the SPI chain at the oil/water interface vs in the aqueous bulk, causing the SPI globulin to unfold in the former case.

Cell-Type-Specific CRISPR/Cas9 Delivery by Biomimetic Metal-Organic Frameworks Mram Z. Alyami; King Abdullah University of Science and Technology, Saudi Arabia

Effective and cell-type-specific delivery of CRISPR/Cas9 gene-editing elements remains a challenging open problem. Here we report the development of biomimetic cancer cell coated zeolitic imidazolate frameworks (ZIFs) for targeted and cell-specific delivery of this genome editing machinery. Coating ZIF-8 that is encapsulating CRISPR/Cas9 (CC-ZIF) with a cancer cell membrane resulted in the uniformly covered C3-ZIF(cell membrane type). Incubation of C3-ZIFMCF with MCF-7, HeLa, HDFn, and aTC cell lines showed the highest uptake by MCF-7 cells and negligible uptake by the healthy cells (i.e., HDFn and aTC). As to genome editing, a 3-fold repression in the EGFP expression was observed when MCF-7 were transfected with C3-ZIFMCF compared to 1-fold repression in the EGFP expression when MCF-7 were transfected with C3-ZIFHELA. In vivo testing confirmed the selectivity of C3-ZIFMCF to accumulate in MCF-7 tumor cells. This supports the ability of this biomimetic approach to matching the needs of cell-specific targeting, which is unquestionably the most critical step in the future translation of genome editing technologies.

Late News: 3D Graphene-Based Sponge for Superior Separation of Heavy Oil-in-Water Emulsions
Ahmed S. Khalil[1,2]; [1]Faculty of Science, Fayoum University, Egypt; [2]School of Innovative Design Engineering, Egypt-Japan University of Science and Technology (E-JUST), Egypt

Oily wastewater generated by industries such as crude oil production, oil refining, and metal manufacturing, can cause major environmental issues, and affect human health [1]. In oily wastewater, oils are classified into two types, a mixture of oil/water, and oil-in-water
emulsion. The later has stable microdroplets smaller than 20 μm with complex wetting behavior [2]. The separation of oil-in-water emulsions has become an extremely important for both environmentally and industrial related applications. Various traditional methods have been used to separate oils [3,4,5]. Herein, a graphene-based sponge (rGO@MF) was developed and utilized for separating various heavy oil-in-water emulsions as well as oil/water mixtures [6]. The superhydrophobic sponge was engineered through facile surface-treatment and hydrothermal steps. The commercially available MF sponges were initially surface treated and subsequently coated with rGO sheets. The surface and structural properties of the rGO@MF sponge and the nanoemulsions were thoroughly characterized by advanced techniques. The high-resolution SEM and EDX mapping confirmed

the homogeneous distribution of rGO sheets surrounding the fibers. The developed rGO@MF sponge showed excellent chemical stability and durability. Five different oils and organic solvents with high concentration (up to 30 g/l) were tested. We aimed to formulate stable and different sized emulsions to explore and study in detail the correlation between the oil type, droplet size and concentration of oil/water mixtures and emulsions, and the rGO@MF adsorption capacity and removal efficiency. The developed superhydrophobic rGO@MF sponge showed water contact angle of ~164 and exhibited superior adsorption capacity and removal efficiency of up to 5647 mg/g and 95 ± 3% respectively, for crude oil-in-water emulsions of 30 g/l. In addition, the rGO@MF sponge maintained its high separation performance over ten consecutive adsorption cycles. The adsorption capacity of the rGO@MF sponge maintained up to 92% of its initial values after ten cycles. The calculated activated adsorption energy for crude oil-in-water emulsion on rGO@MF sponge was 16.59 kJ mol^{-1} indicating a physical adsorption process. The adsorption kinetics and interactions were carefully explored and a general mechanism of separation for both oil-in-water nanoemulsions and oil/water mixtures was introduced.

Late News: Efficient Separation of Heavy Oil-in-Water Emulsion Using Isotropic Polyethersulfone Membranes
Ahmed S. Khalil[1,2]; [1]Faculty of Science, Fayoum University, Egypt; [2]School of Innovative Design Engineering, Egypt-Japan University of Science and Technology (E-JUST), Egypt

Recently, oil-contaminated wastewater treatment has become a research hotspot for both the scientific community and the industry due to the potential disastrous impact of oily wastewater on environment and human health. Huge volumes of stable oil/water emulsions are usually produced from a variety of industries such as oil and natural gas exploration and processing, metallurgical, petrochemical, pharmaceutical, and food industries [1]. Several previously reported techniques are widely used for separation of oil/water mixtures, which involve gravity separation, dissolved air flotation, solvent extraction, coagulation, biodegradation and adsorption [2]. However, these conventional methods have their own drawbacks, such as, high cost, using toxic compounds, large space for installation and generation of secondary pollutants [3]. Membrane separation technology, in particularly, ultrafiltration (UF), has attracted attention as an effective approach for removing dispersed oil droplets smaller than ~10 μm in emulsions. However, membrane fouling is regarded as the key challenge for membrane-based separation processes that results from deposition of oil droplets/aggregates on membrane surface or inside membrane pores causing a severe flux decline
Here, we present the separation performance of isotropic PES membrane that has been successfully developed via VIPS, for different high concentration oil-in-water nanoemulsions [4,5]. Detailed comparison with the well-developed anisotropic membrane was carried out. The as-prepared membranes were analyzed with respect to surface morphology, surface roughness, pore size, overall porosity, water uptake, underwater oil contact angle (UOCA) and surface wettability. The membrane separation performances were evaluated in terms of water

permeance, oil separation efficiency, antifouling performance, and cyclic reusability. Remarkably improved surface hydrophilicity for isotropic PES membrane (contact angle, CA=39°) compared to anisotropic PES membrane (CA=70°), resulting in superior pure water permeance, attaining 4721 L/h.m^2.bar at operating pressure of 0.5 bar. The isotropic PES membrane achieved superior crude oil-in-water nanoemulsion separation (permeance of 713 L/h.m^2.bar and 100 % rejection) at oil concentration of 1 g/L. At extremely high oil concentration of 50 g/L, the PES membrane was not completely fouled and showed permeance of 65 L/h.m^2.bar and 98.2% rejection. Moreover, the flux recovery of the fouled isotropic PES membrane exceeded 59.5% over three subsequent cycles of filtration and back-washing with water. Overall, this study might provide substantial guidance for large-scale manufacturing and application of isotropic PES membrane in treating oil-in-water nanoemulsion under harsh conditions.

Keywords: Isotropic PES membrane, oil-water emulsion separation, super permeance, fouling mitigation

8:00 AM SM13.01.01
Late News: Cross-Linking of Polyetherimide by Bi- and Tetrafunctional Nucleophiles in Ultrathin Layers
Rainhard Machatschek[1,2], Matthias Heuchel[1] and Andreas Lendlein[1,2]; [1]Helmholtz Zentrum Geesthacht, Germany; [2]University of Potsdam, Germany

Polyetherimide (PEI) is a membrane forming material with excellent chemical and mechanical stability. Nevertheless, further chemical modification might be demanded by the designated application. The hydrophobic nature of PEI could cause adsorption of solutes if the material is used in aqueous environments, whereas application in organic solvents may necessitate further stabilization via cross-linking [1]. In these cases PEI has the additional advantage that a ring-opening at the imide groups in the polymer backbone using suitable nucleophiles allows for chemical modification, a strategy that has been widely explored as a method for post-functionalization of PEI membranes and particles. The reaction with water soluble diamines can result in cross-linking via formation of amide or imine groups. An excess of diamine would drive the reaction towards a non-crosslinked state, while also hydrolysis could occur if the pH exceeds a certain value[2]. Also, the chain-length and stiffness of the diamine is likely to have an effect.
Here, we use ultrathin films (1-2 nm) at the air-water interface to investigate the chemical functionalization of

PEI surfaces. In contrast to thicker films or bulk materials, where the majority of molecules is not accessible for chemical reactions, nearly all imide groups can be converted in ultrathin films, making them especially sensitive tools to study the effects of post-functionalization.

By means of interfacial rheology, we determine the optimal conditions for cross-linking of PEI, together with surface potential measurements to detect the formation of a positively or negatively charged groups in consequence of either partial hydrolysis or protonation of free amine groups. We further evaluate the effects of catalytic strategies for amine bonding based on carbodiimides or Lewis acids, and investigate whether tetrafunctional amines result in a better cross-linking than bifunctional ones. The outcome of the chemical modifications is further investigated using IR and/or Raman spectroscopy. In addition, we evaluate the influence of the chemical treatments on the Young's modulus of the modified PEI and determine the molecular arrangement of the chains by atomic force and electron microscopy.

The ultrathin PEI films presented here are not only of interest as model systems for the surfaces of PEI membranes, but also as present stable thin films with can be functionalized and transferred onto almost any substrate.

8:10 AM SM13.01.02
ZnO Molecular Foams for Micropollutant Removal Zachary Warren, Thais Tasso Guaraldo, Davide Mattia and Jannis Wenk; University of Bath, United Kingdom

The accumulation of micro-pollutants such as pesticides and pharmaceuticals in water supplies is of growing concern to public health, as these compounds can bioaccumulate, causing potential health issues as well as being resistant to the methods of wastewater treatment currently employed. Photocatalysis shows promise as a potential solution to this problem but is currently hindered in two main ways:. Photocatalytic slurries require downstream separation or can pose a risk to health themselves, while supported photocatalysts suffer from low exposed surface areas and efficiencies as well as potential leaching, again potentially posing a health risk.
In this work, we present a novel ZnO photocatalytic foam. Briefly, the synthesis is a modification to abased on sol gel synthesis of ZnO, incorporating direct aeration during gel formation followed by high temperature sintering (900 ^{o}C, 12 hrs) to form a highly porous yet mechanically stable ZnO structure in as macroscale foam monoliths (20 mm in height and diameter) without the use of foaming agents nor supercritical drying. These "monoliths or "molecular foams"" were then used in the photocatalytic degradation of carbamazepine as a target pollutant in both batch and recirculating systems. This novel work solves both issues traditionally associated with photocatalysts, as the highly porous nature of the monoliths allows for a high surface area of catalyst to be used, similar to a slurry, while the removal of a support and having a structure of ZnO only, means that there are no binding interactions between catalyst and support, removing the risk of leaching entirely.
These foamsmonoliths were characterised as pure wurtzite ZnO and highly crystalline in nature as well as showing high porosity (90 %), measured using an Archimedes method, and a hierarchical structure, which showed promise for the degradation of target pollutants. FE-SEM micrographs of the foams show a structure consisting of both large channels and smaller pores, allowing for both flow through the foamsmonoliths and a reactive surface for degradation to occur at. Initial photocatalytic tests in the batch system showed 55 % degradation after 4 hours and a kinetic constant of 3.3 X 10^{-3} min^{-1} using 0.5 g L^{-1} loading of foam catalyst. The batch kinetics of the foam system shows promise, as it they are is higher than literature values for immobilised catalysts, but still lower than those reported for slurry systems. and the next goal of the project is to demonstrate

kinetics that are comparable to slurries. Building upon this, further studies were conducted, applying foams in a recirculating batch system where an increase in photocatalytic activityies, of both removal and kinetic constant, was observed. This is attributed , as when applied in this mannerto a fuller use of the as flow of solution through the foam takes advantage of the highly porous and hierarchical structure of the foams, allowing for greater utilisation of the photocatalyst as well as greater mass transfer of the pollutant to the catalyst surface.
These results show promise for the potential application of photocatalytic foam structures as a tertiary treatment step n addition to traditionalin wastewater treatment, for the removal of currently persistent micropollutants. The proposed 3D structure combines the advantages of slurries and immobilised catalysts while simultaneously addressing drawbacks.

8:20 AM SM13.01.03
Quick Formation of Polymeric Membranes at Water/Air Interface Sara Coppola, Giuseppe Nasti, Veronica Vespini and Pietro Ferraro; Institute of Applied Sciences and Intelligent Systems “E. Caianiello”, Italy

Nowadays various methods and technological process are conventionally employed for water treatment and filtration, attempting to contrast the pollution of chemicals, particles and emerging contaminants (i.e. microplastics, industrial residue, oil, pharmaceutical components..). Generally all the processes proposed for water treatment require multistep protocols and the use of expensive device. Over the last decade, a wide range of functional materials have been investigated to separate multiphase liquids and immiscible mixtures, electrochemical catalysts, photocatalysts, reactive and nanomaterials have been recently successful tested for water treatment. Good results in terms of efficiency in separating oil/water mixtures have been obtained using polymeric functionalized membranes but big restrictions still remain unsolved. Different technological methods of microfabrication (two-photon polimerization, soft interference lithography, replica molding and self-folding polymers) have been used but, chemical-physical pre-treatments are often required to gain the desired final properties. To avoid this problem a number of methods have been developed for the fabrication of polymer films, such as solution casting method, interfacial methods, layer-by layer technique or solvent evaporation method. Unfortunately, all this techniques still require special equipment and have severe limitations with respect to the substrate size as well as film quality, stability and, moreover, until now the self-assembling of thin polymeric film into complex 3D structures remains problem. Actually there is a growing interest in competitive candidates methods for membrane technology with the following properties: large area coverage, high structural flexibility, low temperature processing, especially low cost, formation in situ and three-dimensional shaping. Here we describe a water-based bottom-up approach in which we let a biopolymer self-assemble with unprecedented degree of freedom over the water surface. Being a liquid, water can assume flexible shapes taking on the form of its container and, as a direct consequence, the polymer, dispensed over the water using the method described, could self-assemble into different geometries generating thin polymeric films following the existent water profile in a very direct and simple way.The membranes are formed *in-situ*, directly in the place of interest without the need of handling thin membranes and the subsequent risk of deforming and damaging them. The polymer film could be the external container of a liquid core or a free standing layer with personalized design. The membranes produced encasing water have been characterized in terms of physical properties and morphology. The quick liquid packaging approach could be used to lay a film over micropillars, organic and inorganic micro-objects and colloidal particles. With the same technology it is possible to create also millimetre membrane accommodating the area of interest. The packaging process is described in details reporting, for the first time, the real time characterization of the membrane formation in static and dynamic condition, while various application are proposed. We believe that the proposed technology could be further improved in the future also for selective adsorption of pollutants, filtering and liquid separation moreover, being the polymer used a biodegradable one we foresee application of biocompatibility.

Quantitative Holographic Thickness Mapping Reveals the Full-Field Drainage During Thin-Film Moving

Vincenzo Ferraro[1], Zhe Wang[2,1], Lisa Miccio[2] and Pier Luca Maffettone[1]; [1]University of Naples Federico II, Italy; [2]ISASI-CNR, Italy

Thin-film is one of the important components in material world. From semiconductor layer detection to water membrane measurement, quantitative thickness mapping for thin-film has been a widely studied issue in the past decade. However, with the development of imaging technology, single-point measurement of film thickness has been unable to meet the changing scientific requirements. Full-field visualizing and characterizing for thin-film evolution is taking place as a principal tool for related study, which can provide effective data support for membrane science, polymer chemistry, biomaterials, applied Chemistry, etc. In this paper, we show that digital holographic thickness mapping could be a powerful solution to reveal the full-field drainage of thin liquid film. Digital holography (DH) is an interference imaging technology, it has possibility to achieve requisite spatial and temporal resolution for evolution measurement of transparent and translucent materials. In our study, DH has been performed to reveal the thickness mapping of soap films when moving inside a cylindrical metal tube.Herein, customized tubes with different customized radius were used to generate and hold flat thin soap films. The thin-film is formed inside the tube by immersion. The drainage with different air pumping rates is analyzed. In the recording geometry, the tube is placed vertically, then the object beam of DH passes through the film when the film is moved from the middle of the tube to the top. The object beam will carry full-field thickness information and meet the reference beam on the screen of the camera. Finally, the hologram of related thickness distribution will be created by interference. The film will start to drainage and create multiple fingerings due to Marangoni flows around the edges of the film once it moves inside the tube. Thanks to DH, the full-field evolution process of film thickness will be continuously recorded, so we can quantitatively analyze all features of the film surface, by means of a-posteriori holographic numerical reconstruction. In this case, the relationship between film thickness features with motion speed and tube diameter was studied, this will allows revealing the Marangoni flow formation process in the flat film. In order to obtain highly continuous full-field thickness evolution data, we also proposed a 4D phase unwrapping algorithm based on time series in holographic numerical reconstruction. Comparing with the conventional phase unwrapping algorithm, the new approach utilizes the phase change of the same points in the field of view under a long-time sequence to achieve phase tracking, then the accurate phase unwrapping is achieved. Once supported by the large number of continuous experimental records, 4D phase unwrapping allow us to obtain no phase-jump full-field phase distribution, which is the key to perform quantitative holographic thickness mapping with nanometer precision. In this paper, thanks to the customized thin-film generator and 4D holographic thickness extraction algorithm, the drainage process of the flat film during pumping uplift is quantitatively revealed. A series of space-time drainage modes are made to show the thinning process of the soap films, based on holographic thickness mapping. The results show that DH is a reliable and powerful tool that can effectively reveal the full-field thickness variation of thin liquid film under different conditions.

Late News: The Design and Process Development of Electro-Thermal Membranes for Membrane Distillation Applications Noora A. Almarzooqi; Khalifa University of Science and Technology, United Arab Emirates

Introduction

Electro-thermal (ET) membranes based on the joule heating concept were developed for evaporation and membrane distillation applications. This approach is novel since voltage is applied to a porous thin-film carbon nanotube (CNT)/polymer composite membrane, creating a localized heating effect within the bulk of the membrane, allowing vapour pressure difference to occur and flux of fresh water to permeate. We investigated the effect of joule heating in ionizable environments such as high-salinity brines through the use of a novel class of freestanding MWCNT/PVDF composites within an ET setup.

Methods

CNT/PVDF membranes were fabricated using a tape casting method, as illustrated in figure 1. This method

requires low energy and is scalable.

Figure 1 – Fabrication of freestanding CNT/PVDF membranes using tape casing method, different concentrations percentages of CNT were used to test their joule heating behaviour.
Evaporation experiments were performed to provide supplementary understandings for electrothermal powered MD, as illustrated in figure 2.
Figure 2 – Electrothermal evaporation setup incorporating different membrane compositions.

Results

The results show the high temperatures achievable in response to current passage through the in-lab developed CNT/PVDF composite sheets. Moreover, the thermoelectric effect only resulted in fresh water flux when A.C. voltage was applied.
Figure 3 – The temperature response for the CNT composite sheets under different applied voltages, and the performance of the thermoelectric sheets under different D.C. and A.C. voltages.

Discussion

A big challenge was given by the ionisable nature of the saline water, but was overcome by performing A.C. voltage experiments, which have likely prevented concentration polarization effects and limited both the side reactions and electrode degradation. The ET technology presents a great filtration ability to purify different types of feed streams such as high salinity water, brines and brackish water, and calls for the need for further developments.

Pore Size Tuning of Fouling-Resistant, Self-Assembled Zwitterionic Copolymer Nanofiltration Membranes Through Click Chemistry Abhishek N. Mondal, Samuel J. Lounder, Luca Mazzaferro and Ayse Asatekin; Tufts University, United States

Membrane based water purification processes are of enormous importance in water and wastewater treatment due to their scalability, reliability, energy efficiency, and high effluent quality. Fouling, defined by performance loss due to the adsorption and accumulation of feed components on the membrane surface, is likely the most important obstacle to broader use of membranes in these applications. Zwitterions, moieties with equal numbers of positive & negative electrostatic charges, strongly resist the adsorption of biomacromolecules due to their high degree of hydration. This unique characteristic of zwitterions makes them a promising candidate to be incorporated into membranes to restrict fouling. Linear random copolymers of zwitterionic segments and non-zwitterionic (hydrophobic) segments have recently been shown to be extremely promising materials for membrane selective layers that combine exceptional fouling resistance, narrow pore size distribution, and high water permeability. These copolymers self-assemble to form a bicontinuous zwitterionic network with an approximate ~1.5 nm interconnected domains, held together by a hydrophobic phase. While this pore size is intriguing for a variety of wastewater treatment applications, there is a need for a novel, fast, scalable, and versatile approach to tune the effective pore size of these zwitterionic membranes while retaining their fouling resistance and water permeability. This approach needs to be fast and efficient enough to be integrated into roll-to-roll manufacturing techniques. In this current work, we introduce the first use of thiol-ene click chemistry to tune the effective pore size of self-assembled membranes, leading to the formation of robust membranes with high flux, divalent ion rejection, and fouling resistance. The use of click chemistry allows significant changes in effective pore size, measured through the rejection of both organic solutes and salts, in a matter of seconds, with 40 seconds of cross-linking leading to the doubling of riboflavin rejection. These highly cross-linked membranes also combine high divalent salt rejection (e.g. 80% Na_2SO_4 rejection) whereas the monovalent salt rejection was fairly low (e.g. 28% NaCl rejection). The pore size can be easily tuned by simply changing the crosslinking time, hence the selectivity of these membranes are easily tunable for various membrane selectivity. This unique crosslinking technique can be beneficial for tunable separation properties to address specific processes in bio-separations as well as water and wastewater treatment.

Block-Polymer Membranes and Membrane-Like Capsules for Aqueous Separations Jay Werber[1,2]; [1]University of Minnesota, United States; [2]University of Toronto, Canada

The self-assembly of block polymers into microphase-separated domains provides exciting opportunities for the design of high-performance membranes. In this talk, two block-polymer-based membrane systems will be discussed. In the first, we used a co-casting strategy to rapidly and scalably synthesize membranes that exploit the disordered morphology of block polymers. The polymer in our demonstration contained an etchable poly(lactide) block and a copolymer block comprising poly(methyl methyacrylate-*stat*-styrene), with the polymer chemistry tuned to enable an accessible order-disorder transition temperature (T_{ODT}). Rapid thermal quenching from the disordered state kinetically trapped this bicontinuous morphology, with subsequent etching enabling continuous, tortuous pores without need for channel alignment. We employed a co-casting approach wherein a thin block polymer/solvent layer was coated atop a polysulfone/solvent layer. Rapid drying followed by immersion in non-solvent (water) created composite membranes with discrete layers. Competitive water permeances along with sharp molecular-weight cut-offs were achieved. In the second system, we explore the synthesis of polymeric microcapsules as a proof of concept for dispersible facilitated transport membranes, particularly serving as robust analogs of emulsion liquid membranes. The microcapsules were fabricated using a double-emulsion technique and comprised a commercial poly(styrene)-*block*-poly(butadiene)-*block*-poly(styrene) as a diffusive matrix for facilitated transport, in which a copper-selective small-molecule ligand was dissolved. The ligand allowed for selective uptake of copper ions, which were transported into inner acid-containing, aqueous compartments in exchange for protons. Furthermore, the microcapsule approach allows for simple packing into columns to enable simple cycling of extraction and stripping steps. The two systems are both promising demonstrations of block polymer membranes for practical aqueous separations.

12:05 PM SM13.02.04
Oil-Water Separations Using Nanostructured Coatings and 3D Printed Membranes Rigoberto C. Advincula[1,2,3]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]Case Western Reserve University, United States

Oil and water separation and treatment are significant for the oil and gas industry, including clean-up. The preparation of filter formats or coatings has been used to improve the efficiency of the process. We will focus on using new high-performance thermoset and nanocomposite materials for both coatings and 3D printing format in this talk. Polybenzoxazine chemistry and polymerization have enjoyed tremendous growth due to its versatility in chemistry. Several advantages in properties for high-temperature applications compared to epoxy, PU, PF, resins. We report on the preparation of nanostructured polybenzoxazine (PBZ) nanocomposites prepared with nano clay, nano-silica, and graphene to obtain very robust and superhydrophobic coatings that have resulted in efficient anti-corrosion properties and oil-water separators, including anti-icing properties. The monomers are prepared by simpler chemistry enabling additives and other preparation protocols that lead to robust coatings. The addition of telechelic polybutadiene and polyaniline as part of the interpenetrating network (IPN) and semi-interpenetrating network (SIPN) composition results in robust and very conformal coating compositions. Excellent adhesion properties to substrates even at higher temperature (HT) operations may enable these materials to be applied in more demanding conditions. Nanostructured and nanocellulose materials have also been used to produce highly efficient oil-water separators based on the superhydrophobic and super oleophilic properties of coated filters. In another aspect of high-performance materials, we have demonstrated the use of 3D printing to create membranes and oil soaking objects that can be used for clean-up based on

elastomeric silicone materials. Lastly, we demonstrate the use of 3D printing of superhydrophobic structures to demonstrate controlled wetting behavior.

12:15 PM SM13.02.05
Eco-Friendly and Efficient Carbon-Based Adsorbents Produced from Organic Feedstocks for Removing Toxic Organic Pollutants from Groundwater Suraj Pochampally, Soroosh Mortazavian, Padmanabhan Krishnaswamy, Christina Obra, Ashtin Hofert, Erica Marti and Jaeyun Moon; University of Nevada, Las Vegas, United States

Contamination of groundwater by organic compounds, heavy metals, and chlorinated compounds is a current environmental issue. In-situ remediation techniques that use adsorptive materials have recently been developed for more sustainable treatment of contaminated aquifers. Biochars (BCs) are a biomass-derived black carbon with a highly ordered, interconnected networks of micropores, mesopores, and macropores, which is an economical substitute for conventional adsorbents. In this work, we studied the physical and chemical modification processes of the BCs on their surface area, adsorptive capacity, and surface functional groups. We focused on investigating BCs made from three different shell-type biomasses: walnut shells, pecan shells, and peanut shells. The BCs were produced through pyrolysis process at varied temperatures in the range between 500 °C and 900 °C in an inert gas environment. To tailor the physical and chemical properties of the BCs, the pre-pyrolysis processes and post-pyrolysis techniques (e.g., base treatment and acid activation) were employed. The different BCs were used and assessed for effective remediation of toxic pollutants (i.e., trichloroethylene (TCE), and perchloroethylene (PCE)) from water. The unmodified and modified BCs were compared in terms of microstructures and surface states as well as TCE and PCE adsorptive capacity in this study.
The materials were physically and chemically characterized using various tools. Scanning electron microscopy (SEM) characterization showed different porous surface morphologies of various BCs. The surface hydrophilicity of the different types of BCs were characterized by a sessile test, which was correlated with surface functional groups analyzed by Fourier transform infrared spectroscopy (FT-IR). The pyrolysis process of BCs has been fully understood with thermogravimetric analysis (TGA). The results of this work can advance the understanding of different modification effects on BCs' properties, aiming at the wide adoption of cost-effective and eco-friendly adsorbents.

12:25 PM SM13.02.06
Functionalized Cellulose-Chitosan Membranes for Adsorption of Amine Compounds Marshall Frye, Shangradhanva Eswara Vasisth and Juan Nino; University of Florida, United States

According to several recent reports from the United Nations, WHO, and UNICEF, water contamination is a prevalent issue around the world that needs to be addressed. The current water treatment methods, specifically the primary and secondary treatments, are very good at removing large scale waste but fail at removing some microcontaminants and emerging pharmaceutical water contaminants. Developing novel materials for adsorption to complement the filtration of granular materials in the tertiary treatment step of water processing is a promising way to resolve this issue. Nanocellulose is a strong candidate for a filtration material due to its high surface area, zeta potential, and capability for functionalization. It is an excellent adsorbent for dyes, metals, and other organic molecules. Here, we will demonstrate the high potential of cellulose-based materials as an adsorbent for conventional contaminants, as well as emerging microcontaminants, such as opioids. In the case of amine compounds, through adsorption testing we have recently shown that sulfonated cellulose membranes have high adsorption capacity (i.e. 68.56 mg/g). These membranes are fabricated via a two-step process, first sulfonated the cellulose and then crosslinked with chitosan for mechanical stability. We will also discuss the opportunities for using agricultural cellulose waste streams like rice husks and sugarcane bagasse for producing these filters. Scanning electron microscopy demonstrated degradation of the cellulose surfaces after sulfonation, and a reorganization of the cellulose layers when crosslinked with chitosan. Through Fourier transform infrared spectroscopy it was determined that there were chemical changes through the oxidation and sulfonation steps. The maximum concentration of sulfonate groups was determined to be 194.4 mmol/g using a conductometric titration method. The thermal stability of the cellulose membranes was demonstrated through TGA, showing an

extrapolated onset temperature of 281°C. The adsorptive capabilities of these membranes, tested through kinetic and isothermal models, will be presented. Finally, a performance comparison between activated carbon and these cellulose membranes will be performed.

12:35 PM SM13.02.07
Photocatalysts on Transparent Fibers Improve Light and Mass Transport for a "Chemical-Free" UV-AOP Daniel E. Willis, Ella C. Sheets and Kevin M. McPeak; Louisiana State University, United States

Water scarcity is a growing concern across the globe.[1,2] It is imperative that communities develop and implement energy efficient technologies to treat water contaminated by industrial activity, human waste, or harmful microorganisms. Current best methods, such as advanced oxidative processes (AOPs), can be highly effective against targeted contaminants, but often require chemical additives (e.g. chlorine, peroxide, ozone) which increase costs and may lead to the formation of undesirable disinfection byproducts.[3,4] The use of immobilized photocatalysts with strong light absorption, chemical stability, and high surface area could greatly reduce the need for oxidant feedstocks and improve the affordability of UV-AOPs.

Here, we report on the fabrication and characterization titania-based photocatalysts immobilized on quartz-fiber felt for UV-driven water treatment. Our supported titania is mesoporous which, combined with the macroporous (Φ >0.95) fiber, yields a high surface area beneficial for mass transport. By using quartz fibers, we maximize the optical path length of UV (250 – 400 nm) light through our system. Our titania may also be loaded with Au nanoparticles to increase the generation of reactive oxygen species (ROS) and provide alternative reaction pathways for degrading contaminants. We propose a cost/benefit breakdown for the addition of Au in our photocatalytic system.

We test the long-term (>24 hours) stability and efficacy of our fiber-supported photocatalysts to degrade model contaminants under illumination from both UV-A LEDs and germicidal UV-C lamps. Our immobilized photocatalysts produce >100 μM *OH in 20 seconds in a flow reactor and achieve an Electrical Energy per Order (EE_O) of <0.6 for the degradation of Rhodamine B. We also examine the impact of water quality (pH, TOC, scavengers) and propose mechanisms for pollutant breakdown. Lastly, we will discuss the reactor design and relevant transport conditions for our supported photocatalysts, and the improvements necessary to scale our material for practical applications.

Late News: Activated Agro-Industrial Waste Biochars for Heavy Metal Remediation and Nutrient Management Zoe Pollard and Jillian Goldfarb; Cornell University, United States

Sustainable water treatment materials can be derived from carbon-rich agro-industrial wastes through thermal treatment and physical activation, thus shifting away from traditional disposal – landfilling or composting. Cherry pits are an abundant carbon-rich waste biomass in the Great Lakes region and represent a viable feedstock for conversion to biochars and activated biochars for soil amendments and heavy metal adsorbents. These sustainable materials have the potential to remediate local water quality issues including the hazardous eutrophication of the Great Lakes and heavy metal contamination of the region's drinking water. In this work, slow pyrolysis was used to convert waste cherry pits to biochars (1 hour at peak temperatures of 450 and 600°C) and activated biochars (1 hour at peak temperatures of 800 and 900°C). Biochars produced have surface areas between 206 and 274 m^2/g and increased bioavailability of Fe, K, Mg, Mn, and P. The biochars can be implemented as soil amendments to reduce nutrient run-off and serve as a valuable carbon sink (biochars

contain 74-79% carbon), potentially mitigating harmful algal blooms in the Great Lakes. The CO_2-activated biochars exhibited selective metal adsorption of As, Cu, Pb, and Zn from simulated contaminated drinking water. Physical activation increased the metal adsorption capacity by 2.8 and 4.2 times for the biochars activated at 800 and 900°C, respectively. The increased capacity is attributed to high surface areas (up to 629 m^2/g) and a hydrophilic surface (confirmed via FTIR functional group analysis). Through sustainable waste-to-byproduct valorization we convert this waste food biomass into biochar for use as a soil amendment and into activated biochars to remove metals from drinking water, thus alleviating economic issues associated with cherry pit waste handling and reducing the environmental impact of the cherry processing industry.

12:55 PM SM13.02.09
Late News: Facile Size-Selective Defect Sealing in Large-Area Atomically Thin Graphene Membranes for Sub-Nanometer Scale Separations Piran Ravichandran Kidambi; Vanderbilt University, United States

Atomically thin graphene with a high-density of precise subnanometer pores represents the idealmembrane for ionic and molecular separations. However, a single large-nanopore can severely compromisemembrane performance and differential etching between pre-existing defects/grain boundaries in grapheneand pristine regions presents fundamental limitations. Here, we show for the first time that size-selectiveinterfacial polymerization after high-density nanopore formation in graphene not only seals larger defects (>0.5nm) and macroscopic tears but also successfully preserves the smaller subnanometer pores. Low-temperaturegrowth followed by mild UV/ozone oxidation allows for facile and scalable formation of high-density (4–5.5 ×10^12 / cm^2) useful subnanometer pores in the graphene lattice. We demonstrate scalable synthesis of fullyfunctional centimeter-scale nanoporous atomically thin membranes (NATMs) with water (∼0.28 nm)permeance ∼23× higher than commercially available membranes and excellent rejection to salt ions (∼0.66nm, >97% rejection) as well as small organic molecules (∼0.7–1.5 nm, ∼100% rejection) under forward osmosis.

Late News: Zinc Oxide Nanostructures by Hot Water Treatment for Photocatalytic Water Treatment Ranjitha Hariharalakshmanan, Juan Martinez and Tansel Karabacak; University of Arkansas at Little Rock, United States

Over the recent years, zinc oxide (ZnO) nanostructures have gained remarkable attention in the field of semiconductor photocatalysis for water treatment applications. In our previous work, we demonstrated that ZnO nanostructures can be produced in a simple, cost-effective, and environmentally-friendly manner by the method of hot water treatment (HWT) and the nanostructures produced by this method can be used to degrade organic

pollutants via photocatalysis. In this work, we investigate how the photocatalytic degradation is affected by changing the amount of the HWT ZnO nanostructure photocatalyst and the concentration of the organic pollutant. The ZnO nanostructure suspension was made by the HWT of zinc plates in DI water at 75°C for 5 hours. Since the ZnO nanostructures are released into the water as a result of the HWT of the Zn plates, our ZnO nanostructures are in the form of a suspension in water. In order to change the amount of photocatalyst, we changed the volume of the ZnO nanostructure suspension being added. We used 10 ml, 25 ml, and 50 ml of the ZnO nanostructure suspension, added it to methylene blue (MB) at an initial concentration of 2.5 ppm and exposed the mixture to UV light for 4 hours. We observed that 25 ml of the ZnO nanostructure suspension gave the maximum degradation of MB (~65%). When we used 50 ml, the degradation percentage decreased to about 45%. This might be due to increase in turbidity of the mixture, which can lead to a decrease in the penetration of UV light. We then used 25 ml of the ZnO nanostructure suspension and conducted MB degradation tests at 4 different initial concentrations of MB. Maximum MB degradation was at 1 ppm (~84%) and minimum at 10 ppm (~18%). This decrease in MB degradation can be due to the decrease in UV light being absorbed by the photocatalyst as more and more MB molecules get adsorbed to the photocatalyst surface. As a preliminary study, we also did HWT of Zn plates in tap water instead of DI water. We were able to form ZnO suspension in tap water too, and we observed ~47% degradation of MB during photocatalytic degradation experiment. This is an encouraging result as the use of tap water instead of DI water can further bring down the cost and increase the scalability of nanostructure fabrication by HWT.

2:25 PM SM13.03.04
Catalytic Reduction of Graphene Oxide Membranes in Water-Alcohol Separations and Its Impact on Permeation Behavior Yushi Zang[1], Alex Peek[1], Yongsoon Shin[2], David Gotthold[2] and Bruce Hinds[1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Graphene oxide (GO) is considered to have great potential for chemical separation applications due to its unique properties of enhanced 2-D nanofluidic and the ability to control interlayers spacing for size-based chemical selectivity. A GO membrane with highly aligned GO grains was fabricated through a slip casting process and studied for alcohol-water separation application. We found the pressure-driven permeance of water, MeOH and IPA through 5 μm thick GO membranes to be 0.4, 0.12 and 0.8 LMH/Bar (L/m^2-hr-Bar) respectively consistent with literature examples without defects that had given erroneously high flows. Interestingly, the permeance of alcohol-water mixture was found to be dramatically lower (~ 0.01 LMH/Bar) than any of its individual components. Such a mixture of solvents does not permanently affect the GO membrane, as the permeance of pure solvent was recovered to its original level upon removal of alcohol-water solvent mixture. The drop in transmembrane flux was also observed in osmotic tests when alcohol-water solvent mixture was in the feed solution side of the membrane. The osmotic tests showed the selectivity of water over alcohol through GO membrane and rejection of salt. The interlayer space of a dried GO membrane was found to be 8.52 Å which increased to 12.19 Å. 13.26 Å and 16.20 Å upon addition of water, MeOH and IPA. When water saturated GO membranes were exposed to MeOH, a 2 Å decrease in interlayer spacing of GO membrane was seen suggesting the removal of OH groups from GO. Such phenomenon was accompanied by a color change of the membrane at the same time. Permeation was recovered with exposure to oxidants (H2O2). These observations support a newly proposed mechanism of a partial reduction of GO through a catalytic reaction with alcohol-water mixtures.

2:35 PM SM13.03.05
Strategies for the Scale-up of the Photocatalysis Process for Disinfecting Large Quantities of Water Niraj Ashutosh Vidwans, Johnathan Bockenstedt, John Boswell, Terry Gentry and Sreeram Vaddiraju; Texas A&M University, United States

Titanium dioxide (TiO_2) is one of the well-studied materials for applications in photocatalysis. Various forms of TiO_2, such as commercially available Aeroxide® P25, nanowires, phase-pure Anatase crystals, and phase-pure Rutile crystals have been explored for photocatalysis. The capability of TiO_2 in generating reactive oxygen species (ROS) when exposed to ultraviolet (UV) light has been extensively utilized for both removing

contaminants (e.g. dyes) from water and disinfecting water. Here, the high specific surface area obtained when TiO_2 is made in nanocrystalline form (nanoparticles and nanowires) aids in engineering both the efficiencies and the kinetics of the water remediation processes. However, one of the major hurdles in the widespread use of photocatalysis for water remediation is the need to extensively pre-process and post-process the source water and the treated water, respectively for making the source water transparent to light and for the recovery of the TiO_2 photocatalyst. This makes it tedious to employ photocatalysis, unlike processes such as chlorination. In this work, we present a few strategies useful for overcoming the above-mentioned bottlenecks. Flow pattern changes, photocatalyst morphology alterations, and surface chemical compositional changes in a TiO_2 nanowire-based photocatalyst have been employed to make the photocatalysis process useful for treating any kind of water with minimal post-processing. These strategies will be discussed in detail in this talk. The steps involved in implementing these strategies in a bench-scale setup capable of continuously disinfecting 3 gallons of water per minute will also be discussed. The central ideal here is that making photocatalysis easy to implement and effective makes it employable at any stage in the train of technologies used for treating water.

2:45 PM SM13.03.07
Removal of Low Concentration Water Contaminants with Biochar using Novel Mixing Methods Richard M. LaDouceur, Dario Prieto and Alyssa Cook; Montana Technological University, United States

Biochar is a carbonaceous solid commonly referred to as charcoal which results from the pyrolysis of organic matter. These materials are important domestic and industrial adsorbents due to their rich surface chemistry, large micropore volume, and high specific surface area. Recent research indicates that biochar can remove both organic and inorganic contaminants from gas and liquid streams. Careful biomass pyrolysis can lead to structures with the right combination of surface morphology and chemistry to adsorb specific adsorbates. However, biochar morphology and function are both inextricably linked to the pyrolysis conditions and the biomass source. Adsorption methodology has a large effect on the adsorption behavior of high surface area materials which hinders reproducibility. Therefore, a design of experiments was created to attempt to determine ideal conditions for maximum contaminant uptake. Experimental designs for three biochar-contaminant mixing methods, the orbital shaker, rotational mixer, and resonant acoustic mixer (RAM), were formed, with three variable factors being taken into consideration for each: biochar mass, length of mixing time, and intensity of mixing. High, middle range, and low values for each factor were combined to create the matrix for each mixing method. Similar adsorption behavior is noted for the three methods with the time required for maximum adsorption being considerably different between the three methods.

2:55 PM SM13.03.08
Material and Structural Designs of Hydrogels for Solar-driven Desalination and Water Purification Xingyi Zhou and Guihua Yu; The University of Texas at Austin, United States

Solar-powered water evaporation provides a means for sustainable seawater desalination and water purification technologies. Advanced material and structural designs of the evaporative materials are essential for efficient freshwater production. Here we will present our representative works on rational design and molecular engineering of hydrogels and their applications in solar-powered water purification. We designed hybrid hydrogels composed of a hydrophilic polymer framework and solar absorption materials to harvest solar energy and remove contaminants. By tuning the micro/nanostructures and chemical/physical interactions between components, the hybrid gels exhibit attractive synergistic characteristics including high solar absorption, reduced energy consumption for water evaporation, fast water transport, effective thermal management and antifouling property. The highly hydratable polymer networks can be architected to tune the water state, activating water molecules and facilitating water evaporation. The hydrogel evaporator with topology-controlled hydration behavior is also designed to achieve water and heat management simultaneously. These works provide fundamental design principles regarding material selection, molecular engineering and structural modification of these emerging hydrogels for the development of next-generation solar evaporators for seawater desalination and water purification.

Late News: The Role of Additional Oxidation of Graphene Oxide on the Removal of Methylene Blue

Cecilia A. Zito[1], Tarcísio M. Perfecto[1], Talita Mazon[2] and Diogo P. Volanti[1]; [1]São Paulo State University, Brazil; [2]Center for Information Technology Renato Archer (CTI), Brazil

Graphene oxide (GO) has emerged as an efficient adsorbent for environmental remediation, playing an important role in water treatment. GO-based materials have been developed for the sorption and removal of contaminants from water, including dyes,[1] metallic ions,[2] radionuclides,[3] aromatic organic compounds,[4] and so on. In particular, dyes can cause damages to humans and aquatic biota for being toxic and carcinogenic.[5] The chemical composition, degree of oxidation, and size strongly affect the adsorption properties of GO. Herein, we report the repeated oxidation of GO using milder conditions of a modified Hummers' method to obtain the modified graphene oxide (Ox-GO). The impact of the repeated oxidation was evaluated by studying the adsorption performance of the materials towards methylene blue (MB), one of the most used cationic dyes. The materials were characterized by X-ray powder diffraction, scanning electron microscopy, atomic force microscopy, X-ray photoelectron spectroscopy, total X-ray scattering, and pair distribution function analysis. Our results show that the additional oxidation step does not lead to an increased content of oxygenated groups but instead, it causes a small change in the amounts of each functionality, reduces the size and introduces holes in the sheets, facilitates the exfoliation. The adsorption experiments reveal that when using an initial MB concentration of 200 mg L^{-1} at pH 6, Ox-GO shows a dye adsorption capacity of 695.36 mg g^{-1}, nearly 1.32-fold higher than that of GO (527.07 mg g^{-1}). Thus, more than 90% of MB can be removed by Ox-GO, while GO removes only 72.2%. When the pH is decreased to 2 at the same dye concentration, the difference in removal for both materials is more pronounced, where Ox-GO adsorbs 1.45 times more MB than GO, reaching an efficiency of around 79.5%. On the other hand, under alkaline conditions (pH 10), GO can adsorb almost 100% of the dye, but Ox-GO presents a catalytic behavior to converting MB into a different species, violet-colored. Therefore, the additional oxidation step of GO is an efficient method to enhance the MB adsorption performance, enabling the application in water treatment. Moreover, the material also shows catalytic properties that allow more potential applications.

Late News: Elucidating Ionization Anomalies Observed in Nanoporous Polyamide Membranes Cody Ritt[1], Jay Werber[1], Mengyi Wang[2,2], Zhongyue Yang[2], Yumeng Zhao[1], Heather J. Kulik[2] and Menachem Elimelech[1]; [1]Yale University, United States; [2]Massachusetts Institute of Technology, United States

Escalating global water scarcity necessitates high-performance desalination membranes, for which fundamental understanding of structure–property–performance relationships is required. In this study, we comprehensively assess the ionization behavior of nanoporous polyamide selective layers in state-of-the-art nanofiltration (NF) membranes. In these films, residual carboxylic acids and amines influence permeability and selectivity by imparting hydrophilicity and ionizable moieties that can exclude coions. We utilize layered interfacial polymerization to prepare physically and chemically similar selective layers of controlled thickness. We then

demonstrate location-dependent ionization of carboxyl groups in NF polyamide films. Specifically, only surface carboxyl groups ionize under neutral pH, whereas interior carboxyl ionization requires pH >9. Conversely, amine ionization behaves invariably across the film. First-principles simulations reveal that the low permittivity of nanoconfined water drives the anomalous carboxyl ionization behavior. Furthermore, we report that interior carboxyl ionization could improve the water–salt permselectivity of NF membranes over fourfold, suggesting that interior charge density could be an important tool to enhance the selectivity of polyamide membranes. Our findings highlight the influence of nanoconfinement on membrane transport properties and provide enhanced fundamental understanding of ionization that could enable novel membrane design.

Photocatalytic Degradation of Organic Dyes in Presence of Titanium Dioxide Under UV Light María J. Paz Ruiz and Alondra A. Lugo Ruiz; University of Puerto Rico at Ponce, Puerto Rico

There has been a high discharge of non-biodegradable dyes into natural streams and water bodies, thus contaminating them. Many of these dyes are synthesized by carcinogens and can be water-soluble, therefore being more problematic to remove. One of the largest categories of colorants are the azo dyes, over 50% of all the dyes used are azoic dyes. The problem with azo dyes is that they can be reduced into aromatic amines, which are potentially hazardous. One effective way to remove these dyes from our water sources is by using semiconductor nanoparticles in a photocatalytic degradation process. Titanium dioxide is a semiconductor material with intrinsic optical and electronic properties that promote its use in several applications including catalytic processes and organic synthesis. The photocatalytic capacity of TiO2 nanostructures is based on the generation of electron-hole pairs due to the UV excitation of TiO2. The generated pairs diffuse to the surface of the material and participate in the surface reaction leading to the decomposition of absorbed matter. The generation of reactive oxygen species by the electron-hole pairs is responsible for the degradation of organic contaminants like dyes. Based on the considerations above, the objective of this research was to study and evaluate the photocatalytic capacity of the Titanium Dioxide NPs on organic dyes. The results evidenced that the photocatalytic properties of TiO2 degraded the dyes in its majority. The effect of catalysts concentration on the reaction rate constants will be discussed.

5:20 PM SM13.04.02
Effect of the Particle Size and pH on the Photocatalytic Performance of CeO_2 Nanoparticles Natalie M. Lopés Velasco and Sonia J. Bailón- Ruíz; University of Puerto Rico at Ponce, Puerto Rico

Cerium Oxide Nanoparticles (CeO_2 NPs) are recognized as important functional materials because of their exciting applications. These nanoparticles are used as catalytic converters for; internal combustion engines, polishing lenses, optical instruments, pigments, solar cells, and photocatalytic processes. Preliminary studies have reported that CeO_2 has the potential capacity to destroy organic dyes because of their capacity to generate reactive oxygen species (ROS) in aquatic environments as hydroxide radicals (OH). However, there is a concern about the potential adsorption of CeO_2 in aquatic organisms and later toxicity in these living systems. In this way, scarce studies about the nanotoxicity of CeO_2 in the aquatic organism have been reported. Based on the mentioned before, the objectives of this work were: 1) Characterize Cerium Oxide Nanoparticles, 2) Study the photocatalytic degradation of organic dyes with two different sizes of CeO_2 NPs, 3) Evaluate the CeO_2 nanoparticles ROS production capacity (as toxicity in marine organisms), and 4) Determine the effect of the pH

in the photocatalytic capacity of CeO_2 NPs. Nanoparticles of CeO_2 evidenced a high absorption peak in the ultraviolet range, which suggests the charge-transfer transition from O_2- (2p) to Ce^{4+} (4f) orbitals in CeO_2. It is known that Azo dyes are disposed of in aquatic environments without treatment. These dyes are used in printing, pharmaceuticals, laboratory research, and in the textile industry. These toxins can enter the body through the skin and cause; fast heart rate, lung tissue death, and vomiting. In this research, we focused on the azo dye, Tropaeolin O. The catalytic activity of two different Cerium Oxide size nanoparticles were evaluated in aqueous solutions of Tropaeolin O at 70µM of concentration. These solutions were put in a UV light at 302 nm for intervals until it reached 160 minutes. The smallest Cerium Oxide NPs (<5.0 nm) degraded about 40%. The biggest Cerium Oxide NPs (<25.0 nm) degraded about 20%. This result shows that (<5.0 nm) CeO_2 NPs degraded more due to its greater surface area and its capacity to generate more reactive oxygen species (ROS). The capacity of CeO_2 NPs to generate ROS was examined and investigated with the intoxication experiment of shrimps. The toxicity was evaluated in marine crustaceans at different CeO_2 concentrations in the 0ppm to 1000ppm range. The results indicated that Cerium Oxide had a negative interaction in marine organisms with increased concentration and exposure time. At 24 hours of exposure, the smallest NPs had a high mortality rate at CeO_2 concentrations higher than 100ppm. However, when the exposure time was increased by 48 hours, nanoparticles were toxic at concentrations higher than 10ppm. In contrast, the biggest NP showed no high mortality rate after 48 hours of exposure and higher concentrations. This experiment explains that (<5.0 nm) Cerium Oxide nanoparticles are more toxic because of the greater surface area and the generation of ROS radicals. We are currently working with the optimization of both sizes of the CeO_2 NPs by changing their acidic pH to a basic pH. In theory, this would optimize and give a better photocatalytic effect and a more significant degradation percent of different azo dyes like Tropaeolin O.

Solar Evaporators Based on Water Pump of Thermosensitive Hydrogels Hoyeon Kim and Jongwhi Lee; Chung-Ang University, Korea (the Republic of)

Solar desalination system shows great potential as a solution to the issues of global water scarcity because of its eco-friendliness and sustainability. However, the heat loss of evaporation surface to water reservoir, fouling due to the formation of salt crystals on evaporation surfaces, and the difficulty of continuous brine supply without external power are the major obstacles to the practical use of the solar desalination. Herein, using thermosensitive hydrogel composites, a solar evaporator was which could work by diurnal temperature variation with antifouling properties and no heat loss during evaporation. An irreversible water flow was achieved by using composites of thermosensitive poly(N-isopropylacrylamide) (PNIPAm) hydrogel and hydrophobic polydimethylsiloxane (PDMS), which have fast deswelling kinetics. The composites were made by directional melt crystallization (DMC) of solvent. By the DMC method, a porous PNIPAm having aligned and continuous three-dimensional pores was prepared. The structure enables a combination of two different materials. It can be achieved by the infiltration of PDMS to the aligned pores of PNIPAm. Anisotropic composites have PNIPAm/PDMS phase at the bottom of the composites, which has a faster deswelling rate than pure PNIPAm phase. As temperature rises above the LCST of PNIPAm, water can be released from the top surface of the PNIPAm, and this water pumping could be repeated by the diurnal temperature variance. Between the pumping composite and the water reservoir, another porous PNIPAm was placed. During diurnal temperature variance, this bottom PNIPAm can vary its length. At a temperature above LCST, the length of the PNIPAm is shortened, a thermal isolation from the water reservoir results. At a temperature below LCST, PNIPAm is lengthened, and it can absorb brine from the water reservoir and diffuse brine into the entire phases of PNIPAm/PDMS composites. Water from the pumped brine evaporates on the surface of nickel/cellulose composite, which could float on water. Nickel nanoparticles were prepared on the surfaces of cellulose papers. When brine is released, the nickel/cellulose composites float, and salt accumulation is formed at the bottom of the composites. This can solve the decrease in the efficiency of the evaporation due to the fouling by salt crystallization. Our three-dimensional solar desalination system could be operated without artificial power without the fouling problems. Diurnal operating strategy makes the solar evaporator eco-friendly, and the antifouling properties increase the sustainability of solar desalination.

***In Situ* Synthesis of Carbon Dot at Cellulose Nanofiber for Durable and Selective-Removal Membrane via Mild Hydrothermal Carbonization** Jungbin Ahn and Hyungsup Kim; Konkuk Univ., Korea (the Republic of)

Researches on water treatment technology has been steadily studied for innovative improvement of the performances, i.e., high yield and speed of purification process. Conventionally, water treatment membrane was fabricated from synthetic polymers, such as polysulfone and polyethersulfone, with the controlled pore structure. Non-solvent induced phase separation (NIPs) is the most common method to control the pore structure. In the process, polymer solution should be immersed in a coagulation bath containing non-solvent. The overuse of hazard solvents is inevitable during the fabrication. In order to protect the earth from those kinds of pollutions, a substantial candidate for the membrane is crucial. TEMPO-oxidized cellulose nanofiber (CNF) has high potential for the membrane application due to its high aspect ratio and high mechanical strength. Owing to its carboxylate groups, CNF can be easily dispersed in water which enables the membrane fabrication without the help of toxic solvents. Up to now, a number of studies have been reported for high performance membrane based on CNF. However, it is still challenging to increase pollutant removal performance without sacrificing its water flux.
In the study, high-performance water treatment membrane was fabricated using *in-situ* synthesized carbon dot (CD) at CNF. Via simple hydrothermal treatment, CD was homogeneously attached to the CNF surface by amide bonding. CD@CNF had a fibrous structure with rough and bumpy morphology, while the chemical structure of cellulose was not changed. The CD attached on the surface decreased the repulsive force between the CNFs and remarkably increased the thermal and dimensional stabilities of the CNF film. With the structural robustness, CD@CNF showed excellent performance as a dye-rejection membrane of high-water flux and high rejection rate. As well the CD@CNF showed superior selective removal results toward cationic dyes. This study suggests the novel synthesizing method of durable CNF membrane by envelopment of CD for effective water treatment.

Doped Graphitic Carbon Nitride Nanocomposites with Various Dimensions for the Effective Photodegradation of Pharmaceuticals Ruey-An Doong[1] and Thanh Binh Nguyen[2]; [1]National Tsing Hua University, Taiwan; [2]National Kaohsiung University of Science and Technology, Taiwan

In recent years, the presence of pharmaceuticals such as diclofenac and sulfamethoxazole in the aquatic environment has been of growing interest as it poses a threat to aquatic organisms and human health. Graphitic carbon nitride (g-C_3N_4) is a promising green photocatalyst with the visible-light-responsive property. However, the high e^--h^+ recombination rate decreases the photo-activity of g-C_3N_4. Therefore, the doping with other ions as well as the combination with other photocatalysts can not only extends the absorption to the visible light region but also reduces the recombination rate of electron-hole pairs. Herein, the doped C_3N_4 with various morphologies and dimensional was successfully synthesized by a facile hydrothermal–assisted thermal approach as an effective photocatalyst for photocatalytic degradation of pharmaceuticals under visible-light irradiation. The 1-D B, P-codoped g-C_3N_4 various P loadings was fabricated for highly recyclable photodegradation of diclofenac (DFC) under visible light irradiation. The as-prepared 1-D B, P-C_3N_4 exhibits high surface area, visible-light response and photoinduced charge separation to effectively photodegrade > 99% of 10 mg/L diclofenac within 90 min of irradiation. The 1D-BPCN-3 shows good reusability in the photodegradation of DFC for at least 5 consecutive cycles without considerable loss in photocatalytic activity. Moreover, the 3-D flower-like g-C_3N_4@TiO_2 was prepared by the thermal exfoliation of urea and hydrothermal method. The g-C_3N_4@TiO_2 exhibits an excellent photocatalytic performance toward diclofenac degradation under solar light irradiation. The impedimetric and photoluminescence spectra show that 5 wt% g-C_3N_4 can increase the conductivity as well as reduce the recombination rate of g-C_3N_4@TiO_2 nanocomposites, resulting in the enhancement of photodegradation efficiency and rate of diclofenac. The rate constant for diclofenac degradation by 3-D g-C_3N_4@TiO_2 is 0.075 min^{-1}, which is 3–10 times higher than the other g-C_3N_4@TiO_2. These results clearly demonstrate that the various dimensions of doped g-C_3N_4 are reliable visible-light-

responsive photocatalysts for the decomposition of antibiotics and other emerging pollutants in aqueous solutions.

Heterostructured Material—New Science Produces Superior Properties Yuntian T. Zhu[1,2]; [1]City University of Hong Kong, China; [2]Southeast University, China

Strong and tough materials are desired for light-weight applications such as electric cars and aerospace applications. Recently, heterostructures are found to produce unprecedented strength and ductility that are considered impossible from our textbook knowledge and materials history. Heterostructured materials consist of heterogeneous zones with dramatic (>100%) variations in mechanical and/or physical properties. The interaction in these hetero-zones produces a synergistic effect where the integrated property exceeds the prediction by the rule-of-mixtures. Importantly, HS materials can be produced by current industrial facilities at large scale and low cost. There are many scientific issues with such materials that challenge the communities of experimental materials science and computational material mechanics. Heterostructured materials is quickly becoming a hot research field in the post-nanomaterials era. In this talk I'll present the current advances as well as future challenges and issues in this emerging field.

8:25 AM ST01.01.02
Late News: Characterization of Gamma to Alpha Phase Transition in Uranium via XRD and DSC
Christian J. Reiter, Julia Mausz, Christian Schwarz, Bruno Baumeister, Winfried Petry and Peter Muller-Buschbaum; Technische Universität München, Germany

For safety of nuclear fuel, pure metallic uranium disqualifies due to its anisotropic thermal expansion and cycling behavior of its equilibrium alpha phase under operation conditions. In contrast, the body-centered cubic gamma-phase provides the desired irradiation stability, but as this phase is not stable at room temperature, it is necessary to alloy it with elements such as Nb, Ti or Mo. Still, the alloy needs to be quenched rapidly from the

high temperature gamma-phase regime down to room temperature in order to preserve the gamma phase. Uranium-molybdenum alloys, with 4.5 wt.% to 15 wt.% Mo, have been favored, however, the best compromise between fuel performance and uranium density must be made. In order to provide a safe usage, two conditions must be ensured during the entire operation cycle: On the one hand, the stability of phases must be given throughout the operation cycle and on the other hand, the interaction with other materials, especially with the cladding, must be minor or at least predictable.

Exposed to elevated temperatures, the meta-stable gamma-phase of uranium-molybdenum alloys decomposes into other thermal equilibrium phases, i.e. U_2Mo and alpha-uranium following isothermal phase transformation kinetics. Until now, the transformation enthalpy, which is the energy required to transform the decomposed phases back into pure gamma, has not been studied by accounting for the relative fraction of the phases during this re-transformation. The enthalpy change of the phase transformation can be studied by differential scanning calorimetry (DSC).

In the present study, an uranium-molybdenum alloy with 7.8 wt.% has been used, which was deposited onto a copper substrate using physical vapor deposition (PVD). In order to compare the phase composition, X-ray diffraction (XRD) measurements were conducted on fresh and tempered samples, respectively. After heat treatment, the phase proportion between alpha and gamma phase exists according to the corresponding time temperature transformation (TTT) diagram. During the measurement, the respective fraction of the volume undergoes a transformation back from alpha- to gamma-uranium, which can be measured using DSC. However, the phase transition enthalpy cannot directly be normalized by the weight or volume of the sample. Hence, an additional correction of pre-measured fractional phase composition must be carried out. Analysis of DSC data is presented.

8:40 AM ST01.01.03
Nanoporous Gold Thin-Film Dealloying—Process-Structure Correlation Stanislau Niauzorau, Aliaksandr Sharstniou, Natalya Kublik, Venkata Sampath and Bruno Azeredo; Arizona State University, United States

Nanoporous metals with bi-continuous porosity attracts considerable interest due to its high surface area which opens their potential for use in sensing [1], catalysis [2], and energy storage [3]. However, processing-structure (PS) relations for nanoporous gold (NPG) have been largely not understood. Recently, McCue et al. constructed and analyzed a large dataset of porous gold SEM images from various publications to establish correlations between structural parameters (i.e. ligament diameter, aspect ratio, solid area fraction (SAF)), and processing conditions (such as dealloying times and temperatures) [5]. However, the large scatter of this dataset also suggests issues with the reproducibility of NPG synthesis even with the reported fixed dealloying protocol (e.g. precursor alloy composition, etching solution, concentration, etc.). In this study, we experimentally examine the reproducibility of the synthesis of NPG thin films fabricated at constant conditions (i.e. 60 at.% Ag in precursor alloy, 7.85 M HNO_3, 65 °C) and extract structural data to find PS relations. Moreover, we test the influence of processing conditions previously not reported such as the temperature equilibration time of the etchant solution, and sample aging effects such as stress release, grain growth and surface oxidation, all of which have been found to affect the uncertainty of NPG synthesis. This ground work may shed more light at future understanding of the kinetics of morphology evolution in chemical dealloying at a more quantitative level.

8:55 AM ST01.01.04
Investigation of Fundamental Creep Behavior in Thermally Stable Hierarchical and Nanocrystalline Ni-Y Alloys Shruti Sharma, Pedro D. Peralta and Kiran Solanki; Arizona State University, United States

There is a growing interest in developing strategies to increase the high temperature performance of metallic alloys used in extreme conditions, such as those found in many energy generations and propulsion systems, among others. Microstructure refinement has long been considered a potential route for improvement in this regard; however, nanocrystalline (NC) metals and alloys (with grain size less than 100 nm) exhibit significant microstructure instability at high temperatures and even at room temperatures under, e.g., cyclic loads. Thermodynamic (solute segregation to reduce grain boundary energy) and/or kinetic approaches (solute drag, Zener pinning, etc., to pin grain boundaries) can be used to suppress grain growth through the addition of alloying elements and second phases. Some NC alloys such as Cu-10%Ta fabricated using far from equilibrium processing techniques have displayed stability of their microstructures mostly through kinetic mechanisms at various thermo-mechanical loading conditions, leading to an enhanced creep behavior compared to its coarse-grained (CG) counterparts. However, the low melting point of Cu makes Cu alloys ill-suited for advanced applications compared to Ni and Ti. The fundamental creep mechanisms in these alloys also need to be studied in more detail.

This work seeks to study the microstructure stability as well as the fundamental creep mechanisms in hierarchical and NC Ni-Y alloys, where the hierarchical alloys were synthesized using the conventional arc-melting technique in an inert atmosphere and NC alloys by consolidating powders at high temperatures through equal channel angular extrusion (ECAE) processing to retain a fully dense NC microstructure. For the Ni-Y alloys, using a Ni-rich matrix can impart high ductility and formability while leading to high stiffness and a relatively high melting point, thereby delaying the onset of diffusional creep mechanisms. Small additions of Y to Ni would introduce second phase particles from Ni-Y ($Ni_{17}Y_2$), thus possibly improving the kinetic stability (Zener pinning of grain boundaries).

Current research is divided into three major tasks: a) evaluating microstructure and mechanical properties of hierarchical Ni-Y alloys over an appropriate range of compositions to establish a baseline to assess binary alloy behavior, b) high temperature uniaxial compression and creep-testing of both hierarchical and NC alloys, and c) advanced characterization techniques to understand the creep behavior of the alloys. The microstructure of hierarchical alloys studied using characterization techniques like optical microscopy, BSE imaging, EDX, and WDX analysis displayed three major length scales. The ultrafine eutectic length scale of ~300 nm led to the microhardness and yield strength of the alloys comparable to the existing Ni-superalloys. Furthermore, the matrix of the alloys defined by dendritic arm spacing of ~10 μm controlled the microstructural stability of alloys, ascertained by heat treatments and high temperature compression tests. Additionally, grain size (200 μm) in hierarchical alloys is expected to play a significant role in improving creep properties based on the observation of the creep rate possessed by the ultrafine-grained Ni-Y alloys being comparable to that of Ni-

based single crystal superalloys. Characterization has also been performed on as-deformed hierarchical Ni-Y samples using EBSD techniques before and after deformation to see a combination of RT and temperature deformation in the matrix and eutectic phases, understand the deformation behavior, e.g., slip behavior, and correlate crystallography with slip behavior. EBSD combined with higher resolution imaging has also been used to see the effect on the eutectic phase with deformation. Furthermore, SAXS measurements are also performed on the deformed samples to understand the average particle size, particle size distribution, particle surface area, etc. in hierarchal and NC alloys.

9:10 AM ST01.01.05
Microstructure and Mechanical Property Gradients in Stainless Steels Induced by Thermal Gradients in Spark Plasma Sintering Alexander D. Preston and Kaka Ma; Colorado State University, United States

Spark plasma sintering (SPS) is a unique powder metallurgy technique capable of rapid densification due to a combination of joule heating and pressure. The rapid heating rates in SPS and the tooling-sample contact resistances cause thermal gradients, which in turn lead to microstructural gradients. To elucidate the nature of the interaction between starting powder morphology, electric current pathways, and thermal gradients in SPS, the present work investigated the microstructure and mechanical properties of nominally austenitic stainless-steel samples fabricated via SPS of gas atomized and ball milled powders. Microhardness testing and nanoindentation were applied to investigate local mechanical properties at both a micro- and a nanoscopic level. Nanoscratch testing was incorporated to understand the effect of different particle-particle interfaces including the deformation behavior. It was found that a grain size gradient arising from the thermal gradients in SPS lead to changes in local microhardness (ΔH=100MPa~150MPa). Nanoindentation results revealed radial porosity gradients in the samples lead to a radial gradient in Young's modulus (ΔE=30GPa~65GPa).

9:25 AM *ST01.01.06
Tailoring the Configuration of Nanotwins in Sputter Deposited Alloys as a Route to Isolate Dislocation-Twin Interactions Francisco Andrade Chavez, Orcun Koray Celebi, Ahmed Sameer Khan Mohammed, Huseyin Sehitoglu and Jessica A. Krogstad; University of Illinois at Urbana-Champaign, United States

The remarkable strength of nanotwinned metals and metallic alloys has been attributed to a number of mechanisms, all involving frequent dislocation-twin interactions. Despite the high density of nanotwins that have been achieved through a variety of processing routes, the relative distribution of twins remain stochastic. For simple deformation modes, such a distribution of dislocation barriers can be accommodated by adapting traditional strengthening models. However, under cyclic loading conditions, the configuration and spacing between obstacles play a much more nuanced role. Modeling approaches have begun to tackle this problem, but without experimental validation in a controlled microstructure, the impact remains limited. We will emphasize the processing science necessary to develop well defined nanotwin microstructures, complemented by characterization of select twin-dislocation interactions enabled by these configurations. We will demonstrate the impact of deposition conditions and intrinsic properties on the nature and density of nanotwins using Ni-rich Ni-Ti alloys. Specifically, we have employed alloy chemistry, stacking fault energy and substrate constraint to engineer nanotwins that are inclined to the plane of the film. In such a configuration, simple tensile loading can activate complex dislocation-twin interactions, while still allowing for a systematic characterization of these interactions. When paired with computational tools and developing analytical model, these observations provide fundamental insight on the interfacial reactions relevant to fatigue damage accumulation.

10:30 AM *ST01.02.01
Local Phase Transformations—A New Creep Strengthening Mechanism in Ni-Base Superalloys A. Egan[1,1], S. Mukhopaday[1,1], T.M. Smith[2], Maryam Ghazisaeidi[1], S.R. Niezgoda[1], Y. Wang[1] and Michael J. Mills[1,1]; [1]The Ohio State University, United States; [2]NASA Glenn Research Center, United States

Polycrystalline Ni-based superalloys are vital materials for disks in the hot section of aerospace and land-based turbine engines due to their exceptional microstructural stability and strength at high temperatures. In the drive to increase operating temperatures and hold times in these engines, hence increasing engine efficiency and reduction of carbon emissions, creep properties of these alloys becomes increasingly important. At these higher temperatures, new deformation modes become active. Several alloy compositions and microstructure variants of commercial disk alloys are being explored, including g' strengthened alloys as well as compositions promoting g' and g'' co-precipitation. Microtwinning and stacking fault shearing are important operative mechanisms in the critical 600-800°C temperature range. Advanced characterization techniques using scanning transmission electron microscopy with diffraction contrast imaging, high resolution imaging, and energy dispersive spectroscopy have been used to gain new insights into these mechanisms and the rate-limiting processes during high temperature deformation. Atomic-scale chemical and structural changes associated with stacking fault and microtwin interfaces within g' precipitates have been identified and indicate that local phase transformations (LPT) occur commonly during creep of superalloys. Three distinct LPT scenarios have been identified. In the first, the stacking faults and twin interfaces adopt a composition similar to that of the solid solution g matrix and is associated with alloys having lower creep strength. In the second scenario, the superlattice extrinsic stacking fault structure transforms to the DO_{24} η phase and is associated with alloys having improved creep resistance. In the third scenario, superlattice intrinsic stacking faults transform to a local X (DO_{19}) phase, and also appears to provide creep strengthening. Thus, these important deformation modes can be modulated by LPT formation. For instance, for alloys in which η phase formation is favorable, microtwinning is inhibited as a deformation mechanism. The thermodynamic driving force for LPT formation is being explored using DFT modeling, and the predicted segregation profiles are compared with experiment. Phase field dislocation dynamics modeling is being used to explore the interaction of dislocations with g' microstructures under the cooperative shearing and local compositional changes associated with the LPT mechanism. Finally, these time-dependent processes are being incorporated into a microstructure-based crystal plasticity model for creep.

Experimental Evidence of Auxeticity in Ion Implanted Single Crystalline Calcite Substrates Michael E. Liao[1], Chao Li[2], Nachiket Shah[3], Gaurav Sant[1,1] and Mark S. Goorsky[1]; [1]University of California, Los Angeles, United States; [2]Applied Materials, Inc., United States; [3]University of Illinois at Urbana-Champaign, United States

Calcite, a polymorph of calcium carbonate with a trigonal crystal structure, has been predicted to exhibit auxetic behavior – materials with negative Poisson's ratios – but this has not been experimentally determined. Work by Aouni et al.,[1] for example, calculated the predicted crystallographic directions of maximum auxeticity in calcite. In this work, we report the first experimental evidence of auxeticity in calcite by ion implanting (10$\underline{1}$0) oriented single crystalline calcite substrates with Ar ions. Calcite substrates were implanted at room temperature using an ion energy of 400 keV and a dose of 1.0×10^{14} cm^{-2}, resulting in a projected range of ~400 nm. Lattice compression normal to the substrate surface was observed, which is an atypical result when ion implanting materials. Usually lattice expansion normal to the substrate surface is expected when implanting substrates.[2–4] This is due to the ions inducing lattice expansion during the implantation process. The bulk of the substrate beneath the ion projected range applies compressive biaxial stress to the expanding ion implanted region. Hence, materials with positive Poisson's ratios would expand normal to the surface, which can be measured as tensile strain with diffraction measurements. Triple-axis X-ray diffraction measurements were employed to

examine the strain state of the implanted calcite substrates. Reciprocal space maps for the symmetric 30$\underline{3}$0 and asymmetric 14$\underline{5}$0 reflections were measured and revealed that the implanted region was fully strained (pseudomorphic) to the bulk of the substrate beyond the projected range of the implant. A symmetric ω:2θ line scan of the (30$\underline{3}$0) reflection was also measured and X-ray dynamical diffraction simulations were used to model the strain profile to extract the variation of compressive strain as a function of depth normal to the substrate surface. SRIM calculations were also performed to obtain a displacement-per-atom profile. It was found that the strain profile generally follows the displacement-per-atom profile. This study demonstrated the use of ion implantation and X-ray diffraction methods to probe mechanical properties of materials and to test predictions such as the auxceticity on the scale of nanometers to microns depending on the ion energy used.

Mechanical Behavior of Bicrystalline Nickel Thin Films with High Strength and Ductility Rohit Berlia and Jagannathan Rajagopalan; Arizona State University, United States

Metallic thin films typically show high strength but low strain hardening capacity, which leads premature failure. For example, Ni films with a mean grain size less than 100 nm shows ultimate tensile strength of around 1.5 GPa but fail at strains below 3%. Here, we report the mechanical behavior of bicrystalline (111) textured Ni films with incoherent twin boundaries that exhibit high strength and significant ductility. Ni films of thickness varying from 200 nm to 2.5 μm were deposited on Si (111) substrates with a 25 nm Ag buffer layer at room temperature using magnetron sputtering. The microstructure of the films was characterized by TEM, EBSD and XRD, which revealed the presence of two grain variants with (111) out-of-plane texture with an incoherent twin boundary at their interface. Freestanding, dog-bone shaped samples of the films were co-fabricated with MEMS tensile testing stages using standard microfabrication techniques and their uniaxial tensile stress – strain response was measured at quasi – static strain rates. The experiments revealed flow stresses approaching 1 GPa as well as significant strain hardening capacity, which resulted in uniform elongation >10% in the thickest films. Possible mechanisms for this unusually high strength and ductility will be discussed.

Contact Quality of 2D Materials—How Interfacial Atomic Structure Controls Nanoscale Contact, Friction and Adhesion Robert W. Carpick; University of Pennsylvania, United States

2D and layered materials are generating excitement due to their multitude of novel properties. Exciting applications include as high-performance solid lubricants due to their ability to achieve “superlubricity” (nearly zero friction), and as functional materials for flexible electronics due to their exceptional bendability, strength, and electronic behavior. Yet the limits of their durability, friction, and adhesion behavior and not understood.

To explore these limits, we study nanocontacts with 2D and layered materials including graphene, MoS_2, and other transition metal dichalcogenides (TMDs) with atomic force microscopy (AFM). We previously found that

friction is intrinsically low for these materials, but depends strongly on the number of layers underneath the AFM tip. A model attributing this to adhesion-induced "puckering" of the ultrathin 2D layers around the tip [1] was then enhanced by molecular dynamics (MD) simulations showing a strong role of the "quality" of the contact. In particular, energy barriers to sliding are affected by interfacial pinning and commensurability due to subtle deformations of the 2D material [2].

We then discovered another contact quality effect when probing nanoscale sliding against graphite while varying the relative humidity. Water acts as a lubricant only above a threshold humidity; below that, adsorbed water increases friction six-fold relative to dry sliding. Such a non-monotonic dependence of friction has been previously attributed to a humidity-dependent water meniscus. We reveal a new possibility, where the number and location of water molecules at the interface controls friction [3].

Finally, we have discovered another factor that strongly affects static friction, namely, the lattice constant. We compared the friction behavior for a nanoscale single asperity sliding on MoS_2, $MoSe_2$, and $MoTe_2$ in both bulk and monolayer form through a combination of AFM experiments and molecular dynamics (MD) simulations [4]. Under otherwise identical conditions, MoS_2 has the highest friction and $MoTe_2$ the lowest. Simulations and further analysis revealed that the friction contrast is attributable to their lattice constants. While the energy barriers to sliding are similar for all three materials, the larger lattice constants associated with larger chalcogen atoms permit the tip to slide more easily across correspondingly wider saddle points in the potential energy landscape. This emphasizes the critical role of the lattice constant, which can be the determining factor for nanoscale friction behavior.

Late News: Mechanical Strains at Quasi van der Waals Interfaces Cyril Guedj[1], Stéphane Cadot[1], Rémy Gassilloud[1], Damien Caliste[2] and Pascal Pochet[2]; [1]Univ. Grenoble Alpes, CEA, LETI, France; [2]IriG, Univ. Grenoble Alpes & CEA, France

The nanomechanical properties of materials critically depend on the nature of atomic bonds. In the conventional epitaxy, large lattice mismatches inevitably result in the formation of defects which are usually detrimental for the device performances. The weak bonds obtained at quasi van der Waals interfaces on 2D layers can relax this constraint [1], but the detailed mechanical relaxation processes are not fully understood yet, since charge transfers and defect creation might occur, up to the buckling-driven delamination of the 2D films. The strain engineering is critical for devices applications because it can tune the optical and electronic properties [2],[3],[4] at the interface. Hence, a precise insight into the mechanical properties at the atomic scale is needed to probe the links between the grown structures and their physical properties.

In this work, we investigate the strain relaxation mechanisms at quasi van der Waals interfaces using aberration-corrected HRSTEM-HAADF imaging [5] with a spatial resolution of 50 pm. High resolution maps of mechanical strains and bond rotations are derived from cross-analysis of atomistic modeling and microscopy image simulations. In particular, the influence of the possible crystallographic phases on the simulated HRSTEM images is provided to guide our analysis. We report the case of AlN layers grown on multi-layered MoS_2. Our analysis shows that the lattice mismatch is mostly accommodated by interfacial shear strains and

heterogeneous localized distortions. Plastic deformations are prevalently located in MoS_2. These results are compared to recent theoretical predictions about the possible reordering phenomena in 2D layers due to in-plane uniaxial stress [6]. A global overview of the elastic strain fields around the quasi van der Waals interface will be presented. These results provide a basis for future strain and interface engineering of similar systems.

1:40 PM ST01.03.03
Late News: Anisotropic Properties and Electron Redistribution in 3C-SiC Hannah Wiswell and Zubaer M. Hossain; University of Delaware, United States

It is understood that anisotropy in material behavior plays a critical role in deformation, but it is important to also understand how anisotropy is related to the very cores of materials, atoms and their structures, and how a material's genome can be altered at the atomic level to increase strength and toughness. In this study, we apply some of the basic principles of quantum mechanics to explore how strength and toughness change in diamond cubic solids, by taking SiC as an example material. We attempt to understand how electron density changes due to stress and strain under different loading conditions. Two distinct conditions were investigated: the first condition involved hydrostatic deformation which preserves the lattice symmetry, and the second condition involved symmetry-breaking uniaxial deformation along the three principal high-symmetry directions, [100], [110], and [111]. Under hydrostatic deformation, it was found that the nearest-neighbor bonds in 3C-SiC deform equally, regardless of the deformation state of the lattice; thus, there is no relaxation within the lattice, and there is symmetric distortion in the electron density. In contrast, under uniaxial stress deformation, it was found that the elastic energy was highest for loading along the [100] direction, while it was the least for loading along the [111] direction. This is due to the nearest-neighbor bonds during [100] directional loading deforming uniformly, so all energy is equally distributed throughout the lattice, while for the [110] and [111] loading directions, bond lengths change non-uniformly, so parts of the lattice relax while the others do not, leading to quicker failure. After evaluation of the electronic structure basis of the maximum stress the lattice can sustain under uniaxial stress deformation, it was found that for the Carbon atoms, electron redistribution in the s and px orbitals was highest for loading along the [100] direction, with the [111] loading direction inciting the least change in electron occupation. For the Silicon atoms, the opposite results were observed, with the [111] loading direction experiencing the highest change in electron density for those orbitals. Further discussion of the methodology and conclusions from this study will occur during the presentation. In this presentation, it will be shown just how significant this study is; with the connection between solid mechanics and quantum mechanics understood, the future of tough, strong, and electrically conductive materials is brighter, and will allow applications of energy-efficient materials to grow in abundance.

1:55 PM ST01.03.04
Late News: Extreme Mechanical Resilience in Nanolabyrinthine Self-Assembled Metamaterials Carlos Portela[1], A Vidyasagar[2], Daryl Yee[1], Julia Greer[2], Dennis M. Kochmann[3], Sebatian Kroedel[3] and Tamara Weissenbach[3]; [1]Massachusetts Institute of Technology, United States; [2]California Institute of Technology, United States; [3]ETH Zürich, Switzerland

Lightweight materials with tailorable properties have attracted attention for decades, yet stiff materials that can

resiliently tolerate extreme forces and deformation, while being manufactured at large scales, have remained a rare find. Bio-inspired designs such as hierarchical foams and atomic-lattice-mimicking trusses have achieved optimal combinations of mechanical parameters but suffer from limited mechanical tunability, limited long-term stability, and low throughput volumes. Most mechanical metamaterials have relied on symmetry, periodicity, and lack of defects to achieve the desired mechanical response, resulting in sub-optimal mechanical response under the presence of inevitable defects. Shell-type designs, which can mitigate stress concentrations and flaws, have come with high densities and limited recoverability.

We exploit non-periodic nanoscale ceramic shell architectures of ultralow density (reaching 4 mg/cm^3) whose engineered curvature distribution achieves close-to-optimal stiffness scaling and, moreover, whose careful combination of topology, geometry and base material results in mechanical resilience superior to previous mechanical metamaterials. We present a method for scalable fabrication of these materials, guided by natural spinodal decomposition, which results in shell-based ceramic architectures with thicknesses down to ~10 nm and overall sample volumes of up to a few cubic centimeters. We show the capability of these architectures to maintain more than 50% of their original stiffness and strength after ten cycles of compression up to 30% while exhibiting no visible permanent deformation. Guided by simulations, we show how controlling the material morphology leads to the (an)isotropic material response whose directional stiffness distribution, impressively, remains constant over a wide range of shell thicknesses, as demonstrated experimentally. Our approach highlights pathways to harness self-assembly methods in the design and scalable fabrication of novel micro/nanoscale metamaterials with both tunable high stiffness and unsurpassed recoverability, simultaneously unachievable by previously reported mechanical metamaterials.

2:10 PM ST01.03.05
Late News: Effects of H2O Interaction with Graphene Grain-Boundary Under Strain Julia T. Hatoum, Claire Andreasen and Zubaer M. Hossain; University of Delaware, United States

In recent years, graphene has captured wide attention among engineers and researchers for its unique electronic, thermal, chemical, and mechanical properties, which could revolutionize a number of application areas including electronics, nanotechnology, drug delivery, sensors, and catalysis. Since discovery, extensive research has been conducted theoretically, experimentally, and computationally to investigate the behavior of pristine graphene under no strain conditions. With the goal of applications in mind, it is critical to develop a fundamental understanding of the properties of defective graphene under deformed or strained conditions. While line-defects (such as grain boundary) within the graphene lattice are known to degrade its mechanical properties, they can serve as an important source for making the graphene layer function as a chemically reactive 2D material which may be unattainable otherwise. Under defect-free conditions, an ideal and infinite graphene lattice can be deemed non-polar, due to its symmetry preservation across the sheet, which can prevent any measurable interaction with external molecules that may come in contact with. In this work, using density functional theory simulations, we investigate the energetics of an isolated H_2O molecule at a grain-boundary formed between armchair and zigzag graphene sheets. By placing the molecule at different heights from the graphene lattice, we calculate the total groundstate energy of the system. Our findings suggest that if the initial placement of the molecule is parallel to the lattice within the van der Waals interaction distance, the molecule undergoes a reorientation, and the O atom faces the graphene lattice. On the other hand, if the initial position of the molecule is parallel but closer to the graphene lattice, the H atoms become more reactive and they face toward the graphene lattice. We considered six different sites on the hexagon and found similar behavior. An electronic structure analysis suggests that the electron redistribution at the grain boundary affects the behavior of the molecule. Also, due to a separation-distance dependent distinct chemical affinities between the C-O atom vs. C-H atom pairs, the groundstate interaction is strongly affected by the initial position of the molecule. The results are expected to have important implications to our understanding of strain-chemistry of defective graphene. This talk will present the analysis of the results from an electronic structure perspective.

2:25 PM ST01.03.06
Late News: Electron Redistribution Surrounding a Deformed Graphene Mono Vacancy Claire Andreasen,

Julia Hatoum and Zubaer M. Hossain; University of Delaware, United States

Vacancy defects are unavoidable in 2D materials due to the challenges involved in fabricating defect-free lattice from experimental methods. While defects are known to degrade the mechanical properties of a lattice, they offer unique opportunities to tailor the electronic and thermal properties by controlling the mean free path of electrons and phonons. It is therefore important to develop a fundamental understanding of the role of defects in modulating the local electronic character of a lattice. Nevertheless, the understanding of defect-induced alteration of electronic properties (the electronic states for example) remains less understood, particularly under finite deformation. Although researchers have investigated the mechanical and electronic properties of pristine graphene under stress, there is little research on the chirality effects on electron distribution at defective sites in 2D materials under applied stress. In this work, we use the density functional theory simulations and the Mulliken charge population analysis to investigate the electronic behavior of an isolated defect in graphene under the uniaxial loading condition for five different chiralities of the lattice. We analyze how chirality and intensity of loading affect the mechanical properties, bond length and bond angle change, charge distributions, the density of states, and the partial density of states surrounding the vacancy. Our results show that there is a uniform pattern for bond length redistribution as well as electron redistribution at all orientation angles and that such bond and electron redistributions are directly correlated. During all simulations, we observe a bond reconstruction at the defective site at higher deformation. In terms of the orientation angle, we demonstrate that increased orientation angle yields changes in the strength, toughness, stiffness, bond distributions, and electronics surrounding a mono vacancy. We find that differing orientation angles result in different failure processes and speeds. Additionally, the redistribution at the defective site is chirality-dependent, and there is a significant localization of electronic states at the defective site. The pattern of density of states is deformation-dependent. This talk will present a comprehensive view on the specific effects of electron redistribution on mechanical and electronic characteristics of the defective lattice.

Fracture of Two-Dimensional Materials Jun Lou; Rice University, United States

Two-dimensional (2D) materials, such as Graphene, hBN and MoS_2, are promising candidates in a number of advanced functional and structural applications, owing to their exceptional electrical, thermal and mechanical properties. Understanding mechanical properties of 2D materials is critically important for their reliable integration into future electronic, composite and energy storage applications. However, it has been a significant challenge to quantitatively measure mechanical responses of 2D materials, due to technical difficulties in the nanomechanical testing of atomically thin membranes. In this talk, we will report our recent effort to determine the engineering relevant fracture toughness of graphene with pre-existing defects, rather than the intrinsic strength that governs the uniform breaking of atomic bonds in perfect graphene. Our combined experiment and modeling verify the applicability of the classic Griffith theory of brittle fracture to graphene. Strategies on how to improve the fracture resistance in graphene, and the implications of the effects of defects on mechanical properties of other 2D atomic layers will be discussed. More interestingly, stable crack propagation in monolayer 2D *h*-BN is observed and the corresponding crack resistance curve is obtained for the first time in 2D crystals. Inspired by the asymmetric lattice structure of *h*-BN, an intrinsic toughening mechanism without loss of high strength is validated based on theoretical efforts. The crack deflection and branching occur repeatedly due to asymmetric edge elastic properties at the crack tip and edge swapping during crack propagation, which toughens *h*-BN tremendously and enables stable crack propagation not seen in graphene.

4:25 PM ST01.04.02
Anharmonicity and Universal Response of Linear Carbon Chain Mechanical Properties Under Hydrostatic Pressure Keshav Sharma; The University of Alabama, United States

Isolated linear carbon chains (LCCs) encapsulated by multiwalled carbon nanotubes are studied under hydrostatic pressure (P) via resonance Raman scattering. The LCCs' spectroscopic signature C band around 1850 cm−1 softens linearly with increasing P. A simple anharmonic force-constant model not only describes such softening but also shows that the LCCs' Young's modulus (E), Grüneisen parameter (γ), and strain (ε) follow universal P−1 and P2 laws, respectively. In particular, γ also presents a unified behavior for all LCCs. To the best of our knowledge, these are the first results reported on such isolated systems and the first work to explore universal P-dependent responses for LCCs' E, ε, and γ.

4:40 PM ST01.04.04
Mechanical Properties of 3D Freestanding DNA-Inorganic Nanostructure Hybrid Haitao Liu[1] and Feng Zhou[2]; [1]University of Pittsburgh, United States; [2]New York University, United States

This talk will present our recent study on the mechanical properties of free-standing wire-frame 3D DNA tetrahedra in air. The structure was coated with a nanometer thick layer of uranyl acetate. The free-standinig DNA tetrahedron structure, 93 ± 2 nm high in air, withstands 42 ± 22 nN of loading force. The effective hardness (9.1 ± 5.1 MPa) and Young's modulus (77 ± 48 MPa) of this low-density (70.7 kg/m^3) DNA nanostructure are comparable to other reported low-density high-strength materials. Our result suggests a new approach to fabricate low density materials.

4:55 PM ST01.04.05
Strain-Resilient Electrical Functionality Enabled by Two-Dimensional Interlayer Chullhee Cho[1], Pilgyu Kang[2], Amir Taqieddin[1], Yuhang Jing[1], Keong H. Yong[1], Jin Myung Kim[1], Md Farhadul Haque[1], Narayana R. Aluru[1] and SungWoo Nam[1,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]George Mason University, United States

Flexible electrodes suffer unexpected, complete electrical disconnection after the onset of inevitable mechanical fracture across metal thin-films during their uses, severely reducing the functional lifespan of flexible/wearable electronics. Sudden, unperturbed straight in-plane mechanical fracture of metal thin-film was revealed to cause a catastrophic electrical failure of complete disconnection. Here, we report two-dimensional (2D)-interlayer approach that modulates in-plane fracture modes of metals and results in augmented strain-resilient electrical performance of metal thin-film electrodes under a high degree of multimodal deformation. Atomically thin 2D-interlayers, such as semi-metallic graphene, semiconducting MoS_2 and/or insulating hBN, induce continuous in-plane crack deflection (vs. straight) of metal thin-film electrodes and enable unique electrical characteristics which we term 'electrical ductility', where electrical resistance gradually (vs. abruptly) increases with strain allowing extended regions of stable resistance. 2D-interlayer electrodes maintain several orders-of-magnitude ($>10^4$~10^5) lower electrical resistance with resistance locking beyond a strain where conventional metal electrodes would be completely disconnected. Our 2D-interlayer approach is not limited to a certain combination of metals and 2D materials. The electrical ductility enabled by 2D-interlayer offers strategies for early damage diagnosis for the next-generation flexible/wearable electronics preventing abrupt, complete device functional failures.

5:10 PM ST01.02.05
Late News: Crystallographic Anisotropy Dependence of Interfacial Sliding Phenomenon in Nanoindentation of Cu/Nb ARB (Accumulated Rolling Bonding) Nanolayers as Revealed by 4-Axis X-Ray Diffractometer Arief S. Budiman[1,2], Rahul Sahay[2] and Nagarajan Raghavan[2]; [1]BINUS University, Indonesia; [2]Singapore University of Technology and Design, Singapore

Metallic FCC-BCC nanolayers, such as Cu/Nb, have received wide attention due to their extraordinary mechanical properties as well as the unique self-healing capacities due to the interface characteristics. Most recently, the materials have also been shown to exhibit significant and tunable interfacial sliding mechanisms (based on defect structures in the interface). The significant interfacial sliding is all along while maintaining full contact between the layers, and thus one could expect negligible resistance increase upon straining, which would be attractive for stretchable metallic conductor technology. The interfacial sliding has been modeled with some combination of diffusional and displacive mechanisms – the extreme extents of which are afforded by the nanoscale layering in the materials. The exact mechanisms continue to be fully investigated with some of the most cutting-edge materials experimental/characterization techniques as reported in the literature in the past 2-3 years. Nanoindentation has been used widely to investigate mechanical properties of small scale materials such as elastic modulus, hardness and work hardening. In this work, we report a study using nanoindentation with particular emphasis on depth profile (of the indented surface) and the pile-up height upon Berkovich nanoindentation of Cu/Nb nanolayers fabricated by Accumulated Rolling Bonding (ARB) method. The Cu/Nb ARB nanolayers have been reported to have strong anisotropy in mechanical properties in general, but specifically in this study, we show there is strong correlation between pile-up height and the extent of interfacial sliding. Cu/Nb ARB nanolayers (with 16nm individual layer thickness) has been used used as a test material due to its crystallographic anisotropy owing to the presence of contrasting interfaces along rolling (RD) and transverse direction (TD). The Cu/Nb ARB nanolayers were first characterized with X-ray Diffraction with 4-axis diffractometer, resulting in complete 3D crystal orientation/texture of the nanolayers. Nanoindentation was then performed along TD as well as RD of ARB Cu/Nb nanolaminate and subsequently Scanning Probe Microscopy (SPM) data was collected to measure the pile-up along RD and TD in the Cu/Nb nanolaminate. The 16 nm Cu/Nb ARB nanolaminate along RD was found to exhibit significantly higher surface pile-up than TD which is attributed to the variation in the Cu/Nb interface-mediated plasticity (sliding, rotation, etc.) along RD and TD, as well as the crystallography and texture of the nanolayers which determine the availability of slip systems in both Cu and Nb crystals. Further, 2D axisymmetric FEA analysis was performed to compare and validate experimental indentation data. The simulated data was found to compare well with the experimentally generated load-displacement curves whereas qualitative agreement was obtained with the experimentally obtained pileup data. The authors believe that the characterization of surface pile-up is of significant importance for enabling the Cu/Nb ARB nanolayers as the novel stretchable metallic conductor technology (for emerging applications such as electronic skins, soft robotics, etc.).

SESSION ST01.05: Nanocomposites
Session Chairs: Wendy Gu and Matt Pharr

6:30 PM ST01.05.01
Room-Temperature Shear-Banding in $CuAl_2$-CuAl Intermetallic Composite Yuki Ikeda[1,2], Jose Mancias[1] and Robert Maass[2,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Federal Institute for Materials Research and Testing (BAM), Germany

Intermetallics are generally brittle by nature and exhibit little or no plasticity at ambient conditions. However, lamellar eutectics containing an intermetallic phase, such as $CuAl_2$-Al, may exhibit room-temperature plasticity due to confinement effects. In this study, we apply the same idea of plasticity confinement to a CuAl system by designing a $CuAl_2$ matrix containing a nano-scale CuAl-phase via the diffusion-couple approach. This nano-composite is found to undergo room temperature shear deformation during nano-indentation. The indentation curves exhibit a continuously increasing pop-in size with increasing load, a feature typically not known for crystalline nano-indentation plasticity. High-Angle-Annular-Dark-Field Scanning Transmission Electron Microscopy (HAADF-STEM) observation of deformed regions underneath the indent locations provide

evidence for shear-banding in the otherwise brittle $CuAl_2$ phase. TEM observations of the microstructure underneath the indent revealed furthermore the existence of a phase with three-fold symmetry, of which we discuss the origin and structure.

6:45 PM ST01.05.02
Fracture Toughness and Nanowear Behavior of Alumina-Yttria Stabilized Zirconia Composites Yuchen Lin and Kaka Ma; Colorado State University, United States

Yttria stabilized zirconia (YSZ) has important applications in thermal barrier coatings, dental implants and ceramic blades. Fracture toughness and wear resistance are two critical mechanical properties that determine the performance of YSZ. Al_2O_3-YSZ composites have the potential to combine the high hardness of Al_2O_3 and the enhanced toughness of the tetragonal phase of zirconia. The present work aimed to investigate the effect of adding Al_2O_3, specifically, the particle size and distribution of Al_2O_3, on the mechanical behavior of YSZ at both micro- and nanoscale, via the combination of micro-indentation, nanoindentation and nanoscratch. Spark plasma sintering was utilized to fabricate the Al_2O_3-YSZ ceramic composites for its rapid densification rate to minimize grain growth. The results show that the as-sintered Al_2O_3-YSZ composites retain the tetragonal zirconia phase and the grain size of the YSZ matrix decreases with increasing amount of Al_2O_3 addition. Enhanced fracture toughness, as high as 11.32 $MPa \times m^{0.5}$, is achieved by tailoring the distribution of the Al_2O_3. Homogeneous distribution of Al_2O_3 with reduced particle size alters the nanoscratch-induced plastic deformation mechanism and increases the wear resistance of the Al_2O_3-YSZ composites.

Molecular Dynamics Simulations on the Mechanical Behavior of Multilayer Polymer/Metal Nanostructures Under Impact Loading Nuwan Dewapriya and Ronald Miller; Carleton University, Canada

Even though numerous engineering applications of ultrathin multilayers have already been demonstrated, their mechanical behavior under dynamic loading remains poorly understood. Recent advances in experimental techniques have enabled the dynamic testing of nanoscale films. For example, microprojectile impact tests have revealed that ultrathin polymer films absorb approximately ten times more energy per unit mass during the penetration process than that of traditional bulk armor materials. At the same time, it has been well established that metallic nanostructures possess extraordinary mechanical properties when their characteristic dimension is few nanometers. Therefore, multilayer arrangements of nanoscale polymer and metal films could possess superior ballistic performance, and more importantly, their ballistic performance could even be engineered by altering the relative domain size and the spatial arrangement. We tested this hypothesis by conducting a comprehensive molecular dynamics (MD) study on the ballistic impact response of multilayer aluminum-polyurea nanostructures.
Macroscopic experiments have shown that placing a polymer layer on the back face of a metallic target is more effective in terms of impact energy absorption. In contrast, our MD simulations revealed that placing a nanoscopic polymer layer on the strike face is more effective when the individual layer thickness is in the order of a few nanometers. Furthermore, our dislocation analysis revealed that the polymer layer has a remarkable influence on the dislocation processes in the metallic layer. Moreover, the MD simulations demonstrated that the ballistic limit velocity (V_{50}) and the specific penetration energy of the nanoscale multilayers are significantly higher than the experimentally measured values for any nanomaterial. In order to gain further insights into the nanoscale energy dissipation mechanisms, we computed the V_{50} of the multilayers using two existing membrane models. The results of this study demonstrate a potential bottom-up design pathway for developing new structural barrier materials with superior dynamic properties.

Effect of Co-Deformation of Ceramic Layer in Ag/Al-Doped ZnO Nanolayered Composites DongGyu

Kang, Hyeongyun Nam, Dae ho Kim and Seung Min Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Nanolayered composites composed of metal-ceramic layers have been studied to have high strength by effectively constraining the dislocation motion at the interfaces, but unfortunately, unstable deformation occurs due to the brittleness of the ceramic layer. In this study, In order to investigate the effects of the brittle-to ductile transition of the ceramic layer, we explore the deformation behavior of metal-ceramic nanolayered composites at varying ceramic layer thicknesses. Ag and Al-doped ZnO was chosen for metal-ceramic material system. The thickness of Al-doped ZnO was first fixed at 9 nm, which is theoretically expected to be ductile, and the metal thickness varies from 85 nm to 240 nm. For further comparison with thicker Al-doped ZnO that is expected to be brittle, 150 nm Ag/120 nm Al-doped ZnO was studied. In-situ SEM pillar compression showed stable deformation for 9 nm thick Al-doped ZnO samples, and TEM analysis of the deformed specimen was used to confirm the co-deformation of metal and ceramic. For the same 9 nm thick Al-doped ZnO samples, systematic increase in strength was observed with reduction in Ag thickness from 240 nm to 85 nm. For the 150 nm Ag/120 nm Al-doped ZnO, A brittle fracture of the Al-doped ZnO layer was observed to lead to a reduction in flow stress or strain softening after 30% deformation. Finite element analysis showed that the stress of the Ag and the Al-doped ZnO layer reached the stress required for the co-deformation of the two phases.

Effect of Cellulose Nanocrystal and lOw Molecular Weight Molecules on the Mechanical Properties of Polyacrylonitrile/Cellulose Nanocrystal Fibers from *In Situ* Polymerization to Carbonization Hyejin Ju, Jung-Eun Lee, Min Jeong Kim and Han Gi Chae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Cellulose Nanocrystal(CNC) is a naturally abundant environmentally benign material. The large aspect ratio and many hydroxyl groups attached on the surface of CNCs greatly contribute to the orientation of polymer chains when produced as a polymer nanocomposite. In addition, CNC causes a strong interaction with polyacrylonitrile (PAN), a semi-crystalline polymer having nitrile groups used as a carbon fiber precursor, leading to an increase in physical and mechanical properties of polymer nanocomposite.
In the current study, PAN/CNC polymer fibers were prepared through in-situ polymerization by combining CNC to the PAN synthesis. We have conducted the thorough characterizations of CNC dispersion and polymers (molecular weight, molecular weight distribution, rheological properties, and the structure-property of the resulting precursor fibers). The orientation factor of the post-drawn PAN/CNC fiber increased about 2 times compared to the as-spun PAN/CNC fiber, and PAN/CNC fibers by in-situ polymerization had the highest mechanical properties at total draw ratio 18 than mechanical stirred PAN/CNC and control PAN fibers. . In other words, it was confirmed that the fiber with CNC can have high mechanical properties because crystallinity is clearly improved even if it is slightly stretched.
Also, in heat treatment for manufacturing carbon fiber, it is observed that the crystallinity improvement effect by CNC and the influence of low molecular weight molecules with a wide polydispersity index (PDI). These low molecular weight molecules play a role in increasing the intensity ratio of the D and G band (IG/ID) in Raman spectroscopy analysis in the heat treatment. And it confirmed that after carbonization in-situ polymerized PAN/CNC fibers acted as an element capable of having a tensile property value of 1.6 times or more compared to the carbonized control PAN fiber.
This experiment could suggest that the PAN/CNC nanocomposite fiber may be used as a precursor for high-performance carbon fiber.

Manufacturing of Bulk Al/rGO Nanolayered Composite by Accumulative Roll Bonding Sieun Choi and Seung Min Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Metal/graphene nanolayered composites are known to have ultra high strength due to the effectiveness of graphene in constraining the dislocation propagation during plastic deformation. Earlier study on

metal/graphene nanolayered composites involved repeated physical vapor deposition of metal and wet-transfer of graphene and the fabrication method, therefore, has limitations in terms of scalability. Powder metallurgy techniques through mixing graphene flakes into metallic powders has also been reported, but the achieved strengthening effect is not as pronounced as in nanolayered composite produced by alternated thin film deposition and graphene transfer layer-by-layer. In this study, we report a scalable fabrication method for Al/ reduced graphene oxide (rGO) nanocomposite with interlayer spacing of ~200 nm in the bulk form using Accumulative Roll Bonding (ARB). rGO flakes are first sprayed on the surface of an aluminum sheet of thickness using air-spray gun, and the resulting rGO on Al sheet was used in ARB where the Al sheet was stacked, rolled, sectioned and stacked for subsequent rolling. A bulk Al/rGO nanolayered composite with ~200 nm interlayer spacing was successfully fabricated and the mechanical properties of the developed bulk nanocomposite was analyzed for mechanical properties using nanopillar compression testing to show the strengthening effect in comparison to the specimen prepared using layer-by-layer deposition. In order to study the effectiveness of the Al/rGO interfaces in hindering dislocation motion, deformed nanopillars were analyzed using TEM.

Experimental Study on Fracture Nanomechanics Takayuki Kitamura and Takashi Sumigawa; Kyoto University, Japan

The strength of nanoscale materials is one of key properties in development of advanced devises such as semiconductors, small sensors, and micro- and nano-electromechanical-systems (MEMS and NEMS). It is inevitable to understand their fracture behavior in terms of the mechanics for keeping high reliability in manufacturing as well as in service. Especially, focus must be put on the point that the mechanics and mechanism for materials in nanoscale might be significantly different from that in macroscale counterpart. The internal nanostructures including dislocations, grain boundaries, and various defects strongly affect the mechanical properties coupling with the external structures (geometric factor), shape and size of components. Although there are many excellent papers published on the deformation behavior on the bases of nanoscale experiments, few research works have been conducted on the fracture characteristics. It is mainly due to the difficulty of fracture experiments in nanoscale. For describing the fracture laws of materials in macroscale, it is essential to understand the fracture characteristics under diverse fracture mechanism including toughness, fatigue, creep and so on. We have conducted various fracture experiments with *in situ* SEM/TEM observation. In this lecture, we present two topics on the experimental study in terms of the fracture nanomechanics.
Smallest applicable limit of the conventional fracture mechanics [T.Sumigawa *et al*, ACS Nano, 11, p. 6271, 2017]
Fracture of bulk brittle materials such as silicon is characterized by cracking and the mechanics is well explained by the singular stress field formed near the crack tip according to the fracture mechanics (Griffith) theory. The applicability of these continuum-based theories is, however, uncertain and questionable in a nanoscale system due to its extremely small singular stress field of only a few nanometers. We directly conduct *in situ* fracture toughness testing for silicon specimens with a nanocrack using a transmission electron microscope and demonstrate that the Griffith theory can be applied to even 4 nm stress singularity despite their continuum-based concept. We show that the fracture toughness of clean silicon is independent of the dimension of materials and therefore inherent. Quantum mechanics/atomistic modeling explains and provides insight into these experimental results. It also shows that the limit is on around 2-3nm. This work therefore provides a fundamental understanding of fracture criterion and fracture properties in brittle nanomaterials.

Fatigue process of small metal [T.Sumigawa *et al*, Acta Materialia, 153, p.270, 2018]
We develop an *in situ* scanning electron microscope observation technique of micron-scale metal specimens under fully-reversed tension-compression cyclic loading and investigate the unique cracking process in low-cycle fatigue of single crystal copper in micron scale under a constant displacement amplitude. While crystallographic slips spread over the entire test section during the tensile first half-cycle, a locally concentrated slip band appears during the first reverse loading (compression). Crystallographic slip takes place only near the localized band in consecutive cycles, and strain localization due to slip bands leads to nanoscale extrusion/intrusion at the surface. This indicates that, unlike during the fatigue of a typical bulk pure metal, no characteristic dislocation substructure is formed during the extrusion/intrusion process. Moreover, the process required a much higher stress amplitude than in the case of bulk copper specimen. Thus, the fatigue cracking process for copper micro-scale specimen differs significantly from that for bulk copper specimen.

9:25 PM ST01.06.02
A Combined Atomistic-Continuum Model to Examine Interfacial Fracture in Multilayer Ceramics
Aniruddh Vashisth[1] and Mirmilad Mirsayar[2]; [1]University of Washington, United States; [2]Florida Institute of Technology, United States

Ceramic composites have various applications ranging from medical to high-temperature aerospace structures. These multi-material composites usually have two brittle materials sharing a bonded interface. For example, ceramic composites with SiC/SiO_2 interface find applications as microelectronics in semiconductors. However, like other bonded components, performance challenges are inevitable due to the high density of defects existing at SiC/SiO_2 composite interface. A crack or defect can be initiated at the interface during fabrication or as a result of residual mechanical/thermal stresses between the two components. We developed a multi-scale model that simulates the mechanics of interfacial fracture at a strong interface by combining reactive molecular dynamics (ReaxFF) and continuum fracture theory.
Cracks existing in strong interfaces tend to propagate out of interface under mixed-mode (i.e., combined opening/sliding) loading conditions. As temperature varies, the material properties change, thereby affecting the interfacial crack propagation behavior. The mechanical response of both the constitutive materials, namely silicon carbide and amorphous silica, was simulated within a temperature range of 300–1200 K. Amorphous silica (SiO_2) shows a continuous decrease in modulus and strength with increasing temperatures. The modulus of silicon carbide (SiC) plateau between 700 and 900 K while its strength drops continuously as temperature increases. Next, using a multi-scale modeling approach, these temperature-dependent properties are used as inputs to a continuum-based model to investigate fracture behavior as a function of temperature; by employing maximum tangential stress (MTS) criterion.
We found that altering the ambient temperature influences the interfacial fracture toughness in all crack tip deformation modes (pure mode I, mixed-mode I/II, and pure mode II). Depending on the imperfection level, the limits depicted in the mixed-mode fracture toughness curves should vary. It is worth mentioning that the current research was a preliminary analysis, and other significant parameters such as specimen geometry require additional investigations. Depending on the specimen geometry and applied loading configuration, the coefficients of the higher-order terms in the crack tip stress field may also be important in the fracture criteria as well as the singular terms. Future investigations will look into combined environmental and geometric effects for various materials, not only for ceramic composites but also for advanced composites.

9:40 PM ST01.06.03
Enhancing the Fracture Toughness of Polymer-Infiltrated Nanoparticle Films via Polymer Bridging and Entanglement Yiwei Qiang, Daeyeon Lee and Kevin Turner; University of Pennsylvania, United States

The mechanical properties of disordered nanoparticle (NP) packings can be significantly improved through the infiltration of polymers to enhance the interactions between the NPs. Previous work has shown that capillary rise infiltration (CaRI) is a simple and highly effective route to stiffen, harden, and toughen NP packings. While results from previous nanoindentation-based fracture measurements suggest that polymer infiltration can improve the toughness of NP films, it is challenging to fully understand how the relative size of polymer and

nanoparticles and the extent of confinement affect the toughness using nanoindentation-based measurements of fracture toughness. In the present work, a thin-film fracture testing method based on the double cantilever beam (DCB) specimen is developed and used to investigate the fracture properties of polymer-infiltrated nanoparticle films. In the DCB specimen, a crack is propagated in NP films over distances of tens of millimeters, allowing for highly accurate measurements of toughness in a mode I (tensile opening) configuration. The fracture toughness of the polymer-infiltrated NP films is found to be strongly dependent on polymer molecular weight (MW) and NP size. Low MW, unentangled polymers, effectively toughen small NP packings; whereas high MW, entangled polymers, show enhanced toughening in large NP packings. Possible toughening mechanisms, including confinement-induced polymer bridging and polymer entanglement, will be discussed.

Fracture and Plasticity of Nano-Sized Brittle Materials Dongchan Jang[1] and Dahye Shin[1,2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of)

Most of the brittle materials are usually very vulnerable to the existence of the crack because a lack of the intrinsic toughness mechanism, such as tip blunting by the plastic deformation, renders it to propagate unimpededly once a critical condition is reached. Therefore, most of the efforts to mitigate the sudden failure of brittle ceramics have been focused on developing the extrinsic toughening mechanisms that hinder crack propagation behind the tip, such as the fiber bridging. In this work, we experimentally demonstrate that the intrinsic toughening arises even in the brittle monolithic ceramic material like diamond-like carbon (DLC) when its external dimension reduces down to sub-micron scales. This unique phenomenon owes its origin to the decrease of the crack driving force in the small samples, which in turn enables them to bear high enough stresses to activate the local atomic plasticity. Through nanomechanical tensile and bending experiments, electron energy loss spectroscopy analysis and finite element method for stress distribution calculation, we confirmed that the local atomic plasticity associated with sp^3 to sp^2rehybridization is responsible for the intrinsic toughening.

SESSION ST01.07: Integration of Micro/Nano-Scale Materials into Applications and Devices I

Programmable Materials—A New Materials' Design Space? Franziska Wenz[1,2], Ingo Schmidt[1], Alexander Leichner[3], Tobias Lichti[3], Sascha Baumann[4], Heiko Andrä[3] and Christoph Eberl[1,2]; [1]Fraunhofer IWM, Germany; [2]Universität Freiburg, Germany; [3]Fraunhofer ITWM, Germany; [4]Fraunhofer ICT, Germany

Todays' materials design space reaches from electronic structure to microstructure and metamaterials structured on a mesoscopic scale. Nevertheless, the aim is typically to implement novel properties or tune them to a specific task. Instead, Programmable Materials aim to design materials' behavior and let them interact and adapt to the environment. In this talk, an outline will be given how this new design space could be approached and structured. The approach is based on translating physical and mechanical mechanisms into classes similar to modern programming languages. Materials’ specific molecular and mechanical mechanisms will be discussed which enable Programmable Materials to process information or specific user interactions. For a concerted behavior, the interaction between compartmentalized unit cells needs to be finely tuned. Based on simulations and optimization routines, local programming of mechanical metamaterials can be used to implement complex shape morphing into 3D-printed parts. Furthermore, possible routes for mass manufacturing Programmable Materials will be presented.

8:25 AM ST01.07.02
Vertical Graphene—*In Vivo* Biocompatible Strain Sensor Sunghun Lee[1], Seung-Hyun Chun[1], C-Yoon Kim[2] and Yong Ju Yun[3]; [1]Sejong University, Korea (the Republic of); [2]Konkuk University, Korea (the Republic of); [3]Korea University, Korea (the Republic of)

Resistive strain sensors (RSS) with ultrasensitivity has been investigated for widespread applications. However, due to physical/mechanical limits, the development of mechanosensors satisfying the prerequisite of stability, durability and controllability remains a challenge. Also, in-depth toxicology in *in vivo* system is imperative because of in direct contact with skin, even applied to organs, yet has not been reported for RSS. Here, we demonstrate that vertical graphene (VG) RSS can serve *in vivo* biocompatible sensors, and show remarkable sensitivity (gauge factor of 5,000) with revivable status even after broken current path. Three-dimensional tufted VG network structure allowed charge transport depending on crack geometry. We further showed that the signals from rat heartbeat depend on the direction of VG sensor directly attached to the heart, enabling to distinguish the cardiac contractility through its ventricle and atrium. Our finding provides new insight for controllable and permanent mechanosensing system, making VG promising option for *in vivo* biocompatible platform.

8:40 AM ST01.07.03
Measurement of Acoustic Emission Using Ti_3C_2-MXene Films Krzysztof Grabowski[1], Pavitra Belthangadi[2], Shreyas Srivatsa[1], Prosenjit Sen[2], Tadeusz Uhl[1], Saurabh Kumar[2] and Manjunath M. Nayak[2]; [1]AGH University of Science and Technology, Poland; [2]Indian Institute of Science, India

Structural Health Monitoring (SHM) of engineering structures involves damage detection and monitoring during its life-cycle. One of the phenomena used to detect changes within the structure is Acoustic Emission (AE). Structure undergoing the damage mechanism releases the energy in the form of elastic waves. These elastic waves propagating in a structure when captured could be used to characterize and localize the damage. In this work, we demonstrate the measurement of AE waves using the capabilities of two-dimensional nanomaterials - Titanium Carbide MXene (Ti_3C_2-MXene) films. Ti_3C_2-MXenes, discovered in 2011, have good electromechanical properties, film-forming ability, piezoresistivity, and relatively good dynamic response behavior to impact loads. Utilizing these properties of Ti_3C_2-MXene, we subject the films to the Hsu-Nielsen source. The test is performed with the pencil lead in contact with the Ti_3C_2-MXene film sample and the breakage of the pencil lead (which generates the acoustic wave) is detected by the Ti_3C_2-MXene film. Sensors based on Ti_3C_2-MXene can be deposited on the surface of the structure as a coating or potentially as a thin film layer. Ti_3C_2-MXene with its dynamic response properties provide a wide range of opportunities for SHM applications and these are discussed with the experimental results.

8:55 AM ST01.07.04
Printable Magnetoresistive Sensors for On-Skin Interactive Electronics Eduardo Sergio Oliveros Mata[1], Gilbert Santiago Canon Bermudez[1], Minjeong Ha[2], Yevhen Zabila[3], Jürgen Faßbender[1] and Denys Makarov[1]; [1]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [2]Electronics and Telecommunications Research Institute, Korea (the Republic of); [3]Polish Academy of Sciences, Poland

Ultra-portable, imperceptible[1], and shapeable[2] devices are expected to be widespread due to the emergence of flexible electronics as an industrial technology[3,4]. Printing is an affordable and high throughput method to process electronics in soft substrates that is still to be optimized to deliver electrically and mechanically reliable electronic devices[5].

In particular, printable magnetoresistive pastes have been developed as an alternative single-step fabrication method to obtain magnetic field sensors[6]. These pastes usually consist of composites of magnetic particles embedded in a non-magnetic matrix[7,8]. Particle-based pastes can achieve large magnetoresistance ratios at the expense of high resistivity and noise levels[7-9]. Previously, Karnaushenko et al. reported magnetoresistive

pastes based on giant magnetoresistive (GMR) microflakes as an alternative to overcome the problems presented in particle-based pastes[10,11]. Magnetoresistive flakes were produced after the delamination of thin-film stacks from a deposited sacrificial layer. With this technology, it was shown that flakes-based Co/Cu printed sensors exhibit low resistance and 37% GMR response at moderate magnetic fields (500 mT)[11].

Despite the advances in printable magnetic sensors, there are no reports of systems that show good sensitivity at low magnetic fields relevant for safe integration into wearable electronics. Electronics with magnetic components have to perform below the WHO limit of continuous exposure to magnetic fields (<40mT) to comply with this health standard[12]. Furthermore, for on-skin electronics that experience considerable strain, there are not examples of magnetic printed sensors that deliver steady sensing behaviour upon mechanical stretching.

Here, we will present low-noise printable magnetic field sensors sensitive down to sub-mT, which are mechanically stretchable after printing. We demonstrate the fabrication of printable sensors in ultrathin foils (3-µm-thick Mylar) based on magnetoresistive pastes that can undergo 100 % strain and 16 µm bending radius maintaining stable sensing and mechanical performance. The pastes are composites of poly(styrene-butadiene-styrene) copolymer (SBS) with embedded magnetoresistive microflakes. Using $[Py/Cu]_{30}$ and [Ta/Py] flakes, we obtained printed GMR and anisotropic magnetoresistive (AMR) sensors, respectively. We address the key role of SBS to enable an enhancement of two orders of magnitude improvement in bendability and sensitivity at low magnetic fields.

Due to the good performance at low fields, reduced noise levels and high compliance, we will show the direct lamination of the printed sensors as an on-skin interactive device for scrolling through documents or digital maps. We envision that the proposed magnetic sensors will enable printing on-demand utilities for physical activity tracking systems or human-machine interfaces that can improve and even expand our sensing capabilities.

ZnO Nanostructures in SAW Sensing Aurelian Marcu[1], Razvan Mihalcea[1], Cosmin Samoil[2], Emil Slushanschi[2], Viorel Chihaia[3], Ionut Nicolae[1] and Cristian Viespe[1]; [1]National Institute for Laser Plasma and Radiation Physics, Romania; [2]University Politehnica of Bucharest, Romania; [3]National Institute of Physical Chemistry "Ilie Murgulesscu", Romania

Sensors are a key issue in the present technological development and Surface Acoustic Wave (SAW) sensing is just one of the development directions in fluids detection with application from security to industry and medicine. Depending of the fluid composition there are various sensor types and used materials but all of them are basing their functionality on the mechanical and structural properties changes of an ‘active layer’ material in the presence of the detected fluid. Nanostructure or nanostructured materials present a series of enhanced properties compared with the bulk materials, due to the high surface-to-volume ration but their specific

parameters are sometimes rather challenging to control for optimizing sensor performances.
For SAW sensor fabrication we use ZnO material as a versatile bio-compatible wide bang-gap semiconductor, with a good absorption of various gases including hydrogen isotopes. Through the 'Bottom-UP' approach, we use Pulsed Laser Deposition (PLD) - Vapour-Liquid-Solid (VLS) techniques to grow ZnO single crystal [0001] nanowires on sensor patterned active surface area. By controlling several experimental parameters and respectively VLS grow elementary processes we control nanowires morpho-structural properties. Some correlations between these parameters and sensor experimental response are presented. Results interpretation is presented together with few wave propagation theoretical modeling through the sensor active area and respectively simulations on ZnO nanowire absorption. Presented results are aimed for SAW applications in gas detection and pressure measurement and are exemplified for hydrogen isotopes detection.

9:25 AM ST01.06.05
Compliance Grading Motif in Nacre for Enhanced Structural Performance S Kumar; University of Glasgow, United Kingdom

Natural materials exhibit high specific toughness, strength, stiffness and impact resistance[1]. The excellent properties of many such natural materials are attributed to hierarchical arrangement of their structure and spatial material gradients at different length scales[2]. Nacre- an iridescent material, exhibits enhanced strength and toughness though it majorly (>95vol.%) comprises an extremely brittle phase (aragonite)[3]. Nacreous structures show extraordinary toughness due to sliding of the bricks (macroscopic work hardening) over neighboring bricks together with other energy dissipation processes such as crack deflection, micro cracking and crack bridging[5]. Failure in such nacreous materials usually initiates in structurally weak mortar near the corners of the bricks where steep stress gradients exist. In this study, we introduce compliant grading motif (CGM) observed in many natural materials such as spider fang, byssal thread and squid beak, in the mortar of nacreous structure utilizing multimaterial additive manufacturing (AM). We postulate that the CGMs in mortar could play a role in toughening and strengthening the nacreous system by diffusing the peak stresses and moving the stress concentration away from the potential failure zones. Mechanical performance assessment of the AM realized nacreous structures with CGMs in mortar show ~60% improvement in strength, ~ 70% in toughness, and ~30% in strain-to-break, while retaining the macroscopic stiffness. The nature inspired CGMs introduced here is easily realizable in a wide range of 3D printing techniques for developing high performance architected materials with unprecedented properties.

Carbon Fiber-Aluminum Sandwich Plates with Microscale Thickness for Microflyers and Miniature Robots Wujoon Cha, Luke Kasper, Matthew F. Campbell, Thomas Celenza, George A. Popov, Jeremy Wang, Cynthia Sung, Mark Yim and Igor Bargatin; University of Pennsylvania, United States

We have developed hollow carbon fiber-aluminum sandwich plates with high strength-to-weight ratios and microscale thicknesses that can serve as structural components in microflyers and miniature robots. These panels consist of perforated aluminum sheet cores fixed between face plates of carbon fiber-reinforced polymer using epoxy. This combination of aluminum and carbon fiber exhibits both high impact resistance and high specific stiffness and strength[1,2] with areal densities of only 100-200 mg/cm^2 and normalized flexural rigidity values of up to ~7 N-m. Our work represents a simple and inexpensive platform for creating structural components of microflyers and small robots.

Emerging micro-aerial vehicles and small-scale robots require low-weight materials with sufficient structural rigidity to survive substantial collisions[3,4]. This is difficult to achieve because thin light-weight elements suffer from low bending stiffness, which scales cubically with plate thickness. Because of this, sandwich composite plates with lightweight cores and rigid face sheets are widely used to achieve enhanced resistance to bending while maintaining low weight. Although there have been many efforts in creating sandwich plates with microscale thickness[5,6], many require costly and complicated microfabrication. For quick prototyping of mesoscale devices, such as microflyers and small robots, more straightforward methods of producing sandwich plate materials are required.

To fill this gap, we have developed sandwich plates whose faces are carbon-fiber reinforced polymer veneers and cores are aluminum sheets. This combination results in high strength with resistance to the brittle fracture failures that characterize single carbon fiber veneers. We fabricate these plates by using time-curing two-part epoxy to bond 300-μm thick carbon fiber weaves to both sides of a 300-μm thick aluminum sheet. To reduce the weight of our plates, we use waterjet cutting to remove material from the aluminum sheet, yielding a low-density honeycomb-patterned core spacer.

To test our specimens, we subject them to three-point bending experiments in which we monitor their mechanical properties as a function of the plates' micro- and macro-scale geometry and composition, and subsequently we compare our results with finite element simulations. Our results reveal that the flexural rigidity values of our sandwich plates are enhanced by 1 to 2 orders of magnitude relative to those theoretically expected from carbon fiber veneers alone. We are currently exploring more aggressive mass-reducing methods, such as decreasing the fill factor of the aluminum honeycomb core and reducing the volume fraction of epoxy in the composite. Although we are currently investigating aluminum cores, our method can be easily adapted for other lightweight cores, such as a laser-micromachined polyurethane layers.

Mechanical Behavior of Kirigami-Inspired Three-Dimensional Polymer Structures Jungkyu Lee[1], Kian

Bashandeh[2] and Andreas Polycarpou[2]; [1]Bruker Nano Surfaces, United States; [2]Texas A&M University, United States

By using kirigami-inspired structures, highly deformable microscale shape memory polymer structures can be realized. These have a variety of applications in the wearable electronics, biomedical, and aerospace industries. Since many types of structures can be made, a complex assortment of mechanical responses can be observed. Since it's desirable to measure and verify performance, a sensitive mechanical testing instrument is needed. To that end, we fabricated various three-dimensional shape memory polymer (SMP) structures composed of epoxy monomers and studied their mechanical behavior using a nanoindentation instrument. Several important mechanical responses, such as load bearing capacity, hysteresis, and the effect of pre-existing cracks were investigated in detail. Full load-displacement curves were determined for the various structures, both at room temperature and an elevated temperature of 72 °C using a heating stage. The experimental results were coupling with modeling, which was performed to examine the internal stress distributions of the structure under compression conditions, both at room temperature and elevated temperature. This study demonstrates with detail how the mechanical performance of kirigami structures is significantly altered by its design.

Strain Sensing and Electrically-Conductive Kevlar-Reinforced Composites Enabled by Atomic Layer Deposition Robin E. Rodríguez[1], Tae H. Lee[1], Yuxin Chen[1], Tae H. Cho[1], Claire Huang[1], Eric Kazyak[1], Andrea Poli[1], William S. LePage[2], Mihaela Banu[1], M. D. Thouless[1,1] and Neil P. Dasgupta[1,1]; [1]University of Michigan–Ann Arbor, United States; [2]The University of Tulsa, United States

There is a growing motivation to impart electrical properties into polymer fibers and textile structures, in order to enable multi-functional composites[1]. A common approach to manufacturing electrically-conductive fiber-reinforced polymer-matrix composites (PMCs) is to modify the matrix polymer with conductive additives. However, these particle additives can affect the bulk mechanical properties of the final product, which may not be desired. An alternative method to impart electrical conductivity without significantly affecting the bulk mechanical properties is to modify the surface of the fibers by adding a thin, conductive coating. Among the coating techniques that can be utilized, atomic layer deposition (ALD) is an attractive technology that provides unparalleled conformality and sub-nanometer resolution in film thickness and composition.

In this work we demonstrate the fabrication of electrically-conductive Kevlar-reinforced PMCs without measurably affecting the bulk material properties, by pre-coating Kevlar 49 fabrics with aluminum-doped zinc oxide (AZO) via ALD. The core-shell fabric morphology and structure were characterized by SEM, XPS, and XRD. Four-point probe cyclic voltammetry measurements were performed to measure the electrical resistance of the AZO-coated Kevlar. Measurements were taken at both the single-fiber and fabric scales, after varying the thickness of AZO from 40-120 nm. At 40 nm the Kevlar fabric exhibits a low electrical conductivity, which is attributed to the film morphology. As the film thickness increases, the sheet resistance decreases, reaching a value 55.1 Ω/sq at 120 nm. The thickness-dependence of conductivity is well described by an analytical model, which allows for predictive design. This is sufficiently conductive to serves as an electrode material in textile-based devices ranging from thin-film electronics to energy storage devices.

Additionally, we studied the electrical conductivity and strain-sensing capabilities of AZO-coated Kevlar fabrics in PMCs. We demonstrate the potential for these conductive composites in strain-sensing and damage-monitoring applications. The electrical resistance of the sample was continually monitored *in-situ* while loading the sample to failure in a tensile load frame. The average ultimate tensile strength and Young's modulus of the Kevlar-reinforced PMC was not affected by AZO interface coatings, illustrating the advantage of this approach over bulk conductive additives. Furthermore, significant changes in the electrical resistance $(R-R_0)/R_0$ as a function of the strain were observed. These results demonstrate the potential of AZO-coated Kevlar to monitor the strain and provide electrical feedback during the linear elastic regime of the composite, which could be used for structural health monitoring prior to failure.

Late News: Soft Nanofiber Forests Embedded in Liquid Crystals—Sharing of Strain and Emergent Electrooptical Properties Sangchul Roh[1], John Kim[2], Divya Varadharajan[3], Joerg Lahann[2,3] and Nicholas L. Abbott[1]; [1]Cornell University, United States; [2]University of Michigan–Ann Arbor, United States; [3]Karlsruhe Institute of Technology (KIT), Germany

We report the synthesis of surface-attached nanofibers by chemical vapor polymerization of 4-hydroxymethyl-[2,2]paracyclophane into films of nematic liquid crystals (LC) (4-(trans-4-pentylcyclohexyl) benzonitrile and 4-(trans-4-propylcyclohexyl) benzonitrile) supported on indium tin oxide (ITO)-coated glass. Dense arrays of end-attached polymeric nanofibers are observed to form with shapes programmed by the strain engineered into the confined LC film. Upon application of an electric field across the LC-nanofiber film, we observe reorganization of the LC to be coupled to the deformation of the soft nanofibers, generating an electrooptical response that reflects coupling of elastic strain in both the LC and nanofiber. We construct a microscopic electromechanical model that captures the transmission of torques between the LC and nanofibers. We also observe patterned orientations of LCs to lead to patterned arrays of nanofibers (e.g., defining mesoscale vortices) during synthesis, which generate complex electro-optical responses that arise from elastic energy stored in both the LC and nanofiber arrays. Overall, these results reveal that LC-templated nanofiber arrays offer a promising route to optical metamaterials with emergent properties generated by the sharing of strain between soft nanofibers and LCs.

Linking Local and Global Strains—From Films to Lattices Mitra Taheri; Johns Hopkins University, United States

In the quest for improved materials, length scale effects are an option for tuning properties. Reduction in grain size can increase strength and manipulation of strut size and distribution in lattice structures can alter myriad properties. A key challenge in using length scale as a tuning parameter is understanding stresses and strains across scales to inform the design process. This talk reviews recent work that leverages a suite of spatially resolved, electron imaging, diffraction, and spectroscopy techniques to correlate global and local strains and stresses. Specifically, linking grain to subgrain scales is addressed. The work presented describes a platform for reliable, multiscale tuning in systems such as additively manufactured materials, high entropy alloys, and fine-grained metals.

Late News: Characterization of Wear Debris from Carbon-Carbon Composites in Braking Applications Matthew Noor[1,2], Peter Filip[2], Neil Murdie[3], Yanmei Piao[3], Angela Walker[1] and Jeffrey Fagan[1]; [1]National Institute of Standards and Technology, United States; [2]Southern Illinois University, United States; [3]Honeywell International, United States

Carbon-carbon (C-C) composites are often used as friction and brake materials due to their high strength, low density, excellent frictional properties, high thermal conductivity and high heat capacity. When worn, C-C composites produce particulate wear debris. The fine wear debris particles then form a layer on the wear surface, known as a friction film layer, which has the potential to change the overall frictional performance of the system. The size, shape and chemistry of these wear debris particles and friction layers can give information about the mechanisms of wear in the composite and the effects of temperature, humidity, oxidation and other chemical modifications that can occur depending on the wear environment. However, this analysis is rather

difficult to perform due to the wide range of particle size, from small nanoscale primary particles to large microscale aggregates. The chemical and material similarities of the carbon fiber and matrix further complicates decoupling the effects of the different components of wear debris on performance. This research explores particle separation and characterization techniques to obtain information about the C-C wear process. The principle technique for particle separation is density gradient ultra-centrifugation (DGU) in which fibrous and matrix-rich particles are separated based on their density. Orthogonal analysis with Raman and UV-vis spectroscopy, optical and electron microscopy, and X-ray Photoelectron spectroscopy can then be made on separated aliquots. Understanding the properties of the wear particles and friction film gives information about the wear process and can help inform future design and material considerations.

Late News: Studying the Surface and Residual Stress Effects in the Bending Response of Silicon Nanowires—Testing and Modeling Sina Zarepakzad[1], Mohammad Nasr Esfahani[2], Zuhal Tasdemir[3], Nicole Wollschläger[4], XueFei Li[5], Taotao Li[5], Mustafa Yilmaz[1], Yusuf Leblebici[6,7] and B. Erdem Alaca[1,1]; [1]Koc University, Turkey; [2]University of York, United Kingdom; [3]Paul Scherrer Institute, Switzerland; [4]Bundesanstalt für Materialforschung und -prüfung, Germany; [5]Nanjing University, China; [6]Swiss Federal Institute of Technology – Lausanne (EPFL), Switzerland; [7]Sabanci University, Turkey

Nanowires (NWs) are frequently employed as critical components in innovative devices including gate-all-around transistors and next-generation mass spectrometers. Despite all their promising aspects, the level of commercialization of such new technologies remains surprisingly low. There has been a vast effort towards the characterization of materials behavior at the nanoscale while a lot of improvement remains to be accomplished depending on the optimization or development of NW fabrication technologies, physical characterization tests, and integration techniques. Mechanical characterization of NWs considered as building blocks of nanoelectromechanical systems (NEMS) is mainly carried out through tensile or bending tests. The interpretation of test data obtained through such experimental measurements necessitates a comprehensive modeling effort to address the current challenge of understanding the size-dependent behavior of NWs. For instance, modeling of NW deformation at the atomistic level predicts size-dependent elastic properties for NWs only with cross-sectional dimensions less than ~10 nm. We undertake such a study by investigating the elastic modulus of Si NWs with a critical dimension of 28 nm via three-point bending test. Testing effort is accompanied by a comprehensive non-linear model of NW bending, including surface and intrinsic stress effects. The model considers all relevant effects including large deformations, intrinsic stresses, and surface effect with native oxide. The presence of intrinsic stresses is studied through micro-Raman spectroscopy with a precise evaluation of strain profile in the structure. Raman mapping was performed for analysis of the spectra as a line scan along the NW where residual stresses were quantified. In addition, we examine the surface effect by implementing the surface stress and surface elastic through atomistic simulations coupled with the continuum model by introducing the presence of native oxide layer covering the silicon NW. The native oxide structure is characterized through high-resolution transmission electron microscopy where inclusion of oxide layer effect into calculations verifies that the size effect is postulated to be primarily a result of differences in the NW surface and core elastic moduli. An in-depth understanding of the surface effect in NW mechanical properties is a critical step which requires an extensive mechanical analysis including all effective parameters in the deformation behavior of NWs. Overall, the study presents a comprehensive model for completely considering effects from axial extension, surface effect, and intrinsic stress to tackle the bending response of Si NWs.

1:15 PM ST01.09.02
Late News: Mechanical Behavior of ZrTa Metallic Glass Thin Films and Nanolayered Composites Ali Bagheri Behboud[1], Amir Motallebzadeh[2] and Sezer Ozerinc[1]; [1]Middle East Technical University, Turkey; [2]Koç University, Turkey

Metallic glasses are alloys that exhibit a disordered atomic structure. The lack of dislocations makes these materials stronger and harder than their crystalline counterparts. Furthermore, the lack of grain boundaries provides a desirable microstructure for corrosion resistance. Therefore, metallic glasses provide a promising design space for the development of wear-resistant and corrosion-resistant coatings.

Magnetron sputtering of thin films provides binary metallic glasses over wide compositional ranges due to the process's ultra-fast cooling rates. As a result, the sputtering approach enables systematic studies exploring the effect of composition on metallic glass thin films' mechanical behavior. Zr-Ta is one of the promising systems for coating applications, whose constituent elements possess desirable properties of high strength, biocompatibility, and corrosion resistance. However, there has been no study to date focusing on this binary system and its potential as a metallic glass coating. In this work, we explored the structure-property relationships of magnetron sputtered ZrTa metallic glasses.

A magnetron sputterer deposited 1 μm-thick films of ZrTa on oxidized silicon substrates. We employed combinatorial sputtering, which provided a wide range of compositions at a single deposition step. EDS measurements verified the composition, and X-ray diffraction characterized the microstructure. Transmission electron microscopy analyzed selected compositions in further detail. Nanoindentation with Berkovich and cube corner tips determined the elastic modulus, hardness, and fracture toughness of the specimens.

EDS measurements show that the Zr content varies between 21 and 70 at.%. For Zr contents below 30 at.%, the microstructure includes nanocrystalline and amorphous domains. For Zr in the range of 30 to 70 at.%, the microstructure becomes fully XRD-amorphous. Nanoindentation measurements exhibit a monotonic decrease of elastic modulus and hardness with increasing Zr content. For the amorphous films, hardness varies in the range of 5.5 – 9 GPa, and elastic modulus varies in the range of 105 – 130 GPa. Energy-based analysis of nanoindentation data provided the fracture toughness of the coatings. Fracture toughness decreases with increasing Zr content.

The second part of the study investigated nanolayered films composed of alternating layers of $Zr_{35}Ta_{65}$ and $Zr_{70}Ta_{30}$, for layer thicknesses in the range of 10 – 100 nm. The results show that the nanolayered films provide a desirable combination of high strength and fracture toughness. We attribute these results to the strong modulation of strength and elastic modulus at a length scale comparable to the size of the shear bands. The abrupt variations in the mechanical properties distort the stress state in the structure and hinder the rapid propagation of the shear bands.

In summary, we obtained ZrTa metallic glass thin films over a wide compositional range and determined the effect of composition on the mechanical behavior. The nanolayered form of the metallic glass thin film provided promising results that combine high hardness and fracture toughness. The findings can guide future studies towards the development of wear-resistant coatings that exhibit corrosion resistance and biocompatibility.

1:30 PM ST01.09.03
Understanding Hardness and Imprint Formation in Low-Load Nanoindentations of FCC, BCC and HCP Metals Jorge Alcala[1], Javier Varillas[2,3] and Jan Ocenasek[2]; [1]Universitat Politècnica de Catalunya, Spain; [2]University of West Bohemia in Pilsen, Czechia; [3]The Czech Academy of Sciences, Czechia

Nanocontact plasticity of metal surfaces involves sudden imprint formation processes along with the inception and evolution of entangled defect networks in the subsurface. Our investigation provides a fundamental

comprehension to nanoindentation experiments through massive molecular dynamics simulations of face-centered cubic Al, Cu and Ni; body-centered cubic Ta and Fe, and hexagonal closed-packed Mg performed across temperatures, tip penetration velocities, and nanoindenter tip sizes. We first investigate the critical contact resistance p_c rendering defect inception as a function of the incipient defect nucleation mechanisms and effective elastic modulus E of the crystal. Systematic analyses are performed on the subsequent pop-in events attained with increasing tip penetration, which lead to the onset of a steady-state nanoindentation regime characterized by constant hardness p_p. An insight is then gained into the specific nanoimprint formation mechanisms in cubic and hexagonal metals which comprise specific, collective dislocation emission and glide processes, individual nanotwin inception, and the development of unique nanostructured subgrain arrangements. A discussion is given on the role of these mechanisms upon the onset of higher values for the p_p/E ratio in BCC Ta and Fe and for the smaller p_p/E attained in FCC Cu, FCC Ni and HCP Mg. Finally, we investigate the correlation between the nanoimprint formation at the steady-state hardness p_p and the dislocation mobilization events triggered within the incepted defect networks at the uniaxial yield strength σ_{ys}. It is found that the p_p/σ_{ys} ratio approaches ≈7 and ≈10 in FCC and BCC metals, respectively.

1:45 PM ST01.09.04
Revealing the Lattice Scale in Microcompression of Nb Quentin Rizzardi[1], Cameron Elfresh[2], Douglas Stauffer[3], Jaime Marian[2] and Robert Maass[4,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of California, Los Angeles, United States; [3]Bruker Nano Surfaces, United States; [4]Federal Institute of Materials Research and Testing (BAM), Germany

Here we present temperature-dependent micro-compression data of Nb single crystals. We focus on the changes of the discrete plastic flow response between 370 and 170 K. Whilst the flow stress as a function of temperature is in excellent agreement with thermally-activated bulk plasticity models for bcc metals, a temperature insensitive component is revealed when tracing the change of displacement discontinuities with decreasing temperature. It I found that the scale of the displacement jumps changes from a scale-free like behavior at high temperatures to a scale-dependent behavior at the lowest temperature, where the length scale converges towards the scale of the lattice parameter. 3D discrete dislocation dynamics simulations are done to shed light onto the underlying dislocation behavior, revealing that the athermal plasticity component is governed by screw-dislocation activity. The temperature insensitivity of this screw-dominated plasticity can be shown to depend on high local stresses that significantly exceed the Peierls stress in the studied Nb microcrystals. This work is based on earlier efforts that aim at understanding stress-strain fluctuations in microcrystals (Phys. Rev. Mat. 2 (2018) 120601; Phys. Rev. Mat. 3 (2019) 080601).

2:00 PM *ST01.09.06
Fabrication and Mechanical Characterization of Ultra-Stiff and Ultra-Light Nano-Cardboard Structures Joost J. Vlassak and Jong-hyoung Kim; Harvard University, United States

Nano-cardboard structures are shell structures that consist of two face plates held together by hollow tubes that serve as ligaments [1]. These structures are fabricated entirely using thin films with thicknesses on the order of 100 nm or less. As a result of their geometry, nano-cardboard structures have a very low density and are ten times stiffer than aerogels or nanolattices of the same densities (5-20 kg/m^3). Additionally, they exhibit recoverable deformation similar to nanolattices and have a low thermal conductivity similar to aerogels [2, 3]. Nano-cardboard structures are light enough to be levitated by photophoretic forces[4, 5], they can serve as substrates for sensors, and may be of interest in geoengineering applications [5]. Here, we describe a low-cost and fast process for fabricating scalable nano-cardboard structures. The fabrication process relies on inexpensive silicon wafers that are patterned by means of deep reactive ion etching to form sacrificial scaffolds. The sacrificial scaffolds are then uniformly coated with a thin ceramic layer using atomic layer deposition. In a final step, the silicon is etched away through small openings in the top face using XeF_2 gas, leaving a ceramic nano-cardboard with dimensions comparable to those of the original silicon wafer. Using this approach, nano-cardboard can be fabricated from many different ceramics and metals, with no limitation on the size of the nano-cardboard other than the wafer dimensions. We have analyzed the mechanical behavior of nano-cardboard

with various periodic ligament patterns including a hexagonal and basket-weave patterns using finite elements. The nano-cardboard stiffness, buckling load, and post-buckling behavior depend sensitively on both the ligament pattern and dimensions, allowing optimization of the structure for maximum specific stiffness and strength. Because of their macroscopic dimensions, nano-cardboard structures can be tested relatively easily using a range of different mechanical techniques. Here, we present results of bending experiments on nano-cardboard structures with various patterns performed using nanoindentation.

High-Cycle Fatigue *In Situ* in the Transmission Electron Microscope Christopher M. Barr[1], Ta Duong[2], Daniel C. Bufford[1], Abhilash Molkeri[2], Nathan Heckman[1], David P. Adams[1], Ankit Srivastava[2], Michael Demkowicz[2], Brad L. Boyce[1] and Khalid Hattar[1]; [1]Sandia National Laboratories, United States; [2]Texas A&M University, United States

The exceptional properties that have been reported for nanostructured metals have made them appealing in both applications at decreasing dimensions and increasingly complex environments. The incorporation of nanoscale metals into thin-film solar cells, electrical sensors, and electronic textiles means that these materials will experience the day-to-day fatigue from thermal cycling through bodily motion. Fatigue is one of the most common causes of failure in metals, but to date is poorly explored in nanostructured metals. This presentation will highlight recent in-situ transmission electron microscope (TEM) investigations into the tension–tension fatigue behavior of nanocrystalline copper and platinum at frequencies from 1 Hz to 100s of Hz, enabling accumulations of up to 10^6 cycles within 1 h. Fatigue loading combined with the high spatial resolution of the TEM permits observations at crack growth rates of $\sim 10^{-12}$ m/cycle. As a result of this exceptional resolution, new insights into grain growth, twin elongation, and crack healing mechanisms that occur in the crack initiation regime of pure nanocrystalline metals can now be directly observed. When in-situ TEM fatigue experiments are coupled with automated crystal orientation mapping (ACOM), the interplay among grain orientation, grain boundary character, and fatigue crack propagation becomes apparent. This addition of ACOM also permits direct coupling to atomistic and mesoscale modeling, which can add or remove microstructural elements not possible experimentally to fully elucidate the active mechanisms. This new capability to directly observe with nanometer resolution grain growth, twin elongation, crack healing and potentially other active mechanisms has the potential to drastically change our understanding of the crack initiation portion of fatigue failure. Ongoing efforts to expand this in-situ TEM to approach and other materials systems and extreme environments will also be highlighted if time permits.

4:25 PM ST01.10.02

Full Characterization of an Individual 5nm Film Within a Bilayer—Stiffness Degradation Due to Surfaces and Dopants in Low-k Dielectrics Travis D. Frazer[1], Joshua Knobloch[1], Jorge Nicolas Hernandez Charpak[1], Kathleen Hoogeboom-Pot[1], Damiano Nardi[1], Sadegh Yazdi[1], Weilun Chao[2], Erik Anderson[2], Marie Tripp[3], Sean King[3], Henry Kapteyn[1], Margaret Murnane[1] and Begoña Abad Mayor[1]; [1]University of Colorado Boulder, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Intel Corporation, United States

Nanofabricated systems, from electronics, to spintronics, to quantum devices, rely on increasingly 3D stacks of ultrathin films. However, as feature sizes push below 10nm, there are both new and long-standing challenges to improving device performance. For example, an established problem in nanoelectronics is that doping interlayer dielectric films with hydrogen (hydrogenation) to improve electrical performance can degrade mechanical performance to the point of device failure [1]. However, a potential new challenge is the dominant influence of surfaces and interfaces for ultrathin nanoscale films, which can change the film's properties compared to bulk materials. Depending on the composition of the film, the influence of surfaces has been shown to either increase stiffness or increase compliance in ultrathin films [2,3]. Moreover, for sub-25 nm films at the leading edge of technology, traditional techniques struggle to measure the mechanical properties of films without overwhelming influence from the substrate. In this work, we use our ultrafast acoustic technique based on coherent extreme ultraviolet (EUV) light [4] to fully and nondestructively characterize the mechanical properties of films as thin as 5nm, even for an individual film in a bilayer. We study SiOC:H films and SiC:H bilayers to illuminate how surfaces affect the mechanical properties of these low-k ($k < 4.2$) dielectric materials being developed for next-generation nanoelectronics. Comparing the two materials, we distinguish between the stiffness degradation induced by dopants and that induced by the surface of the film. In particular, in very thin (5-nm) SiC:H films with low hydrogen doping, we find that surface effects induce a substantial reduction in stiffness—by almost an order of magnitude—compared with the same doping in thicker (46-nm) films [5]. However, for SiOC:H films with high hydrogenation, we observe no change in mechanical properties down to 11 nm. We attribute this difference in behaviors to the large loss of stiffness already induced by the hydrogen doping in SiOC:H, such that the surface has less of a relative effect. These findings have important implications for informed design of ultrathin films in a host of nano- and quantum technologies and most directly for improving the switching speed and efficiency of advanced nanoelectronics.

Late News: Exploring Three-Dimensional Architectures of Crystalline III-V Thin Films by Compressive Buckling Jihun Lim, Dejiu Fan, Byungjun Lee and Stephen Forrest; University of Michigan–Ann Arbor, United States

Three-dimensional (3D) microstructures of thin film materials are emerging technologies with a growing range of applications. The formation of residual compressive stresses is a common method to transform in-plane microstructures to 3D architectures. Here, we present a 3D strain scheme for compressive buckling in free-

standing semiconductor thin films spanning between thin gold gridlines. The residual stresses are determined while transferring and bonding the films with the gridlines on their surfaces onto a substrate by cold pressure welding. Computational models are implemented using finite element analysis to predict the residual stresses and post-buckling morphologies in the free-standing films. Experimental results demonstrate a variety of scalable 3D architectures from nanometers to tens of microns, depending on the gridline spacings and bonding conditions. Additionally, the buckling microstructures elastically respond to external forces. We show the thickness dependent buckling mode transitions in the free-standing films. The film buckling phenomena offer an opportunity for achieving a diversity of 3D shapes such as nearly flat surface, upward buckling, telephone-cord buckling, and geometrical circle segmentation. Indeed, strain engineering of 3D thin metamaterial microstructures on inelastic platforms can lead to unprecedented material functions useful for energy harvesting and deployable microstructures.

4:55 PM ST01.10.04
Late News: High-Strain-Rate Behavior of Polyurea Under Microparticle Impact David Veysset[1,2], Yuchen Sun[1], Steven E. Kooi[1] and Keith Nelson[1]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States

Hierarchical elastomers, such as polyureas or polyurethanes, have gained interest for their high energy absorption capabilities and impact protection performance, where deformation-induced glass transition has been suggested to play a determining role. Here, we investigate the dynamic response of polyurea under temperature-controlled micro-impact experiments. We impact micron-scale silica projectiles at subsonic velocities on a polyurea target using the laser-induced microparticle impact test platform. Using high-speed imaging, we measure impact and rebound velocities and determine the absorbed impact energy as a function of target temperature from 20°C to 160°C. We observe a local elevated energy absorption around 115°C, which we attribute to the dynamic glass-to-rubber transition. The soft-segmental α_2-relaxation is extracted and fit with a Havriliak–Negami function from dielectric spectroscopy measurements. We find that the α_2-relaxation at 115°C correlates well with the characteristic strain rate of the impact experiments. The results confirm that the deformation-induced glass transition leads to enhanced energy dissipation. This work further supports the importance of the dynamical T_g as an important factor in the design of impact-resistant materials.

5:10 PM ST01.10.05
Late News: Atomistic Processes of Surface-Diffusion-Induced Abnormal Softening in Nanoscale Metallic Crystals Sixue Zheng, Xiang Wang and Scott X. Mao; University of Pittsburgh, United States

Ultrahigh surface-to-volume ratio in nanoscale materials, could dramatically facilitate mass transport, leading to surface-mediated diffusion similar to Coble-type creep in polycrystalline materials. Unfortunately, the Coble creep is just a conceptual model, and the associated physical mechanisms of mass transport have never been revealed at atomic scale. Akin to the ambiguities in Coble creep, surface atomic diffusion in nanoscale crystals remains largely unclear, especially when mediating the process of yielding and plastic flow. Here, by using *in situ* nanomechanical testing under high-resolution transmission electron microscope, we found that the diffusion-assisted dislocation nucleation induced the transition from a normal to an inverse Hall-Petch relation of the strength-size dependence, and the surface diffusional creep led to an abnormal softening in flow stress with the reduction in the size of silver nanocrystals, contrary to the classical “alternating dislocation starvation” behavior in nanoscale platinum. This work provides novel insights into the atomic-scale mechanisms of diffusion-mediated deformation in nanoscale materials, and impact on the design for ultrasmall-sized nanomechanical devices.

5:25 PM *ST01.10.06
Nanomechanical Behavior of Hierarchical Metallic Microstructures Amit Misra; University of Michigan–Ann Arbor, United States

In metallic microstructures, hierarchical architectures of multiple phases with varying sizes and morphologies

shown to be effective in simultaneously enhancing yield strength, due to the strong glide dislocation interactions with their nanoscale features, and plastic deformability, due to increased strain hardening from microstructure hierarchy. In some hierarchical microstructures, impedance of crack growth via deflection along interfaces that have relatively low shear strength and bridging via relatively softer micro-scale composite domains can also lead to enhanced crack growth resistance. Examples will be presented from a variety of microstructures produced by magnetron co-sputtering (Cu-Mo, Cu-Ta), laser rapid solidification (Al-Si) and laser direct metal deposition (Cu-Fe). The challenges and opportunities in elucidating nanomechanical response of a microstructure comprised of multiple length scales, morphologies and chemical heterogeneities will be discussed.

Late News: Mechanical Behavior of Micro/Nanostructures Based on the Couple Stress Theory Jae-Hoon Choi, Hojang Kim, Byung-Chai Lee and Gi-Dong Sim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Classical continuum theory is widely used as a tool to predict structural behavior. However, the behavior of micro/nanostructures cannot be appropriately predicted based on classical continuum mechanics. The structural stiffness predicted by classical continuum theory is much more flexible than that of the real structure. In the past decades, various higher-order deformation theories have been developed to simulate size effect within a continuum scale. In higher-order deformation theories, additional material properties are introduced besides the Lamé constants. Since the additional material properties have a unit of length, they are called length scale parameters. In the couple stress theory, which has only one length scale parameter, couple stress is introduced as additional resistance to deformation.
In this study, structural behavior at micro/nano-scale is analyzed based on the couple stress theory by using the finite element method. It is observed that the bending rigidity increases as the thickness of microcantilever beams decreases. When a tensile load is applied to a flat plate with a hole, the stress concentration factor decreases as the size decreases. The buckling load of the thin structure increases as the thickness decreases.
In order to predict the structural behavior of micro/nanostructures based on the higher-order deformation theory, measurement of the length scale parameter must be preceded. We introduce two experiments to measure the length scale parameter. The first experiment is bending test. Microcantilevers can be fabricated via MEMS fabrication process and a line load is applied using a nanoindenter equipped with a wedge tip. The second experiment is buckling of membranes. After fabricating free-standing thin membranes, the temperature is gradually increased to measure the temperature at which buckling occurs. The material length scale parameter can be calculated inversely from the magnitude of the buckling loads. The experimental results are predicted from the finite element analysis based on the couple stress theory.

Thermo-Mechanical Characterization of Graphitized and Activated Carbon Structures Formed from Polyacrylonitrile/Carbon Nanotube Composites Exhibiting Interphase Structural Control Conor Doyle, Kenneth Benson and Marilyn L. Minus; Northeastern University, United States

This research focuses on observations of polyacrylonitrile (PAN)/singe wall carbon nanotube (SWNT)

composite films processed through pyrolization cycles for the production of ordered graphitic and activated carbon structures. The precursor composite films were processed using a solvent-based phase separation approach to promote the formation of extended-chain PAN interphase development at the SWNT surface as well as a hybrid through-thickness morphology. Previously reported work has outlined the advantages of this structural formation of crystalline PAN interphase regions within the precursor for the formation of ordered carbon at low temperatures between 900 °C to 1100 °C. In this work, PAN/SWNT precursor films underwent identical stabilization and carbonization cycles in air and argon gas, respectively. After low temperature turbostratic carbon formation, annealing cycles were then performed for various time and temperature combinations (up to 10 hours at 1700 °C) before activating the samples in carbon dioxide. These studies aim to correlate the stability of the low-temperature carbon forms to heal during annealing and subsequently survive activation toward forming graded porosity structures in these hybrid films. Dynamic mechanical analysis was used at each intermediary step of pyrolysis to evaluate the development of tensile strength (σ) and modulus (i.e., Storage (E') and Loss (E'') moduli). Overall material morphological composition was also evaluated using X-ray diffraction/scattering and electron microscopy both before and after activation. The results to be presented demonstrate the development and thermo-mechanical characterization of unique graded activated carbon architectures with potential applications such as filtration, electrochemical, and shielding.

8:40 PM ST01.11.06
Mechanical Behavior of Passivated Al Thin Films Hojang Kim, Sun Kun Choi and Gi-Dong Sim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Metal thin films are widely used in various small-scale devices such as integrated circuits, gas sensors, micro-actuators, and micro-heaters. In most of the devices, it is hard to find freestanding thin films; instead, a number of layers of different materials are stacked in a complex way. In other words, metal films are generally surrounded by other materials. Dielectric materials commonly cover metal thin films in order to insulate electricity and heat conducted through the metal layer, and to prevent oxidation of the metal surface.
In this presentation, we will introduce two *in-situ* experimental techniques utilizing Si-based micromachining process to characterize the mechanical behavior of passivated metal thin films. Experiments were carried out on submicron thick aluminum thin films passivated with a few tens of nm thick SiNx.
The first technique is performed through use of a custom-built in-situ scanning electron microscope (SEM) mechanical tester for measurement of the mechanical properties of Al thin films with and without a passivation layer. The apparatus has a stroke of 250μm with a displacement resolution of 10nm and a load resolution of 9.7μN. It utilizes pre-calibrated leaf spring, capacitive displacement gauge, and piezo actuator with a built-in displacement sensor. The second technique utilizes an in-situ SEM nanoindentation system equipped with a diamond wedge tip. Micro-scale bridge-shaped membranes and cantilever samples are fabricated via standard microfabrication process, and deflected by applying a line load. Stress–strain curves can be determined from load-displacement curves. Metallic thin films with a passivation layer exhibit enhanced strain hardening behavior because the passivation layer forms a strong interface, which acts as an obstacle to dislocation motion. Future plans for measurements at elevated temperatures will be introduced.

8:45 PM ST01.11.07
Mapping Elastic and Viscoelastic Contacts Across the Surfaces of High-Entropy Alloys Catherine B. Ott[1], Quentin Rizzardi[1] and Robert Maass[2,1]; [1]University of Illinois at Urbana-Champaign, United States; [2]BAM, Germany

Complex multi-principle element alloys, also referred to as high-entropy alloys (HEAs), have complex chemical and topological fluctuations at the atomic scale. This lead to a pronounced locality of the dislocation behavior and therefore the plastic response of such alloys. Here we focus on single-phase solid solution HEAs and trace the microplastic response of collective dislocation rearrangements (avalanches). A detailed analysis of the time-resolved response of crystallographic slip suggests that internal length scales much larger than the interatomic distance control the dislocation motion. To shed further light onto this observation, we use spatially resolved property mapping at the nano-scale with the aim of linking the length-scales derived from time-resolved slip

with correlation lengths determined from nano-mechanical fluctuations.

8:50 PM ST01.11.08
Structure Evolution and Corresponding Mechanical Behavior of Carbon Fibers Upon Post Heat-Treatment Jung-Eun Lee, Hyejin Ju and Han Gi Chae; UNIST, Korea (the Republic of)

Carbon fibers have been of great interest in many industrial applications due to their high specific mechanical properties as compared to steel or glass fibers. The polyacrylonitrile (PAN)-based commercial carbon fiber has as high as 7 GPa of tensile strength, and the highest tensile modulus is about 600 GPa although their theoretical properties are known to be 150 GPa and 1060 GPa, respectively. The property discrepancy, especially in tensile strength, is attributed to the defective structures such as bulk defects (voids, cracks, and cavities), surface defects (notches and punctures), and structural defects (disordered carbon and radial heterogeneity). Therefore, many researches regarding the correlation between microstructure and corresponding mechanical properties of carbon fibers upon carbonization have been conducted. Irrespective of carbon fiber's intrinsic properties, one has to keep in mind that it is mainly used in the form of carbon fiber-reinforced plastics (CFRP) or carbon-carbon composites rather than being used by itself. The carbon fibers are oftentimes subjected to very high temperature not only in the application but also during processing. In the due course, the structure and properties of carbon fibers are supposed to be varied. It would be beneficial that one has the information how their structure and the corresponding mechanical properties are changed upon application of such an extreme condition.
In the current study, the structure evolution and respective mechanical behavior of commercial PAN-based carbon fibers, H2550 and H3055 (Hyosung Co.), were analyzed upon post heat-treatment from 1600 to 2400 ºC. With increasing heat-treatment temperature, the tensile modulus continuously increased due to the improvement of crystal size and orientation factor. However, the tensile strength exhibited abnormal behavior, which decreased in the temperature range of 1600-1800 ºC, increased in the range of 2000-2200 ºC, and decreased again at higher temperature than 2200 ºC . This is correlated with the microstructure by considering above-mentioned various defects. The fibers heat-treated in the range of 2000-2200 ºC showed the highest tensile strength value among them because of a high fraction of amorphous and disordered carbon, leading to effective energy dissipation. On the other hand, at 2400 ºC, the strength was drastically diminished due to the graphitization and the generation of a rough surface. Radial heterogeneity and elongated void development were also observed at high temperatures, but it appeared that they don't have a significant effect on strength. It is noticeable that the Weibull modulus, which represented the fiber's uniformity and reliability in fracture, also showed unusual behavior depending on the temperature, and was highest at 2400 ºC for both fibers (8.8 of H2550 and 6.4 for H3055). This suggests that post heat-treatment can also tailor the structural uniformity of fibers. The current study will provide the fundamental information of carbon fibers' structure-property relationship and can be used to predict the property variations of fibers in composites when used in high-temperature applications.

8:55 PM ST01.11.09
Late News: Atomistic Basis of Anisotropic Poisson's Ratio in 3C-SiC Zubaer M. Hossain and Henry Fidlow; University of Delaware, United States

Poisson's ratio (PR) of a material plays an important role in governing the lateral response of a solid subjected to symmetry-breaking deformation. Traditionally, PR is represented as a single material constant which, by construction, refers to the linear part of the stress-strain curve. The understanding of a possible coupling between crystallographic direction and PR remains more elusive. Here, we report the observation of anisotropic PR in defect-free 3C-SiC lattice, using quantum simulations based on the Density Functional Theory. We analyze the lateral response of 3C-SiC to an applied strain along the three high-symmetry crystallographic directions, [100], [110], and [111]. From our ab initio calculations, we use the linear and nonlinear regimes of mechanical deformation to determine Poisson's ratio as a function of applied strain for a given axial and transverse direction. Asymmetric deformation in the lattice of the [110] direction results in two Poisson functions dependent on the lateral orientation. One of these indicates a positive value, while the other a negative

value (regardless of the strain state of the lattice). This suggests simultaneous existence of both positive and negative PRs in the material. Conversely, uniaxial loading along either of the other two high-symmetry directions, the [100] and [111] directions, yields identical lateral behavior, allowing for a single Poisson function. From the four Poisson's functions, the maximum and minimum Poisson's ratios are reached in the two different lateral directions of the [110] direction. The first function reaches a maximum Poisson's ratio of 0.5, indicating incompressibility and maximum contraction of the lateral direction for applied tensile loads. The second function is auxetic, exhibiting purely negative Poisson's ratios throughout the true strain range. This translates to lateral expansion in tension and lateral contraction in compression. In both the [100] and [111] directions, all values of the Poisson's functions exist within the range of 0 to 0.3. Anisotropic behavior is similarly witnessed in the strength and toughness of 3C-SiC for the three high-symmetry directions. Here it can be noted that loading along the [100] direction exhibits optimal strength and toughness while loading in the [111] direction displays maximum stiffness. Analysis at the atomic scale reveals relationships between crystallographic structure and anisotropy of Poisson's ratio. Linear and angular bond deformation influences the lateral strain behavior based on lattice symmetry with respect to the axial direction. Additionally, further investigation of the electron redistribution properties of both silicon and carbon atoms was investigated to determine relationships between Poisson's ratio and electron density in the various orbitals. Coupled with improvements in grain manufacturing technologies, these observations can be utilized toward the optimization of mechanical properties of 3C-SiC and other diamond cubic structures in practical applications.

9:00 PM ST01.11.10
Mechanical Behavior of Micro-Scale NiTi Shape Memory Alloys Ji-Young Kim, Abdul Rehman and Gi-Dong Sim; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

Shape memory alloys (SMA) are a class of alloys which show unusual deformation depending on temperature or loading condition. Nickel-Titanium (NiTi) alloys is one of the most attractive SMAs due to its remarkable work output per unit volume, significantly higher strain recovery, and superior thermo-mechanical stability. However, majority of research on NiTi alloys have focused on the bulk-scale mechanical properties, and it is still challenging to apply NiTi SMAs in micron-scale applications such as electric and/or biomedical sensor. Few studies have reported that small-scale NiTi shows different shape memory behavior compared to its bulk counterpart, but our understanding on size effect is yet premature and a comprehensive study is required.
In this study, we conducted in-situ tensile test of NiTi alloys, utilizing two experimental techniques for investigation of the small-scale mechanical behavior. In the first technique, tensile specimens are prepared by sputter deposition and Micro-electro-mechanical-system (MEMS) fabrication process. Tensile tests are conducted by using a customized in-situ scanning electron microscope (SEM) tensile tester. In the second experimental technique, micro-scale tensile bars are fabricated within a bulk-scale NiTi sheet by utilizing femtosecond laser and focused ion beam (FIB) milling. Femtosecond laser machining is used for fast, but rough, specimen mass production, and FIB milling is performed for fine cleaning. Micro-scale mechanical testing is conducted utilizing a nanoindenter equipped with a diamond gripper. By comparing the mechanical response between sputter deposited NiTi thin films and micro-scale tensile bars carved out from a bulk crystal, we aim to gain better understanding of microstructural effect on the superelastic behavior of micro-scale NiTi SMA alloys.

Late News: Investigating Grain Size, Grain Arrangement and Dislocation's Structure on Mechanical Behavior of Heterogeneous Materials Khaled Adam[1,2]; [1]Kennesaw State University, United States; [2]University of Benghazi, Libya

It is well known that the mechanical behavior of polycrystalline material changes largely with their mean grain diameter. In this work, we explore the grain size-dependent phenomenon in heterogeneous structure material using a continuum dislocation theory coupled with ViscoPlastic Fast Fourier Transform (VP-FFT) method. A dislocation-based strain gradient plasticity model was developed to predict the grain size effect over a wide range of length scales. The effect of the GNDs density was incorporated into the model for the mean free path

of dislocations.

9:10 PM ST01.11.12
Late News: Combinatorial and High-Throughput Experiments on Co-Based Alloy Thin Films Taeyeop Kim[1], Daegun You[1], Kooknoh Yoon[2], Eun Soo Park[2] and Dongwoo Lee[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Superalloys are structural materials for high-temperature applications such as gas turbines and space vehicles. Co-based superalloys have been spotlighted as they can be utilized at a higher temperature than traditional Ni-based alloys. Investigations of composition-microstructure-property relationships are required to develop next generation superalloys. However, due to the enormous number of the possible combinations, it is challenging to acquire the property data that can illustrate the relationships. In this study, we carried out the combinatorial synthesis and high-throughput experiments to investigate the composition and microstructure dependent properties of Co-Cr-Ti alloy thin films library, which are known to produce the γ/γ' microstructures in bulk scale. Combination synthesis and high throughput experiments provide an effective pathway for obtaining large amounts of experimental property data. We used magnetron co-sputtering to produce hundreds of different Co-Cr-Ti thin-film alloys on a single wafer. We then characterized composition-dependent phase formation as well as electrical and mechanical properties by performing X-ray diffraction, 4-probe resistance mapping, and nanoindentation experiments. The correlation among the measured properties and their implication on bulk properties will be discussed.

9:15 PM ST01.11.13
Late News: Tribological Properties of Magnetic Nanoparticles Reinforced Polymer Nanocomposites Salman Ahmed Syed and Zainuddin Shaik; Tuskegee University, United States

In this study, Fe_3O_4 and Fe_2O_3 nanoparticles were used to improve the tribological performance of the Epoxy resins. The composites were prepared by adding the nanoparticles to the epoxy resin and techniques like sonfication and thinky mixing were used to get good dispersion of the nanoparticles. The effects of Fe_3O_4 and Fe_2O_3 nanoparticles on the wear rate, friction coefficient and hardness of the composites were investigated using Bruker's UMT Tribolab. The results showed that the composite exhibited improved wear resistance, lower friction coefficient and better hardness values compared to neat epoxy resin. With the incorporation of 3% Fe_2O_3, the hardness values of the composites enhanced to 9.3 HV (increased by 165%), 16.9 HV (increased by 160%) and 26.2 HV (increased by 159%) for 20 N, 40 N and 60 N, respectively. Similar increasing trend can be seen with incorporation of 3% Fe_3O_4, with hardness values increased to 9.1 HV (increased by 160%), 17.1 HV (increased by 163%) and 27 HV (increased by 167%) for 20 N, 40 N and 60 N, respectively. From the scratch test results, we can see a decreasing trend in the COF values for the samples, with 5% samples showing the lowest COF values. The improved tribological performance of the composites can be ascribed to the improved mechanical and lubricating properties of the nanoparticles.

9:20 PM ST01.11.14
Late News: Property Degradation of Helium Ion Irradiated Tungsten Based Alloy Thin Films Haechan Jo, Sanghun Park, Daegun You and Dongwoo Lee; Sungkyunkwan University, Korea (the Republic of)

Tungsten (W) is one of the promising candidate materials for plasma-facing materials (PFMs) in fusion reactors due to its high melting point, high thermal conductivity, and low sputtering rate. PFMs are known to be irradiated by the by-products of fusion reaction, such as helium ions & neutron, which can lead to structural and mechanical degradation. It has been reported that the addition of rhenium (Re) and tantalum (Ta) can mitigate irradiated damages and hiders helium bubble formation. In this work, we performed helium irradiation experiments on combinatorially sputter deposited W-based alloy thin films to investigate the microstructure- and composition-dependent irradiation damages. XRD was used to analyze the structural damages, and nanoindentation and 4-point measurement were used to measure the mechanical and electrical property changes, respectively. The correlation between the microstructural changes and the materials' properties are discussed.

9:25 PM ST01.11.15
Late News: Mechanical and Thermal Properties of Multi-Walled Carbon Nanotube w/ PHBV Azizi Turner; Tuskegee University, United States

Biocomposites can be specifically tailored to improve their multifunctional properties for a wide variety of applications by the addition of carbon nanoparticles. In this study, thin films of Poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) nanocomposites were prepared by adding 0.1- 0.5 % Multi-Walled Carbon Nanotubes (MWCNTs). In the construction of the films, chloroform was used as the solvent for the PHBV nanocomposites and the MWCNTs. Sonication was used to enhance the dispersion of the MWCNT throughout the solvent, and a magnetic stirrer was used to help in mixing the solution with the polymer. When adding MWCNT into PHBV, there was an improvement during the following tests: tensile test, thermogravimetric analyses, and differential scanning calorimetry. In addition, the tested samples were analyzed using scanning electron microscopy and transmission electron microscopy to see how the effect of MWCNT's addition on the surface of PHBV.

9:30 PM ST01.11.16
Multiscale Mechanical Characterization of Additively Manufactured Inconel 718 Kwanghyeok Lim[1], Ken-Hee Ryou[1], Jeong-Hwan Lee[2], Gwang-Hyo Choi[1], Won-Seok Choi[1], Pyuck-Pa Choi[1] and Gi-Dong Sim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of)

Additive manufacturing is an emerging technology due to its superiority in complex and customized design. These advantages lead to applications such as turbofan engines, power plant turbines, and spacecraft engine parts. Inconel 718, which is widely applied to the above applications, has now become one of the main additive manufacturing research targets. However, it has the possibility of containing inclusions such as titanium nitride (TiN) due to being exposed to air during deposition despite the injection of shielding gas. The effect of such inclusions on the high-temperature mechanical properties of additively manufactured Inconel 718 is not yet well understood.
In this study, multi-scale (bulk-scale and meso-scale) uniaxial tensile tests are performed to investigate the effect of TiN inclusions on the mechanical properties of additively manufactured Inconel 718 at elevated temperatures. Inconel 718 is deposited on the substrate using the direct laser deposition (DLD) method. Wire electrical discharge machining (EDM) is applied to fabricate dog-bone shaped bulk-scale specimens with gauge lengths of 10mm, gauge widths of 2mm, and thickness of 0.3mm. Tensile tests are carried out at room temperature, 400°C, 600°C, 650°C, 700°C, 750°C, and 800°C at the strain rate of 10^{-4} /s. According to the experimental results, additively manufactured Inconel 718 maintains a yield strength of 550MPa while increasing the temperature up to 650°C, and exhibits the highest value of 670MPa at 700°C. In addition, as temperature increases, uniform elongation decreases from 16.5% at room temperature to 1% at 700°C. Scanning electron microscope (SEM), energy-dispersive spectroscopy (EDS), and X-ray diffraction (XRD) analysis are conducted to examine the presence of TiN inclusions and the failure mechanisms of additively manufactured Inconel 718. EDS and XRD results show that TiN inclusions are contained numerously, and SEM images indicate that TiN inclusions show a trace of brittle fracture, while the matrix of the material is ductile.
We will also introduce ongoing efforts trying to understand the effects of a single TiN inclusion on the high-temperature tensile properties via small scale experiments. Femtosecond laser machining is utilized to fabricate dog-bone shaped meso-scale specimens with gauge lengths of 2mm, gauge widths of 0.5mm, and thickness of 30. A meso-scale tensile tester, capable of testing at temperatures up to 1000°C has been custom-built. Future plans of meso-scale experiments at elevated temperatures will be discussed.

9:35 PM ST01.11.17
Late News: The Measurement of Modulus and Hardness of Different Cross-Linked SU-8 via Nanoindentation Prakash Sarkar, Prita Pant and Hemant Nanavati; Indian Institute of Technology Bombay, India

The effect of cross-linking on the modulus (E) and hardness (H) of an epoxy polymer was studied using nanoindentation. Experiments were carried out on SU-8, which is an epoxy-based thermoset polymer extensively used for fabricating micro-electrical mechanical system (MEMS) components. The extent of cross-linking was varied by modifying the curing steps (post-exposure baking, hard baking) of standard photolithography process. The amount of cross-linked segments was measured via in-situ Fourier-transform infrared spectroscopy. Nanoindentation experiments were carried out under constant strain rate conditions. Using the conventional Oliver-Pharr method yielded high E and H values for less cross-linked sample and less values for high cross-linked samples. A careful analysis showed that the main reasons for these inverse values are adhesion between the tip surface and sample surface, viscoelastic effect on unloading and errors in calculation of contact area. We propose a new methodology to correct for these potential sources of error. Thereafter, E values of 4.61 ± 0.13 GPa and 5.02 ± 0.18 GPa, and H values of 256.97 ± 1.42 MPa and 285.48 ± 1.17 MPa were obtained for less (~ 82 %) and high (~ 95 %) cross-linked samples, respectively.
Keywords: SU-8; Photolithography process; FTIR; Nanoindentation; SPM

9:40 PM ST01.11.18
Late News: Mechanical Properties of Sputter Deposited Aluminum-Carbon Alloy Thin Films Injong Oh[1], Hojang Kim[1], Hyunjoo Choi[2] and Gi-Dong Sim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Kookmin University, Korea (the Republic of)

Aluminum is a widely used metal in transportation, aviation, and energy due to its advantages of low density. Aluminum and its alloys are also being used in MEMS (Micro-electromechanical system) devices due to properties such as low resistivity, high conductance, high reflectance, and low residual stress. However, as aluminum possesses low strength, it is crucial to increase strength by tailoring the microstructure via altering deposition conditions, heat treatment, and/or alloying. In previous works, nickel, molybdenum, and copper were alloyed with Al to increase the strength. One possible way to enhance the mechanical properties of aluminum is to reinforce it with strong materials (e.g., carbon nanotubes, graphene, etc.), producing aluminum-based composite. However, it is still challenging to uniformly disperse nano-carbon material in the aluminum matrix without forming carbides. Recently, a new way to increase strength of aluminum using super-saturated Al-C phases has been proposed. Carbon atoms from individually dispersed C60-fullerenes, are intercalated into the interstitials of aluminum matrix, producing supersaturated Al-C phases with artificially moderated lattice structures. However, the underlying strengthening mechanism of atomically adding carbon atoms to aluminum matrix has not been deeply understood.
In this presentation, we discuss the mechanical properties and microstructure of sputter deposited aluminum (Al)-carbon (C) alloy thin films. Aluminum-carbon alloy thin films with various compositions were produced by co-sputtering aluminum and carbon without substrate rotation. Through this method, Al-C coatings with compositional spread can be fabricated, and the effect of carbon on the deformation mechanism can be analyzed. Thin film specimens having micro-scale dimensions were fabricated utilizing MEMS processing techniques. The tensile characteristics of thin film specimens were evaluated utilizing a custom-built micro tensile tester. The sputter deposited Al-C alloy thin films exhibit higher yield stress (~ 420 MPa) compared to that of pure aluminum thin films without loss of ductility (~ 10%). The deformation mechanism of the aluminum-carbon alloy thin films was analyzed based on mechanical and microstructural analysis.

9:45 PM ST01.11.19
Late News: Misorientation Development Near Grain Boundaries and Twin Boundaries in Pure Copper and Copper-Aluminium Alloy Sandhya Verma, Prita Pant and M. P. Gururajan; Indian Institute of Technology Bombay, India

During deformation of bulk polycrystalline materials, boundaries impose constraints due to requirements of compatibility across boundaries. Pure bulk Copper and Copper-aluminium samples were subjected to interrupted tensile tests coupled with electron backscatter diffraction (EBSD) analysis, to study the evolution of misorientation at specific boundaries. Our results show that misorientation development (in terms of Kernel

Average Misorientation, KAM) near boundaries is a function of orientation of grains on each side, but it is also influenced by the presence of other boundaries nearby, and constraints such as triple points. We have noticed that KAM values near boundaries does not behave monotonically for both Cu and Cu8Al. For Cu, in one case it increases as well as decreases in values, while in other case it remains constant. Similarly, for Cu8Al it reduces in values for most of the cases and increases or remains constant with strain in few cases. So while developing models for deformation of polycrystals, detailed information regarding grain orientation and neighbouring grains should also be incorporated. We have analysed our results in terms of Schmidt factors of the grains on either side of the boundaries. Results for copper are compared with Cu-Al alloy, which has significantly finer twins in the microstructure. Hence there are greater constraints.

Keywords: EBSD; Misorientation; Orientation gradient; Grain boundary; Schmid factor; KAM

9:50 PM ST01.07.06
Optimization of Micro/Nano-Scale Mechanical and Surface Properties of PMMA Thin Layer for Simple and Low Cost-Nanoimprinting Process Silambarasan Anbumani, Mariana Zavarize, Helio T. Obata, A.A.G. von Zuben and Monica A. Cotta; University of Campinas, Brazil

Surface micro/nano patterning is essential for diverse applications including next generation-solar cells, photonics and bio-interface devices. Nanoimprint lithography offers such patterning with high resolution and high throughput. However, since such technology usually requires sophisticated instruments and clean room facilities, it is cost-effective only if performed in high-volume mass production that limits its role in most research and development needs and various niche applications. To overcome such limitations of nanoimprinting process, we utilize a thermoplastic polymer with a thorough knowledge of the imprinting conditions at micron to nano scale such as filling behavior, pattern fidelity, and surface properties.

In the present study, we describe an optimized process for imprinting sub-micron to nano-structures to poly(methyl methacrylate) (PMMA), a thermoplastic polymer, using simple soft PDMS (Polydimethylsiloxane) templates. Initially, a range of imprinting depth of 200nm PMMA thin layer was explored with micron to nano scale features of a template for a low imprinting pressure (~3 bar). Sub-micron patterned features have complete depth of trenches as template compared to micron size patterns; in both cases, the obtained patterns depend on applied pressure and imprinting temperature. The imprinting at temperatures higher than that for PMMA glass transition leads to increased pattern trench depths; however the imprinted PMMA layer shows poor surface quality due to the high temperatures employed. We addressed this problem by using PMMA solvent mixed with acetone to improve the surface quality of PMMA layer. Therefore, relatively low surface roughness and good anti-sticking properties were obtained. The thermal behavior and etching rate of the polymer prepared with mixed solvent were studied. By tuning nanoscale mechanical and surface properties, we successfully imprinted features at submicron and nano scales and demonstrate pattern transfer to substrates after metallization and lift off process.

SESSION ST01.12: Micro/Nano-Scale Characterization and Mechanics IV

2:15 PM *ST01.12.01
Measurement of Hardness and Elastic Modulus by Depth Sensing Indentation—Improvements to the Technique Based on Continuous Stiffness Measurement Warren C. Oliver[1], Phani Sudharshan[2] and George M. Pharr[3]; [1]KLA Corporation, United States; [2]ARCI, India; [3]Texas A&M University, United States

The method to measure hardness and elastic modulus of small volumes of material by instrumented indentation presented in the seminal works of Oliver and Pharr in 1992 and 2004, has revolutionized the field of small scale nanomechanical testing. Several recent advances in measurement electronics have enabled testing over a wider range of test conditions (speeds) using methodologies that were developed earlier, which requires a critical assessment. In the backdrop of the latest developments in instrumentation and test methodologies, an overview of the various factors affecting the precision and accuracy of the nanoindentation test results at different test conditions with specific focus on Continuous Stiffness Measurement (CSM) technique will be presented.

2:40 PM ST01.12.02
Late News: High-Pressure Studies of Nanostructured Ultra-Incompressible Superhard Materials Shanlin Hu[1], Jialin Lei[2], Richard Kaner[1] and Sarah Tolbert[1]; [1]University of California, Los Angeles, United States; [2]Washington State University, United States

Hardness is a complex physical property that includes both intrinsic and extrinsic effects. In the past, to design intrinsically hard materials, we have explored the use of late transition metal borides that possess intrinsically high incompressibility due to high valence electron density, and added covalency through the formation of metal borides as a way to increase resistance to shear. At the opposite end of the spectrum, we find extrinsic effects, including grain boundary processes, such as grain boundary sliding, diffusion and grain rotation. In nanocrystalline material, these extrinsic effects compete with intrinsic effects (grain interior dislocations) and lead to unique plastic deformation behavior. While the size effects have been explored in the ductile metal system, little is known about whether these same phenomena dominate in nanocrystals of much harder materials, such as transition metal boride nanocrystals, mostly due to a lack of materials with size tunable nanosized domains.

Here, we demonstrate the size dependency of plastic deformation mechanism in the nanosized superhard ReB_2 system. In order to understand the lattice specific mechanical failure that is related to bonding motifs, in-situ high-pressure radial X-ray diffraction was conducted. A large magnitude of uniaxial stress state was generated in the diamond-anvil cell (DAC), while X-ray diffraction is simultaneously collected, allowing us to probe the changes in bonds under compression and obtain the differential strain (t/G), which describes the material's ability to resist shear stress. In addition, texture analysis on the radial diffraction data provides quantitative information on slip planes within a material, revealing the extrinsic effects interacting with the grain interior dislocations. Different sizes of nano-ReB_2 (20 nm and 50 nm) were synthesized by molten-salt method and bulk-ReB_2 was synthesized by arc-melting method. In-situ radial X-ray diffraction was performed under high pressure up to ~60 GPa. The lattice specific differential strain was experimentally measured and the diffraction patterns were analyzed by Rietveld refinement. In the nano-ReB_2, extrinsic effects compete with grain interior dislocations and lead to plastic deformation behavior that is very different from bulk-ReB_2. A Hall-Petch size dependence was observed, as the grain size gets smaller, the increasing the grain boundary content impedes plastic deformation and results in enhanced resistance to dislocation glide. Texture analysis was performed on the nano-ReB_2 system, because the grains in the nano-samples are fine enough that the peak intensity variation with azimuth angle correlates to the slip systems and grain orientation. From the inverse pole figures, the texture has its maximum intensity along the (0001) direction in both nano-samples, suggesting that the deformation is primarily controlled by the basal slip system. Furthermore, the pole density is more concentrated at (0001) pole as the grain size gets smaller, suggesting closing of slip system as the grain boundary concentration increases.

2:55 PM *ST01.12.03
Low-Temperature Time-Dependent Ductility in Single Crystal Silicon at Micro Scale Taher Saif; University of Illinois at Urbana-Champagin, United States

Materials at small scale behave differently from their bulk counterparts. This deviation originates from the abundance of interfaces at small scale. Quantifying the properties and revealing the underlying mechanisms requires experiments with small samples in situ in analytical chambers. However, small size poses the challenge

of sample handling, but offers the opportunity of in situ inspection of mechanism during testing in analytical chambers. In order to overcome the challenge and take advantage of the opportunity, we developed a MEMS based micro scale testing stage where the sample and the stage are co-fabricated. The stage suppresses any misalignment error in loading by five orders of magnitude. The stage allows in situ inspection of samples during testing in SEM and TEM. We employed the stage to explore the effect of size on brittle to ductile transition (BDT) temperature (540C) in single crystal silicon. Here, the sample is a micro scale single crystal silicon beam subjected to bending which limits the high stress region to a small volume of the sample, and minimizes the probability of premature failure from random flaws. We found that silicon indeed deforms plastically at small scale at temperatures much lower than 540C. Ductility is achieved through a competition between fracture stress and the stress needed to nucleate dislocations from the surface. Our combined SEM, TEM and AFM analysis reveals that as a threshold stress is approached, multiple dislocation nucleation sites appear simultaneously from the high stressed surface of the beam with a uniform spacing of about 200 nm between them. Dislocations then emanate from these sites with time, lowering the stress while bending the beam plastically. This process continues until the effective shear stress drops and dislocation activities stop. A simple mechanistic model is presented to relate dislocation nucleation with plasticity in silicon.

Nanoscale Science for Geoscale Phenomena: Mechanisms of Rock Friction Revealed by Atomic Force Microscopy, Nanoindentation and Atomistic Simulations David L. Goldsby[1], John McClimon[1], Zhuohan Li[2], Izabela Szlufarska[2], Robert W. Carpick[1], James Batteas[3], George M. Pharr[3], Xin Zhang[4] and Kevin Rosso[4]; [1]University of Pennsylvania, United States; [2]University of Wisconsin–Madison, United States; [3]Texas A&M University, United States; [4]Pacific Northwest National Laboratory, United States

Earthquakes are frictional instabilities that initiate on faults in Earth's crust at slow, quasi-static slip rates of nm/s to μm/s. Unstable fault slip results from interactions between the mechanical properties of the rocks which load the fault and the frictional behavior of the fault itself. Like several engineering materials, the quasi-static frictional behavior of rocks is described by rate-variable and state-variable friction (RSF) “laws”, which are actually empirical relations based on data from laboratory experiments. These descriptions of friction agree with many (but not all) data from lab experiments, and reproduce a rich variety of earthquake behavior when employed in full-cycle earthquake rupture models. However, the physical and/or chemical mechanisms that yield the observed rock friction behavior are unknown, making extrapolations of RSF laws beyond the limited range of conditions of the experiments that form their basis fraught with uncertainty.

The most fundamental observation from experimental studies of rock friction is that friction increases with the log of the time of stationary (or nearly stationary) contact. This is typically studied in slide-hold-slide experiments, wherein restarting sliding after a “hold” period without sliding results in an increase in peak static friction. This increase in *state* of the frictional interface during the hold may occur with the time of stationary contact, or with the slow slip of shear-loaded contacts. Time- or slip-dependent aging manifests as a velocity dependence of friction, the sign of which determines whether unstable frictional sliding (an earthquake) is possible.

Because the frictional behavior of faults emerges from the collective behavior of myriad nanometers- to microns-sized contacting asperities, fundamental rock friction mechanisms can be studied at the single-asperity level by atomic force microscopy (AFM) and nanoindentation. The canonical view is that aging results from increases in contact area due to plasticity and creep of asperities in contact. Results of our recent AFM and nanoindentation experiments, coupled with first-principles simulations, however, point to chemical bonding across frictional interfaces as an important mechanism of friction. Extensive AFM studies with oxidized silicon tips and samples, and more recently with quartz tips on quartz samples, and coordinated simulations demonstrate that log-time aging results from chemical bonding across asperity contacts, in the absence of plastic deformation. Moreover, our AFM experiments reveal many of the phenomena observed in friction experiments on rocks - notably a critical slip (or memory) distance D_c , variations in the dependences of friction on sliding velocity, increases of friction with slow as well as no slip during holds, and stick-slip behavior. Our

nanoindentation experiments show that the yield stress and creep behavior of quartz at room temperature are independent of relative humidity (RH) in the range ~0 to 50%, whereas macroscale friction tests on quartz reveal no aging at RH <5% due to a supposed lack of asperity yielding and creep. These observations thus preclude plastic deformation as the primary mechanism of frictional aging. Our studies collectively point to chemical bonding as an important mechanism of rock friction, and motivate our current models of rough rock surfaces in contact that incorporate both chemical bonding and asperity yielding and creep.

Late News: A New Machine Learning Framework for Accelerating Mechanical Characterization at Small Scales Christos E. Athanasiou, Xing Liu, Nitin Padture, Brian W. Sheldon and Huajian Gao; Brown University, United States

Investigating mechanical properties at small scales is a challenging endeavor. It requires sophisticated micro-/nano-scale experimental methods combined with laborious/time-intensive finite element computations. In this talk, a new framework for materials characterization at small scales using the latest developments in machine learning will be presented. This framework involves multi-fidelity deep learning and active learning methods limiting the need for finite element simulations. Its application for predicting the fracture toughness of microscale pentagonal cross-sectional ceramic cantilevers will be showcased, demonstrating that it can significantly accelerate fracture toughness characterizations at small scales.

4:00 PM ST01.12.06
Microparticle Impact at Very High Velocities Does Not Necessarily Improve Bonding Ahmed A. Tiamiyu, Yuchen Sun, Keith Nelson and Christopher Schuh; Massachusetts Institute of Technology, United States

Impacts at very high velocities have been widely perceived to promote particle flattening and bonding during additive manufacturing processes such as cold spray. Using the laser-induced particle impact tester, we perform site-specific studies with well-known particle sizes and velocities, and show that particle impact at some very high velocities can counter-intuitively deteriorate coating quality. We identify a particle rim peeling mode that hinders extensive lateral particle flattening and also appear to cause debonding at the particle-substrate interface close to the particle periphery, even prior to the undesirable hydrodynamic particle penetration regime. To the extent that high velocities are required for permanent particle adhesion, this work points to the possibility of a more narrow velocity range within which high quality particle bonding may be achieved.

SESSION ST01.13: On-demand
Wednesday Morning, April 14, 2021
ST01

8:00 AM ST01.04.03
Inverse Layer Dependence of Friction on MoS_2 Achieved Through Intercalation of Dopants Ogulcan Acikgoz[1], Alper Yanilmaz[2], Omur E. Dagdeviren[3,4], Cem Çelebi[2] and Mehmet Z. Baykara[1]; [1]University of California, United States; [2]Izmir Institute of Technology, Turkey; [3]McGill University, Canada; [4]École de Technologie Supérieure, Canada

We present the results of atomic-force-microscopy-based friction measurements on Re-doped molybdenum disulfide (MoS_2). In stark contrast to the seemingly universal observation of decreasing friction with increasing number of layers on two-dimensional (2D) materials, friction on Re-doped MoS_2 exhibits ananomalous, i.e. inverse dependency on the number of layers. Raman spectroscopy measurements reveal signatures of Re intercalation, leading to a decoupling between neighboring MoS_2 layers and enhanced electron-phonon interactions, thus resulting in increasing friction with increasing number of layers – a new paradigm in the

mechanics of 2D materials.

8:15 AM ST01.07.07
Tuning Field-Effect Mobility of Ultrasensitive Hybrid Transistors with UV Light Che-Hsuan Cheng, Kanak Datta, Da Seul Yang, Jinsang Kim and Parag Deotare; University of Michigan–Ann Arbor, United States

Light-powered and chemically fueled artificial molecular applications have long been recognized as the key building blocks of the functional materials of the future. In this work we employ an azobenzene based molecules A3 that undergoes reversible structural change between *trans* and *cis* forms upon irradiations of UV and visible light respectively. Using this, we develop highly sensitive phototransistors with tunable and ultra-high field-effect carrier mobility based on tungsten diselenide (WSe_2) monolayer. By stretching and contracting the underlaying A3 molecules using UV and visible light (from 9 Å to 5.5 Å), the hole mobility of the hybrid FET device can be tuned from 100 cm^2/Vs to as high as 1025 cm^2/Vs, which is over an order of magnitude higher than typical TMDs based transistors. The observed mobility is comparable to that of conventional semiconductors such as silicon and germanium. We investigated the enhancement mechanisms by electrically characterizing the hybrid device before and after UV exposure. Consequently, we conclude strain to be the primary mechanism for channel current enhancement.
Furthermore, we monitored the UV photoresponse of the hybrid transistor and found that the UV photocurrent extinction ratio to be 75% higher than that of the bare WSe_2 device, making it a promising candidate for UV detection application. Such hybrid platform can potentially be used for designing next generation devices as well as ultrasensitive UV photodetectors.

SESSION ST02.01: Plasticity at Small Length Scales—Metals and Alloys
Session Chairs: Christoph Gammer and Erdmann Spiecker
Thursday Morning, April 22, 2021
ST02

8:00 AM *ST02.01.01
***In Situ* Transmission Electron Microscopy Deformation Study on Dislocation Plasticity in FeCoCrMnNi High-Entropy Alloy** Subin Lee[1], Christian Liebscher[1], Sang Ho Oh[2], Karsten Albe[3] and Gerhard Dehm[1]; [1]Max Planck Institute for Iron Research, Germany; [2]Sungkyunkwan University, Korea (the Republic of); [3]Technische Universität Darmstadt, Germany

In the past decades, high-entropy alloys (HEAs) have been intensively investigated not only because of fundamental scientific interests, but also their outstanding mechanical properties, for example, high ductility and fracture toughness. Among hundreds of different combinations of principal elements, the equiatomic FeCrCoMnNi alloy, the so-called Cantor alloy, has been studied as a model system, which is a single-phase material with face-centered cubic (FCC) structure at room temperature and shows outstanding ductility and strain hardening especially at cryogenic temperatures.

However, dislocation-based deformation mechanisms of HEAs remain elusive and require a fundamental understanding to tailor their mechanical properties. Several models have been suggested possible strengthening mechanisms of HEAs, for instance, the high entropy effect and the lattice distortion effect. In the case of the Cantor alloy, the main strengthening mechanism was identified as deformation twinning with critical twinning stress of 720 MPa. At room temperature, dislocation slip by full dislocations is dominant, however, at strains exceeding 20 % and high flow stresses, deformation twinning was also observed. To reveal the strengthening mechanism in more detail, direct observation of dislocation plasticity and deformation dynamics is required.

Here, we present a study correlating the microstructure and dislocation plasticity of FeCrCoMnNi FCC phase HEA by employing an in-situ transmission electron microscope (TEM) compression and tensile deformation. The threshold shear stress for dislocation glide in a thin foil is measured from dislocation curvature as exceeding 400 MPa. Interestingly, dislocations are prevented from straightening upon unloading due to high frictional stresses. Moreover, an atomic-scale chemical analysis is conducted by aberration-corrected scanning TEM energy-dispersive X-ray spectroscopy (STEM-EDS) and atom probe tomography to investigate chemical inhomogeneity. Lastly, the origin of the jerky glide motion of dislocations observed during the in-situ TEM straining tests is further analyzed by using atomistic simulations.

8:30 AM *ST02.01.02
***In Situ* TEM Straining Experiments Cantor's HEA Alloy at Liquid Nitrogen and Room Temperature**
Daniela Oliveros[1], Anna Fraczkiewicz[2], Antonin Dloughy[3], Stefan Sandfeld[4] and Marc Legros[1]; [1]CEMES-CNRS, France; [2]Ecole des Mines de Sainte Etienne, Cours Fauriel, France; [3]Czech Academy of Sciences, Czechia; [4]Forschungszentrum Jülich GmbH, Germany

Despite possessing similar glide systems as an fcc metal, the equiatomic CoCrFeMnNi high entropy alloy (HEA) (Cantor alloy) continues to intrigue metallurgists around the word. Many key questions such as the origin of its strength, the preferential activation of twinning at low temperature or the nature of obstacles to dislocation movement remain to be understood. In particular, the possibility of a friction stress that would arise from the distorted structure of the HEA instead of an extended core as in bcc metals or covalent materials is still debated. In this study, we have carried out tens of in situ straining tests in a TEM at room and liquid nitrogen temperature to assess these questions. Dislocations are used as probes, whose dynamic behavior under stress serve as local markers of the average of punctual obstacles strength they have to overcome. Quantitative stress measurements are made and confronted to those provided by bulk tests, including the size effects arising from thin foil testing.

9:00 AM ST02.01.03
Late News: *In Situ* Synchrotron Diffraction Study of Structural Evolution in a Ductile Bulk Metallic Glass Under Tension at Micro-Scale Sinan Liu[1], Jiacheng Ge[1], Xun-li Wang[2] and Si Lan[1]; [1]Nanjing

University of Science and Technology, China; [2]City University of Hong Kong, Hong Kong

The development and application of metallic glasses can benefit from the in-depth understanding of the structure-properties relationship during plastic deformation. The limited tensile plasticity of metallic glasses hindered the in-situ study of structural response under tension. Here, we report an in-situ synchrotron study of a metallic glass after canning compression under tension at a micro-scale. Our experimental results show that the canning-compressed metallic glass has much better tensile ductility and much higher ultimate strength than its initial state. The real-space analysis of synchrotron diffraction data indicates that the cluster connectivity and ordering at medium-range length scale play an essential role in plastic deformation. Our results may shed light on developing ductile metallic glasses and their devices at micro-scales.

9:15 AM ST02.01.05
Spatial Localization of Dislocation Avalanches During Microplasticity of a High-Entropy Alloy Quentin Rizzardi[1] and Robert Maass[1,2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Bundesanstalt für Materialforschung und -prüfung (BAM), Germany

We attempt here an in-situ experiment to reconcile the recorded mechanical activity of dislocation avalanches during small-scale plasticity of a high-entropy alloy with the observed formation and evolution of slip line morphology on the sample. Correlating the intermittent microplastic events with their corresponding slip-line pattern allows us to define two main event types: events that lead to the formation of new slip lines, and those that involve reactivation of already existing slip lines. The formation of new slip lines reveals statistically larger and faster avalanches that lower the stress-integrated scaling exponent of the global distribution of all occurring events. The opposite tendency is seen for avalanches involving reactivation of already existing slip lines. The combination of both these types of events represents the highest degree of spatial avalanche delocalization, forming a group of events that determine the truncation length-scale of the truncated power-law scaling. These observations link stress-strain fluctuations in a typical small-scale deformation experiment l to the spatial localization of dislocation avalanches, underlining their non-trivial scaling behavior.

SESSION ST02.02: MEMS, High-Strain Rate, High Temperature & Environmental Testing
Session Chairs: Christoph Gammer and Thomas Pekin
Thursday Morning, April 22, 2021
ST02

10:30 AM *ST02.02.01
High Strain Rate Testing from Micro-to-Meso Scale Rajaprakash Ramachandramoorthy[1,2], Szilvia Kalácska[2], Patrik Schuerch[3], Manish Jain[2], Jakob Schwiedrzik[2], Wabe Koelmans[3], Laetitia Philippe[2], Xavier Maeder[2] and Johann Michler[2]; [1]Max-Planck-Institut für Eisenforschung, Germany; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Exaddon AG, Switzerland

Dynamic properties of materials at high strain rates are vital to assess their suitability and reliability in applications ranging from common drops to demanding impact-protection applications. Macroscale mechanical testing at high strain rates, though challenging, is already a well-established field of research. But recently, given the push towards miniaturization, small scale mechanics has also been a topic of intense research over the last two decades. However, till date the micro and nanomechanical experiments have been largely limited to testing samples made using focused ion beam (FIB) milling at quasi-static speeds. Small scale sample preparation using FIB-based milling is a serial and time-consuming process that typically limits the number of samples tested in micromechanical studies, while allowing the fabrication of only simple geometries. On the other hand, the limitation in testing speed is primarily attributed to the lack of instrumentation capable of high speed actuation and simultaneous high speed capture of loads and displacements with micronewton and

nanometer resolution.

This presentation will introduce a newly developed piezo-based micromechanical tester capable of conducting high strain rate micromechanical testing at speeds up to 10mm/s. The relevant hardware requirements and protocols specific to high speed testing at the small scale will be elaborated. Further, a localized electrodeposition based metal additive micromanufacturing (μAM) technique will be introduced as a viable method for fabricating full-metal microarchitectures. A large array of ideal copper micropillar test-beds built using this technique will be presented along with electron backscatter diffraction (EBSD) based microstructural characterization showing two distinct microstructures: microcrystalline and ultrafine grain (UFG). The mechanical properties of these copper micropillars, explored as a function of strain rate from 0.001/s to 500/s, will be shown as a function of initial pillar microstructure. Relevant, stress-strain signatures, thermal activation parameters and post-deformation microstructural analysis using EBSD and transmission kikuchi diffraction (TKD) for the copper micropillars will also be presented.

The last part of the presentation will highlight the capabilities of μAM to fabricate complex full-metal 3D microarchitectures such as microlattices and microsprings. Copper microlattices with different geometries, chosen from an energy absorption perspective, including honeycomb, octet and kelvin foam will be presented along with their dynamic compressive properties upto a strain rate of ~150/s. Further, a detailed structural and microstructural characterization conducted using FIB-based 3D slice-and-view and EBSD/transmission electron microscopy (TEM) respectively will be compared between the undeformed and deformed lattices. Finally, a finite element methods (FEM) based simulation aimed at understanding the structural evolution of the metal lattices under high speed deformation will be presented. It will be explained that the FEM simulation model takes into account the defect structures determined using the reconstructed 3D slice-and-view lattices and the appropriate constitutive laws identified from the high strain rate compression of copper micropillars.

11:00 AM ST02.02.02
Beyond Strain Bursts in Intermittent Crystal Plasticity—Ultrafast Dislocation Avalanches and Mean Swept Distances Across Microsample Sizes in FCC and BCC Metals Jan Ocenasek[1], Jeffrey Wheeler[2], Javier Varillas[1,3], Jaafar El-Awady[4] and Jorge Alcala[5]; [1]University of West Bohemia in Pilsen, Czechia; [2]Swiss Federal Institute of Technology in Zürich, Switzerland; [3]The Czech Academy of Sciences, Czechia; [4]The Johns Hopkins University, United States; [5]Universitat Politècnica de Catalunya, Spain

Plastic deformation in crystalline materials consists of an ensemble of collective dislocation glide processes, which lead to strain burst emissions in micro-scale samples. Prior investigations of plastic intermittencies involved the large strain bursts triggered with dynamically-reactive testing systems. Under these driving conditions, the microcrystal is rapidly compressed as a function of the system's dynamic response, which ultimately governs the termination of the instability and its overall size. We argue that a dynamically-induced plastic instability or strain burst is comprised of many of the currently measured individual dislocation avalanche events, propagating over minuscule time scales, which are ubiquitous to crystal plasticity.
To investigate the onset of the ultrafast individual dislocation avalanches, we performed a comprehensive set of strict displacement-controlled micropillar compression experiments in conjunction with large-scale molecular dynamics and physics-based discrete dislocation dynamics simulations. It is shown that the size distributions of these dislocation events exhibit a gradual transition from an incipient power-law slip regime (spanning ≈2.5 decades of slip sizes) to a large avalanche domain (spanning ≈4 decades of emission probability) at a cut-off slip magnitude s_c. This cut-off slip provides a statistical measure to the characteristic mean dislocation swept distance, which allows for the scaling of the avalanche distributions *vis-à-vis* the archetypal dislocation mechanisms in face-centered cubic (FCC) and body-centered cubic (BCC) metals. Our statistical findings provide a new pathway to characterizing metal plasticity and towards comprehension of the sample size effects that limit the mechanical reliability in small-scale structures.

11:15 AM ST02.02.03
High Temperature *In Situ* Mechanics of Ni-Based Superalloys and Bond Coatings Sanjit Bhowmick;

Bruker, United States

High-strength structural materials such as Ni-based superalloys and diffusion bond coats are widely used in challenging environments and with exposure to mechanical fatigue, particle impact, and erosion at elevated temperatures. Diffusion platinum-aluminide bond coatings are an example of compositionally and microstructurally graded coatings with significant variation in engineered mechanical properties across the cross-section. In this study, an SEM nanomechanical instrument with an integrated high-temperature stage and an active tip heating was used to conduct pillar compression of aluminide bond coating and substrate at room temperature to 1000ºC. With combined analysis of chemistry and microstructural changes, the results were used to understand local mechanical properties variation as a function of temperature.

11:30 AM ST02.02.04
Isothermal, Self-Actuated MEMS-Based High-Temperature Nanomechanical Test Platform Longchang Ni[1], Ryan Pocratsky[2] and Maarten De Boer[1]; [1]Carnegie Mellon University, United States; [2]Fischione Instruments, United States

Relatively little is known about freestanding thin film creep at elevated temperature. In MEMS, polycrystalline silicon (polysilicon) thermal actuators are frequently used as on chip actuators, but they typically operate at temperatures 300-500 °C higher than the substrate to generate useable displacement and force output. This is because polysilicon's coefficient of thermal expansion (CTE, 2.7 με/°C) is the same as the silicon substrate. When actuated by Joule heating, heat flows to the specimen, which can induce experimental artifacts. Instead of using polysilicon, we demonstrate refractory metal tantalum (Ta) thin films as a new structural material for MEMS nanomechanical test platforms. The CTE of Ta films is double that of polysilicon (5.9 με/°C). Therefore, self-actuation simply by raising the temperature is possible. A stress relaxation test can be performed under an isothermal condition, and strains up to 30 % are possible. We have fabricated Ta thermal actuators using conventional surface micromachining after resolving key fabrication issues. Self-actuation has been successfully demonstrated. Using a platinum specimen for demonstration, we have validated a process flow to co-fabricate the specimen with Ta thermal actuators. High-temperature, stress relaxation experiments on structural Pt films at temperatures up to 500 °C will be performed and presented. This work demonstrates for the first time a powerful drift-free in-situ stress relaxation test of structural thin films at elevated temperatures.<!--![endif]----><!--![endif]---->

11:45 AM ST02.02.05
Variable-Humidity Nanoindentation—Challenges and Opportunities Joseph Jakes; USDA Forest Service, Forest Products Laboratory, United States

A wide variety of materials, including thin film microelectronics and lignocellulosic materials, have moisture-dependent mechanical properties that can vary substantially depending on the ambient relative humidity (RH). Under high RH conditions, moisture sorption can weaken interfaces or plasticize materials. The effects of moisture can be especially challenging to study at interfaces and in composite materials with small micron- and nanoscale components. To overcome this challenge, protocols were developed to perform nanoindentation experiments over a wide range of humidity. Using an external RH generator, the environment inside of a Hysitron TriboIndenter enclosure was controlled and varied from dry air up to 95% RH. Analysis of calibration nanoindentations in the air and in fused silica supported that the nanoindenter functioned properly over the entire humidity range provided that enough time was given to equilibrate at the RH. However, some corrosion was observed in metal fasteners on the instrument, which suggests that keeping the nanoindenter under high RH conditions is not advisable over the long term. Nanoindentation results studying the moisture-dependent properties of porous organosilicate glass (SiCOH) thin films and wood will be presented. In SiCOH, elastic modulus was found to not depend on humidity, whereas the hardness and fracture behavior were intimately linked to the nature and concentration of the absorbed water. Wood cell walls are plasticized by the absorbed water and both the elastic modulus and hardness decrease with increasing RH. Additionally, using dynamic nanoindentation the mechanical damping of the wood cell walls was assessed over three decades of frequency

and a moisture-dependent glass transition of the amorphous polysaccharides in the wood cell wall could also be observed as a peak in mechanical damping.

12:00 PM ST02.02.06
Electro-Chemo-Mechanical Coupling—A Novel Approach to Micro Actuation Evgeniy Makagon[1], Ellen Wachtel[1], Lothar Houben[1], Sidney Cohen[1], Yuanyuan Li[2], Junying Li[2], Anatoly Frenkel[2] and Igor Lubomirsky[1]; [1]Weizmann Institute of Science, Israel; [2]Stony Brook University, United States

The chemo-mechanical effect in solids refers to dimensional change due to change in stoichiometry. Dimensional change due to electrochemically-induced compositional change has been termed the electro-chemo-mechanical (ECM) effect. The mechanical instability inherent in this effect is clearly deleterious for batteries or fuel cells, but, as recently suggested, has potential for use in actuation[1]. The structure of an actuator device that operates on the ECM principle comprises a micrometer thick solid electrolyte (SE) sandwiched between two ECM-active, working body (WB) layers. An electrochemical reaction must occur in these layers, causing them to alternately expand or contract. In order to facilitate the ECM response, the WB layers should have mixed ionic and electronic conductivity and a large chemical expansion coefficient.
We have constructed a 2mm diameter thin film membrane ECM actuator device comprising 20mol% Gd doped CeO_2 (20GDC) as the SE and [$TiO_{2-\delta}$\20GDC] or [$V_2O_{5-\delta}$\20GDC] composites as the WBs[2]. Selected area electron diffraction measurements showed the composite to be nanocrystalline, a morphology that promotes interfacial oxygen ion diffusion. Synchrotron X-ray absorption (XAS) measurements detected a mixture of Ce^{3+}/Ce^{4+} (~[0.4]/[0.6]) and Ti^{3+}/Ti^{4+} (~[0.1]/[0.9]) oxidation states in the WB. XAS measurements under bias showed changes in the short-range order of Ti and V oxides supporting the presence of a redox reaction. The deformation of the ECM actuator was observed to be in the bending regime producing large vertical displacements (~3 μm) and ~4 MPa stress. The stress/voltage ratio yields a pseudo piezoelectric stress coefficient of e_{31}=1.26 C/m^2, comparable to common lead-free piezoelectrics such as lithium niobate, lithium tantalate and alkali niobates.

SESSION ST02.03: In Situ Techniques—Strain Mapping
Session Chairs: Christoph Gammer and Wendy Gu
Thursday Afternoon, April 22, 2021
ST02

1:00 PM *ST02.03.01
Imaging Defects and Their Dynamics Using Scanning Electron Microscopy Approaches Daniel Gianola; University of California, Santa Barbara, United States

The past several years has witnessed a surging popularity of two techniques for defect characterization in crystalline materials: (*i*) scanning transmission electron microscopy (STEM) using diffraction contrast imaging, and (*ii*) electron back-scattered diffraction (EBSD) mapping. Advantages of diffraction-contrast STEM methods over conventional TEM include the suppression of dynamical effects and spurious contrast, as well as the ability to image relatively thick specimens. In parallel, the use of transmission modalities in the scanning electron microscope (SEM) has attracted recent attention. Here, we link these capabilities by employing an field emission SEM equipped with a transmission detector for defect characterization – termed transmission SEM (TSEM). Imaging modes that are similar to conventional CTEM bright field (BF) and dark field (DF) and STEM are explored, and some of the differences due to the varying accelerating voltages highlighted.
As an alternative approach more amenable to bulk materials, EBSD has evolved to be a widespread and

powerful characterization technique for the mapping and analysis of phases in crystalline materials, providing key information about crystal orientation, morphologies, lattice strain, topology, and crystallographic texture. Whereas the advent of direct electron detection (DED) that circumvents inefficient conversion between electrons and photons has revolutionized the field of TEM, owing to single electron sensitivity for beam sensitive samples and ultrafast detection for time-resolved studies, the use of DED in the vastly more accessible SEM environment is in its infancy. Here, we demonstrate how the richness of information encoded in EBSD patterns is amplified by a new generation of direct electron detectors that enable high speed mapping and acquisition of high-fidelity patterns that can be used for statistically-meaningful defect analyses.
We further show that these SEM-based approaches provide significant advantages for dynamic *in situ* characterization. We employ location-specific *in situ* tensile experiments to study the nature of dislocations dynamics in several structural alloys. By selecting specific crystallographic orientations relative to the tensile axis, we observe the underpinnings of several plasticity mechanisms including shear localization, cross-slip, and dislocation junction formation and evolution. To illustrate the power of these new methods for defect-contrast studies, we show examples on several emerging structural materials such as superalloys and refractory multi-principal element alloys.

1:30 PM *ST02.03.02
***In Situ* 4D-STEM** Andrew M. Minor[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

In situ transmission electron microscopy (TEM) experiments are typically recorded either in real space or diffraction space. However, it would be ideal to have both real and diffraction space for when transient events occur that cannot be repeated exactly (ie- defect generation or irreversible phase transformations). Real space imaging provides context for these transient events by spatially-resolving microstructural features to one another while diffraction space provides better structural clarity about phase identification and lattice parameters. Four-dimensional scanning transmission electron microscopy (4D-STEM), can come close to providing both simultaneous real-space imaging and diffraction analysis during *in situ* testing. With the advent of fast direct electron detectors it is possible to perform strain mapping via diffraction pattern analysis during in-situ deformation in a TEM with the precision of a few nanometers without stopping the experiment. Images of the same overall experiment can then be formed using virtual apertures applied to the accumulated diffraction patterns. This talk will highlight recent *in situ* 4DSTEM experiments that explore transient events where both information from diffraction space and real space are used. The diffraction patterns are used to identify different phases, orientations and relative strain, while the images formed by using virtual apertures provide microstructural context for the analysis. Example experiments include defect generation and interactions in metals, local strain evolution in bulk metallic glasses, and structural transformations in functional oxides under deformation.

2:00 PM ST02.03.03
Assessment of Template Matching (TeMA) and Geometric Phase Analysis (GPA) in Quantifying Large Deformation Strains/Displacements Around Defects Ahmed Sameer Khan Mohammed, Florian Brenne and Huseyin Sehitoglu; University of Illinois at Urbana-Champaign, United States

This study assesses the applicability of advanced atomic resolution displacement measurement techniques to characterize dislocation character in metallic materials using simulated images derived from anisotropic elasticity and actual measurements in high entropy alloys. We draw attention to two techniques: the real space method of template matching (TeMA) and the reciprocal space method of geometric phase analysis (GPA) and provide a critical assessment. These techniques have limitations for direct evaluation of full dislocations Burgers vector or when local displacements exceed certain value. This value depends on the displacement direction in relation to the crystal structure. A cut-off for reliable displacement measurement is proposed as the boundaries of the Wigner-Seitz cell drawn on the 2D HRTEM image of the crystal structure. This effect is illustrated with simulated arctangent displacement profiles reminiscent of dislocation cores. An approach for circumventing this limitation is suggested in the form of a nearest neighbor correction. Additionally, a

methodology for determination of the Burgers vector is introduced on the basis of a vectorial rendering of the displacement field upon consideration of two zone axis measurements and applied to TeMA and GPA. The experimental results conform to the Burgers vector of a full lattice dislocation in the FCC crystal structure of the High-Entropy Alloy (HEA). The comparison of simulated and experimental images proves the efficacy of the HR-TEM (High Resolution Transmission Electron Microscopy) displacement mapping techniques while pointing to the need for caution in case of large displacements.

2:15 PM ST02.03.04
Stress and Crystal Orientation Mapping in Thin Films with Micro Reflectance Anisotropy Spectroscopy
Joan Sendra, Nerea Abando, Henning Galinski and Ralph Spolenak; ETH Zürich, Switzerland

The mechanical characterization at small length scales is of fundamental importance to obtain insights of deformation mechanisms. In particular, stress mapping is of great interest since it allows the study of fracture mechanics, e.g. visualizing the stress distribution around a crack tip. Conventional lab scale stress mapping techniques are based on electron microscopy and Raman spectroscopy. Common drawbacks are the required high vacuum for electron microscopy and the need of polarizable materials for Raman spectroscopy, hindering the range of materials that can be analyzed. X-ray diffraction is also an established technique for mechanical studies, however its need for a large interaction volume poses problems for ultra thin film studies while still being limited in lateral resolution. Synchrotron X-ray diffraction bypasses these drawbacks and achieves high spatial resolution and strain sensitivity for thin crystalline materials but requires significant resource investment. In contrast, reflectance anisotropy spectroscopy (RAS) can be employed for a wide range of materials, environments and sample thicknesses to become an attractive technique for non-destructive mechanical studies. RAS is an ellipsometric technique that measures the difference in reflectance between linearly polarized light along two orthogonal directions of the sample. However, usual resolution of conventional RAS setups is in the order of millimeters. Here, we present an advanced reflectance anisotropy spectroscopy (RAS) microscope based on a super continuum laser source as a non-destructive stress mapping technique. Our microscope enables insight into the electronic band structure, phase and crystal orientation.
We sputter metallic thin films on flexible substrates and employ focused ion beam (FIB) milling to modify surface topology. We then demonstrate the capabilities of the technique by externally applying uniaxial strain on the fabricated FIB structures and mapping of the strain distribution on the surface of the sample. Furthermore, mechanical properties are highly influenced by microstructure. Since RAS signal is dependent on crystal orientation, we also prove grain mapping in polycrystalline copper and compare the RAS signal of different grains to outline the possibility of grain orientation indexing in a similar fashion to electron backscattered diffraction. The potential simultaneous stress and grain orientation mapping will enable future studies on the fracture mechanics of thin films and novel materials with different microstructure and environmental conditions.

Nanoscale Imaging of Strain and Defect by Bragg Coherent X-Ray Diffractive Imaging Wonsuk Cha; Argonne National Laboratory, United States

In the past decades, Coherent X-ray Diffractive Imaging in Bragg geometry (BCDI) has become one of major nanoscale imaging techniques. Unique sensitivity to lattice [1] enables BCDI to image three-dimensional morphology as well as internal deformation field distribution of nano-scaled and/or micro-scaled materials including metal, metal oxide, minerals, and so on. Nowadays, in-situ and operando BCDI is a main driver to address scientific questions on materials.
In this talk, I will introduce current state-of-the-art of BCDI and the 34-ID-C beamline in the Advanced Photon Source where BCDI experiments can be performed. This talk will also cover recent experimental results on in-situ and operando BCDI, e.g. unique lattice distortion in ZSM-5 zeolites [2], annealing effect on gold grains on gold thin films [3], dislocation imaging under tensile loading [4], and current development on combining Laue diffraction to BCDI [5]. In addition, some estimates of BCDI in the future will be discussed.

Deformation in Sub-10 nm Nanocrystals and Nanoclusters Wendy Gu, Abhinav Parakh and Qi Li; Stanford University, United States

Sub-10 nm metals have fascinating physical, optical and chemical properties. By applying stress to these nanomaterials, it is possible to study atomistic motion near surfaces, as well as investigate structure-property relationships at the smallest length scales.

Here, we use diamond anvil cell techniques to compress nanocrystals and nanoclusters under hydrostatic and non-hydrostatic pressures. Synchrotron X-ray diffraction is used to detect structural changes within 4 and 6 nm Au nanocrystals. It is found that crystalline defects (e.g. stacking faults) form in the 4 nm nanocrystals under pressure, and remain in the nanocrystals after pressure is removed. In contrast, twins within 6 nm Au nanocrystals are removed during high-pressure compression, such that single crystalline nanocrystals are formed. These single crystalline nanocrystals were found to be metastable. The nanocrystals were recovered after compression, and placed in the TEM, where the nanocrystals reverted to the twinned state under the electron beam.

At even smaller length scales, fcc cuboctahedral and icosahedral nanoclusters such as Au_{21}, Au_{25}, and $Ag_{28}Pt_1$ were compressed while optical absorbance and photoluminescence spectroscopy were performed in-situ. In combination with density-functional theory, it was found that increased interaction between surface metal atoms and the surrounding organic ligands leads to the observed high pressure behavior.

4:30 PM *ST02.04.02
***In Situ* TEM Tensile Testing of Crystalline Metallic Nanowires** Yong Zhu; North Carolina State University, United States

Metallic nanowires have been widely used in a variety of nanoengineering applications, including nanoelectromechanical systems, nanosensors, transparent electrodes, optoelectronics, and flexible and stretchable electronics. Mechanical behaviors of metallic NWs play a crucial role in reliability of the nanowire-based devices. Here I will present the recent work in my group on in-situ nanomechanics of crystalline metallic nanowires inside transmission electron microscope (TEM). First, we report competition of deformation mechanisms - twinning and slip - in single-crystalline metallic nanowires. We found that the competition depends on the cross-sectional shape of the nanowire, which affects the change of surface energy associated with each deformation mechanism. Second, we found unexpectedly, through careful cross-sectional TEM study, that most of the synthesized single-crystalline nanowires include a central twin boundary along the entire length of the nanowire, so we call them bi-twinned nanowires. Here we also found two competing deformation mechanisms - localized dislocation slip and delocalized plasticity via an anomalous tensile detwinning mechanism - depending on the volume ratio between the two twin variants and the cross-sectional aspect ratio.

The mechanism of the observed tensile detwinning was investigated. Furthermore, the twin boundary was found to cause interesting recoverable plasticity and Bauscinger effect, as well as strain hardening. Finally, we probe hydrogen embrittlement using metallic nanowires as a model system. We found increasing yield strength and brittle failure with the presence of hydrogen, which was attributed to the hydrogen-induced suppression of dislocation nucleation at the free surface of nanowires.

5:00 PM ST02.04.03
Molecular Crystal Compaction at the Microscale Daniel Bufford, Christopher M. Barr, Jeremy Lechman and Marcia Cooper; Sandia National Laboratories, United States

Molecular crystals consist of discrete molecules bonded together not by ionic, covalent, or metallic bonds, but by weaker cohesive forces. The almost endless variety of molecular shapes and bonding forces gives rise to a plethora of structures, and, accordingly, deformation and fracture processes that vary greatly among molecular crystals. Mechanical behavior in these materials generally remains less completely understood than in other materials. Small-scale and in-situ mechanical testing approaches have made great contributions to the understanding of deformation mechanisms in many other classes of materials; nanoindentation has already proven useful in examining molecular crystals, but to date in-situ methods have seen little application. This talk present results from single particle compression studies conducted in-situ inside of a scanning electron microscope. Individual micron-sized particles of hexanitrohexaazaisowurtzitane, an organic molecular crystal and energetic material, were compressed to the point of fracture. Challenges and successes in sample preparation, experiment execution, and interpretation of the resulting data will be discussed. The combination of microscopy and quantitative load-displacement data allowed for estimation of stresses and strains associated with yielding and fracture processes, and may suggest an extrinsic size-dependent strength phenomenon. The approach here is generalizable, and may contribute to the understanding of deformation and fracture in other molecular crystals.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. DOE's National Nuclear Security Administration under contract DE-NA-0003525. The views expressed in the article do not necessarily represent the views of the U.S. DOE or the United States Government.

5:15 PM ST02.04.04
Quantifying Size-Dependent Deformation Mechanisms in Metal Nanoparticles via In Situ TEM Mechanical Testing Soodabeh Azadehranjbar[1], Ruikang Ding[1], Andrew Baker[1], Ingrid M. Padilla Espinosa[2], Ashlie Martini[2] and Tevis Jacobs[1]; [1]University of Pittsburgh, United States; [2]University of California, Merced, United States

While bulk material strength is determined by the size of microstructural features, such as the size and distribution of grains, precipitates, twin boundaries or dislocations, nanoscale deformation is strongly dependent on the size of the body being deformed. In the range of tens of nanometers of particle diameter, deformation is accommodated through a Coble-creep-like mechanism where the strength depends on strain rate and the size of the spherical particle. However, even this Coble-creep-like mechanism may break down for single-digit-diameter nanoparticles, when surface faceting becomes dominant.
In the present work, we used *in situ* compression tests of platinum nanoparticles to quantify the size-dependence of deformation mechanisms. Platinum nanoparticles were synthesized with sizes ranging from tens of nanometers down to single-digit nanometers. These particles were compressed inside of a transmission electron microscope (TEM), enabling the combination of high-resolution video with real-time measurement of force and deformation. The morphology and load response of the deforming nanoparticles were analyzed to demonstrate the dominant deformation mechanism in various size regimes. Finally, results were compared with matched atomistic simulations for atomic-scale insight into driving forces and particle behavior.

5:30 PM ST02.04.05
Late News: *In Situ* Observations of Phase Transitions During Berkovich Indentation of Silicon Thin Films Yvonne B. Gerbig and Chris Michaels; National Institute of Standards and Technology, United States

The indentation-induced phase transformation of crystalline silicon thin films was studied *in-situ* during the indentation with a Berkovich probe using Raman spectroscopy-enhanced instrumented indentation. The *in-situ* Raman spectroscopic analysis showed the formation of high-pressure phases during indentation loading, calling into question the common view that pressure release is a pre-condition for this transformation. The observations suggest strain and time as important but overlooked factors in nucleation and growth of high-pressure phases and provide new context to previous works on the pressure-induced phase transformations of silicon.

SESSION ST02.05: Nanoscale Deformation & Fracture

8:15 PM ST02.05.03
Deformation Twinning in $Au_{30}Ag_{70}$ Alloy Nanowire Under Tensile Strain Wonsik Kim[1], Kkotchorong Park[1], Seung Jo Yoo[1,2], Byungil Hwang[3], Bongsoo Kim[1] and Seung Min Han[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Electron Microscopy Research Center, Korea Basic Science Institute, Korea (the Republic of); [3]Chung-Ang University, Korea (the Republic of)

Single element metallic nanowires have been deeply studied for their wide range of applications. Alloyed nanowires are known to have distinct characteristics and deformation behavior compared with single element nanowires that comes from difference in stacking fault energies. They are known to have potential to be used in various plasmonic devices for their chemical stability and broad applicable range of wave lengths. However, more detailed analysis mechanical properties is needed for comprehensive understanding of such material systems. In this study, defect-free single crystalline $Au_{30}Ag_{70}$ alloy nanowires are synthesized by topotaxial growth method and tested in tension using an in-situ pico-indenter. Deformation twinning followed by superplastic deformation of the alloy nanowires is experimentally observed and the critical dimension of $Au_{30}Ag_{70}$ alloy nanowires at which transition from ordinary plasticity to deformation twinning is determined to be ~333 nm, which is about 2 time larger than that of Au nanowires. Stacking fault energy, which is the key element determining the deformation mode, of $Au_{30}Ag_{70}$ alloy nanowires is calculated to be 21 mJ/m^2, which is smaller than that of Au nanowire with stacking fault energy of 31 mJ/m^2. The decrease in the stacking fault energy in the alloy nanowire resulted in stabilization of deformation twinning to a larger critical dimension before transitioning to ordinary plasticity.

8:30 PM ST02.05.04
Late News: The Study of Structure-Mechanical Relationship of SU-8 via *In Situ* Characterization Prakash Sarkar, Prita Pant and Hemant Nanavati; Indian Institute of Technology (IIT), Bombay, India

SU-8 is a cross-linked thermoset polymer which is extensively used for design micro-electrical mechanical system (MEMS) components. The effect of cross-linking amount on the mechanical properties i.e. modulus (E) and hardness (H) was studied using nanoindentation. Different cross-linked samples were fabricated by changing the curing steps (post-exposure baking, hard baking) of standard photolithography process. The accurate measurement of cross-linked segments is done via in-situ Fourier-transform infrared spectroscopy. Nanoindentation experiments were performed under constant strain rate loading conditions. Using the conventional method yielded high E and H values for less cross-linked sample and less values for high cross-

linked samples. A careful analysis showed that the main reasons for these inverse values are adhesion between the tip surface and sample surface, viscoelastic effect on unloading and errors in calculation of contact area. We propose a new methodology to correct for these potential sources of error. Thereafter, less E and H values for less cross-linked sample and high values for high cross-linked sample were obtained. The values are 4.61 ± 0.13 GPa and 5.02 ± 0.18 GPa of E, and 256.97 ± 1.42 MPa and 285.48 ± 1.17 MPa of H for less (~ 82 %) and high (~ 95 %) cross-linked samples, respectively.
Keywords: SU-8; Photolithography process; FTIR; Nanoindentation; SPM

Nanoscale Dynamic Observations of Grain Boundary Fracture, Deformation, Migration and Twin Formation in Ceramics Yuichi Ikuhara[1,2,3]; [1]University of Tokyo, Japan; [2]Japan Fine Ceramics Center, Japan; [3]Tohoku University, Japan

Ceramics have been widely used for structural applications because of their superior mechanical properties. It has been known that the behavior of GB fracture, deformation and migration is strongly dependent on the GB characters such as misorientation angle between two adjacent crystals and GB plane, however, such effect has not been clarified yet. In this study, in order to clarify the atomistic mechanisms of GB fracture and deformation, bicrystal studies have been performed to find the relationship between the atomic structures and GB behavior of $SrTiO_3$ and Al_2O_3 ceramics. Several kinds of bicrystals including GBs with specific geometrical configuration were fabricated, and some of them were doped by rare-earth elements to enhance the GB segregation.

It has been reported that single crystal of $SrTiO_3$ can be plastically deformed even at R.T. by dislocation slip like metals. So far, many experimental investigations have been tried for understanding the dislocation-grain boundary interaction, but these experiments were mostly carried out statically, and the fundamental processes are still not well understood yet. In this study, the nanoindentation experiments were conducted for $SrTiO_3$ crystals their bicrystals inside TEM. The $SrTiO_3$ single crystals were indented with the sharp diamond tip and successfully observed the dislocation dynamics. In the case of the GBs, the interaction between the introduced lattice dislocations and the GBs were directly observed. The dislocation-GB interaction and its dependence on the GB characters will be discussed in detail.

GB fracture in Al_2O_3 is strongly dependent on the GB characters and the dopant segregated at GBs. In order to clarify the atomistic GB fracture mechanism and its dopant effect in Al_2O_3 ceramics, Al_2O_3 bicrystals including GBs with specific geometrical configuration were systematically fabricated, and some of them were doped by rare-earth elements. Then, the atomic structures and chemistry in thus fabricated GBs were characterized by atom-resolved STEM, and the dynamic behavior of GB fracture was observed by TEM nanoindentation experiment. The relationship between GB characters, segregated dopants and GB fracture behavior of Al_2O_3 will be discussed in detail.

It is known that Al_2O_3 shows twin formation at R.T. under high stress concentration. So far, many experimental investigations have been tried for understanding the twin formation mechanism, but these experiments were also carried out statically, and the fundamental atomistic processes are still not well understood yet. In this study, TEM *in situ* nanoindentation experiments were conducted also for Al_2O_3 single crystals and the bicrystals. Al_2O_3 single crystals were indented with the sharp diamond tip, and the twinning dynamics were successfully observed. In this case, the deformation twinning often occurs in the present experimental condition, and the mechanism can be explained by a shear process for each lattice layer, which is caused by twinning dislocations. It is suggested that the non-basal twinning systems, such as the rhombohedral twinning in Al_2O_3, can be completed by not only simple shear but also atomic shuffling. In this study, the dynamic behavior and atomic structures of the twinning dislocations were investigated for rhombohedral twinning in Al_2O_3, and the twin -GB interaction and its dependence on the GB characters will be discussed in detail.

9:15 PM ST02.05.06
Late News: Analysis of Mechanical Behaviour of Ti/TiN Multilayer Using Micro-Cantilever Beam Bending Ashwini K. Mishra[1], Hariprasad Gopalan[2], Marcus Hans[3], Christoph Kirchlechner[4], Jochen Schneider[3], Gerhard Dehm[2] and Nagamani Jaya Balila[1]; [1]Indian Institute of Technology Bombay, India; [2]Max-Planck-Institut für Eisenforschung GmbH, Germany; [3]RWTH Aachen University, Germany; [4]Karlsruhe Institute of Technology, Germany

Nitride ceramics have wide application as a protective coating but suffer extreme brittleness. In this work, the mechanical behavior of physical vapor deposited Ti/TiN multilayer has been studied. Effect of varying layer thickness and volume fraction of elastic-plastic Ti in Ti-TiN multilayer is observed by testing micro-cantilever bending. FEM simulations were carried out for various multilayer thickness and volume fraction to establish the theory behind it. R-curve behavior of multilayer is also discussed using simulation results. Finer spacing in multilayer enhances the fracture toughness of multilayer. Fracture properties of multilayer in comparison to monolithic TiN layer will be reported.

9:30 PM ST02.05.07
Late News: Microscale Mechanical Studies in Barium Titanate—Deformation and Fracture Nidhin G. Mathews[1], Ashish K. Saxena[2,3], Christoph Kirchlechner[2,4], N Venkataramani[1], Gerhard Dehm[2] and Balila N. Jaya[1]; [1]Indian Institute of Technology Bombay, India; [2]Max-Planck-Institut für Eisenforschung GmbH, Germany; [3]Vellore Institute of Technology, India; [4]Karlsruhe Institute of Technology–Institute for Applied Materials, Germany

Barium Titanate (BTO) is a widely used lead-free piezoelectric ceramic used at micron length scales as thin films in MEMS applications. Here we study the mechanical behaviour BTO single crystals and thin film systems using different micromechanical experiments and finite element modelling (FEM). Microscale mechanical behaviour of single crystalline BTO was studied by uniaxial *in situ* micropillar compression for different sizes. It was observed that pillars below 1μm diameter reached their theoretical strength whereas larger pillars yielded at lower stress values with multiple stress drops confirming slip activity. The strain accommodation mechanism at smaller length scales is by plastic flow, with a size exponent close to 1 and enhances the elastic strain limit of the material, which is an important consequence that can be exploited in sensors/actuators. Microcantilever fracture measurements revealed that, single crystal BTO showed a 45% higher K_{IC} than the bulk, while the polycrystalline thin film showed a 60% lower K_{IC} due to the weak inter-columnar boundaries. Different geometrical aspects and loading parameters on the stress intensity factor of single cantilevers are investigated using FEM to propose testing standards that can be used by future users. The variation of stress intensity factor and mode mixity (K_{II}/K_I) with respect to the relative position of the notch, beam cross-section, notch tip radius, notch geometry and arm length of the cantilever and loading direction are studied. Effect of bilayers and elastic modulus mismatch between the layers on the crack driving force are also discussed.

8:00 AM *ST02.06.01
On the Role of Surfaces and Interfaces in Dislocation Nucleation-Controlled Plasticity of Nano-Objects—Comparison of In-Situ Experiments with Atomistic Simulations Zhuocheng Xie[1], Aruna Prakash[2], Saba Khadivianazar[3], Nadine Schrenker[3], Daniel Gianola[4], Erdmann Spiecker[3] and Erik Bitzek[3]; [1]RWTH Aachen University, Germany; [2]Technische Universität Bergakademie Freiberg, Germany; [3]FAU-Erlangen-Nürnberg, Germany; [4]University of California, Santa Barbara, United States

Nanoscale metallic objects like thin films, nanoparticles, nanowires, or nanoporous metals receive sustained attention due to their size-dependent mechanical properties, which can include changes in deformation mechanisms, pseudoelastic behavior and increased yield strength compared to the bulk material. Many of these nano-objects have well-defined morphologies and are initially dislocation-free, which make them ideal model systems to study, e.g. dislocation nucleation and dislocation – interface interactions. These properties of such nano-objects also predestinate them for direct comparisons between experiments and simulations.

Here we present recent results on in situ experiments on single crystalline, nanotwinned and five-fold twinned nanowires as well as on nanoporous gold and compare them with atomistic simulations. The latter allow for controlled variation of the size and morphology, surface quality and loading conditions. Such carful studies allowed to show that twin boundaries not only act as obstacles to dislocation motion leading to hardening, but also fundamentally change the deformation mechanisms and failure mode. The loading mode (tension, compression, bending) and boundary conditions, the location of the twin boundary and most importantly the intersection of the twin boundaries with other interfaces are shown to critically influence the deformation behavior. These observations demonstrate the fundamental differences between dislocation processes in nanotwinned polycrystals and in nanotwinned nano-objects. The simulations furthermore highlight the need for realistic sample sizes and morphologies to capture and understand essential, experimentally-observed, deformation mechanisms.

8:30 AM *ST02.06.02
***In Situ* Mechanical Testing of Elastic and Plastic Properties of Metal Nanowires** Erdmann Spiecker[1], Lilian Vogl[1], Peter Schweizer[1], Nadine Schrenker[1], Xin Zhou[1], Marco Moninger[1], Felix Werner[1] and Gunther Richter[2]; [1]University of Erlangen-Nuremberg, Germany; [2]Max Planck Institute for Intelligent Systems, Germany

In situ microscopy has been established itself as a key technique for studying the mechanical properties of materials at small length scales. In particular, the application of in situ microscopy to nanowires and nanowhiskers has been very successful, not only because such nanostructures can be produced with high quality but also because preparation artefacts like FIB damage can be avoided. As result the intrinsic mechanical properties of nanowires and nanowhiskers can be reliably studied down to very small dimensions. Such investigations consolidated the notion of ‘smaller is stronger’ which refers to an almost universal trend of increased strength with decreasing size of nanostructures subjected to mechanical loads. Reducing the size of nanostructures not only affect their plastic deformation behavior but also changes their elastic properties as result of the increased surface-to-volume ratio. However, the observations of size effects on elastic properties are less consistent and the underlying mechanisms are still controversially discussed.
In this contribution we present results of in situ microscopy studies on individual metal nanowires carried out over the past years at the Center for Nanoanalysis and Electron Microscopy (CENEM) in Erlangen. In the first part we focus on the elastic properties of gold nanowires and demonstrate a profound influence of both, shape and size of the nanowires. The elastic properties are determined using in situ mechanical testing in SEM and TEM by means of resonance excitation and uniaxial tension. The combination of bending and tensile load types, performed subsequently on the same wire, allows for an independent and correlative calculation of the Young’s modulus. For this, the cross-sectional area and resulting second moment of area are determined for each individual nanowire by performing high resolution TEM on FIB cross sections of undisturbed nanowire areas after mechanical testing. Based on a detailed comparison of nanowires with different size and shape we find both cases of softening as well as stiffening, depending critically on the interplay between size and shape of the—

wires. Our results clearly demonstrate that not only size but also shape matters for the elastic properties at small scales. Different models from the literature are discussed which can in part explain the behavior.
In the second part we focus on the plastic deformation behavior and failure modes of five-fold twinned silver nanowires which are used as conduction lines in flexible transparent electrodes. Upon uniaxial straining of such electrodes some nanowires experience tensile loading and fracture while others are set under compressive stress resulting in buckling and kink formation, depending on the orientation of the nanowires with respect to the external load axis. We employ different in situ microscopy techniques in TEM, SEM and light microscopy to study the mechanisms of kink formation for both freestanding nanowires and nanowires on flexible substrates, respectively. We determine the critical strain for kink formation under these conditions and study the fundamental defect mechanisms associated with this deformation mode. Moreover, we demonstrate the potential of in situ light microscopy to study the deformation behavior of single nanowires on flexible substrates under ambient conditions. Finally, we report on first in situ microscopy studies under conditions of cyclic loading and discuss the role of kink formation and nanowire fracture on the overall failure behavior of flexible transparent nanowire electrodes.

9:00 AM ST02.06.03
Late News: Correlating Intrinsic and Extrinsic Damping Factors of Single Nanowire Resonators Using *In Situ* SEM and LM Lilian Vogl[1], Peter Schweizer[1], Peter Denninger[1], Gunther Richter[2] and Erdmann Spiecker[1]; [1]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [2]Max Planck Institute for Intelligent Systems, Germany

Microcantilevers are already successfully implemented in mass sensing devices, offering an improved sensitivity down in the range of few picogram. The performance of such nanomechanical devices is given by a high resonance frequency combined with a high quality factor. While for mass sensing applications the frequency shift is used, the quality factor additionally depends on the ambient medium and scales inversely with the pressure in the molecular flow regime. However, the measureable pressure range of commercial micro-sized cantilevers is restricted, which limits the application ability. To expand the pressure range, the size of the cantilevers has to be further reduced: A beam with a thickness in nm range, would shift and additionally broaden the measurable regime to higher pressure values. Therefore, a precise characterisation of the vibrational properties of nanowires is required, which is the fundament for futher research of next-generation devices.
We present a correlative electron and light microscopic approach to characterize the vibrational properties of single nanowires in dependence of the gas atmospheres and pressure level. The resonance properties of nanowires and the assigned quality factor depends on the pressure of the ambient medium. The high vacuum state of $10^{-6} – 10^{-7}$ mbar in SEM and TEM enables the characterization of the intrinsic vibrational properties, which is directly related to the microstructure and surface quality. To analyze the damping effect caused by the interaction of the gas molecules with the nanobeam, the *in situ* resonance measurements have to be performed within the molecular flow regime (~ 50 mbar -200 mbar). For this purpose, the single nanowire is mounted within a compact chamber for the light microscope, which allows to observe the changing resonant behavior in dependence of the applied gas atmosphere (He, N_2, Air, Ar) and pressure level. By using the resonance vibration, we demonstrate the pressure sensing capability of a single nanowire. Moreover, the damping effect is used to examine the molar mass of the surrounding atmosphere and therefore the nanowire can be seen as ultrathin nanoscale resonant gas sensor. The *in situ* measurements of the same nanowire in the electron and light microscope offers the opportunity to analyze the complex interplay of several damping factors and gives direct insights in the vibrational behavior. While the intrinsic damping factor can be tuned by the microstructure, the nanowire thickness determines the sensitive pressure regime. The extrinsic factors are given by the interaction of the vibrating nanobeam with the surrounding gas atmosphere and are used for sensing applications.

9:15 AM DISCUSSION

9:30 AM ST02.06.05
A Study of Mechanical Size Effects by Optical Means—Using Reflectance Anisotropy Spectroscopy to Test Metallic Thin Films at Smaller Scales Micha Calvo and Ralph Spolenak; ETH Zürich, Switzerland

Thin film technologies have enabled the life we know today. There is barely any product released in today's market that does not involve thin film technologies at any point during its fabrication. As less material usually means lower costs, these thin films have been downsized to the dimension that is just barely sufficient to fulfill their purpose. For applications like e.g. diffusion-barriers or reflective coatings these dimensions are reaching nowadays well below 20 nm.
It is of interest to study films of small dimensions, because the material exhibit different properties at small length scales, usually referred to as size effects. Mechanical size effects have been studied extensively during the last two decades. Amongst others, by the means of Nano-indentation, Synchrotron XRD, Wafer-curvature, micropillar-compression, bulge-testing, cantilever-bending, nanowire-tensile experiments, and lately also by Reflectance Anisotropy Spectroscopy (RAS).
When it comes to polycrystalline thin films however, all the above mentioned techniques (except RAS) are getting less reliable when it comes to ultra-thin films, with thicknesses below 50 nm. This is due to the nature that the probed interaction volume becomes too small and the signal-to-noise ratio decreases. In our setup, we use white light from a common Xe-lamp for excitation. For metals at these optical frequencies, the interaction volume is confined to a few tens of nanometers below the surface. This makes RAS an excellent candidate to investigate metallic ultra-thin films below 50 nm.
RAS is best described as phase-modulated near-normal incidence Ellipsometry. It probes the difference of reflectance in two orthogonal directions, which correspond to anisotropies in the dielectric function. The Piezo-optical tensor relates strain to the dielectric function, which makes this technique highly sensitive to anisotropic changes in lattice spacing (e.g. under uniaxial loading). The method is not limited to any material or materials class, as long as the films are continuous and the material has an electronic transition in our detection range (1.5 - 5.5 eV). Our metallic films are on a flexible substrate, which allows us to strain them considerably in uniaxial tension. By the subsequent unloading of the stress the polymeric substrate drives the metallic film into compression. This is required as the technique is blind to residual biaxial strains.
We will present a new *in-situ* mechanical size effect study on pure fcc metals (namely gold, copper, and silver) down to 20nm thin polycrystalline films on flexible substrates. Sample fabrication has been proven most critical, as the technique is highly sensitive to surface morphology (e.g. anisotropic pores, roughness) and texture. To reduce roughness of the metal surface that is probed a substrate transfer is performed after deposition, usually referred to as template stripping. This results in metallic thin films on polymeric substrates with the same roughness as a silicon wafer. We will clearly outlay the potential as well as the limitations of this technique.

9:45 AM ST02.06.06
Analyzing the Fracture Characteristics of Twisted Tri-layer Graphene using Molecular Dynamics Hassan Shoaib[1,2,3], Qing Peng[1] and Abduljabar Alsayoud[1,2,3]; [1]King Fahd University of Petroleum and Minerals, Saudi Arabia; [2]Saudi Aramco, Saudi Arabia; [3]King Abdullah University of Science and Technology, Saudi Arabia

The field of Graphene Twistronics has been gaining significant traction in recent times due to the excellent superconductive behavior of these materials and their potential use in various applications. However, while the electronic properties of twisted multi-layered graphene have been extensively studied in the literature, there is a lack of research concerning the mechanical properties of twisted tri-layer graphene (tTLG). Therefore, this paper aims to mechanically test tTLG under tensile loading and evaluate the mechanical properties by constructing an accurate model of the system using a twist angle of ± 1.53 ° which is known to exhibit highly superconductive behavior. To develop our system and assess the fracture mechanism, we opted to use the AIREBO-M potential to precisely mimic the behavior of multi-layer graphene with varying sizes of cracks. The results indicate that TTLG possesses exceptional mechanical properties with pristine tTLG exhibiting a Young's modulus of 1.506 TPa and an ultimate strength of 146.36 GPa. Furthermore, the fracture characteristics are also excellent with a fracture toughness of 4.79 ± 0.085 MPa $M^{1/2}$ and as expected, the critical stress reduces with increasing crack size a0. it also interesting to note that critical strain equilibrates to approximately 0.072 after a crack length of 1.85 nm. Twisted Tri-layer graphene has been known to exhibit exceptional electrical properties and this study validates the excellent mechanical properties as well.

New Insights into Plasticity by Combining Nanomechanics, High-Resolution Characterization and Simulation Ruth Schwaiger; Forschungszentrum Jülich GmbH, Germany

Mechanical behavior of crystalline materials strongly depends on the microstructure and its evolution at different length scales which is governed by, e.g., crystallography, the distribution of defects, grain morphology, or texture. Understanding and predicting macroscopic mechanical responses requires appropriate descriptions of the micro- and nanoscale response, i.e., the evolution of the underlying microstructure, or intra- and inter-granular stresses. Following the advancement of experimental techniques, it is becoming possible to link computational models with real-life observations of deformation and failure.

In this presentation, an overview of current approaches integrating advanced experimental methods with high-resolution characterization and modeling will be discussed in the context of dislocation plasticity. In situ microcompression experiments, electron backscatter diffraction, and high-resolution digital image correlation allow the determination of local strains and identification of activated slip bands. In combination with transmission electron microscopy and computational analysis, the formation of dislocation structures and the interaction of dislocations with grain boundaries is analyzed. Geometrically necessary dislocation densities can be quantified at the nanoscale by using electron diffraction methods and the Kröner-Nye dislocation density tensor, thereby giving insights into, e.g., the indentation size effect. With those methods, experiment and simulation move closer together facilitating an understanding of relevant mechanisms in plasticity and fracture.

12:15 PM *ST02.07.02
Micromechanics with A.I.—Towards Combining High Resolution with Statistical Observations Setareh Medghalchi[1], Carl Kusche[1], Talal Al-Samman[1], Ulrich Kerzel[1,2] and Sandra Korte-Kerzel[1]; [1]RWTH Aachen University, Germany; [2]IUBH International University of Applied Sciences, Germany

High performance materials, from natural bone over ancient damascene steel to modern superalloys, typically possess a complex structure at the microscale. Their properties exceed those of the individual components and their knowledge-based improvement therefore requires understanding beyond that of the components' individual behaviour. Electron microscopy has been instrumental in unravelling the most important mechanisms of co-deformation and in-situ deformation experiments have emerged as a popular and accessible technique. However, a challenge remains: to achieve high spatial resolution and statistical relevance in combination. Here, we overcome this limitation by using panoramic imaging and machine learning to study damage in a dual phase steel. This high-throughput approach now gives us strain and microstructure dependent insights into the prevalent damage mechanisms and allows the separation of inclusions and deformation–induced damage across a large area of this heterogeneous material. Aiming for the first time at automated classification of the majority of damage sites rather than only the most distinct, the new method also encourages us to expand current research past interpretation of exemplary cases of distinct damage sites towards the less clear-cut reality. Often, the collection of ground truth data may be the limiting step, for this reason we will also addressed using data augmentation to achieve transferability, for example between different stress states like uniaxial, bending and biaxial loading.

12:45 PM ST02.07.03

Atomistic Simulations of the Facet-Dependent Deformation of sub-10-nm Platinum Nanoparticles Ingrid M. Padilla Espinosa[1], Ruikang Ding[2], Andrew Baker[2], Soodabeh Azadehranjbar[2], Tevis Jacobs[2] and Ashlie Martini[1]; [1]University of California, Merced, United States; [2]University of Pittsburgh, United States

Small metallic nanoparticles are promising in a variety of fields due to their chemical, optical and electronic properties. Understanding the deformation mechanisms and mechanical response of these small nanoparticles to compression is necessary to determine their stability and suitability for applications. Most prior descriptions of nanoparticle deformation, such as Cobble-creep-like deformation, are defined assuming spherical nanoparticles. However, at very small sizes (<10 nm), metallic nanoparticles tend to form different shapes (such as icosahedra, dodecahedra, and cubes). The shape/size dependency of nanoparticles is a result of the anisotropy of the surface energies of the different facets. These facets determine the mechanical deformation of the small nanoparticles because different facets facilitate or impede processes such as atomic diffusion and defect nucleation.
Here, molecular dynamics simulations were performed to understand the relationship between faceting and the mechanical deformation of platinum nanoparticles. Simulated compression tests were performed, with matched conditions to *in situ* experimental testing inside of a transmission electron microscope. Dynamic facet rearrangement was observed during compression, and qualitatively linked as a result of crystal deformation, dislocation mobility, and residual mechanical strain. Taken together, the simulated and experimental results demonstrate the size- and facet-dependence of deformation in small platinum nanoparticles.

Evaluation of Uncertainty in Clustering of Nanoindentation Data Bernard Becker, Eric Hintsala, Benjamin Stadnick, Ude Hangen and Douglas Stauffer; Bruker Nano Surfaces, United States

High throughput nanoindentation is powerful technique for evaluating highly localized mechanical properties in materials with complex microstructures. This allows for study of spatial and statistical variations in properties for materials with different phases or features of interest. Prominent examples include composite materials, multi-phase metallic alloys, gradient microstructures, or heat affected zones from processing. This makes it useful for speeding up development of new structural materials, especially since a lot more data can be generated versus traditional bulk mechanical testing for the same sample preparation time. This data can furthermore be easily correlated to the microstructure through use of complementary techniques, such as scanning electron microscopy and electron backscatter diffraction. In order to extract useful information from these techniques, automated analyses also need to be developed in tandem since such datasets are composed of many thousands of points, typically.
We have been exploring clustering as such an accompanying analysis technique. This encompasses several algorithms which are used to group similar data together. The primary current application is getting statistics from individual phases in the microstructure. This can also identify the size and position of these phases. In the future, more advanced analyses are expected to be developed as well. For now, determining the best clustering methods is still a relevant question. Many algorithms exist to choose from, along with choosing the correct number of clusters, how to do outlier removal, and the number of measurements needed to capture the property distributions. To that end, we have been developing an analytical framework based upon bootstrapping to compare the bias and uncertainty in different clustering techniques, as applied to nanoindentation. This will be demonstrated on complex structural materials, including Damascus steel, dual-phase iron high entropy alloys, and additively manufactured T91.

1:15 PM ST02.07.05
Density Functional Theory and Molecular Dynamics Simulations of Shock Wave Propagation Through Polymer/Ceramic Multilayers Nuwan Dewapriya and Ronald Miller; Carleton University, Canada

The thermodynamic equilibrium states of materials under shock loading (i.e. the shock Hugoniot) can be used to characterize their high strain-rate behaviors. The shock Hugoniot for a given material is generally obtained by conducting shock wave experiments. The current experimental techniques are, however, unable to elucidate all the complex atomistic mechanisms associated with the shock wave propagation, which can only be realized

through comprehensive atomistic simulations. For example, first-principle density functional theory (DFT) calculations can be used to compute the shock Hugoniot of materials with very high accuracy. However, the system size that can be simulated in DFT is quite small (a few hundred atoms) due to the extremely high computational cost associated with DFT, which could be problematic if the dynamic response of the systems is size-dependent. Moreover, the high computational cost of DFT only allows us to model the equilibrium thermodynamic state behind the shock front (i.e. the Hugoniot states), rather than the dynamic shock wave propagation itself. Alternatively, classical molecular dynamics (MD) simulations can be used to explicitly model the shock wave propagation in larger systems containing millions of atoms. In addition to providing the shock Hugoniot, the explicit modeling of the shock wave propagation provides more useful information like spatiotemporal evolution of temperature and pressure.

In this work, we first conducted both DFT-based-quantum and classical MD simulations to obtain the shock Hugoniot of polymers and compared them with the existing experimental data. This exercise revealed the upper limits of the shock wave speed that can be accurately modeled using classical MD. Thereafter, we employed classical MD to explicitly model the dynamic shock wave propagation and spallation of polymers as well as polymer/ceramic multilayers. We conducted DFT calculations to obtain accurate MD force field parameters to model the adhesive interactions between the polymer and the ceramic. In order to investigate the atomistic mechanisms associated with the penetration process, we conducted full-scale classical MD simulations of ballistic impact tests of the polymer/ceramic multilayers. Our study demonstrates that the atomistic simulations provide a great insight into the nanoscale mechanisms associated with the dynamic behavior of materials under extreme conditions.

1:30 PM ST02.07.06
Late News: Slip and Deformation Twinning Mechanisms on First Order Pyramidal Plane of Magnesium—Molecular Dynamics Simulations and First Principal Studies Reza Namakian[1], George Voyiadjis[1] and Piotr Kwasniak[2]; [1]Louisiana State University, United States; [2]Center of Digital Science and Technology, Cardinal Stefan Wyszynski University in Warsaw, Poland

Molecular dynamics (MD) simulations and first-principles calculations are carried out on first order pyramidal plane (FOPP) of magnesium (Mg) to study both compression twinning (CTW) and dislocation slip. To this end, a generalized stacking fault energy (GSFE) analysis is employed on dense and loose spaced planes of Mg FOPP. The crystal shearing resistance is extracted by using a minimum-energy path (MEP) finder called the nudged elastic band (NEB) method. The MEP regarding slip system on loose plane of FOPP shows that the unfaulted crystal structure is recovered in the middle of the path with non-straight and pronounced curved slip trajectories. Besides, it will be revealed that metastable configurations on the half of the MEP for the slip system are indeed related to a dissociated extended dislocation of loose pyramidal-I slip. Also, after extracting the dissociation mechanism related to this dislocation, it will be shown that loose pyramidal-I slip can involve shuffling. Moreover, the MEP for dense pyramidal-I slip shows transmutation of this slip into CTW in the middle of the path. This transmutation process will be further examined on CTW growth, and it will be demonstrated that this CTW mechanism is energetically more favorable compared to other twinning mechanisms.

SESSION ST02.08: Quantitative In Situ Deformation
Session Chair: Kelvin Xie
Friday Afternoon, April 23, 2021
ST02

2:15 PM *ST02.08.01
Novel *In Situ* TEM Analysis for Amorphous Materials Enabled by Fast, Sensitive Detectors Thomas C. Pekin[1], Christoph Gammer[2], Colin Ophus[3], Robert O. Ritchie[3,4] and Andrew M. Minor[3,4]; [1]Humboldt-Universität zu Berlin, Germany; [2]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria; [3]Lawrence Berkeley National Laboratory, United States; [4]University of California, Berkeley, United States

Four dimensional scanning transmission electron microscopy (4DSTEM) is a versatile and powerful electron microscopy technique that has been used to measure strain, polarization and orientation, among other properties, at the scale of traditional TEM analysis. This technique, enabled by a new generation of electron detectors, is based on the computational analysis of thousands to hundreds of thousands of diffraction patterns rapidly acquired while the electron beam is scanned across a sample. It can further be combined with *in situ* TEM to provide novel insight into bulk metallic glasses (BMG). This talk will highlight how the evolution of strain and structural order in bulk metallic glasses prior to shear band formation can be spatially correlated during *in situ* deformation. The development of *in situ* heating and crystallization 4DSTEM techniques for BMGs will also be discussed. Additionally, if time allows, this talk will cover some of the more versatile aspects of 4DSTEM, such as *in situ* strain mapping in crystalline materials, orientation mapping nanoparticle grains, and the development of the software required to perform the analysis shown.

2:45 PM *ST02.08.02
Probing Deformation Mechanisms in Ultrafine Grained Al and Au Thin Films by Quantitative *In Situ* TEM Deformation Josh Kacher, Sandra Stangebye, Yin Zhang, Ting Zhu and Olivier Pierron; Georgia Institute of Technology, United States

Understanding dislocation generation mechanisms and interactions with obstacles such as grain boundaries and other dislocations is central to understanding the mechanical behavior of metals and alloys. This has motivated decades of research into the unit processes governing dislocation interactions by *in situ* transmission electron microscopy (TEM) mechanical testing, resulting in the establishment of basic rules that govern how these interactions occur. However, much of this research has focused on the deformation of coarse-grained polycrystals where the grain boundaries are largely isolated from each other and dislocation glide is primarily transgranular. In ultrafine grained and nanocrystalline materials, the high volume fraction of grain boundaries can lead to the activation of additional deformation mechanisms, such as grain growth, grain boundary sliding, and intergranular dislocation propagation. This paper presents results on quantitative *in situ* TEM experiments of deformation of ultrafine grained materials with a focus on deformation-induced grain boundary migration. A unique aspect of this study is the ability to measure the apparent and true activation volumes associated with the material deformation using a micro-electromechanical system (MEMS)-based deformation platform. This study also takes advantage of progress in electron detection technology, with simultaneous high and low resolution recording now possible via digital zoom.

In this paper, I will discuss our results from two different systems: nanocrystalline Al and ultrafine grained Au thin films. In both cases, grain growth accompanies the deformation, but the rates and migration behavior differ significantly. The reasons for these differences, including the activity of disconnections and the role of grain boundary character, will be discussed and explored using atomistic simulations. I will also discuss the effects of the electron beam on deformation mechanisms, which are significant even when operating well below the knock-on damage threshold. This influence can be seen in the deformed microstructure and quantified via activation volume measurements.

3:15 PM *ST02.08.03
Integration of Microscopy and Data Science to Access Multiscale Defect Distributions Mitra Taheri; Johns Hopkins University, United States

Grain boundary (GB) stability may be defined as the ability of a GB to continue to absorb point defects without becoming saturated and without changing its macroscopic degrees of freedom (misorientation, inclination), or degrees of freedom. Much debate revolves around local GB stresses and how they evolve with radiation. Through the use of quantitative in situ microscopy, atomic and mesoscale simulations, and machine learning, we explore how GBs evolve as a function of point defect absorption, and specifically, how local stresses evolve throughout the dynamic radiation process. The results have profound implications in developing thermally stable, bulk nanocrystalline materials, and damage tolerant materials.

3:45 PM ST02.08.04
Late News: Atomistic Processes of Grain Boundary Phase Transformation During Shear-Mediated Migration Zhengwu Fang and Scott X. Mao; University of Pittsburgh, United States

Stress-driven grain boundary (GB) migration can lead to grain growth and GB network evolution during the deformation of polycrystalline materials. The theoretical models with disconnection, dislocation, and shuffling mechanisms have been proposed to describe the GB migration. However, GB phase transformation during migration, the process of which cannot be described by these models, has never been explored experimentally at the atomic scale, especially for asymmetrical tilt GBs (ATGBs), one of the most common GBs in polycrystalline materials. Here, by performing in-situ high-resolution transmission electron microscopy, GB phase transformation was discovered at two faceted ATGBs in Au. Both of them were found to form $\sum 11(113)$ symmetrical tilt GBs, either via facet phase transformation or GB dissociation, during the shear-mediated migration process, which was further confirmed by molecular dynamics simulations. This work provides the first insights into the atomistic mechanisms of GB dynamic phase transformation during the migration of ATGBs and the impact of it on the microstructural control during the thermal-mechanical processing in polycrystalline materials.

4:00 PM ST02.08.05
Quantitative *In Situ* Study of Strength-Governed Interfacial Failure Between h-BN and Polymer-Derived Ceramic Boyu Zhang[1], Xing Liu[2], Hua Guo[1], Kaiqi Yang[1], Brian W. Sheldon[2], Huajian Gao[3,2] and Jun Lou[1]; [1]Rice University, United States; [2]Brown University, United States; [3]Nanyang Technological University, Singapore

Nanomaterials, such as carbon nanotubes, hexagonal boron nitride (h-BN) and graphene platelets, are promising candidates for reinforcing ceramic matrix composites. They are known for their high strength and have shown potential for improving the fracture toughness of monolithic ceramics. Much of the current understanding of these nano-reinforcements is based on extrapolation from the existing literature on much larger reinforcements such as microfibers. According to these studies on micro-reinforcements, the interaction between a crack and the interface is typically an energy governed process. However, in the case of nano-reinforcements, especially 2D reinforcements, this mechanism has yet to be fully explored due to the lack of systematic experimental studies on the interfacial properties of composites reinforced with nanomaterials.
In this work, the interfacial behaviors between multi-layer h-BN nanosheets and a polymer-derived ceramic (PDC) were investigated to promote the understanding of interfacial failure at small scales with *in-situ* pull-out experiments. By using nanoindentation-assisted micro-mechanical devices integrated with scanning electron microscopy (SEM), the detailed interfacial sliding and debonding behaviors between 2D materials and ceramic matrix were quantitatively measured for the first time. Interfacial mechanical properties, *i.e.*, interfacial modulus and strength, were measured to be 5.65 ± 1 GPa*μm^{-1} and 66.4 ± 16.8 MPa, respectively. Furthermore, based on the experimental observations, an analytical cohesive shear-lag model was established to understand the failure mode of the interface in h-BN/PDC composite. It is found that the strength of the interface, rather than interfacial fracture energy, governs the interfacial failure at nanoscales, which provides valuable insight that is expected to motivate future work on the mechanical properties of nanomaterial-reinforced composites.

5:15 PM ST02.09.01
Predicting the Long-Time Creep Dynamics of Gels from Their Static Structure by Machine Learning
Han Liu and Mathieu Bauchy; University of California, Los Angeles, United States

Upon sustained loading, gels tend to feature delayed viscoplastic creep deformations. However, the relationship, if any, between the structure and creep dynamics of gels remains elusive. Here, based on accelerated molecular dynamics simulations and classification-based machine learning, we reveal that the propensity of a gel to exhibit long-time creep is encoded in its static, unloaded structure. By taking the example of a calcium–silicate–hydrate gel (the binding phase of concrete), we extract a local, non-intuitive structural descriptor ("softness") that is strongly correlated with the dynamics of the particles—wherein the macroscopic creep rate exhibits an exponential dependence on the average softness. We find that creep results in a decrease in softness in the gel structure, which, in turn, explains the gradual decay of the creep rate over time.

5:30 PM ST02.09.02
Late News: *In Situ* Raman Spectroscopic Measurements of Silicate Glasses During Indentation Yvonne B. Gerbig and Chris Michaels; National Institute of Standards and Technology, United States

This talk describes the design and integration of a custom-built optical instrument for in-situ Raman microscopy suitable for collecting high-quality spectroscopic data during the indentation of glass materials. It will further show that the reported experimental setup and optimized experimental parameters enable meaningful in-situ spectroscopic observations during indentation of fused silica at forces in the millinewton range. In this context, the talk will also touch upon possible pitfalls in in-situ Raman measurements on indented glasses and describe the misinterpretations that may result.

5:45 PM DISCUSSION

6:00 PM ST02.09.04
Spectroscopic Explorations of Thermal Transitions of Polyurea Nha Uyen Huynh[1,2] and George Youssef[1]; [1]San Diego State University, United States; [2]University of California, San Diego, United States

The quest for in-situ characterization has placed an emphasis on spectroscopic methods with penetrative, noninvasive, nondestructive attributes, thus bringing terahertz-based techniques to the forefront. Terahertz time-domain spectroscopy operating in the transmission mode is most suitable for investigation of polymers in-situ or ex-situ. Polymers are nearly transparent to terahertz waves, indicating inheritance of the molecular information by the propagating electromagnetic wave as it interacts with the polymer continuum, regardless of the sample form. The research leading to the presentation is focused on elucidating the thermal transition, e.g., glass transition, of polyurea. Polyurea is a thermoset elastomer prepared by mixing oligomeric diamine and diphenylmethane diisocyanate at a stoichiometric ratio of 96%, yielding a viscoelastic polymer with significant strain-rate sensitivity. Polyurea has been integrated in a plethora of applications due to its superior physical properties, the prime of which is the impact mitigation to guard structures and human from hypervelocity projectiles and biomechanical dynamic loading, respectively. However, prolonged exposure to environmental conditions was reported to deteriorate the material and adversely affect its mechanical properties. Therefore, this research strives to elucidate the structure-property interrelationship of polyurea using the noninvasive THz-TDS technique as a function of temperature spanning from -103°C to -3°C since the glass transition temperature of polyurea was previously reported to be -49°C. The approach is to control the temperature of the sample in a cold finger by isothermally soaking at each temperature step for 2 min, before collecting the terahertz signal

with the sample in the propagation path with a spectral bandwidth of 1.7 THz extending from 0.3 - 2.0 THz and peak width of 0.18 mm. The time-domain data was transformed to the frequency domain using discrete Fourier transform. The optical and dielectric properties were deduced from the spectral data of each sample, where a shift in the sensitivity to change of the optical properties with respect to temperature was noticed around the thermal transition of polyurea. The polyurea samples, with ~16 mm diameter, were extracted from a 1 mm sheet that was prepared using slab molding technique, where a subset of the samples were continually exposed to ultraviolet radiation of 15 weeks at an exposure level of 5122 mJ/cm^2/hr and 8553 mJ/cm^2/hr of UV-A and UV-B, respectively. This prolonged exposure resulted in discoloration, minor changes in the elastic, hyperelastic, and viscoelastic behavior, and materials degradation in the form of crazing and microcracks. However, the extent of degradation was found to be limited to 45 μm below the surface, which is thought to attribute to the insignificance of the property changes. Investigation with THz-TDS in cryogenic temperature was able to accurately identify the glass transition temperature and radiation-related changes, since changes in molecular vibrations associated with conformational changes are encoded in the terahertz signal as it propagates through the sample. Future research seeks to couple the experimental results with molecular dynamic simulations to accurately elucidate the type and source of conformational changes.

6:15 PM ST02.09.05
Late News: Rheological Yielding in Nanotube Reinforced Metallic Composites Kang Pyo So, Myles Stapelberg, Yu Ren Zhou, Mingda Li, Mike Short, Ju Li and Sidney Yip; Massachusetts Institute of Technology, United States

We propose and demonstrate a rheological yielding mechanism in metallic matrix nanotube composites, which may aid in improving the mechanical properties of such composites. Machine learning-based analysis of *in situ* transmission electron microscopy (TEM) tensile test videos is used to identify microstructural defects in an aluminum-carbon nanotube (CNT) nanocomposite and thereby uncover nanoscale yielding processes during mechanical deformation. Observed defects near CNTs include notch evolution, new surface creation, material sliding, dislocation glide/cross-slip, and localized shear strain at <100nm length scale. Non-shearable CNTs provide strong pinning points against dislocation glide or cross-slip, triggering high local shear strains, which result in deformation via shear transformation. CNTs parallel to the load axis bridge evolving notches, hindering further penetration and inducing substantial nanoscale load transfer, which may contribute to the exceptional strength observed in these Al-CNT composites.

Late News: Condensation Induced Blistering as a Measurement Technique for Adhesion Energy of Nanoscale Polymer Films Jingcheng Ma, David Cahill and Nenad Miljkovic; University of Illinois at Urbana-Champaign, United States

Polymeric coatings having nano-to-microscale thickness show immense promise for enhancing thermal transport, catalysis, energy conversion, and water collection. Characterizing the work of adhesion (G) between these coatings and their substrates is key to understanding transport physics as well as mechanical reliability. Due to the rapid development of nanoscale devices and coatings, there is an increasing need to develop methods to quantitatively measure the work of adhesion at ever smaller length scales, both in terms of lateral spatial resolution (< 100 μm) and film thickness (< 100 nm). Experimentally quantifying the work of adhesion of nanoscale films with high spatial resolution is difficult. The most common method for measuring work of adhesion involves characterizing the contact or ‘pull-off’ force between a probe coated with the thin film of

interest and the surface of interest using atomic force microscopy. However, surface force measurement is highly sensitive to adsorption of airborne hydrocarbons or water vapor on the test surface. To obtain accurate measurements of adhesion, it is necessary to separate the two surfaces of interest prior to interaction with the surrounding atmosphere. Conventional mechanical approaches for adhesion energy measurement, such as the peel test and four-point bending test delaminate the film from its substrate directly, thus preserving the interface. However, these methods are only appropriate at larger scales (> 1 mm lateral length for adhesion measurement) due to the difficulty of applying the delamination force without damaging the film via stress concentration. Here, we demonstrate that water vapor condensation blistering is capable of *in situ* measurement of work of adhesion at the interface of polymer thin films with micrometer spatial resolution. We use our method to characterize adhesion of interfaces with controlled chemistry such as fluorocarbon/fluorocarbon (CF_n/CF_m, n, m = 0 ~ 3), fluorocarbon/hydrocarbon (CF_n/CH_m), fluorocarbon/silica (CF_n/SiO_2) and hydrocarbon/silica (CH_n/SiO_2) interfaces showing excellent agreement with adhesion energy measured by the contact angle approach. We demonstrate the capability of our condensation blister test to achieve measurement spatial resolutions as low as 10 μm with uncertainties of ~10%. The minimization of energy dissipation enables us to probe extremely weak adhesion, which can be as low as 10^{-6} J/m^2 at Sapphire/Teflon interface. The outcomes of this work establish a simple tool to study interfacial adhesion.

Fracture of Micro-Architected Solids—Does a Toughness Exist? Angkur Shaikeea[1], Huachen Cui[2], Rayne Zheng[3] and Vikram S. Deshpande[1]; [1]University of Cambridge, United Kingdom; [2]Virginia Tech, United States; [3]University of California, Los Angeles, United States

Rapid progress in additive manufacturing methods has led to the creation of a new class of ultralight, stiff and strong 3D architected metamaterials comprised of a network of struts resembling a periodic truss structure. The performance of these micro-architected metamaterials is ultimately be limited by their tolerance to damage and defects, yet experimental investigations of their fracture toughness have remained elusive primarily due to manufacturing limitations. Using octet-truss metamaterial specimens comprising in excess of a million unit-

cells we show that not only is stress intensity factor, as used in conventional elastic fracture mechanics, is insufficient to characterise fracture in these metamaterials but also that conventional fracture test methods using two-dimensional specimens with through-thickness cracks are inappropriate. Via a combination of finite element (FE) calculations and asymptotic analyses we extend the application of the ideas of fracture mechanics to metamaterials with a view to developing a continuum theory and measurement protocol for the failure of such architected metamaterials.

8:55 AM ST03.01.02
Effects of Buckling Struts on the Fracture Toughness of Triangular Lattices Melle Gruppelaar, Eral Bele and PJ Tan; University College London, United Kingdom

Introduction and Aim
Microarchitected lattices have attracted significant interest as lightweight, resource-efficient structural materials. One of their notable advantages is the ability to attain high weight-specific mechanical properties by manipulating how material is distributed in space. Here, we will present numerical and experimental results to reveal how the buckling of struts, hitherto neglected, affects the crack tip field, the location of fracture initiation and propagation, and their concomitant effects on the fracture toughness of regular triangular lattices.

Hitherto, the fracture toughness of lattices had mainly been studied numerically, assuming idealized geometry and material properties, and specimen size that is free from the influence of edge effects. The above can all have a significant impact upon the deformation of stretch-dominated lattices with slender struts (low relative density) even in the absence of material nonlinearities, but few studies have examined how local geometric instability affects fracture initiation and the subsequent crack growth in 2D prismatic lattices.

Methods
The influence of strut buckling in elastic-brittle triangular lattices is assessed numerically, through a Boundary Layer Method (BLM) for infinite-sized specimens, and results compared to those from simulations of finite-sized, Single Edge Notched Tension (SENT) specimens. In the former, crack-tip displacements field from LEFM were imposed as periodic boundary condition to a Representative Volume Element, and the latter follows the standard procedure described in BS8571:2018. Eigenvalue analysis was performed and it will be shown that stress-bifurcation (buckling) in the struts can occur under certain conditions prior to fracture. The effects of mixed-mode loading are also evaluated using the BLM through a range of boundary conditions with varying Mode I and Mode II contributions. Interaction between buckling and intrinsic size-effects of finite-sized specimens is addressed for lattices with $16<W/l_0<128$ cells across the width, and crack-sizes of $0.15<a/W<0.65$, where W is specimen-width, a is the crack-length and l_0 is the characteristic length of the unit cell. For validation, experimental results using SENT specimens, manufactured by laser-cutting of PMMA sheets, will also be presented.

Results
It is demonstrated that stress bifurcation in struts near the crack-tip occurs below a critical transition relative density. The latter is sensitive to the nonlinear strain of the strut material and shows good agreement with predictions by elastic buckling calculations. In infinite-sized lattices, the fracture initiation in pure Mode I loading is insensitive to buckling, however increased Mode II contribution leads to earlier onset of buckling and fracture at loads up to 70% lower than initially predicted. These phenomena are observed at practically relevant relative densities (up to ρ=0.2), *e.g.* a reduction of 68% at ρ=0.1. Finite-sized SENT specimens reveal fracture initiation in the post-buckling regime, with toughness values up to 60% below that predicted by standard scaling law. In deeply notched finite-sized specimens ($a/W>0.48$), buckling and fracture are first observed at the remote edge from the crack. Experimental results confirm the occurrence of strut buckling before fracture in SENT specimens and validate the numerically obtained fracture toughness scaling law.

Conclusions
It is shown that elastic strut buckling is an active mechanism in the fracture initiation of lattice materials, and

can lead to material failure at smaller loads than predicted by current analyses. Finite deformation of individual struts is shown to significantly affect the bulk mechanical properties of the lattices.

9:10 AM ST03.01.03
Tailoring the Mechanical Properties of High-Strength Mechanical Metamaterials Chantal Kurpiers[1], Artur Böttcher[1], Stefan Hengsbach[1] and Ruth Schwaiger[2]; [1]Karlsruhe Institute of Technology, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Technological advances in additive manufacturing techniques have enabled the fabrication of novel three-dimensional nano- and micro-architected lattice materials, which facilitate the exploration of yet unreachable property combinations. Specifically designed lattice materials have great potential in particular in the field of lightweight materials, since high specific strength and stiffness combined with low densities and remarkable robustness can be achieved. For the fabrication of geometrically complex structures with small feature size, light-based additive manufacturing methods, such as 3D direct laser writing (3D-DLW), are the most promising ones. In combination with various post-processing steps, such as annealing, pyrolysis, and the application of coatings, the overall behaviors of the printed structures can be further adapted. However, the failure processes are not yet clear, in particular since the writing parameters themselves might affect the materials properties very locally affecting individual components of the architectures.
In this work, we fabricated tetrahedral microlattices via 3D-DLW using two different photoresists (IP-Dip, IP-S). The writing parameters were varied during the writing process of the microlattices to induce local changes of the material properties. The polymeric structures were then converted into glassy carbon through pyrolysis, which is accompanied by significant shrinkage of the lattices depending on the selection of temperatures. The mechanical behaviors of both the lattices and materials was investigated by compression tests using a nanonindenter. Raman Spectroscopy and X-ray Photoelectron Spectroscopy (XPS) were applied to further characterize the structural variations. A variation of the 3D-DLW parameters and the post-processing steps showed a significant influence on the materials structures and therefore the deformation and failure behavior of the microlattices. Understanding the relation between the chemical morphology and the mechanical behavior will contribute to our understanding and prediction of properties of architectures fabricated through 3D-DLW, which will further enhance the applicability of high-strength mechanical metamaterials.

Late News: Mechanical Properties of a Truncated-Hexagonal Lattice Milad Omidi and Luc St-Pierre; Aalto University, Finland

Bending-dominated lattices offer superior energy absorption capacities and one of the most commonly used topologies is the hexagonal lattice. This architecture is frequently used as the core of sandwich panels, for example, because its simple geometry can be manufactured easily. The rapid development of additive manufacturing, however, allows us to produce much more complex architectures and this raises the question: could other bending-dominated topologies outperform the hexagonal lattice? This study reports the behaviour of a truncated-hexagonal lattice: a 2D prismatic bending-dominated topology with mechanical properties superior to those of the hexagonal lattice.
The truncated-hexagonal lattice is a semi-regular tesselation where each vertex is connected to two dodecagons and a triangle. It has a nodal connectivity of three (like the hexagonal lattice) and consequently, its behaviour is bending-dominated. We derived analytical expressions for the elastic modulus and strength of the truncated-hexagonal lattice when subjected to (i) uniaxial compression and (ii) shear. These analytical expressions were then validated using finite element simulations. Both analytical and numerical work assumed that the lattice is made from an elastic, perfectly plastic solid and that the bars are sufficiently slender to behave as Euler-Bernoulli beams.
The results showed that a truncated-hexagonal lattice is particularly stiff for a bending-dominated lattice. In fact, its Young's and shear modulii are both 85% stiffer than those of the hexagonal lattice. This result is independent of orientation since the truncated-hexagonal lattice has in-plane isotropic elastic properties. The truncated-hexagonal lattice fails by plastic collapse when it is loaded in compression or in shear. Its plastic

collapse strength is 11% higher than that of the hexagonal lattice.
In summary, we conclude that the stiffer and slightly stronger truncated-hexagonal lattice would be a good replacement to the hexagonal lattice in applications where energy absorption is critical. Experimental work is currently underway to corroborate the analytical and numerical results reported above.

Double Elasticity Transition in Multistable Architected Materials Agustin Iniguez-Rabago[1] and Johannes Overvelde[1,2]; [1]AMOLF, Netherlands; [2]TU/e, Netherlands

Advances in fabrication technologies are enabling the production of architected materials with unprecedented properties. While most of these materials are characterized by a fixed geometry, an intriguing avenue is to incorporate internal mechanisms capable of reconfiguring their spatial architecture, therefore enabling tunable functionality. Inspired by the structural diversity and foldability expored in origami, researchers have started to create reconfigurable materials comprising assemblies of plates and hinges. Here our focus is on achieving architected materials with a finite range of encoded behaviors. We achieve this by harnessing nonlinear mechanical behavior that arises either through the underlying 3D geometry, or by direct assuming a nonlinear description for the folding behavior of the hinges, resulting in multistability. Guided by numerical analysis and physical prototypes, we systematically explore the mobility of the designed structures through the use of local actuation, in an effort to uncover and classify their potential behavior. By doing so, we find two transitions in the elastic behavior of these materials depending on the ratio between the stiffness of the plates and hinges. Given that the underlying principles are scale-independent, our strategy can be applied to design the next generation of reconfigurable structures and materials, ranging from transformable meter-scale architectures to nanoscale tunable photonic systems.

Controlled Chemical Evolution of a 3D Biogenic Structure for Tailored Mechanics Sunghwan Hwang, Raheleh Rahimi, Mohsen Damadam, Jiaqi Li, Alexander Strayer, Mahdi Dehestani, Grigorios Itskos, David Bahr and Ken Sandhage; Purdue University, United States

Diatoms are single-celled algae that produce, and live within, 3-D, microscopic, nanostructured, porous silica glass-based shells (called “frustules”). Diatom frustules have evolved over hundreds of millions of years to provide resistance to being crushed by predators. Indeed, micromechanical tests and simulations have indicated that *Fragilariopsis kerguelensis* frustules are capable of accommodating local compressive and tensile stresses in excess of 600 MPa and 500 MPa, respectively (C. E. Hamm, et al., *Nature*, 421, 841-843 (2003)). The robust nature of silica-based *F. kerguelensis* diatom frustules has led us to question how such microscale structures would behave if these structures were comprised of metallic or oxide/metal composite materials (i.e., materials that are ordinarily more resistant to fracture than bulk monolithic silica).

To address this question, SiO_2-based *F. kerguelensis* diatom frustules were reactively converted into 3-D replicas comprised of Ti and MgO/Ti composites. Live *F. kerguelensis* diatoms were graciously provided by Prof. Rebecca Robinson (University of Rhode Island). Diatom culturing was conducted in L1 medium at 4°C using 13 h light/11 h dark cycles. After harvesting and then washing of the diatom cells in water and ethanol, the cells were heated in air at 600ºC for 4 h to remove organic material to yield SiO_2 frustules. A series of gas/solid reactions was then used to convert these SiO_2 frustules into MgO/Ti and Ti replicas. Reactive

conversion experiments were conducted on two types of specimens: i) a shallow bed of frustules (to allow for X-ray diffraction analysis at each stage of reactive conversion), and ii) isolated individual frustules on inert polished substrates (to allow for evaluation of the preservation of the overall frustule morphology and surface features at each stage of conversion via electron microscopy and to allow for *in-situ* mechanical tests). The latter specimens were oriented with the valve or the girdle band of the frustule or frustule replica facing upwards (to allow for compression tests with both orientations). Secondary electron microscopic images of individual frustules confirmed that the 3-D frustule morphology was preserved at each stage of reactive conversion. The micro/nanochemical evolution during such shape-preserving reactive conversion was evaluated using X-ray diffraction analysis, energy-dispersive X-ray analysis, and selective area electron diffraction analysis (via transmission electron microscopy).

In-situ mechanical tests were conducted with a Hysitron PI-88 system installed in a scanning electron microscope to allow for direct observation of the deformation behavior of SiO_2 *F. kerguelensis* frustules, and of Ti and MgO/Ti replicas of such frustules. Single and partial loading-unloading load functions were applied to these diatom frustules and frustule replicas. Load-displacement plots indicated that the SiO_2 frustules exhibited fully elastic and brittle behavior, whereas appreciable plasticity was detected for the Ti frustule replicas. While the SiO_2 frustules and Ti frustule replicas exhibited some similarities in apparent crack initiation locations and in crack propagation behavior, higher failure loads were accommodated by the Ti frustule replicas prior to catastrophic failure than for the SiO_2 frustules. The MgO/Ti frustule replicas exhibited higher stiffness, and sustained appreciably higher loads prior to catastrophic failure, than the Ti frustule replicas, while retaining notable plasticity. The use of such *in-situ* micromechanical tests and simulations to evaluate structural motifs responsible for such mechanical behavior will be discussed.

12:25 PM ST03.02.04
Multifunctional Metallic Nanolattices with Ultra-High Tensile Strength Enabled by cm-Scale Crack-Free Self-Assembly Zhimin Jiang and James H. Pikul; University of Pennsylvania, United States

Biology creates complex porous structures to realize materials that are mechanically strong and lightweight, and have added chemical or physical functionalities, like bone or wood. Inspired by these remarkable materials, engineers have been adding pores to metals to make strong and lightweight multifunctional structures. Porous metals fabricated by traditional methods, however, have mechanical strengths far below their theoretical limits [1]. High-resolution 3D printing is one manufacturing technique that has realized nanolattices that approach the theoretical strength of their constituent materials through topological design, structural optimization, and size effects in nanomaterials. 3D printing, however, has inherent trade-offs between resolution and printing time that severely limit the scale-up of 3D printed nanolattices, which has restricted almost all nanolattice mechanical property measurements to compression by micro/nanoindentation [2]. The tensile properties of nanolattices, therefore, have been mostly unexplored. To truly take advantage of the remarkable properties of nanolattices, it is essential to realize new methods for fabricating macroscopic nanolattices and to understand how their chemistry and physical properties affect their tensile properties.
In this work, we demonstrate a crack-free self-assembly approach to fabricate 2 cm long multifunctional metallic nanolattices with 100 nm periodic features and 30 nm grain size, which translates to 1,000X more unit cells in the loading direction than prior studies. Benefiting from the scalability of this fabrication approach, we grow the first large-area multifunctional nickel nanolattices and measure the tensile properties with macroscopic testing equipment. We show that they can achieve an ultra-high 227 MPa tensile strength at a density less than aluminum, which is 3 times stronger than what has been reported for porous metals with the same relative density at any scale. We also found that the key to enhancing the tensile strength is to combine a lattice geometry that reduces stress concentrations with control of the nanostructure and grain size which reduce the size of inherent defects, such as voids, and increase the metal strength. The resulting nickel nanolattices have excellent structural photonic coloration, approach the theoretical limit of their upper tensile strength, and realize a new combination of strength and relative density for porous metals and nanolattices. The combination of high strength and high specific strength makes these nickel nanolattices ideal for resisting bending loads: they can resist the same load with 50% smaller volume than porous titanium, 50% lower mass than porous iron, and,

importantly, 10X less volume than other nanolattices. The new ways developed in this work to fabricate metal nanolattices and characterize their performance will further the design and fabrication of lightweight high-strength multifunctional porous metals.

Electrically-Driven Soft Robots via 3D Printed Handed Shearing Auxetics Ryan L. Truby, Lillian Chin and Daniela Rus; Massachusetts Institute of Technology, United States

Electrically-mediated actuation schemes offer great promise beyond popular pneumatic and suction-based approaches in soft robotics, but they often rely on bespoke materials and manufacturing approaches that constrain design flexibility and widespread adoption. Following the recent introduction of a class of architected materials called handed shearing auxetics (HSAs), we present a 3D printing method for rapidly fabricating HSAs and HSA-based soft robots that can be directly driven by servo motors. To date, HSA fabrication has been limited to laser cutting of extruded Teflon (PTFE) tubes. Our work expands the HSA materials palette to include flexible and elastomeric polyurethanes. Herein, we investigate the influence of material composition and geometry on printed HSAs' mechanical behavior. In addition to individual HSA performance, we evaluate printed HSAs in two robotic platforms - four degree-of-freedom (DoF) platform and a soft gripper - to confirm that printed HSAs perform similarly to the original PTFE HSA designs. Finally, we demonstrate new soft robotic capabilities with 3D printed HSAs, including fully 3D printed HSA actuators, higher force generation in multi-DoF devices, and demonstrations of soft grippers with internal HSA endoskeletons. We anticipate our methods will expedite the design and integration of novel HSAs in electrically-driven soft robots and facilitate broader adoption of HSAs in the field.

12:55 PM ST03.02.06
Effect of Fibre Length and Distribution on the Structural Properties of Bamboo-Fibre Foams Hosna Malekzadeh and Eral Bele; University College London, United Kingdom

Introduction/Aims
Solid foams are structurally efficient materials, and as such, are particularly attractive in weight sensitive applications, e.g. in packaging and insulation. The typical base materials of commercial foams are metallic or petrochemical, both of which pose some disadvantages due to energy intensity of manufacturing, and reliance on non-renewable resources respectively. Natural fibres can be exploited to create and reinforce biodegradable cellular materials, e.g. to increase rigidity, strength and energy absorption.

In this work we consider the use of cellulose fibres extracted from bamboo culms, and used in two configurations: as reinforcement for close-celled cellulose-matrix foams, and as a structural open-celled fibre network. Topology optimisation is used to improve the reinforcement efficiency of such fibres, with the aim of obtaining comparable mechanical properties to commercial foams. We present results on the effect of fibre length and distribution on the macroscopic mechanical response and deformation mechanisms in compression and bending.

Methods
This study uses relatively simple manufacturing techniques to fabricate closed and open-celled foams. Cellulose fibres are extracted from bamboo culms and used as the primary source of raw material, to reinforce a pulp slurry that is subsequently drained and solidified, and to create a fibre network that bound at the joints through microfibril bridges created by partial surface hydrolysis.

The material properties of fibres, the fibre/matrix interfacial strength, and critical fibre length are obtained through microtensile tests. The mechanical response of the resultant foams is reported in uniaxial compression and 3-point bending. These tests are coupled with strain mapping through digital image correlation (DIC), and microstructural investigation of deformation mechanisms through scanning electron microscopy (SEM).

Results

In close-celled foams, the internal microstructure consisted of interpenetrating ellipsoidal voids, with an aspect ratio of 1.5, and the compressive response was typical of elastic-brittle foams. Fibre reinforcement was exploited by two mechanisms: the delay of fracture propagation during uniaxial compression, and shear transfer during bending. The former resulted in an increase in the energy absorption/density ratio with fibre volume fraction, and the latter in an increase in the flexural rigidity and strength. A critical fibre length is reported for effective reinforcement in both cases. Bending stiffness and strength were largely determined by this parameter, but the reinforcement efficiency in compression was more sensitive to preferential fibre distribution than length.

In fibrous networks, surface treatment through partial hydrolysis was used to control the number of inter-fibre bridges. The latter increase density but reduce stiffness, due to a low joint strength. The effect of fibre length was shown in a linear compressive stiffness/density relationship, indicating that the network response was dominated by fibre stretching.

Conclusions

The response of these first cellular materials created from bamboo fibres showed that the mechanical properties are within the range of current foams. The results showed that there is a critical fibre length and distribution for optimal reinforcement efficiency. These findings indicate a potential route towards the manufacturing of sustainable lightweight materials for structural applications.

Bayesian Optimization with Multi-Fidelity Sources for the Design of Non-Uniform Architected Lattices with Optimal Failure Properties Chengyang Mo, Paris Perdikaris and Jordan R. Raney; University of Pennsylvania, United States

Architected cellular solids and lattices (2D and 3D) have been widely studied and integrated into many applications in mechanics. Past research has mainly focused on uniform, periodic lattices. However, lattices can be architected to possess non-uniform struts and non-periodic arrangements with interesting mechanical properties. Previous work has explored variations of non-uniformity, including linearly-graded or harmonically-graded lattices that result in staged failure. Yet designing more general non-uniform structures that optimize desired mechanical properties is challenging due to the large number of parameters. Machine learning algorithms such as neural networks can help in the design process by generating all possible geometric patterns and finding candidates that match the desired properties. However, this approach is limiting, as it is only feasible for low dimensions and can only be experimentally validated for a few design candidates that have been identified. Here, we discuss the use of a framework based on Bayesian optimization that incorporates multi-fidelity data originating from both experimental and numerical results in the pursuit of optimized properties. In this approach, the Bayesian optimization is a closed-loop design process based on Gaussian process regression which guides the choice of design variables for each iteration of experiments. We implemented this approach for the design of both 3D (body-centered cubic lattice) and 2D structures (square

cellular solids), seeking to optimize for desirable combinations of mechanical properties (such as toughness, yield stress, etc.). As a "low-fidelity" data source we use numerical simulations in ABAQUS to simulate compression of architected lattices with non-uniform strut thicknesses. As a "high-fidelity" data source we perform experimental compression tests on structures that have been 3D printed using stereolithography (SLA). These data sources are fed into the multi-fidelity Bayesian optimization algorithm. The algorithm guides the choice of the next experiments/numerical simulations until sets of optimal parameters are found.

Architected Liquid Crystalline Elastomers with Strain Rate-Adaptive Extreme Energy Absorption Sung H. Kang; Johns Hopkins University, United States

An architected material allows new opportunities in material design and synthesis by enabling new properties that are not observed in natural materials or from a bulk material that the "material" is made of based on the interplay between material and geometry. We have investigated liquid crystalline elastomer-based architected materials that harness energy absorption mechanisms across multiple length scales for extreme energy absorption. Moreover, the architected material shows strain-adaptive energy absorption behaviors with power-law relation between energy absorption and strain rate whose exponent can be tuned via controlling microscale mesogen alignment by couple nonlinear geometric and nonlinear material properties. We will report our characterization results of energy absorption behaviors of architected liquid crystalline elastomers over 6 orders of magnitudes strain rate ranges and numerical modeling results to investigate its strain-rate adaptive energy absorption mechanisms based on viscoelastic property characterization data of liquid crystalline elastomers over 20 orders of magnitudes frequency ranges. The findings from our study can contribute to realizing extremely lightweight and high energy absorbing materials, which will be beneficial for various applications, including automotive, aerospace, and personal protection.

Late News: Kirigami-Inspired Graphene with Programmable Thermo-Mechanical Properties Jun Cai and Hamid Akbarzadeh; McGill University, Canada

Tuning and programming the multiphysical properties of advanced materials is of critical importance for developing the next generation of adaptable multifunctional metamaterials. This study demonstrates the tunability of thermo-mechanical properties of graphene sheets by inspiring from kirigami mechanical metamaterials. The theoretical investigation, multiscale simulation, and experimentations show that the stress-strain response, the buckling-induced 3D patterns, as well as the thermal conductivity of nano-architected kirigami metamaterials can be tuned by altering geometrical parameters and cutting patterns. The thermal conductivity of kirigami-inspired graphene metamaterial can be further regulated and managed by an external mechanical strain. By analyzing and comparing the results from atomic simulation and continuum-based simulation, the effect of the length scale is discussed to explore the connection across the scales. Analytical models are also developed to predict the thermo-mechanical properties of heterogeneous kirigami and offer an explicit tool for the rapid engineering of graphene-based metamaterials to achieve desired stress-strain response and thermal conductivity. This work facilitates the applications of programmable kirigami-inspired nano-metamaterials in wearable nanoelectronics and nanoscale heat transport systems.

Spectral Selective Transparent Porphyrin Thin Films with PT- and PV- Dual Modality for Energy-Efficient Building Skin Jou Lin and Donglu Shi; University of Cincinnati, United States

In solar harvesting for energy sustainability, the porphyrin compounds have been found to exhibit both photovoltaic (PV) and photothermal (PT) effects due to their unique structures. Both chlorophyll and

chlorophyllin belong to the porphyrin compounds that are structurally characterized with a large ring molecule consisting of four pyrroles, denoted as the porphyrin ring. The optical properties of these compounds are typically characterized with strong absorptions near the UV and NIR regions, and high average visible transmittance. The porphyrin compounds are well-known for dye-sensitized solar cells (DSSC), bulk-heterojunction solar cells (BHJSC), and perovskite solar cells (PSC). Some of the porphyrin compounds have also been shown to exhibit strong photothermal effects. Upon sufficient solar harvesting, the photon energy can be converted to electricity or thermal energy by PV or PT through the same porphyrin thin film in an alternative fashion. Therefore, a PT- and PV- dual-modality can be designed and engineered for energy applications. In this study, the spectral-selective porphyrin thin films are applied on the window inner surface for thermal insulation in a single pane design. Upon solar irradiation, the window surface temperature can increase appreciably by the PT coating resulting in significantly reduced heat transfer, characterized by a low U-factor. Therefore, thermal insulation can be achieved optically without any interfering medium as conventionally required in the double- or triple- glazing. The building skin with a large surface area with the PT coating can also serve as an ideal substrate for PV panel for energy generation, with the dual modality that can be altered seasonably. We report the experimental results on the PT- and PV dual modality building skin based on porphyrin thin films for energy saving and generation. Also reported are the porphyrin compounds synthesis, thin film deposition, optical absorption characterization, and the photothermal/photovoltaic measurements.

3:15 PM ST03.03.06

Late News: Nano-Architected Carbon for Supersonic Impact Mitigation Carlos Portela[1], Bryce Edwards[2], David Veysset[1], Yuchen Sun[1], Keith Nelson[1], Dennis M. Kochmann[3] and Julia Greer[2]; [1]Massachusetts Institute of Technology, United States; [2]California Institute of Technology, United States; [3]ETH Zurich, Switzerland

The use of architecture in materials has been reported to enable novel combinations of mechanical properties such as high stiffness- and strength-to-density ratios. Furthermore, interesting size effects can appear when architected nanometer-scale features are achieved such as in pyrolytic carbon struts, which have recently been shown to exhibit rubber-like response. While this size effect has been explored in the quasi-static response of 3D beam-based architected materials, no work has explored its implications under extreme conditions. Exploiting these size effects in the dynamic regime has potential to enable ultralightweight impact-resistant materials for applications such as ballistic impact, blast loading, and micrometeoroid shielding in space. We propose a method to fabricate and test nano-architected carbon lattice materials at supersonic ballistic impact speeds of up to ~1 km/s, allowing for in situ and post-mortem characterization. Using beam-based architectures as the periodic building-blocks, we fabricate these materials using a two-photon lithography process followed by pyrolysis, yielding a carbon-based nano-architected material. Using ~2 μm tetrakaidekahedral unit cells, with beam diameters ranging from 300-800 nm, we explore the effects of relative density (i.e., fill fraction) on the impact response. Employing 14 μm-diameter projectiles via the laser-induced particle impact test (LIPIT), we analyze the effects of varying impact velocities from 50 – 1,100 m/s, attaining nominal strain rates on the order of 10^6 s−1 to 10^7 s^{-1}. We observe three distinct response regimes: (*i*) elastic impact, (*ii*) cratering and particle rejection, and (*iii*) cratering and particle capture, depending on the relative density of the lattice material as well as the impact energy. Our experiments demonstrate impact energy dissipation of up to 1.1 MJ/kg in these materials, outperforming traditional impact-resistant materials such as steel, aluminum, PMMA, and Kevlar. By analogy to planetary impact, we also introduce predictive tools for crater formation in these materials using dimensional analysis. These results uncover an extreme-condition regime over which nano-architecture can enable the design of new generations of ultra-lightweight, impact-resistant materials.

5:45 PM *ST03.04.01
Design of Patterned Structures for Deformable Devices In-Suk Choi; Seoul National University, Korea (the Republic of)

How can we overcome the formability of materials beyond original materiality ? To answer this question, we have adopted "**simple geometric patterned structures**" that significantly enhance flexibility and stretchability of brittle or stiff materials. Geometrical design such as *auxetics*, *origami* and *kirigami* provides us many examples of the formation of delicate and, detailed patterns leading to the effective distribution of stresses. Instead of process control and complex structure design, we employed the simple juxtaposition of unit design leading to simple, cheap and easily processed flexible, stretchable and deployable structures for deformable devices. In addition, newly developed computational approach expands our design dimension to the next level. We believe that geometrical modulation by controlled size, shape, and symmetry adds another dimension unleashing the limitation of conventional design space of structure materials

6:10 PM ST03.04.02
Mechanical and Structural Properties of Nanostructured Metalattices Probed by Coherent EUV Beams
Begoña Abad Mayor[1,2], Joshua Knobloch[1], Travis D. Frazer[1], Jorge Nicolas Hernandez Charpak[1], Hiu Yan Cheng[3], Alex Grede[3], Noel Giebink[3], Tom Mallouk[3], Pratibha Mahale[3], Nabila Nova[3], Andrew Tomaschke[1], Virginia Ferguson[1], Vincent Crespi[3], Venkatraman Gopalan[3], Henry Kapteyn[1], John Badding[3] and Margaret Murnane[1]; [1]University of Colorado Boulder, United States; [2]University of Basel, Switzerland; [3]The Pennsylvania State University, United States

Phononic crystals represent a very promising route for tuning the properties of next-generation nanoelectronics, thermoelectrics, and ultralight materials. These consist of periodic arrays embedded in an elastic medium, arranged in a specific lattice symmetry [1,2,3]. Nanofabrication techniques can now produce nanoscale phononic crystals with dimensions <<100 nm (referred to as metalattices) which make it possible to engineer new elastic and transport properties [4,5]. To fabricate metalattices, nanospheres are first assembled into a colloidal crystal with face centered cubic order. This base structure can be tuned from monolayer to microns in thickness, with sphere sizes from the nanometer (nanoscale opals) to microns (opals) [1,6]. The interstitial space between the nanospheres of the colloidal crystal is then infiltrated with another material, forming a metalattice structure for periodicities in the sub-100nm. To understand the mechanical properties of metalattices, studies to date have focused only on one component of the metalattice—either the template or the etched-out structures, and always for periodicities >100 nm. In this work, we present a nondestructive method to accurately extract, for the first time, the mechanical and structural properties of metalattices with much smaller feature sizes. Specifically, we probe silicon metalattices fabricated from sphere diameters of 14 nm and 30 nm, with periodicities of 19 nm and 42 nm, respectively. These metalattices contain feature sizes that are an order of magnitude smaller than opals that have been characterized to date. We use an ultrafast laser pulse to heat a set of transducer gratings, which impulsively launch surface acoustic waves (SAW) in the metalattice. The wavelength of the SAW can be tuned by varying the transducer grating periodicity, which also changes the SAW penetration depth into the metalattice and the silicon substrate. We then monitor the SAW frequency from the time-dependent change in extreme ultraviolet (EUV) light diffracted off the grating. This method allows us to simultaneously extract the acoustic dispersion, as well as the Young's modulus, thickness and filling fraction of the metalattice. Interestingly, the extracted mechanical and structural properties agree well with macroscopic predictions, while the transport properties of the same metalattices do not agree with bulk models. Additionally, the measured metalattice thicknesses agree with scanning electron microscopy images and the extracted Young's moduli agree with nanoindentation measurements, while achieving higher accuracy. Finally, this technique represents the only approach to date to nondestructively validate the filling fraction of deep-nanoscale metalattices. It also has advantages over destructive electron imaging because it probes over large areas and does not suffer from material contrast issues. These results can enable precise fabrication, characterization and understanding of materials with tailored mechanical and transport properties.

6:25 PM ST03.04.03
Optimizing Steel-Reinforcement in Concrete—Using Topology Optimization and Digital Fabrication to Develop Ductile Concrete for Specific Loading Conditions Brian Salazar, Parham Aghdasi, Michael Herrmann, Sharjeel Laeeq, Levi Seidel, Claudia Ostertag and Hayden Taylor; University of California, Berkeley, United States

As concrete is a brittle material, it must generally be reinforced for use in building applications. Steel-reinforced concrete is a composite in which the majority of the compressive strength stems from the concrete and the steel reinforcement provides the tensile strength. Typically, the steel reinforcement often takes the form of a 1-D reinforcing bar or 2-D cage. However, the reinforcement geometry is not usually optimized for the particular loading scenario that the structure will experience. Additionally, the placement of the concrete itself may be optimized for particular applications, which may reduce the CO2 emissions for concrete structures.

The minimum amount of steel reinforcement in a concrete structure is dictated by the loads it must withstand. Further, building codes specify a maximum amount of steel allowed within a structure; concrete structures typically do not have a steel reinforcing ratio greater than 6%. As our goal is to optimize the amount and placement of both the steel reinforcement and the concrete within the overall structure, this is a constrained, multi-material topology optimization problem. Our approach is innovative, as we use the specific loading structure to inform where the steel and concrete should be placed and use digital manufacturing techniques to create that optimal steel reinforcing structure.

We use the Topology Optimization (TopOpt) Grasshopper tool developed at the Technical University of Denmark to inform the optimal steel placement within the concrete structures. TopOpt's objective is to minimize the structure's compliance, with constraints on the material volume and the void shape. TopOpt assumes that the concrete has a compressive stiffness that is 10 times greater than its tensile stiffness. This material anisotropy serves to ensure the concrete and steel are placed properly within the geometry. The loading scenario considered here is a flexural beam undergoing four-point bending. When using these topology optimization results to inform the 3-D reinforcement geometry design, the result is a steel volume fraction of 6%.

Digital fabrication technologies are well-suited to creating these complex reinforcement structures. We used an Omax 2626 to waterjet cut these architected, steel reinforcement geometries, placed this optimized steel reinforcement geometry into a 3" x 3" x 11" mold, and casted concrete around it. In this first structure, the placement of steel is optimized, but the placement of concrete is not. We created a second concrete geometry, wherein both the placement of steel and the concrete is optimized. This geometry contained 30% less concrete than the first geometry. Finally, we created a non-optimized, straight, steel rebar geometry and used it to reinforce a 3" x 3" x 11" concrete beam (for comparison purposes).

In four-point bending tests, we found that the beam with optimized steel reinforcement reached a peak load that is 1.28 times greater than the peak load reached by the beam with straight rebar reinforcement, despite the two beams having the same steel reinforcing ratio. Additionally, the beam with optimized steel reinforcement reached a toughness that is 1.38 times greater than the toughness reached by the beam with straight rebar reinforcement. When we compared the beam with optimized steel reinforcement and the beam with both optimized steel reinforcement and optimized concrete placement, we saw that the peak load is reduced by 18%, and the toughness is reduced by 26%.

These results suggest that optimizing the placement of steel reinforcement within concrete structures can have a significant improvement on the overall mechanical properties. Additionally, optimizing the placement of the concrete—and reducing the amount of concrete used—allowed us to create a structure with a 30% weight reduction, which may be beneficial in seismic applications.

6:40 PM ST03.04.04
Architecting Lithium-Ion Battery Electrodes with Acoustic Focusing Emilee Armstrong[1], Keith Johnson[2], Drew S. Melchert[2], Matthew R. Begley[2,2] and Corie L. Cobb[1]; [1]University of Washington, United States; [2]University of California, Santa Barbara, United States

Lithium-ion batteries (LIBs) with high energy and power density are crucial for energy storage applications such as vehicle electrification. Traditional LIBs have planar electrodes wherein their performance can be optimized for energy or power, but not both simultaneously. Three-dimensional (3D) electrodes have been shown to mitigate these trade-offs by using 3D architecture to enable fast ion transport in thick battery electrodes.[1] However, there is a need for more scalable, large-area fabrication methods for 3D electrodes. In this work, we expand a computational model[2] to analyze the feasibility of combining acoustic focusing with additive manufacturing to fabricate line-patterned battery electrodes. Acoustic focusing uses acoustic forces to control particle placement in a fluid, and its ability to align particles on a micron-scale make it a promising technique for 3D electrode fabrication. In our model, we solve for trajectories of particles in a fluid using analytical models of the focusing forces, which we compare to experimental results. We apply this model to battery-relevant materials to determine how focusing parameters such as viscosity, particle size, and volume fraction impact electrode geometry for optimizing battery energy and power performance. Our initial results suggest that lithium cobalt oxide ($LiCoO_2$) and lithium nickel manganese cobalt oxide ($LiNi_{0.33}Mn_{0.33}Co_{0.33}O_2$) are highly compatible with acoustic focusing.

6:45 PM ST03.04.05
Design Considerations and Performance of Bi-Material Lattices Amanda Ruschel and Frank Zok; University of California, Santa Barbara, United States

Cellular materials, including stochastic foams and ordered lattices, have been used extensively for their weight efficient properties. The nearly-constant crushing stress of stochastic foams make them ideal for energy absorption applications. Notwithstanding, their strengths are low relative to those of ordered lattices. Although ordered lattices can attain higher strengths, they exhibit internal buckling and concurrent strain softening during compressive loading, making them undesirable for energy absorption applications. Although the performance of single-material foams and lattices has been studied extensively, recent advancements in additive manufacturing have opened new possibilities of *multi-material* lattice structures.

This talk will outline the design considerations for bi-material lattices that have potential for tuning the balance between high strength and high straining capability. To begin, a primitive structural motif that exhibits the desired behavior is identified and its compressive response is analyzed. A 2D multi-cell lattice based on the primitive motif is designed and several material variants are fabricated and tested. Analysis of test results addresses effects of finite node dimensions, constraints on member rotation at the nodes, free edges, and friction with the loading platens as well as limits dictated by rupture of tensile members or buckling of compressive members. The study culminates with guidelines on design of bi-material lattices with high strength and high straining capability.

7:00 PM ST03.04.06

***De Novo* Discovery of Disordered Mechanical Metamaterials by Machine Learning** Han Liu and Mathieu Bauchy; University of California, Los Angeles, United States

Topology-optimized architected materials can feature unique mechanical behaviors, including unusual density-stiffness scaling. However, such materials have then been largely limited to periodic lattices. Here, we use machine learning and molecular dynamics to explore the effect of disorder as a new degree of freedom. We develop a Bayesian optimization framework that prescribes targeted topologies, which are subsequently validated by molecular dynamics simulations, which, in turn, generate new data to refine our machine learning model. This iterative learning pipeline is used to accelerate the discovery of light yet stiff disordered phases. We show that, at constant average local topology, disordered phases behave differently than their crystalline counterparts. This establishes disorder as a promising degree of freedom to discover new exotic phases with unusual mechanical properties.

9:00 PM *ST03.05.01
Mechanical Behavior of Ordered Porous Ceramic Architecture Made by PnP Seokwoo Jeon; KAIST, Korea (the Republic of)

Numerous three dimensional (3D) nanofabrication methods have been proposed for novel applications in mechanical metamaterials. However, highly periodic 3D fabrication in large area and volume has limited success. Here I present our recent efforts to expand the limit in size of highly periodic 3D nanostructures through Proximity field nanoPatterning (PnP) which uses conformal phase masks with outstanding scalability and easiness of the large area patterning. After brief overview of 3D nanofabrication technique and potential application fields, mechanical behaviors of nanocomposites based on 3D nanostructures will be discussed. Current applications are stretchable light scatter, interphase boundary nanocomposites (ceramic-polymer, ceramic-metal). The change of optical and mechanical behavior by changing the constitute materials and the geometry and thickness of cellular materials will prove the importance of structural motif in submicron, ordered porous materials and composites.

9:25 PM ST03.05.03
Bulk Fabrication 3D Ultralight Nanocomposite with High Resilience and Recoverability Jongbeom Kim and Seung Min Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

3D lightweight, architectured cellular structures that are fabricated via additive manufacturing methods are currently receiving much interest due to the tunable properties that can be realized by simply tuning the architecture. In addition, the use of nanoscale materials that have excellent mechanical properties as building blocks to create a large scale bulk material via hierarchical structuring allows for realization of a bulk material that display the excellent properties of the constitutive nanoscale materials. In this study, a simple bulk fabrication based on directional freeze-drying method was developed for synthesis of fully recoverable ultralight 3D porous nanocomposite that is composed of Ag nanowire/cellulose nanofiber(CNF). Freeze-drying method is a one-step process via ice crystal formation followed by sublimation of ice crystal which leaves behind the Ag nanowire/CNF nanocomposite walls to form the 3D porous structure. Compression tests on vertically and horizontally aligned Ag nanowire/CNF nanocomposite walls showed highly anisotropic mechanical properties. An optimized concentration of Ag nanowires resulted in the compressive strength of 100 kPa at a relative density of 0.96%, which has 1.5 times higher strength when normalized by the material density

compared to that of metal microlattices fabricated by lithography methods. Horizontally aligned 3D porous structure showed perfect restoration while maintaining sufficient electrical conductivity that is suitable for flexible electronics and 3D strain sensors. Proposed freeze-drying methodology was also used to fabricate other 3D nanocomposite using polyvinylalcohol and Ag nanowire as a hard core that was then infiltrated with PDMS to create a hard core-soft matrix composite. The compression tests of the developed 3D bulk nanocomposite indicated excellent resilience and recoverability.

9:40 PM ST03.05.04
Late News: The Twisting of Dome-Like Metamaterial from Brittle to Ductile Lizzie Cheng; City University of Hong Kong, Hong Kong

Architected materials can exhibit mechanical properties that do not occur with ordinary solids. By integrating hierarchy and size effects, micro-architected metamaterials fabricated by two-photon lithography with metallic or ceramic coating can be ultra-strong but lightweight. However, the attainment of both strength and ductility is generally mutually exclusive. Inspired by the Pantheon dome in Rome, which can withstand high load while keeping low density, micro-architected domes with a gradient helix are designed and deposited in a hierarchical nanostructured aluminum film with ultrahigh strength and considerable plasticity. Despite a thick coating usually causes catastrophic collapse, the thick-walled metallic dome shows recoverability during compression. The compressive strength significantly increases compared to current ductile-like micro-lattices. Detailed experimental and computational works reveal the graceful (non-catastrophic) failure due to the helical twisting and plastic flow in the supra-nano material. It is a promising method of suppressing brittle failure via a combination of architectural and material design. It can be used to impart enhanced functionality, making programmable stiffness, and tailored energy absorption all possible.

9:45 PM ST03.05.05
Mechanical and Microstructural Characterization of Non-Polymeric Architected Materials Fabricated Using a Cost-Effective and Scalable Stereolithography 3D Printing Technique Changquan Lai; Nanyang Technological University, Singapore

Architected materials hold much promise in achieving unprecedented structural properties that can significantly benefit applications are required to be stiff, strong and energy absorbent, with minimal mass, such as those in the aerospace, automobile and sports industries. The recent advent of additive manufacturing has sped up the pace of research in this field considerably by allowing complex, optimized designs to be realized easily and reliably. Nevertheless, many non-polymeric materials remain incompatible with most 3D printing schemes, and the few that are, require specialized equipment and treatments that remain far too costly for many industries to adopt. Here, we attempt to address this innovation gap by developing materials that are compatible with commercial stereolithography 3D printers originally designed for photosensitive polymers. Such printers are cost-effective, scalable and can produce structures that are mechanically isotropic with a fine resolution. Two strategies were adopted. First, non-polymeric powders were mixed into photosensitive resin and subjected to SLA 3D printing. Second, 3D printed polymeric structures were dip-coated in a mixture of non-polymeric powder and resin. In both cases, subsequent de-binding and sintering steps were required to remove the polymers and coalesce the non-polymeric powders. Lattices with solid struts and hollow tubes, made out of metal, ceramic and composites were successfully demonstrated. The microstructures of these lattices were examined in detail through SEM and micro-CT scans and related to their mechanical properties using simple analytical relationships.

10:00 PM ST03.05.06
Late News: Omnidirectional, Broadband Light Absorber with Hierarchical Nanoturf Structures for Solar-Thermal Conversion Jong Uk Kim[1], Seung Ji Kang[1], Seok Joon Kwon[2] and Tae-il Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Institute of Science and Technology (KIST), Korea (the Republic of)

Although much attention has been paid to the development of photothermal materials and designs that can convert solar irradiation into exploitable thermal energy, it remains some obstacles such as limited light absorbing band and narrow incident angle. This study proposes a black gold-coated hierarchical nanoturf (Au/h-nanoturf) membrane incorporated with randomly distributed high aspect ratio (AR) nanostructures and micro-through holes. Thanks to structural advantages, this large area membrane exhibited good absorption of the broadband solar light spectrum. The h-nanoturf is further combined with a microcone array to enhance solar absorption extended to the near-infrared range as well as the omnidirectional incident direction of the light. The fundamental mechanism of the strong omnidirectional broadband absorption performance of the h-nanoturf was thoroughly analyzed with computational electrodynamics simulations. Consequently, we employed the Au/3D h-nanoturf with microscale hole (μ-hole) membrane to fabricate an advanced solar-vapor generator.

8:00 AM *ST03.06.01
Recent Progress on 3D Chiral Mechanical Metamaterials Martin Wegener; Karlsruhe Institute of Technology (KIT), Germany

In this review talk, we present our experimental and conceptual progress on three-dimensional (3D) microstructured chiral mechanical metamaterials, which we have introduced (T. Frenzel et al., Science 358, 1072 (2017)) and summarized (I. Fernandez-Corbaton et al., Adv. Mater. 31, 1807742 (2019)) previously. This includes recent results for the dynamic as well as for the (quasi-)static regime.

In the dynamic regime, we have previously discussed the possibility of chiral metamaterial phonons and acoustical activity, the elastic counterpart of optical activity (T. Frenzel et al., Nature Commun. 10, 3384 (2019)). In 3D metamaterials, the magnitude of the polarization rotatory power as well as the operation frequency can be tailored by rational design. However, acoustical activity has been highly anisotropic in these simple-cubic lattices and essentially restricted special propagation directions. More recently, we have designed architectures enabling nearly isotropic chiral phonons and nearly isotropic acoustical activity in 3D over a large bandwidth. This includes the possibility of 3D chiral quasi-crystalline mechanical metamaterials (Y. Chen et al., Phys. Rev. Lett. 124, 235502 (2020)) as well as of chiral triclinic (Y. Chen et al., submitted (2020)) and chiral simple-cubic truss lattices (Y. Chen et al., in preparation (2020)). The different underlying principles behind obtaining isotropic elastic behavior in 3D are discussed and compared.

In the (quasi-) static regime, 3D chiral mechanical metamaterials allow for further behaviors “forbidden” in classical Cauchy elasticity such as, e.g., conversion of strain to twist. These behaviors are intimately connected to a loss of scale invariance, i.e., the mechanical behavior depends on the number of unit cells in the metamaterial specimen. We build on our previous conceptual work on tailoring a characteristic chiral length scale. When divided by the lattice constant, the characteristic length scale turns into the characteristic number (P. Ziemke et al., Extreme Mech. Lett. 32, 100553 (2019)). We have designed more practical architectures that we have manufactured by multi-focus multi-photon 3D laser nanoprinting with as many as more than one hundred thousand unit cells total and more than three hundred billion voxels. Specifically, we can tailor the twist/strain to increase linearly up to a characteristic number of unit cells, beyond which the twist/strain asymptotically decays inversely with the number of unit cells. We achieve characteristic numbers as large as about ten experimentally. Conceptually, the characteristic number can probably be made arbitrarily large. This statement is backed up by numerical simulations on different levels of approximations as well as by a simple and intuitive analytical model (T. Frenzel et al., in review (2020)).

8:25 AM *ST03.06.02
Metamaterials as a Platform for Sustainable Power Generation Miso Kim[1,2]; [1]Korea Research Institute of Standards and Science, Korea (the Republic of); [2]Sungkyunkwan University (SKKU), Korea (the Republic of)

Mechanical energy harvesting (MEH) is the technology that utilizes ambient mechanical energy available in nature such as sound, vibrations, and all human-derived kinetic motions to convert into useful electricity. MEH is regarded as a great platform to provide sustainable power solution to operate wireless sensors, one of the key essentials for Smart City, particularly without the need to replace after a certain amount of time. Although attractive, insufficient power generation is still the issue to solve in MEH. Metamaterials, artificially engineered structures, have proved useful for input mechanical energy manipulation, thus providing a new paradigm of solution to enhancing power generation in MEH. Here, I will summarize a collection of advances that push the boundaries to achieve a new paradigm of energy harvesting systems using various metamaterial designs ranging from phononic crystals, elastic and acoustic gradient index (GRIN) metamaterials, locally-resonant acoustic materials, to elastic instability-based mechanical metamaterials. These metamaterials exhibit unconventional material properties such as negative mass density, negative bulk modulus, and programmable stiffness, thus enabling intriguing phenomenon including band gaps, negative refractions, and shape and pattern transformation capabilities. All these unusual and intriguing phenomena can contribute to tailoring and amplifying input mechanical energies, ultimately leading to drastic enhancement in overall power generation of MEH systems.

8:50 AM ST03.06.03
Electrochemistry for Fabricating Nanoarchitectured Mechanical Metamaterials Chris Gunderson, Nadia Rohbeck, Maxime Tranchant, Janne-Petteri Niemelä, Ivo Utke, Jakob Schwiedrzik, Laetitia Philippe and Johann Michler; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Two-photon lithography is a well-established technique for the creation of 3D polymer structures with sub-micron architecture. Recent work in the past few years has focused on the combination or integration of two-photon lithography with other fabrication processes for creating 3D nanoarchitectured structures from other materials such as ceramics and metals. Toward this goal, two fabrication schemes will be presented for creating 3D nanoarchitectured mechanical metamaterials from metals using electroforming, also called template-assisted electrodeposition. In the first example, two-photon lithography is used to create a 3D photoresist structure that serves as a template for fabricating a 3D nanoarchitectured metal matrix composite with a ceramic nanolattice reinforcement through electroforming and atomic layer deposition. Structural characterization and initial *in situ* micromechanical testing data will be shown, including studies at high temperatures. In the second example, the resolution of 3D electroforming is improved to below 200 nm by pyrolysis of two-photon lithography templates. We fabricate metal nanolattices with strut diameters down to 150 nm and test the resolution of the technique by creating free-standing single metal nanowires/pillars with diameters down to 60 nm. *In situ* micromechanical testing of these lattices will be presented.

9:05 AM ST03.06.04
Late News: Fabrication of 3D Architectures Using Near-Field Electrospinning Ahsana Sadaf, Monsur Islam, Dario Mager and Jan Gerrit Korvink; Institute of Microstructure Technology, Karlsruhe Institute of Technology, Germany

In this work, we present preliminary results towards fabrication of 3D architectures using near field electrospinning as a novel additive manufacturing technology. Electrospinning is a technique of drawing a nanofibril string from a charged polymer droplet under a high electric field. In far-field electrospinning, the distance between the spinneret and the collector is quite large (5-10 cm), which leads to bending instability along the nanofiber jet resulting in random distribution of the deposited fibers on the collector. Keeping the electric field constant, reducing the distance between spinneret and collector (typically $\leq$ 1 cm) results in a highly focused electric field which leads to a precise deposition of the fibers. Such low-distance electrospinning

is termed as near-field electrospinning (NFES). NFES has enabled the fabrication of several 2D geometries of various materials ranging from polymers to ceramics for a wide range of applications including piezoelectric nanogenerators, biomedical devices, wearable sensors, FETs, photodetector, and MEMS structures. Due to the ability of precise nanofiber deposition, several researchers have attempted to develop NFES as an additive nanomanufacturing tool. However, these studies lack fundamental analysis of the NFES and involve additional complex components. Here we focus on exploring the fundamentals of NFES towards developing it as a high-speed additive nanomanufacturing tool. Currently we are characterizing several process parameters, such as electric field, printing speed, viscosity, conductivity, and dielectric constant of the solution towards enabling the nanofibers to stack onto each other leading to the fabrication of 3D structure. The outcome of this work will enable NFES to fabricate high aspect ratio 3D structures of stacked nanofibers with various geometries at a high processing speed, compared to other additive nanomanufacturing technologies. Such structures can be useful for various applications such as electrodes for energy devices and scaffolds in tissue engineering.
We have used polyethylene oxide (PEO) as the polymer, and a rotating drum as the high-speed moving collector to make 3D walls of stacked nanofibers. We have studied the effect of different solvents and collector material on the 3D stacking of the nanofibers. The results show that collector conductivity and vapor pressure of the solvent play a crucial role on the stacking of the fibers. The experiments so far have resulted in a 3D stacked wall of PEO with a maximum height of ~250 μm and diameter of ~10 μm, while using a chromium/gold substrate and dichloromethane as the solvent.
Our ongoing work is to optimize the processing parameters to narrow down the diameter of nanofiber and to achieve the straight wall of stacked fibers with high aspect ratio. We plan to use these NFES-driven 3D stacked walls of nanofibers as scaffolds for tissue engineering. Furthermore, we target to achieve 3D structures of various other materials such as carbon and metal oxides using this NFES-driven additive nanomanufacturing process.

9:20 AM ST03.06.05
Late News: Extensible 3D Hierarchical Woven Materials Carlos Portela[1], Widianto Moestopo[2], Arturo Mateos[2], Ritchie Fuller[3] and Julia Greer[2]; [1]Massachusetts Institute of Technology, United States; [2]California Institute of Technology, United States; [3]Independent Artist, United States

Most architected materials to date have enabled properties such as extreme stiffness and strength, at levels unattainable independently by their constituent materials, with few works focusing on the compliant, extensible regime pertinent to applications such as flexible electronics and tissue engineering. While exceptional mechanical properties such as extreme resilience and high deformability have been realized in many three-dimensional (3D) architected materials using beam-and-junction-based architectures, stress concentrations and constraints induced by the junctions limit their mechanical performance. Compliant architected materials that overcome these limitations, in combination with conductive components or constituent materials, could open a new path for the applicability or architected materials.

We present a new hierarchical design concept for flexible 3D architected materials in which fibers are interwoven to construct effective beams, such as the ones in classical monolithic-beam lattice architectures. Via in situ tension and compression experiments of additively manufactured polymeric woven and monolithic lattices at the microscale, we demonstrate the superior ability of woven architectures to achieve high tensile and compressive strains (>50%)—without failure events—via smooth reconfiguration of woven microfibers in the effective beams and junctions. Cyclic compression experiments reveal that woven lattices accrue less damage compared to lattices with monolithic beams. We employ numerical studies of woven beams with varying geometric parameters to present new design spaces for the development of architected materials with tailored compliance that is unachievable by similarly configured monolithic-beam architectures. This woven hierarchical design offers a pathway to make traditionally stiff and brittle materials more deformable by introducing a new building block for 3D architected materials, with complex nonlinear mechanics, applicable to flexible electronics applications.

9:35 AM ST03.06.06

Late News: Liquid-Induced Topological Transformations of Cellular Microstructures Shucong Li, Bolei Deng, Alison Grinthal, Alyssha Schneider-Yamamura, Jinliang Kang, Reese S. Martens, Cathy T. Zhang, Jian Li, Siqin Yu, Katia Bertoldi and Joanna Aizenberg; Harvard University, United States

The fundamental topology of cellular structures -- the location, number, and connectivity of nodes and compartments -- can profoundly impact their acoustic, electrical, chemical, mechanical, and optical properties, as well as heat, fluid and particle transport. Approaches harnessing swelling, electromagnetic actuation as well as mechanical instabilities in cellular materials have enabled a variety of interesting wall deformations and compartment shape alterations, but the resulting structures generally preserve the defining connectivity features of the initial topology. Achieving topological transformation presents a distinct challenge for existing strategies: it requires complex reorganization, repacking, and coordinated bending, stretching, and folding, particularly around each node where elastic resistance is highest due to connectivity. Here we introduce a two-tiered dynamic strategy to achieve systematic reversible transformations of the fundamental topology of cellular microstructures that can be applied to a wide range of materials and geometries. Our approach only requires exposing the structure to a liquid whose composition is selected to have the ability to first infiltrate and plasticize the material at the molecular scale, and then, upon evaporation, to form a network of localized capillary forces at the architectural scale that zip the edges of the softened lattice into a new topological structure, which subsequently re-stiffens and remains kinetically trapped. Reversibility is induced by applying a mixture of liquids separately acting at the molecular and architectural scales -- thus offering modular temporal control over the sequence of the softening-evaporation-stiffening actions -- restoring the original topology or providing access to intermediate modes. Guided by a generalized theoretical model connecting cellular geometries, material stiffness and capillary forces, we demonstrate programmed reversible topological transformations of various lattice geometries and responsive materials, undergoing fast global or localized deformations. We then harness dynamic topologies for developing active surfaces with information encryption, selective particle trapping and bubble release, and tunable mechanical, chemical and acoustic properties.

SESSION ST03.07: Synthesis and Fabrication of Architected Materials II

ST03

11:45 AM *ST03.07.01
Late News: Contacting but not Connected—Interpenetrating Lattices Benjamin White[1,2], Anthony P. Garland[1,2], Ryan Alberdi[1,2] and Brad L. Boyce[1,2]; [1]Sandia National Laboratories, United States; [2]Center for Integrated Nanotechnologies, United States

Traditional lattice metamaterials have greatly expanded the range of achievable material properties; however, they are generally physically continuous throughout their volume, and thus cannot take advantage of contact interactions or multi-body behavior. Here we present the new concept of an interpenetrating lattice, where two or more lattices interlace through the same volume without any direct connection to each other. Interpenetrating lattices greatly expand design possibilities, allowing single material printers of all types to print composite metamaterials irrespective of material or length scale. While the geometry defining interpenetrating lattices has been studied since the days of Euclid, additive manufacturing allows us to turn these mathematical concepts into physical objects with remarkable properties including reduced transmission of thermal, electrical, shock and vibration loads, increased toughness, multi-stable/negative stiffness behavior, and unusual energy transduction. In this first study on interpenetrating lattices, we reveal remarkable mechanical properties including improved toughness, multi-stable/negative stiffness behavior, and electromechanical coupling.

12:15 PM ST03.07.02

Direct Ink Writing of Short Carbon Fiber-Reinforced Phenolic Resins for Production of C/C Composites Caitlyn M. Clarkson, Matthew Dickerson and Hilmar Koerner; Air Force Research Laboratory, United States

Carbon-carbon (C/C) composites are utilized by the aerospace industry primarily as structural materials due to their high thermal stability, low density, and good mechanical properties. Because of the aerospace industry relevance and unique properties of these materials this work will explore opportunities to manufacture complex parts via AM. Direct ink writing (DIW), an AM technique, offers a unique advantage in that it is amenable to printing of chopped fiber reinforcements and continuous fiber reinforcement. In DIW, complex structures are formed from the deposition of shear-thinning inks (suspensions or pastes) extruded through a nozzle. An added benefit of this process is that alignment of the fiber reinforcement is achieved during processing, allowing access to conventional fiber composite configurations. Here we present a route for the production of C/C composites by DIW of phenolic-based carbon fiber composite inks. Molecular gelators were employed as rheological modifiers to facilitate DIW of an otherwise low-viscosity liquid phenolic resin and chopped carbon fiber with an acid catalyst to accelerate low temperature curing. The rational for ink formulation and assessment of the subsequent rheological behavior will be discussed as they pertain to printability in addition to its effects on the conversion of these materials to C/C.

12:30 PM ST03.07.03
Late News: Multifunctional 3D Self-Supported Hybrid Aerogels Prepared from Sol-Gel Electrospun Nanofibers Vahid Rahmanian, Tahira Pirzada and Saad A. Khan; North Carolina State University, United States

Owing to their outstanding properties including ultralow density, high specific surface area, and low thermal conductivity, aerogels are being considered for several applications including separation, thermal insulation, tissue scaffold, electromagnetic and sound absorption, sensors, supercapacitors, and catalysis. Generally, conventional aerogels are synthesized from a gel (either hydrogel or organogel) including multiple solvent exchange steps followed by solvent removal *via* oven, freeze, or supercritical drying. The complexity of this process not only raises the cost of fabrication but also significantly increases the duration of the process. We present a sustainable approach to prepare aerogels from sol-gel electrospun hybrid organic-inorganic nanofibers of polyvinylpyrrolidone (PVP)-titania (TiO_2). This facile and robust methodology resulted in the fabrication of a 3D self-supported cellular structure with elasticity, low density (~10 $mg.cm^{-3}$), and hierarchical porosity consisting of primary (1-5 μm) and secondary pores (10-60 μm). XPS analysis and SEM demonstrate that titania networks developed during sol-gel electrospinning and uniformly distributed inside the nanofibers. Moreover, FTIR analysis provides evidence that PVP and TiO_2 components chemically interact during the sol-gel processing through Ti-O-C linkage. The PVP-TiO_2 nanofibrous aerogel exhibit high mechanical flexibility, hierarchical porosity, and low density demonstrating their possible applications in diverse fields like filtration, CO_2 capture, and antimicrobial.

12:45 PM ST03.07.04
Multiscale Modeling of Nanoarchitected Materials Under Large Deformations Joshua Crone, Richard Becker and Jaroslaw Knap; U.S. Army Research Laboratory, United States

Recent advances in additive manufacturing have enabled the production of nanoarchitected material, consisting of truss structures with sub-micron geometric features. These materials have achieved unprecedented specific stiffness and strength as well as extraordinary energy absorption and recoverable compressibility. As additive manufacturing techniques continue to improve, scaling of nanoarchitected materials will reach the component level. Modeling of these parts will require a multiscale approach to span the range of length scales between the sub-micron features of the trusses and the component scale. While numerous homogenization schemes have been developed for multiscale modeling of architected materials, most are limited to capturing material and geometric effects in the linear and early yield regimes. While these methods may be sufficient for predicting the specific stiffness and strength, they are not useful in designing materials for energy absorption and large deformation applications.

In this work, we present a multiscale model for architected materials that captures material nonlinearities including yield, hardening, and failure as well as geometric nonlinearities including buckling, post-buckling softening, and densification. We employ an FE^2 approach where the component-scale deformation is modeled by finite element (FE) analysis and the microscale deformation is modeled by another FE simulation of the representative unit cell (RUC). A homogenization scheme is used to determine the stress-strain constitutive relation for the component-scale FE simulation through numerous evaluations of the RUC. The model is integrated into a computational framework for multiscale modeling that handles resource management and fault tolerance to allow many RUC evaluations to occur in parallel, enabling efficient use of high-performance computing resources.

1:00 PM ST03.07.05
A Mechanical Analysis of Planar and Corrugated Metamaterials as Relativistic Light Sails for Interstellar Travel Matthew F. Campbell[1], Mohsen Azadi[1], Pawan Kumar[1], George A. Popov[1], John B. Brewer[2], Aaswath Raman[2], Prashant K. Purohit[1], Deep M. Jariwala[1] and Igor Bargatin[1]; [1]University of Pennsylvania, United States; [2]University of California, Los Angeles, United States

We propose a composite light sail composed of nanometer-thick corrugated layers of alumina and molybdenum disulfide that can be used to accelerate a gram-scale probe to relativistic velocities for interstellar space travel. Our mechanical calculations suggest that this sail can sustain radiation pressures of tens of Pa, necessary to achieve a velocity of roughly a fifth the speed of light. In addition to our numerical analysis, we are demonstrating the manufacturability of this concept by producing prototype sections of the composite material using standard microfabrication techniques. Our results represent one of the first evaluations of sail robustness and fabricability of ultrathin light sails and highlight the need for additional research on the optical and mechanical properties of thin Al_2O_3 and MoS_2 films, particularly at elevated temperatures.

The Breakthrough Starshot Initiative aims to send an ultralight spacecraft to Proxima Centauri B within the next half century by accelerating it using a highly reflective light sail and an array of Earth-bound high-power lasers[1]. A sail that will accomplish this must have a total mass of approximately 1 g and an area of 1-10 m^2 to minimize the size of the laser system, a high reflectivity over the entire doppler-shifted laser wavelength range to minimize the required laser power, a high emissivity at mid-infrared wavelengths for efficient radiative cooling, a shape that provides beam-riding stability over long distances, and mechanical robustness to maintain its form without tearing or fracturing. Several recent studies have examined the optics and dynamic stability of sails, proposing spherical designs[2], planar photonic heterostructures[3], and textured photonic metasurfaces[4]. However, few studies have incorporated mechanical robustness and manufacturability assessments into their proposals.

Therefore, we propose a novel sail that addresses mechanical robustness, manufacturability, beam-riding stability, optical characteristic, and mass property considerations. Our design involves a ~2 m circular, spherically curved sheet comprised of several interlocking gores, each of which is composed of roughly 70 layers (~50 nm) of highly reflective (>50%) MoS_2 sandwiched between two 5-nm optically transparent Al_2O_3 films. We have incorporated a micron-scale hexagonally patterned corrugated rib structure into the sail that increases its bending stiffness[5] by 10-100× and reduces its tensile stiffness[6] by 2-3× relative to planar films, preventing it from clinging to itself and making it more robust against deformation and fracture. Our stress calculations, performed using a thin-walled pressure vessel model, confirm that the sail can tolerate the laser-induced acceleration forces with failure margins of 10-30%. Planned next steps include using finite element methods to validate our calculations and implementing an energy balance to quantify the temperature variation of the sail throughout its acceleration and the impact of thermal effects on its mechanical response.

Finally, to demonstrate this concept, we are fabricating small prototype sections of this sail. We use photolithography and deep reactive ion etching on a silicon wafer to create a hexagonal rib mold, use atomic layer deposition to conformally-coat the mold with a thin Al_2O_3 film, transfer a thin MoS_2 flake to the surface of

the film, deposit a second Al_2O_3 film, and release the result using XeF_2 etching. We intend to extend this process to larger areas using chemical vapor deposition to directly synthesize MoS_2 upon the Al_2O_3. Taken together, our modeling and fabrication results indicate the possibility of laser-driven relativistic interstellar travel.

Tensegrity-Inspired Nanoarchitected Materials Lucas Meza, Caelan Wisont and Lucas Meza; University of Washington, United States

The field of architected materials has been invigorated by a revolution in additive fabrication methods with micro- and nanoscale precision, enabling the creation of architected materials that can exploit the enhanced properties of nanomaterials. Despite many developments in this area, the mechanical properties of these nanoarchitected materials are impaired by designs that i) have little mechanical tunability and ii) have a poor distribution of load carrying elements. This work investigates the fabrication and mechanical characterization of a new class of highly tunable, tensegrity-inspired nanoarchitected materials. These are created in a two-step process involving two-photon lithography (TPL) to create a polymeric framework followed by pyrolysis to convert the material to amorphous carbon. This procedure relies on the size-dependent shrinkage of beams during pyrolysis, which enables nanoarchitectures to be controllably prestressed by varying the size of different elements in the structure. We demonstrate that these amorphous carbon nano-tensegrities have highly tunable mechanical properties that can be varied independently of their relative density, allowing more optimal strength and stiffness per unit mass.

2:15 PM *ST03.08.01
Design of Architected Materials Using Freedom and Constraint Topologies (FACT) Jonathan Hopkins; University of California, Los Angeles, United States

Designing architected metamaterials is overwhelming for many computational approaches because of the large number and complexity of flexible elements that constitute their architecture—especially if such elements don't repeat in periodic patterns or collectively occupy irregular bulk shapes. In this work, we introduce the freedom and constraint topologies (FACT) methodology, which leverages simplified assumptions regarding the topology, geometry, and constituent properties of such materials to enable their design with ~6 orders of magnitude greater computational efficiency than other approaches (e.g., topology optimization).

FACT utilizes a comprehensive library of intuitive geometric shapes, which embody the mathematics of screw theory, constraint-based design, and projective geometry. One set of shapes, called freedom spaces, represent all the ways a compliant system can deform with high compliance. Another set of shapes, called constraint spaces,

represent the region of space within which flexible elements should be placed for exhibiting the compliant deformations of their complementary freedom spaces. By obeying simple systematic rules, designers (or an automated code) can rapidly search the full design space of compliant topology solutions, embodied by the complementary geometric shapes of the complete FACT library.

In this work, we will explain how FACT can be used specifically to design directionally compliant metamaterials, transmission-based architected materials such as materials that achieve desired Poisson's ratios, and materials with Poisson's ratio's that fluctuated spatially and temporally.

2:40 PM ST03.08.02
Metallic Films with Architected Bimodal Microstructures—Synthesis and Mechanical Properties Rohit Berlia and Jagannathan Rajagopalan; Arizona State University, United States

Materials with heterogeneous microstructures have been shown to exhibit a superior combination of strength, ductility and toughness compared to both homogeneous nanostructured and coarse-grained materials. However, only limited progress has been made in the synthesis of heterogenous microstructure materials with robust control of key microstructural parameters. Here we report a novel technique to synthesize metallic films with precisely defined bimodal microstructures using magnetron sputtering, wherein the size, volume fraction and connectivity of nanocrystalline (< 100 nm) and coarse domains (> 1000 nm) can be explicitly controlled. Using this technique, we synthesized pure iron films in which the nanocrystalline and coarse-grained domains were configured to be in different spatial arrangements like series and parallel. Along with the spatial arrangements, the volume fraction was also varied by changing the size of these domains. The microstructure of these films was characterized using EBSD and TEM, and tensile testing was performed using MEMS based testing stages. As anticipated, the spatial arrangement (series versus parallel) of the nanocrystalline and coarse domains markedly altered the stress-strain response, with the parallel arrangement leading to co-deformation and higher strength. In addition, films containing higher volume fraction of nanocrystalline domains showed higher strength. More interestingly, the orientation of the coarse domains with respect to the loading axis also had a significant influence on the mechanical behavior due to the constraints it imposed on dislocation motion. These results indicate that this synthesis method can be used to systematically tailor the mechanical behavior of metallic films in a repeatable manner.

2:55 PM ST03.08.03
Nanoarchitected Coatings with Extreme Thermal and Mechanical Resilience Nishita Anandan and Lucas Meza; University of Washington, United States

Premature failure of materials in extreme thermal and mechanical environments has been a challenge for decades. Extreme temperatures can enable enhanced efficiencies, e.g. in jet engines, or they may be required for normal operation, e.g. in hypersonic vehicles and spacecraft. The ceramic coating layer used for protection are prone to cracks and delamination due to inherent property mismatch between the layers. This talk describes the development of durable nanoarchitected alumina coatings with high impact and thermal shock resistance.

The coating was designed to have a gradient spinodal shell structure, its uniform stress distribution and minimize stress concentrations to prevent cracking and the stiffness of the spinodal shell was tailored by setting a preferential surface formation direction. A spinodal structure with gradient stiffness is chosen to ensure better mechanical interfacing with the metal substrate. The mechanical resilience of the material is achieved by using an architecture that exploits shell buckling as the dominant deformation mechanism. The thermal shock resistance was enhanced by maintaining the relative density below 0.04. The performance of the coating was investigated through numerical and experimental investigations. High strain rate and sequential thermo-mechanical simulations were performed to evaluate the stress and temperature distribution in an extreme environment. Nanoindentation and laser thermal shock experiments were performed to explore the failure mechanism. Through this work we demonstrate a new approach to create thermal protection coatings. Instead of searching for new advanced materials, we use the existing materials and use nanoarchitecture to make them

resilient to extreme thermal and mechanical loads.

3:10 PM ST03.08.04
Analyzing Microscale Toughening Mechanisms in Bioinspired Nanoarchitectured Materials Zainab S. Patel and Lucas Meza; University of Washington, United States

Natural materials exhibit remarkable toughness and damage tolerance, properties that stem from their hierarchical architecture built up from the nano- and microscale. Many of the underlying mechanisms behind these novel mechanical properties are not well understood at microstructural length scales. Replicating the architectural complexity of natural materials is not only challenging in terms of fabrication but is also time-consuming and expensive. Therefore, it is important to systematically develop and study complex nano- and microarchitectures to understand their effect on mechanical properties and thereby develop effective material design strategies.

In this study, we analyze crack propagation and energy absorption in dense microscale nanoarchitected Bouligand beams inspired by the dactyl club of a mantis shrimp. We developed a fabrication process utilizing two-photon lithography to create polymeric beams with increasing architectural complexity, starting from a beam with unidirectional fibers and moving to a herringbone structured beam with out-of-plane wavy fibers. We extended these methods to include a secondary ceramic phase between the polymeric fibers to understand the effect of material modulus mismatch on crack propagation at the microscale, a feature commonly witnessed in tough natural materials. We present the results of in-situ nanomechanical testing of microscale three-point bend specimens with nanoarchitected beams.

The results of this study help to develop a fundamental understanding of the effect of architectural tortuosity on crack propagation, energy dissipation, and toughening mechanisms at the microscale. Moreover, it reveals the microscale fracture properties of nanoarchitected materials, importantly illustrating how fracture processes change when the sample size is comparable to the process zone size and how that can affect macroscale properties. This combined understanding of the effect of both architecture and specimen length scale on toughness is crucial and will pave the way to successfully engineer tougher materials with bioinspired strategies.

3:25 PM ST03.08.05
Magnetron Sputtered Micro-Lattice Structures Alina Garcia Taormina[1], Chantal Kurpiers[2], Ruth Schwaiger[3] and Andrea Hodge[1]; [1]University of Southern California, United States; [2]Karlsruhe Institute of Technology, Germany; [3]Forschungszentrum Jülich GmbH, Germany

A prevalent focus of materials research is the development of ultra-lightweight, multifunctional materials that exhibit unparalleled mechanical properties. Within the last decade, technological advances in additive manufacturing (AM) have enabled the fabrication of novel three-dimensional nano- and micro-architected lattice materials, allowing researchers to investigate previously unexplored phenomena and property spaces. Current printing techniques are mainly restricted to polymer-based systems, which narrow the functionalities and mechanical robustness of these architected lattice materials. While a handful of nano-architected ceramic and metallic systems have been realized by way of pyrolysis, namely SiOC, nanoporous Ni, and glassy carbon, new printable material systems are limited by the chemistry of the resin blend and require further research. Thus, alternative approaches such as the deposition of metallic and ceramic coatings on polymer-based lattice scaffolds offer a flexible and feasible route for expanding the mechanical and functionality space of these advanced materials.
Several novel nano- and micro-lattice materials have been developed through means of various light-based AM methods and coating deposition approaches, namely atomic layer deposition and plating techniques. However, such methods are limited to materials that undergo specific chemical reactions. Thus, magnetron sputtering, a technique that allows for the deposition of a nearly unlimited selection of metals, alloys, and ceramics can be utilized to further expand the synthesis space of these materials. Several recent publications have employed

planar magnetron sputtering configurations to deposit a wide range of materials on nano- and micro-lattice structures, from high entropy alloys to bulk metallic glasses. Nonetheless, sputtering is a momentum-driven line-of-sight process, and thus achieving uniform coatings on fine-featured lattice materials remains a prominent challenge. As such, our work is based on inverted cylindrical magnetron sputtering, a novel coating approach that allows for an unprecedented 360° line-of-sight. With enhanced line-of-sight, it is expected that higher ionization rates and bombarding energy can be achieved as compared to planar cathodes under the same sputtering conditions. Overall, inverted cylindrical magnetron sputtering can lead to a greater understanding of the effect of cathode geometry and deposition parameters on coating uniformity on complex 3-D topologies.

8:00 AM *ST04.01.01
Tuning Phase Formation, Microstructure and Properties of High Entropy Alloys and Chemically Complex Composites Jurgen H. Eckert[1,2]; [1]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Austria; [2]Montanuniversität Leoben, Austria

This talk explores the structural diversity that can be achieved in high entropy alloys and multiphase composites developed through a combination of concepts for designing chemically complex alloys and metallic glasses using rapid quenching and annealing or severe plastic deformation for tuning phase formation and microstructure development. The role of length-scale modulation and phase transformation upon heating or loading will be critically assessed with respect to structural stability and mechanical behavior. Examples for changes in deformation mechanism, e.g. from crack-controlled to dislocation-dominated deformation, twinning or cooperative deformation of shear bands and interfacial sliding, will be presented and discussed as ways to control strength, ductility and fracture toughness in a wide range. Besides, also examples for developing novel nanostructured and ultrafine-grained complex materials via composition and process control will be given, attempting to derive guidelines for how to tune the microstructure and properties of non-equiatomic chemically complex alloys with optimized properties.

8:25 AM ST04.01.02

Late News: Discontinuous Deformation of FCC High and Medium Entropy Alloys at Close to 0 K Aditya Srinivasan[1], Theresa Hanemann[1], Klaus-Peter Weiss[1], Jens Freudenberger[2], Martin Heilmaier[1] and Alexander Kauffmann[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Leibniz Institute for Solid State and Materials Research, Germany

Discontinuous deformation or serrated plastic deformation, at temperatures close to 0 K, has formerly been reported in some metals and alloys. Based on the previous reports, concentrated substitutional FCC solid solutions are expected to show this phenomenon in an intense fashion. This would correspondingly provide the conditions to most effectively evaluate the phenomenon. To that end CoCrNi and CoCrFeMnNi were tested and observed to exhibit very intense serrated plastic behavior during deformation near 0 K [Tirunilai et al. Acta Materialia 200 (2020) 980-991]. CoCrFeMnNi, was especially interesting, as it showed low temperature serrations at a higher temperature than previously reported for any other metal or alloy. While previous reports have put forth theories on the cause for serrations, the reports fail to characterize serration trends and make evaluations with respect to active deformation mechanisms. Presently, in order to understand and characterize this serrated plastic deformation, (i) general deformation characteristics at temperatures near 0 K have to be understood, (ii) the influence of the deformation mechanisms seen at these temperatures (dislocation based deformation, deformation twinning and epsilon martensite formation) have to be evaluated and (iii) the serrated plastic deformation has to evaluated based on the influence of temperature and deformation. This was done using the alloys CoNi, CoCrNi and CoCrFeMnNi.
(i) The initial microstructure of the alloys in question was evaluated using XRD and SEM. Subsequently, the specimens were subjected to macroscopic tensile tests at different temperatures in the range between 295 and 4.2 K. Using SEM and TEM, deformation twinning was identified in CoCrNi and CoCrFeMnNi. Additionally, martensite was indexed post deformation in CoCrNi, but not in CoCrFeMnNi, contrary to the expectation based on SFE – temperature relation [Huang et al. Scripta Materialia 108 (2015) 44-47]. However, it was clear that in both these alloys deformation twinning was the primary contributor to strengthening.
(ii) Deformation twinning and martensitic transformations are associated with instability in single crystals and are influential in high temperature serrated plastic deformation. However, tensile tests conducted on CoCrFeMnNi at different temperatures indicate that no new deformation mechanism can be attributed as the cause for serrations. Additional tests on martensite forming CoCrNi and non-twinning CoNi verify the lack of influence of both, deformation twinning as well as martensite formation.
(iii) Serration intensity trends, measured as serration stress amplitude, were evaluated at different temperatures as well as in the pre-deformed condition. Correspondingly, the current results are consistent with the basis proposed by Seeger [Seeger in Fisher et al., Dislocations and Mechanical Properties of Crystals, Wiley, Ney York (1956)], according to which the serrations were a result of 'avalanche slip' of dislocations piled up at Lomer-Cottrell (LC) locks. This theory proposes a basis for the phenomenon, but the current work establishes a qualitative model that validates both present results as well as those in former publications.

8:40 AM ST04.01.03
Thermal Stability of the Microstructure and the Hardness of Multi-Principal Element Alloys Processed by Severe Plastic Deformation Hung T. Pham[1], Megumi Kawasaki[2], Jae-Kyung Han[2], János L. Lábár[1,3] and Jeno Gubicza[1]; [1]Eötvös Loránd University, Hungary; [2]Oregon State University, United States; [3]Institute for Technical Physics and Materials Science, Centre for Energy Research, Hungarian Academy of Sciences, Hungary

Multi-principal element alloys (MPEAs) or Complex Concentrated Alloys (CCA), including high-entropy alloys (HEAs) are designed with multiple principal elements of equal or near equal molar ratios. The strength of MPEAs can be further enhanced by refining the microstructure into the nanocrystalline state using severe plastic deformation (SPD) techniques. In this study, the influence of thermal treatment on the microstructure and hardness of nanocrystalline MPEAs processed by SPD was investigated. The SPD process was carried out using high-pressure torsion (HPT) technique up to ten turns at room temperature. The effect of heat treatment was studied from room temperature up to 1000K using differential scanning calorimetry (DSC). It was found that a single phase HfNbTiZr MPEA transformed into multiple phases at elevated temperatures. On the other

hand, CoCrFeNi MPEA remained single phase solid solution throughout the annealing process. The microstructures and the chemical compositions of the different phases were examined by transmission electron microscopy (TEM) and energy-dispersive X-ray spectroscopy (EDS). In addition, X-ray diffraction line profile analysis (XLPA) technique was used to monitor the evolution of the crystallite size and the dislocation density of CoCrFeNi, as well as to identify the different decomposed phases in the nanocrystalline HfNbTiZr MPEA. The average hardness of the annealed samples was also measured and correlated to the microstructure. This study demonstrated a comparative analysis of the results obtained in these alloys.

8:55 AM ST04.01.04
Late News: High Entropy Alloy Multilayers—A Processing and Deformation Study Khushbu Dash[1], Satyam Suwas[2] and Gandham Phanikumar[1]; [1]Indian Institute of Technology Madras, India; [2]Indian Institute of Science, India

High entropy alloys are next generation potential materials which have the calibre of performing as a structural material. High entropy alloys show improved properties sue to several underlying effects such as: high configurational entropy, lattice distortion, sluggish diffusion and cocktail effect. They exhibit strength-ductility synergy which is an important aspect which is a paradox in conventional materials. Recent works on high entropy alloys span from thermomechanical processing of the same to sever plastic deformation in order to enhance their mechanical performance. The severe plastic deformation induces fine grain structure making the material possess delayed failure. Metallic sheets have wide range of applications starting from large body structures to acting as small components in aerospace and automobile sectors. Sheet forming along with a high performance ensures a high-quality product. The sheet possessing ultrafine grains as well as a gradient microstructure and texture will enable better mechanical behaviour. Multilayered sheets are a method to achieve the above attributes, hence we propose to design this by accumulative roll bonding.
This work presents the processing of hard cantor alloy into ultrafine grained multilayered sheet using hot accumulative roll bonding (ARB) to study its microstructural and texture evolution. The Cantor alloy FeCrCoMnNi was cast and cold rolled to obtain a sheet of thickness of 0.4 mm followed by annealing. The sheet was characterized and studied for its microstructure and annealing texture, along with its mechanical properties. This sheet was then accumulatively roll bonded with a sheet of same alloy at 450 C by imparting a reduction of 50% in each pass upto 3rd pass using a cladding process. The ARB processed multilayer sheet was investigated for microstructure, bulk texture and microtexture. The strain gradient induced during accumulative roll bonding is instrumental in creating a gradient microstructure and texture along the thickness of the multi-layered sheet. Electron back scattered diffraction will be helpful in predicting the grain structure and the local strain in the deformed material.

9:10 AM ST04.01.05
Late News: Exceptionally High Spallation Strength for a High-Entropy Alloy Demonstrated by Experiments and Simulations Daniel Thürmer[1], Shiteng Zhao[2], Hye-Sook Park[3], Camelia Stan[4], Iyad A. Alhafez[5], Orlando Deluigi[6], Eduardo M. Bringa[6,7], Herbert Urbassek[5], Marc Meyers[8] and Nina Gunkelmann[1]; [1]Clausthal University of Applied Technology, Germany; [2]University of California, United States; [3]Lawrence Livermore National Laboratory, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]University Kaiserslautern, Germany; [6]University of Mendoza, Argentina; [7]Universidad Mayor, Chile; [8]University of California, San Diego, United States

High entropy alloys (HEA) are materials with an increasing number of technological applications. Among them, the Cantor Alloy, FeMnCoCrNi, shows desirable mechanical properties at normal loading conditions. In this study we focus on the performance of the Cantor alloy at ultrahigh deformation rates of shock waves. Intense shock waves may lead to spallation of the sample. In this study we perform molecular dynamics simulations of shock-induced spallation and compare our results with experiments using laser shocks and scanning transmission electron microscopy of the unloaded samples. Our molecular dynamics simulations were carried out with three different piston velocities, which allow us to gather more information and compare the data about the influence of the velocity on a

microscale. Both experiments and simulations show a high spall strength which would be beneficial for certain applications, with experiments giving 12 GPa at $10^7 s^{-1}$ and MD 30 GPa at $10^9 s^{-1}$. Post-mortem analysis of the experimental samples show nanotwins near the spall plane, while MD simulations show a highly dissordered region giving rise to void nucleation and spall.

9:15 AM DISCUSSION

9:30 AM ST04.01.07
Late News: High-Entropy Ceramics for Electrochemical Applications Ben Breitung[1], Qingsong Wang[1], Miriam Botros[1], Simon Schweidler[1], Abhishek Sarkar[2], Yanjiao Ma[1], Torsten Brezesinski[1] and Horst Hahn[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]KIT-TUD Joint Research Laboratory Nanomaterials Institute of Materials Science, Technische Universität Darmstadt, Germany

In recent years, the transition from high-entropy alloys to high-entropy ceramics[1] (e.g. high-entropy oxides, oxyfluorides, fluorides, etc.) has paved the way for a completely new field of materials and applications. The strong structure/property relationships and the unique possibility to tailor the compositions of high-entropy materials make them ideal candidates when aiming to prepare novel materials with adjustable properties for a variety of different applications.
Here, the utilization of several different high-entropy ceramics in the electrochemical sector will be presented. Conversion battery anodes and cathodes could be prepared using high-entropy oxides and fluorides, offering unexpected properties and advantages compared to conventional materials, which make them interesting for further research.[2] It could be shown that the high entropy plays a decisive role regarding the performance of the electrodes and serves as an “adjusting screw” when the material is tailored towards a desired property. High-entropy insertion and intercalation materials could also be synthesized by introducing high-entropy oxyfluorides and layered high-entropy structures, respectively.[3,4] Moreover, high-entropy oxides and high-entropy metal organic frameworks were applied to design post-Li battery electrodes for Na insertion. These materials do stand out due to their high reversibility and high accessible C-rates over reversible de/sodiation. Finally, the utilization of high-entropy molybdates and fluorides as catalysts for oxygen evolution reactions will shortly be demonstrated.[5]

9:45 AM ST04.01.08
Late News: High Entropy Oxides for Reversible Energy Storage Simon Schweidler[1], Qingsong Wang[1], Miriam Botros[1], Abhishek Sarkar[1], Torsten Brezesinski[1], Ben Breitung[1] and Horst Hahn[1,2]; [1]Karlsruhe Institute of Technology (KIT), Germany; [2]Technische Universität Darmstadt (TUD), Germany

In recent years, transition metal oxides (TMOs) have gained increasing interest in the field of rechargeable energy storage materials. One of the reasons is that often TMOs have a large theoretical specific capacity > 1000 mAh/g, which is attributed to the conversion reaction mechanism with its multi-electron redox processes during cycling.[1] This makes TMOs promising anode materials compared to graphite (theoretical capacity = 372 mAh/g). However, conventional TMOs suffer from rapid capacity degradation due to severe structural changes (large volume changes) during cycling.

Our recent studies show that transition metal-based high entropy oxide (TM-HEOs) $(CoCuMgNiZn)_1O_1$ exhibit reversible long-term lithium storage properties. The cycling stability might be attributed to an entropy stabilizing effect, additionally, it turned out that the electrochemical behavior of the TM-HEO is strongly influenced by each of the metal cations present. This makes it possible to change the electrochemical properties by simply changing the elemental composition.[2,3] Furthermore, using *operando* XRD and SAED, it was shown that, unlike conventional TMOs, the entropy-stabilized crystal structure serves as a kind of host matrix for the conversion reaction and that it is retained even in the fully lithiated state. The *operando* gassing study further showed that similar cycling performance and stability was obtained for cells with EC and FEC containing electrolytes. The gas analyses showed that H_2 and C_2H_4 were the main gas species during cycling. After the first cycle, especially the evolution rate of C_2H_4 decreased significantly, indicating the formation of a stable SEI layer on the HEO particles and emphasizing further the unique entropy-stabilized mechanism.[4] In addition, further preliminary electrochemical studies show the successful use of TM-HEO as anode material in coin-type and pouch-type full cells. The cells were found to provide an initial specific discharge capacity of 446 mAh/g, which was maintained at 300 and 256 mAh/g after 50 and 100 cycles, respectively.[5]

SESSION ST04.02: High Entropy Materials II
Session Chairs: Robert Ritchie and Cemal Cem Tasan
Friday Morning, April 23, 2021
ST04

11:45 AM *ST04.02.01
Damage-Tolerance and the Effects of Local Order in High-Entropy Alloys Robert O. Ritchie[1,2], Andrew M. Minor[1,2], Mark Asta[1,2], Jun Ding[2], Sheng Yin[2], Flynn Walsh[2,1], Ruopeng Zhang[2,1], Shiteng Zhao[2,1], Qin Yu[2], Jon Ell[1,2] and Yang Yang[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Face-centered cubic (*fcc*) high-entropy alloys (HEAs) can display exceptional combinations of strength, tensile ductility and fracture toughness, properties that can be further enhanced at cryogenic temperatures. Body-centered cubic (*bcc*) refractory HEAs, conversely, can display exceptional strength and compressive ductility at elevated temperatures, but are often compromised by poor lower-temperature behavior. We examine here the damage-tolerance of these two classes of multiple principal-element alloys, and show that whereas some of the *fcc* HEAs exhibit the highest fracture toughness on record, the *bcc* HEAs can display extremely low toughness (and ductility) when subject to tensile loading. We further examine the role of short-range order (SRO) in these two alloy classes, theoretically using DFT-based Monte-Carlo and Molecular Dynamics simulations and experimentally using energy-filtered TEM and 4D-STEM techniques. Whereas atomistic simulations predict the existence of SRO in *fcc* and *bcc* HEAs, together with its influence on plastic deformation behavior, *e.g.*, slip behavior, dislocation mobility, *etc*., direct experimental evidence is difficult. We believe that we have unequivocal evidence for SRO in *fcc* HEAs, with an understanding of the role of magnetically-driven ordering

in CrCoNi-based systems; studies for the *bcc* systems, however, are still in process. Our emphasis now is on defining the mechanistic role and quantitative effect on mechanical properties, with respect to how SRO can affect the strength, strain-hardening, ductility and toughness.

12:10 PM ST04.02.02
Short-Range Order Strengthening in 3D Transition Metal-Based Complex Concentrated Alloys Hyunseok Oh[1], Michael Xu[1], Jein Lee[2], Koichi Tsuchiya[2], James M. LeBeau[1] and Cemal Cem Tasan[1]; [1]Massachusetts Institute of Technology, United States; [2]National Institute for Materials Science, Japan

Due to their multi-component nature, preferential chemical ordering, which is otherwise known as short-range order, has been proposed in various concentrated alloys. Short-range order can be caused by various origins such as magnetic frustration, strong electronic interaction, and the formation of complexes with interstitial elements. Here we present a first systematic study of the methods to control the degree of SROs and the resultant mechanical properties in 3d transition metal-based complex concentrated alloys (3d CCAs). Theory-based proposals for the effects of short-range order will be discussed via the in-situ deformation studies using various scanning electron microscopy techniques. Our findings call for revisiting the classical understanding of the deformation behavior of 3d CCAs taking into account chemically ordered configuration effects.

12:25 PM ST04.02.04
Design of Multi-Principal Element Alloys with a Modified Miedema Scheme John D. Cavin, Zhaohan Zhang, Arashdeep Thind and Rohan Mishra; Washington University in St. Louis, United States

Traditionally, alloying has involved the addition of relatively small concentrations of foreign elements to a base metal. In recent years, there has been a paradigmatic shift in alloying wherein three or more elements are mixed in near equal fraction to obtain multi-principal element (MPE) alloys. The inclusion of many elements increases the mixing entropy and results in the stabilization of solid solutions and has been shown to improve mechanical and electrochemical properties. This approach has also been extended beyond pure metallic alloys to solid solutions of oxides and carbides with multiple cations. While the combinatorics of cation choice result in large phase spaces of possible MPE alloys, entropic stabilization is limited by its ability to overcome positive mixing enthalpies, i.e., not all MPE alloys will have single phase solid solutions at reasonable synthesis temperatures. A computational model that can predict the stability of MPE alloys based on a limited set of first-principles calculations would be an invaluable tool for rapid screening of promising candidates for subsequent synthesis and characterization. Here, we present a method for calculating the equilibrium phase diagram of N-component MPE alloys. This method combines the mixing enthalpy of equimolar components calculated using density-functional theory with a modified Miedema scheme [*1*,*2*] to predict temperatures above which a single-phase solid solution can be stabilized. A functional form for the mixing enthalpy is determined by fitting a $(N-1)$-dimensional polynomial to the equimolar mixing enthalpies of an N-component MPE alloy and the $(N-1)$-, … , 2-component alloys of the constituent compounds. By including a contribution from the configurational entropy, $(N-1)$-dimensional Gibbs free energy surfaces are generated and used to construct phase diagrams. In addition to providing miscibility temperatures for solid solutions, our method can identify regions of metastability and can be used to predict the stability of near-equimolar alloys. Where applicable, stable ordered alloys are also included in our analysis. Results for MPE alloys of refractory metals, oxides, carbides, and transition metal dichalcogenides will be discussed.

Modeling, Prediction and Analysis of the Temperature-Dependent Strength Properties of High-Entropy

Alloys, and Comparison with Nickel-Based Superalloys Baldur Steingrimsson[1,2], Xuesong Fan[3], Michael Gao[4] and Peter K. Liaw[3]; [1]Portland State University, United States; [2]Imagars LLC, United States; [3]The University of Tennessee, Knoxville, United States; [4]U.S. Department of Energy National Energy Technology Laboratory, United States

We present a bilinear log model for modeling and predicting the temperature-dependent strength properties of high-entropy alloys (HEAs). We have applied the model to prediction of the ultimate strength of HEAs and evaluated its effectiveness for 21 compositions. We model the logarithm of the yield or ultimate strength vs. temperature in terms of two linear regimes, a low-temperature and a high-temperature regime with a break temperature, T_{break}, in between. We present a global optimization approach for simultaneously optimizing the parameters of the bilinear model over the low-temperature and high-temperature regimes and for accurately estimating T_{break}. We consider the break temperature an important parameter for the design of materials with attractive high-temperature properties, one warranting inclusion in alloy specifications. For reliable operation, the operating temperature for the corresponding alloys may need to stay below T_{break}. Previous models for the temperature dependence of the yield strength of alloys only accounted for a single exponential. Hence, there was no break temperature.
The bilinear log model is founded on physical interpretations provided in a 2019 Acta Materialia paper by Senkov, Gorsse and Miracle titled “High Temperature Strength of Refractory Complex Concentrated Alloys”. Here, the authors show that, once above T_{break}, materials lose strengths rapidly due to rapid diffusion leading to easy dislocation motion and dissolution of strengthening phases (if any). According to Senkov et al., the diffusion processes required to initiate phase transformations generally become noticeable at temperatures $T > 0.4\ T_m$, where T_m represents the melting temperature, while at $T < 0.4\ T_m$ the phase transformations are kinetically restricted. In case of the low-temperature regime, atoms cannot move out of the lattice, and no phase transformations can take place. This is the case for low-entropy alloys (LEAs), medium-entropy alloys (MEAs), and HEAs, and serves to explain the two exponentials. A solid-solution strengthening model by Rao et al. does not take into account diffusion effects and agrees well with the experimental data only at relatively low temperatures, where diffusion-controlling deformation mechanisms can be ignored. Then, as the temperature increases, the chemical bonds between the elements become softer. The diffusion-controlled regime generally occurs above ~ 0.5 - 0.6 T_m. It can be distinguished from the low-temperature regime by a more rapid drop in strength with increasing temperature, because dislocations are able to move more easily around obstacles.
We then investigate the suitability of our bilinear regression model to commercial alloys, including Ni-based superalloys. Anomalous yield stress behavior is common among superalloys strengthened by L12 order intermetallics. We analyze suitability of our bilinear model for predicting the yield strength of commercial alloys, with or without evidence of the anomalous yield stress phenomenon. We compare and contrast our observations with the physical interpretations of Senkov et al., per the 2019 paper in Acta Materialia.

Predictive Models for Slip-Twin Interactions Explaining Strain-Hardening of HEAs Ahmed Sameer Khan Mohammed, Orcun Koray Celebi and Huseyin Sehitoglu; University of Illinois at Urbana-Champaign, United States

Much of the outstanding mechanical behavior of High Entropy Alloys (HEAs) in monotonic loading and in fatigue can be attributed to its propensity to strain-harden under large deformation. Such strain-hardening fundamentally arises from interactions between dislocations and twin boundaries. Recent work from our group has shown the role of such slip-twin (also twin-twin) interactions in increasing strain-hardening rates (*M. Bönisch, Y. Wu, H. Sehitoglu, Acta Materialia 153 (2018) 391-403*), decelerating fatigue-crack growth, their dependence on crystallographic orientation with respect to load *(R. Sidharth, W. Abuzaid, H. Sehitoglu, Intermetallics 126 (2020) 106919)*, and a strong correlation with Burgers vector residuals of slip-twin (or twin-twin) interactions. Although such interactions have been a subject of intensive study via Molecular Dynamics and Dislocation-Dynamics methods, the methods employed are not truly predictive as they rely on some form of empiricism. Tapping the full potential of strain-hardening from High-Entropy Alloys requires an ab-initio understanding of these interactions, one that does not involve any empiricism, captures the orientation-

dependence and roots the critical stresses of these interactions in fundamental fault energy parameters such as those parametrizing the Stacking-Fault Energy (SFE) landscape (e.g. intrinsic SFE, unstable SFE). We develop such a predictive framework for Dislocation-Twin-Boundary (D-TB) interactions within Generalized Peierls-Nabarro theory, predicting the critical stress for several dislocation reactions on twin boundaries. From a scientific standpoint, there has been a longstanding knowledge-gap in understanding core-structures of sessile dislocations such as stair-rods on twin boundaries. This gap has been the primary obstacle to modeling such dislocation reactions. We propose a core-structure for such dislocations, illustrating their evolution during their reaction and linking the changing core-width to the observed interaction stresses. The proposed framework establishes the dependence of the critical stresses on fundamental energy barriers of the crystal structure namely the intrinsic SFE, the unstable SFE and the unstable twinning energy. The physical fidelity of the model is validated by comparing against recent experimental data on HEAs showing good agreement, particularly in explaining the orientation-dependent behavior. By applying the model on several FCC materials and preparing Ashby-like plots we explain the reason behind such unseen strain hardening behavior of HEAs to be their critical stresses of D-TB interaction, finding them to be considerably higher than conventional FCC metals and alloys. We forward this predictive framework as a useful tool in designing HEA compositions and polycrystalline textures tailored to push boundaries of strength and toughness.

High Entropy Nanomaterials—Synthesis, Application and Accelerated Discovery Yonggang Yao[1] and Liangbing Hu[2]; [1]Huazhong University of Science & Technology, China; [2]University of Maryland, United States

High entropy materials have shown superior mechanical performances owing to the unique random mixing structure with multielement solid solution strengthening and stabilization. When scale down to nanometers, high entropy nanomaterials are promising for functional applications such as catalysis due to the exposed reactive surfaces. Particularly, the multielement mixing enables continuously tunable surfaces and properties while the high entropy structure provides the critical stability for using in harsh reactive conditions. However, in considering the large multielement compositional space and complex structures, the general synthesis of uniform mixing structure and the rapid screening of high entropy nanomaterials are still extremely challenging. In this report, we introduce the enabling and controllable thermal shock synthesis of high entropy nanomaterials (including alloys, oxides, and others) and their specific formation guidelines. In addition, the promising of high entropy nanomaterials as highly active and stable catalysts were demonstrated for both thermochemical and electrochemical reactions. Finally, combined with computational guide and high throughput screening, we briefly layout a potential way for accelerated discovery in the rarely explored multidimensional space.

Late News: Microwave Plasma Synthesis of High Entropy Transition Metal Diborides Bria C. Storr and Shane A. Catledge; University of Alabama at Birmingham, United States

The study explores the boro-carbothermal reduction synthesis of high entropy transition metal diborides via microwave plasma. High entropy diborides are promising materials due to ultra-hardness and resistance to high-temperature oxidation. The use of microwave plasma is a novel approach for high entropy diboride formation that capitalizes on its ability to transfer thermal energy to chemical reactions produced via the low-temperature plasma. Aiming to produce a five-component equimolar diboride, the starting powders consist of metal oxides (HfO_2, TiO_2, ZrO_2, Ta_2O_5, MoO_3) with carbon black blended by high energy ball mill, then combined with

boron carbide. By annealing the sample using microwave plasma, both boro-carbothermal reduction and a single-phase high entropy diboride $(Hf_{0.2}, Zr_{0.2}, Ti_{0.2}, Ta_{0.2}, Mo_{0.2})B_2$ were achieved in a single step.

2:55 PM ST04.03.03
Manipulate Ionic Transport Through Entropic Design—Case Studies on Disordered Rocksalt Oxides Bin Ouyang[1], Zhengyan Lun[1], Deok-Hwang Kwon[2], Linze Li[3], Chongmin Wang[3] and Gerbrand Ceder[1]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Pacific Northwest National Laboratory, United States

Metal oxides are promising materials for energy storage applications. For instance, disordered rocksalt types of metal oxides are promising Li-ion battery cathodes. Such materials are always made as a solid solution, in which short-range order (SRO) usually occurs and plays a crucial role on the Li transport properties. In this work, we developed a modeling suite that combines first-principles calculations, cluster expansion Monte Carlo simulations, electron diffraction prediction and Li percolation analyses to understand the evolution of Li transport properties with the increasing entropy. The impact of entropy on transport properties is evaluated from two types of compositional design: 1) Adding more species (such as F) into the anion site while maintaining three or four species on the cation sites; and 2) adding more than seven species on the cation sites. It has been found that the engineering of entropy on an anion site (O site) will lead to diverse evolution of transport properties, which is determined by how cations are mixed. On the other hand, once more than seven species are introduced to the cation site, the SRO generally evolves to be more favorable for Li transport. As a result, our findings lead to two routes of improving Li transport properties. For both directions of compositional engineering, we validated our theoretical predictions with experiments, which also lead to the discovery of new Li cathode materials with much higher capacities and rate capability than other state-of-the-art cathode materials. With the understanding of entropic effect on ionic transport, we hope to provide broader insights into understanding and exploring novel high entropy ceramic materials with extraordinary properties.

3:10 PM ST04.03.04
Catalytic High Entropy Oxide Heterostructures Stabilized with Vacancy Contributed Configurational Entropy Chris D. Riley[1], Andrew De La Riva[2], Abhaya Datye[2] and Stanley S. Chou[1]; [1]Sandia National Laboratories, United States; [2]The University of New Mexico, United States

High entropy oxides (HEO) are single phase oxides that combine traditionally immiscible metal cations through the increase of configurational entropy, by incorporating five or more cations. In some ways, this mimics a material's natural tendency to stabilize surfaces by the introduction of point defects to increase configurational possibilities of atoms. Using this concept, we demonstrate that a HEO can be designed with vacancies as an integral component of its structure. In this manner, we design structures with atomic porosities to yield a significantly vacant final product. For this, we utilize conventional alumina as a base, and through solid-state diffusion, induce sub-stoicheometric formations and vacancies as cations are introduced on its surface. The final product, a heterostructure, demonstrates a defined interface and unique vacancies sites that do not exist in conventional alumina-based structures, whether perovskites or spinel, and affords us to design catalytic active sites for tailored reactions. As a demonstration of the utility of this approach, we use the CO oxidation reaction as exemplar. In this case, the designed atomic porosities/vacancies engender oxidation pathways through the Mars Van Krevelen mechanism, which conventionally do not exist in alumina supports. In this manner, we demonstrate the catalytic potential of a highly engineered HEO, yielding a catalyst with performance that rivals the best state-of-the art single atom ceria-based catalysts.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science. Oxygen Vacancies in High Entropy Perovskite Oxides for Thermochemical Hydrogen Generation Jiyun Park[1], Jie Pan[2], Jian Luo[3], Xingbo Liu[4] and Yue Qi[1]; [1]Brown University, United States; [2]Michigan State University, United States; [3]University of California, San Diego, United States; [4]West Virginia University, United States

High entropy perovskite oxides (HEPOs) with A-, B-, or both-site mixing are promising redox materials to enable solar thermochemical hydrogen (STCH) generations with the improved efficiency, stability, and kinetics. In the STCH process, hydrogen is generated through a two-step cycle, where oxygen vacancies are created at high temperature and filled at low temperature by splitting water and releasing hydrogen. The efficiency of hydrogen production via the STCH process is, therefore, controlled by the difference between oxygen vacancy concentrations (δ) at the two steps, Δδ. We hypothesized the HEPOs can allow more oxygen vacancies (V_O) without a phase transition. Thus, a thorough study on the oxygen vacancy formation in the HEPOs is needed.

In this study, we combined density functional theory (DFT) calculations with statistical thermodynamics to investigate the oxygen vacancy formation and interactions in the randomly mixed systems $\{A\}\{B\}O_{3-\delta}$. This method enabled us to investigate the effects of multi-ions mixing in $\{A\}\{B\}O_{3-\delta}$ and to calculate the oxygen vacancy concentrations (δ) and the difference in δ at two stages (Δδ). The δ and Δδ are governed by the chemical potential of oxygen which varies with experimental conditions such as dry, wet, or ideal conditions. We analyzed a set of A-site elements, {Ba, Sr, La, Y, Gd, Nd, Pr, Sm}, and that of B-site elements, {Al, Ga, Mn, Fe, Ni, Co}, in $\{A\}\{B\}O_{3-\delta}$. We further compared the predicted vacancy concentration δ and Δδ with experimental observations in different STCH cycles. The atomistic insight, such as the oxygen formation energy was more sensitive to the charge of the {A} site ion, can be used to guide the design of new HEPO compositions with the improved properties for the STCH production.

3:40 PM ST04.03.06

Magnetocaloric Study of Aluminum-Doped $Gd_3Fe_{5-x}Al_xO_{12}$ Ferrite Dipesh Neupane[1], Arjun K. Pathak[2], Surendra Dhungana[1] and Sanjay R. Mishra[1]; [1]The University of Memphis, United States; [2]SUNY Buffalo State University, United States

The solid-state magnetic refrigeration technique is the convincing alternative reversible technique to replace the conventional gas compression refrigeration method based on the Magnetocaloric effect (MCE). The MCE is the intrinsic property of the magnetic materials. Rare earth (RE) iron garnets are complex ceramic oxides, having the chemical formula $A_3B_2C_3O_{12}$, (where A = RE^{3+} ion, B and C = Fe^{3+} ions) is suitable for MCE for low temperature. The garnet structure contains three different crystallographic sites, namely, dodecahedral (c), octahedral (a), and tetrahedral (d) site. The magnetic properties in rare-earth garnets arise from the antiferromagnetic exchange interactions of these sites. In $Gd_3Fe_5O_{12}$, two sublattices of ferric ions couple antiferromagnetically via the superexchange interaction through oxygen anions. The formula unit consists of three Fe^{3+} cations on tetrahedral sites and two Fe^{3+} cations on octahedral sites. The Gd^{3+} ions are also antiferromagnetically coupled to the net moment of the Fe^{3+} ions. Since the Gd^{3+} ions are disordered at room temperature and ordered at low temperature, the moment of Fe^{3+} ions are governed at high temperature, and Gd^{3+} dominates at low temperature. In this temperature range, interactions between neighboring spins and magnetic frustration result in finite entropy. In the present study, Al is doped in $Gd_3Fe_{5-x}Al_xO_{12}$ to investigate crystal structure and magnetic properties, including the magnetocaloric effect. $Gd_3Fe_{5-x}Al_xO_{12}$; x = 0.0, 0.25, 0.50 and 1.0 samples were synthesized via autocombustion method and heat-treated in air at 1100^OC for 12 h. The phase identification and lattice parameter of the powders performed using x-ray diffraction show the presence of high-crystalline single phases garnet (JCPDS-48-0077). With Al^{3+} doping, a gradual shift in the peaks to the left as compared to pure garnet is observed that showed a decrease in lattice parameters from 12.50A to 12.44A due to smaller ionic radii of Al^{3+} ion (0.535 A) replacing Fe^{3+} ions (0.645 A). Magnetic measurements were performed using SQUID magnetometer. Temperature dependence of the zero-field-cooled (ZFC) curve exhibits transition temperature at ∼50 K that is associated with glass transitions. Noticeably, there

is a sharp decrease in the FC magnetization below ~120 K, which coincides with the magnetic ordering temperature of the Gd sub-lattice. Saturation magnetization increased gradually with *x* content and reached an optimum value 43 emu/g for x=0.5 from 18 emu/g for x = 0.0 and followed by a decrease with x content at 5K. Observed enhanced magnetization for x = 0.5 is due to the optimal distance between Fe^{+3} ions, thus enhancing pair exchange interaction. To evaluate the MCE of the samples, the magnetization isothermal curves were collected at different fixed temperatures ranging from 10 to 250 K and in the field range between 1-3T. The magnetic entropy change(ΔS_M) as a function of the temperature curve shows a broad peak for x = 0.0. The peak position is shifted towards lower temperatures as *x* increases. This trend is consistent with our observation that the maximum magnetic entropy change (ΔS_M^{Max}) of the x=0.50 sample at 40K increases abruptly with an applied magnetic field of 3T. The increase in ΔS_M is mainly due to superexchange interaction between Fe–Fe ions and particle size. Arrot plots showed the positive slope of the curve, indicating a second-order phase transition in Al-doped nanoparticles. Cooling efficiency can be calculated from the peak position of ΔS_M^{Max} called relative cooling power(RCP). RCP values of our nanoparticle samples lie between 5 and 90 $Jkg^{-1,}$ with 90 Jkg^{-1} being the maximum for x = 0.50. These results make our compounds promising materials for magnetic refrigeration technology. Our study suggests that up to a certain level of non-magnetic atom doping, enhancement in MCE is possible. Thus, the proposed compound is cost-effective in terms of reducing the expensive rare-earth element.

3:45 PM ST04.03.07

Magnetocaloric Properties of RE Doped $Gd_{3-x}RE_xFe_5O_{12}$ (RE=Sm, Dy and Nd) Garnets Dipesh Neupane[1], Arjun K. Pathak[2], Surendra Dhungana[1] and Sanjay R. Mishra[1]; [1]The University of Memphis, United States; [2]University at Buffalo, State University of New York, United States

Rare earth(RE) iron garnets are complex ceramic oxides, having interesting magnetocaloric properties. The garnet structure contains three different crystallographic sites that hold a wide variety of cations. The magnetic properties in rare-earth garnets arise from the antiferromagnetic exchange interactions. In $Gd_3Fe_5O_{12}$, two sublattices of ferric ions couple antiferromagnetically via the superexchange interaction through oxygen anions. The formula unit consists of three Fe^{3+} cations on tetrahedral sites and two Fe^{3+} cations on octahedral sites. The Gd^{3+} ions are also antiferromagnetically coupled to the net moment of the Fe^{3+} ions, but this coupling is weaker than that between Fe^{3+} ions. Since the Gd^{3+} ions are disordered at room temperature, the ferrimagnetic properties of the material at high temperatures are governed by the moments of the Fe^{3+} ions. At low temperature, however, the Gd^{3+} lattice becomes ordered and dominates the magnetic properties of the material due to the larger magnetic moment of Gd compared with that of Fe ions. In this temperature range, despite interactions between neighboring spins, magnetic frustration due to the geometric configuration results in a disordered cooperative paramagnetic state with finite entropy. Besides structure, MCE also depends on morphology and defects. The present study investigates MCE in rare-earth-doped $Gd_{3-x}RE_xFe_5O_{12}$ where Gd ion is replaced by RE=Dy, Sm, and Nd. Doped $Gd_{3-x}RE_xFe_5O_{12}$ samples were synthesized via autocombution method and heat-treated in the air at 1100^OC for 12 h. The influence of replacing Gd^{3+} ions by rare-earth ions (RE3+) ions on the structural, morphology, magnetic, and magnetocaloric properties have been investigated using X-ray diffraction, scanning electron microscopy, and SQUID. The diffraction patterns showed the garnet structure (JCPDS-48-0077) of the cubic group Ia3d with the absence of any impurity phases. The lattice parameter of the powders calculated from the XRD pattern. The analysis of the XRD data confirmed that all compositions are single phase with garnet structure. The Dy doped garnet showed a decrease while Sm and Nd-doped garnet showed an increase in lattice volume. This systemic changes in the lattice volume are the result of the difference in ionic radii of RE ions. The temperature-dependent magnetization of the as-prepared pure phase RE doped samples was measured with field and zero-field cooling(FC and ZFC). Dy doped garnet had transition temperature at 90K, whereas Nd and Sm doped samples showed similar transition temperature with pure garnet. All RE3+ doped samples showed paramagnetic behavior at RT and antiferromagnetic behavior at 5K. The isothermal magnetic entropy changes (ΔS_M) calculated by using Maxwell equation from the isothermal magnetization curves that were collected at different fixed temperatures ranging from 10 to 250 K. $-\Delta S_M$ as a function of temperature curve shows a broad peak for x = 0.00. The peak position is independent with applied fields for the same material, whereas the peak shifted as RE^{3+} doped. ΔS_M increased with Dy^{3+} increases,

whereas Nd^{3+} showed decreases with x content. For Sm^{3+}, x = 0.25 has maximum ΔS_M. This trend is consistent with our observation that the maximum magnetic entropy change (ΔS_M^{Max}) of the Sm^{3+} (x=0.25) sample at 40K increases abruptly with the applied magnetic field of 3T. The variation in ΔS_M^{Max} is mainly due to super-exchange interaction between Fe – Fe ions. By doping Dy^{3+}, the distance between Fe^{3+} – Fe^{2+} ions decreases, so the exchange interactions and the super-exchange interaction become strong, resulting in the enhance of . Moreover, increased ~ 23% for Dy^{3+} x=0.75 sample and ~ 73% for Sm^{3+} x = 0.25 sample. These values are relatively high and comparable to some noticeable magnetocaloric material. Thus, based on these results, our samples are promising materials for magnetic refrigeration technology.

SESSION ST04.04: High Entropy Materials IV

5:15 PM *ST04.04.01
Unique High-Temperature Deformation Dominated by Grain Boundary Sliding in Heterogeneous Necklace Structure Formed by Dynamic Recrystallization in HfNbTaTiZr High Entropy Alloy Nobuhiro Tsuji[1], Rajeshwar R. Eleti[1], Atul Chokshi[2] and Akinobu Shibata[3]; [1]Kyoto University, Japan; [2]Indian Institute of Science, India; [3]NIMS, Japan

Microstructural evolution of dynamically recrystallized (DRX) grains and grain boundary sliding (GBS) in the heterogeneous necklace structure of HfNbTaTiZr refractory high entropy alloy (RHEA) was studied systematically during high temperature deformation. Uniaxial compression testing was carried out to different strains at 1000 °C and a strain rate 10^{-3} s^{-1} . Significant bulging of grain boundaries led initially to the formation of DRX grains. The fraction of DRX grains increased with strain, and typical necklace structures of fine ($d \leq 1.5$ μm) DRX grains formed at strain $\varepsilon \geq 0.3$. The DRX grains showed limited grain growth, and heterogeneous microstructures composed of coarse unrecrystallized regions surrounded by the characteristic DRX necklace structure were formed at larger strains. Interrupted testing with marker grids revealed that DRX grains deformed by a GBS mechanism. The DRX necklace regions connected mesoscopically and also displayed diamond network morphologies, with unique “Y-shaped”, “T-shaped”and “X-shaped” junctions. The formation of different types of junctions were rationalized on the basis of GBS accommodated by local dislocation slip in unrecrystallized regions. The unrecrystallized regions showed preferred <001> / <111> micro-textures, consistent with conventional dislocation slip in the BCC crystals. On the other hand, the newly formed DRX grains initially had similar orientations to those of the parent grains, but they displayed a random texture with increasing strain, as expected from GBS. The randomized texture of DRX grains and the stability of DRX grains size represented GBS in the DRX necklace regions.

5:40 PM ST04.04.02
Late News: Element Redistributions During Early Stages of Oxidation in a Ni38Cr22Fe20Mn10Co10 Multi-Principal Element Alloy Elizabeth J. Kautz[1], Sten Lambeets[1], Daniel Perea[1], Angela Gerard[2], Junsoo Han[2], John Scully[2], James Saal[3] and Daniel Schreiber[1]; [1]Pacific Northwest National Laboratory, United States; [2]University of Virginia, United States; [3]Citrine Informatics, United States

Element redistributions after initial oxidation of a $Ni_{38}Cr_{22}Fe_{20}Mn_{10}Co_{10}$ (at.%) multi-principle element alloy at 120 °C and 300 °C is captured via *in situ* atom probe tomography. All cations contribute to the oxide in both conditions, consisting of a Cr-rich inner oxide and a Fe, Mn, Co and Ni-rich outer oxide. At lower temperature, Ni tends to be trapped at the outer/inner oxide interface, while Ni enriches at the oxide/metal interface at higher temperature in tandem with Cr metal depletion. These observations confirm oxidation of complex alloys involves the formation of metastable, multi-layered oxide films, with a distinct tendency for solute trapping.

5:55 PM ST04.04.03

Cyclic-Deformation Behavior in a Ductile Multicomponent B2 Precipitates-Strengthened High-Entropy Alloy Rui Feng[1,2], You Rao[3], Chuhao Liu[4], Xie Xie[1], Dunji Yu[2], Yan Chen[2], Maryam Ghazisaeidi[3], Tamas Ungar[5], Huamiao Wang[4], Ke An[2] and Peter K. Liaw[1]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]The Ohio State University, United States; [4]Shanghai Jiao Tong University, China; [5]Eötvös University, Hungary

Fatigue failures in engineering structures can cause catastrophic accidents without obvious warning. Thus, a fundamental understanding of cyclic-deformation and fatigue-failure mechanisms is critical for developing fatigue-resistant structural materials. Here we report a ductile multicomponent B2 precipitates-strengthened high-entropy alloy (HEA), which exhibits the outperforming fatigue life, relative to traditional materials, at low strain amplitudes. Its real-time cyclic-deformation mechanisms are revealed by *in-situ* neutron diffraction, transmission-electron microscopy, crystal-plasticity modeling, and Monte-Carlo simulation. Multiple cyclic-deformation mechanisms, including dislocation slips, multicomponent-precipitation strengthening, deformation twinning, and reversible stress-induced martensitic transformation, are observed in the studied HEA. Its excellent fatigue performance is attributed to the outstanding fatigue-crack-initiation resistance, resulting from the high elasticity, plastic deformability, and martensitic transformation of the B2 phase that leads to the effective load redistribution and strain partitioning with the face-centered-cubic (FCC) matrix. Guided by this study, fatigue-resistant alloys strengthened by ductile multicomponent intermetallic phases can be developed.

6:10 PM ST04.04.04

Late News: Phase Diagram and Phase Transformations of Refractory High Entropy Superalloy Sang Jun Kim, Ji Young Kim, Hyunseok Oh and Eun Soo Park; Seoul National University, Korea (the Republic of)

Recently, various refractory high entropy superalloys, which have unique microstructure containing cuboidal nano-precipitates in BCC high entropy alloy (HEA), reported. They exhibited superior mechanical properties at both ambient and high temperature. However, there are many unsolved issues to attract even greater attention such as precipitation control of unwanted compounds, optimal phase selection between ordered and disordered BCC, and optimization of mechanical properties etc. In the present study, we studied the phase diagram and phase transformations of refractory high entropy superalloy through a bulk combinatorial approach in Ti-Zr-Nb-Ta-Al quaternary HEAs. Microstructural evolution for the non-equiatomic HEA compositions obtained by a bulk combinatorial approach were systematically investigated by considering phase transformation mechanism as well as phase equilibria. This result could provide an effective guideline for tailoring microstructure of HEAs with ordered and disordered BCC phases, and developing a promising high entropy superalloy with customized microstructure for ultra-high temperature structural application.

6:25 PM ST04.04.05

Lattice Distortion in Refractory High-Entropy Alloy Chanho Lee[1], Yi-Chia Chou[2], George Kim[3], Michael Gao[4], Ke An[5], Jamieson Brechtl[5], Chuan Zhang[6], Wei Chen[3], Jonathan D. Poplawsky[5], Gian Song[7], Yang Ren[8], Yi-Chia Chou[2], Nan Li[1], Saryu J. Fensin[1] and Peter K. Liaw[9]; [1]Los Alamos National Laboratory, United States; [2]National Chiao Tung University, Taiwan; [3]Illinois Institute of Technology, United States; [4]U.S. Department of Energy National Energy Technology Laboratory, United States; [5]Oak Ridge National Laboratory, United States; [6]Computherm LLC, United States; [7]Kongju National University, Korea (the Republic of); [8]Argonne National Laboratory, United States; [9]The University of Tennessee, Knoxville, United States

The lattice distortion is the core effect of HEAs to enhance the strength at room as well as high temperatures. The number of constituent elements with various atomic sizes have the identical possibility to occupy at atom positions of a crystal lattice, which induces a severe distortion of the crystalline lattice. Several studies have attempted to quantitatively measure the lattice distortion with increasing the number of alloying elements, using x-ray diffraction (XRD) and neutron diffraction (ND). However, only limited alloy systems have succeeded to demonstrate the correlation between lattice distortion and mechanical properties. In this study, we have

systematically investigated the evolution of lattice distortions for Nb-Ta-Ti-V-Zr systems as function of number of additional elements and its effect on mechanical properties, using experimental [atom-probe-tomography (APT at CNMS), transmission-electron microscopy (TEM)] and modeling methods [density-functional-theory (DFT)]. It is found that lattice distortions have a critical role in improving yield strength.

6:40 PM ST04.04.06
Late News: Microstructural Evolution of TRIPLEX Refractory High Entropy Alloy Composites Fabricated by Spark Plasma Sintering Sang Jun Kim[1], Jin Yeon Kim[1], Da Hye Song[2], Jin-Kyu Lee[2] and Eun Soo Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Kongju National University, Korea (the Republic of)

Recently, BCC high entropy alloys (HEAs) composed by Group-4 to Group-6 elements were reported to exhibit superior mechanical properties up to high temperature above 1273 K comparing conventional Ni-based superalloy. However, RHEAs is their industrial application is limited due to the high melting point and poor ductility in room temperature. In this study, TiVNbTaW RHEA powder with single BCC phase was prepared by high-energy ball milling and the fabricated powder were sintered using spark plasma sintering. Sintered TiVNbTaW high entropy alloy exhibited TRIPLEX nanostructure consisting of (Nb,Ta)-rich BCC, W-rich BCC and TiO FCC phase, which was formed during the sintering process by decomposition of single BCC phase in as-milled powder. Microstructural evolution of TRIPLEX nanostructure was analyzed in terms of metastable thermodynamic equilibrium related with segregation of solutes and diffusion kinetics in a complex multi-principle system. This result could provide an effective guideline for tailoring the nanostructure of RHEAs fabricated by powder metallurgy.

Late News: Bi-Continuous Refractory HEA/Cu Composite with Superior Thermal Conductivity at High Temperature Kooknoh Yoon, Il Hwan Kim and Eun Soo Park; Seoul National University, Korea (the Republic of)

Due to its high melting point, low deuterium/tritium retention, high thermal conductivity and so on, Refractory metals including tungsten(W) has been recognized as the most promising candidate of plasma facing materials (PFMs) for fusion reactors. Moreover, Refractor high entropy alloys (RHEA) is known to exhibit higher strength and thermal conductivity at elevated temperatures than W alloys due to solid solution strengthening as well as high resistivity against neutron irradiation damage.
Meanwhile, copper(Cu) based alloys have been proposed as the heat sink materials behind the plasma facing material due to its excellent thermo-mechanical properties. The joining of W to copper based heat-sink (CuCrZr) remain a main problem in the development of plasma facing component (PFC) due to the large difference in the coefficient of thermal expansion (CTE) between these two materials.
In this research, therefore, we fabricated composites of R-HEA and Cu by liquid metal dealloying (LMD) process. To utilize this technique, we prepared a precursor material which contains elements having positive and negative enthalpy of mixing with Cu simultaneously, and we immersed it into high-temperature liquid copper to form bi-continuous composite material. Finally, we analyze strength and thermal conductivity of the composite systematically. This work will give a guide line for designing PFMs with improved properties.

Single-Crystal Mechanical Properties of Equiatomic and Non-Equiatomic High-Entropy Alloys of the Cr-Mn-Fe-Co-Ni System Haruyuki Inui; Kyoto University, Japan

The plastic deformation behavior of single crystals of the FCC equatomic and non-equiatomic high-entropy alloys of the Cr-Mn-Fe-Co-Ni system has been investigated in a temperature range of 10-1273 K both in tension and compression. Deformation occurs via slip of the {111}<110> system exclusively in the whole temperature range for all alloys investigated. The CRSS values increase with decreasing temperature, especially below room temperature, so that the concept of 'stress equivalence' is obeyed. This is a clear indication that the strength of these alloys should be described by a mechanism based on solid-solution hardening. The CRSS values at 10 K seems to be well scaled by the mean-square atomic displacement from the regular FCC lattice points (calculated based on density-functional theory). Deformation twinning occurs in later stages of deformation at low temperatures below room temperature in many of these alloys. The correlation between twinning stress and the stacking-fault energy will be discussed.

8:40 PM ST04.05.02
Late News: Solid Solution Strengthening of Local Atomic Clusters (LAC) in CrMnFeCoNi High Entropy Alloys Kooknoh Yoon[1], Hyunseok Oh[2], Batiste Gault[3], Dierk Raabe[3] and Eun Soo Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States; [3]Max-Planck-Institut für Eisenforschung GmbH, Germany

Since high entropy alloy (HEA) is constituted with multi-principal elements, it can be understood in a very severe condition of solid solution strengthening (SSS). In particular, the local atomic clusters (LAC), sub-nano scale atomic structure, can be easily formed in HEAs by having preferential bonding among specific elements with thermodynamic stability. Understandably, the LACs can drive HEAs to extreme condition of SSS. Moreover, some former researches have reported that this structure can also affect on the bulk properties of HEAs, such as stacking fault energy (SFE) and so on.
In the present study, we systematically evaluate the influence of LAC formation on the degree of SSS in various CrMnFeCoNi HEAs. The LAC formation was carefully controlled by solidification history intensive structural analysis including APT, EXAFS and so on. Finally, this work will establish a tuning recipe for SSS in HEAs, which uses the sub-nano scale structural information.

8:55 PM ST04.05.03
Late News: *In Situ* Neutron Scattering Study of Plastic Deformation Mechanism in a High-Entropy Alloy with Chemical Short-Range Ordering Si Lan[1], Huiqiang Yin[1] and Xun-li Wang[2]; [1]School of Materials Science and Engineering, Nanjing University of Science and Technology, China; [2]City University of Hong Kong, China

Like elements choose to gather together and tend to form chemical short-range ordering in compositionally complex alloys, i.e., high-entropy alloys. The role of chemical short-range ordering in plastic deformation of a CoCrFeNiPd alloy has been studied using in-situ neutron diffraction and small-angle neutron scattering. The FCC single-phase CoCrFeNiPd alloys show much more substantial nanaoscale heterogeneity than CoCrFeNiMn Cantor alloy, indicating the existence of pronounced chemical short-range order. Moreover, lattice strain analysis reveals that the stacking fault probability is much higher in CoCrFeNiPd alloy than that of Cantor alloy due to the increase of stacking falt energy by chemical short-range ordering. Analysis of diffraction and microscopy data confirms that dislocations interations and propagations, rather than stacking faults or twinning, play an essential role at the early stage of plastic deformation in CoCrFeNiPd, leading to higher yield strength without compromising strain hardening and tensile ductility than those in Cantor alloy.

9:10 PM ST04.05.04
Late News: Correlation Between Medium-Range Order and Magnetic Structure in a High-Entropy Fe-Er-Ho-Tm-Y-Dy-Nb-B Metallic Glass Jiacheng Ge[1], Sinan Liu[1], Si Lan[1] and Xun-li Wang[2]; [1]Nanjing University of Science and Technology, China; [2]City University of Hong Kong, China

In-situ synchrotron high-energy X-ray diffraction and small-angle neutron scattering have been employed to study the kinetics of static structure and magnetic structure evolution in a high-entropy Fe-Er-Ho-Tm-Y-Dy-Nb-B metallic glass with an anomalous exothermic phenomenon upon heating. Our experimental evidence reveals that the high-entropy glassy alloy of a calorimetric anomaly would undergo a liquid-liquid phase transition accompanied by structure changes on medium-range ordering in the supercooled liquid region. Moreover, there is an increase of magnetic correlation length with the enhanced connectivity of medium-range ordering, resulting in the higher saturation magnetization for the sample after the liquid-liquid phase transition. Our results may help build a correlation between the medium-range order and the magnetic structures in soft-magnetic high-entropy metallic glasses.

9:25 PM ST04.05.05
High-Throughput, Combinatorial Study of Mechanical Properties of NiCoCr Thin Film Semin Park and Seung Min Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

High- and medium-entropy alloys are presumed to form a stable single phase of a random solid solution due to the high configurational entropy and are reported to have novel mechanical properties where they hold decent combinations of strength and toughness even under extreme conditions. One of the critical factors in designing HEA and MEA is to ensure stability of the solid solution, which typically is metastable unless the heat treatment temperature is sufficiently high to ignore the enthalpy term. Therefore, solid solution of HEA or MEA cannot be designed based on entropy alone, but the extent of enthalpy affecting solid solution stability should also be considered. In addition, atomic interactions affecting the short-range order and stacking fault energy can largely affect the expected mechanical properties. In this study, non-equiatomic NiCoCr HEA alloy is chosen to study the effect of composition on the mechanical properties using combinatorial high throughput method. Thin film composition library was fabricated via co-sputtering at different processing temperatures. Chemical mapping of the composition library indicated formation of NiCoCr with composition range of Ni varies from 18 to 51 at.%, Co from 19 to 59 at.%, Cr from 20 to 56 at.%, and x-ray diffraction was performed to analyze the phases. Measurement of Young's modulus and hardness was performed using nanoindentation methods, where thin film model was used to accurately determine the mechanical properties of the NiCoCr thin film by removing substrate effects. This study is first to report a high throughput method involving a thin film combinatorial method in studying the effect of composition of NiCoCr on the mechanical properties via nanoindentation.

10:00 PM ST04.05.06
Late News: Comprehensive Composition-Microstructure Maps of High-Entropy Alloys from High-Throughput First-Principles Study Zhidong Leong and Teck Leong Tan; Institute of High Performance Computing, A*STAR, Singapore

While refractory high-entropy alloys (HEAs) exhibit exceptional mechanical properties, insights into the underlying microstructures are limited—experimental data appear scarce relative to the vast composition space. Here, we present a high-throughput first-principles study of Mo-V-Nb-Ti-Zr, a refractory HEA known for its high-temperature strength and biomechanical compatibility. Using cluster expansion and Monte-Carlo simulations, we compute the temperature dependence of the microstructures across the whole composition space. We demonstrate that as the high-temperature solid solution cools, Zr preferably segregates from Mo and V (rather than from Nb and Ti), leading to secondary phases that are enriched in Zr with randomly dispersed Nb and Ti. Across compositions, the segregation is more pronounced for a higher segregation T_c, which increases with higher Mo and V contents. We elucidate the origins of the phase separation and elemental distribution via tracing the short-range ordering tendency of the different elemental pairs. Not only do our results reproduce numerous sets of experimental observations within a consistent framework, they also provide predictions for much of the compositional space lacking experimental data. Finally, using the segregation T_c, we discuss the

phase stability of solid solutions and identify compositions for which solid solution formation is prohibited. Our work provides the much needed insights into the HEA's microstructures, guiding future experiments in the design of HEAs with superior mechanical properties.

10:15 PM ST04.05.07
Late News: Development of Classical and Machine Learning Based Force Fields for Robust High Entropy Alloys Structure-Property Predictions Bhumika Longakshi, Siddharth Krishnan and Raghavan Ranganathan; Indian Institute of Technology Gandhinagar, India

High Entropy Alloys (HEA) form a fascinating class of materials with various technological applications arising from their interesting properties. Due to the complex nature of these systems, a detailed and reliable exposition of nanoscale structure-property correlations via full atomistic simulations is a considerable challenge.
In this work, we generate robust parametrized Embedded Atom Method (EAM) potentials and critically compare it with a generalized Machine Learning-based Moment Tensor potential for predictions of mechanical properties in the Fe-Ni-Co-Cr-Cu alloy system. These potentials are fit to results from detailed ab inito Molecular Dynamics (AIMD) simulations yielding energies, stresses and atomic positions under various conditions (varying temperature, strains and defects), with the advantage of using the same DFT training set for both the classical EAM potential, and the Machine Learning Interatomic Potential. Model structures in training include constituent unaries, equiatomic binaries and ternaries and a few non-equiatomic compositions of the quinary alloy. We show that although the EAM potential for the alloy is able to capture the static structural properties and near-equilibrium dynamic properties well, the MTP potential with active learning of the potential resulting from on-the-fly calculations of atomic trajectories, yields superior results even for far-from-equilibrium dynamic conditions such as high-strain rate tension and compression. This modeling protocol serves as a high-fidelity approach for large-scale atomistic simulations of structure-property correlations in HEAs.

10:20 PM ST04.05.08
Late News: First-Principles Calculation of Stacking Fault Energy of Multi Principle Component Alloys Using Bilayer-SQS Sufyan M. Shaikh[1], Budaraju Srinivasa Murty[1,2] and Satyesh K. Yadav[1]; [1]Indian Institute of Technology Madras, India; [2]Indian Institute of Technology Hyderabad, India

Deformability of high entropy alloys (HEAs) has been shown to strongly depend on their stacking fault energy (SFE). Reducing the SFE of HEAs can lead to enhanced twin susceptibility, which can ultimately lead to improved deformability of the alloys. CoCrFeMnNi shows good deformability at room temperature, which is attributed to low SFE. We observe that SFE of CoCrFeMnNi is lower than SFE of each of its constituent elements. This hints towards a way of lowering the SFE of BCC metals (which are less deformable than FCC alloys), by alloying them to from multi principal component alloys. To predict effect of alloying elements reliably, first-principle density functional theory (DFT) technique is used.

Special quasi-random structure (SQS) supercells are widely used to calculate the SFE of HEAs. Such SQS attempt to mimic random occupancy of each lattice site by constituent elements in the bulk, we call this approach as “bulk-SQS” method. This approach does not guarantee same stoichiometry in each plane as in the bulk, which results in large variation in calculated SFE depending on type and number of atoms in the two planes being sheared.

Here we propose a new “bilayer-SQS (bSQS)” methodology to reliably calculate the SFE of HEAs. Instead of considering the correlation in the entire volume of the supercell, in bSQS method, the correlations are considered only in the two neighboring planes. First, a bilayer, i.e. SQS with 2 planes (in which SFE need to be calculated) is generated with the same chemical composition as the alloy. This bSQS is then repeated 5 times to get 10 slip planes in the supercell. A minimum of 10Å of vacuum is added to prevent the effect of neighboring faults due to the periodic boundary condition.

The bSQS methodology gives the same SFE value irrespective of which slip plane is sheared. We also optimize the minimum number of slip planes and the minimum number of atoms per plane required to reliably calculate the SFE of HEAs. The SFE values are said to be converged when the values from two consecutive atoms per plane supercells are within 1meV/atom (which is typical DFT error). This gives us the minimum number of atoms required in the supercell to get a reliable SFE value. In present work, the bSQS methodology is used to calculate the SFE of {110}<111>, of Ti, Zr, Hf, Nb, Ta, and their equiatomic binaries, ternaries and quaternaries.

Insights of Capacitance Increase Over Repetitive Charge/Discharge for Lignin Carbon Nanofiber-Based Supercapacitors Azega Rajendra Babu K. Arasi, Qi Li, Mazharul Haque, Per Lundgren and Peter Enoksson; Chalmers University of Technology, Sweden

The production of free-standing carbonized electrospun lignin carbon fibers (ELCF) is similar to that used in large scale paper making. This makes ELCF highly prospective for commercially viable supercapacitor electrodes, being a low-cost and bio-renewable starting material. However, untreated ELCF -based electrodes for supercapacitors face several challenges due to their poor mechanical performance and limited conductivity. Thermal treatments applied for carbonization and activation vastly improve both electrochemical performances and mechanical properties by giving rise to fiber crystallization. Yet as supercapacitor electrodes, their microporous structure faces the issue of electrolyte ion accessibility. The charge transfer impedance is known to increase due to the inaccessibility of electrolyte ions to the porous structures, resulting in decreased charge storage ability [1]. Understanding the correlation between the electrode physiochemical properties and the charge storage is key to guide the production and commercialization of ELCF materials for supercapacitor applications. In this work, ELCF were fabricated by electrospinning and carbonized at 1000 °C. The ELCF performance was evaluated in a coin cell configuration with two symmetric electrodes in 6M KOH electrolyte over 5k, 10k, 20k, and 50k cycles. There was a constant increase in performance up to 2-fold from 3.8 mF/g to 7.7 mF/g after 50k cycles. The capacitance increase is accompanied by an interfacial resistance decrease that is caused by the interaction between the bulk electrolyte and the electrode’s interface as inferred from the Nyquist

plots. This improvement behaviour with cycling is attributed to the better accessibility of the alkaline KOH electrolyte ions to outer pores over repeated cycling. Another contribution to the increased capacitance could be related to lignin being a complex natural biopolymer incorporated with various functional groups [2]; more reactive functional groups could be made available during the consecutive cycling for the charge transfer to take place [3]. The K^+ electrolyte ions are adsorbed on the exposed reactive sites in the larger lignin chains over their repeated intercalation and deintercalation during redox reactions resulting in slower and steady growth in capacitances with highly stable cycling behaviour. This can also be explained by the common behaviour during electrochemical analysis that the unreactive constituents remain inactive to capacitive behaviour initially and begin electroactivity additionally after the reaction. To further corroborate these explanations, the specific surface area, pore size, and functional groups of the ELCF before and after cycling will be investigated by using Brunauer-Emmett-Teller (BET) and X-ray Phototelectron Spectroscopy(XPS) characterization analysis. Additionally, a thorough electrochemical investigation will be carried out regarding the improved capacitive performance with cycling, alongside with the quantification of electrostatic (pore) and pseudocapacitive (functional group) charge storage of ELCF material.

Late News: Mechanical Degradation in 3D Metal Scaffold Structured Silicon Anodes Soheil Daryadel, Beniamin Zahiri, Nathan J. Fritz, Paul Braun and Jessica A. Krogstad; The University of Illinois at Urbana-Champaign, United States

3D structuring significantly enhances the cycle life performance of silicon anodes by accommodating large volume changes during de/lithiation and enables fast charging. The accumulation of mechanical stress induced by large volume changes and understanding its impact on cell performance is key toward optimizing the cycle life of these structured anodes. In this presentation, we report on the contribution of mechanical degradation to capacity fading in Si-coated 3D Ni scaffolds. We propose a novel approach to investigate the mechanical properties of the electrode materials decoupling the geometry evolution. The mechanical resilience of the anodes, including the active material and metallic support, the SEI, and the associated interfaces, are probed throughout cycling using nanoindentation. Additionally, the microstructural evolution and structural disintegration of Si and the metallic scaffold were investigated at different stages of cycling. Results revealed a reduction of strength and connectivity in the Ni scaffold during cycling and provided critical insight into the design optimization of durable high energy density anodes. A fundamental understanding of the coupling between mechanics and electrochemistry in lithium-ion battery electrodes can be advantageous in developing reliable next-generation energy storage technologies.

8:20 AM ST05.00.03

Non-Classical Electrostrictive Phenomena in Hydrated Acceptor Doped $BaZrO_3$— Proton Trapping and Dopant Size Effect Evgeniy Makagon[1], Maximilian Hoedl[2], Rotraut Merkle[2], Eugene Kotomin[2,3], Joachim Maier[2] and Igor Lubomirsky[1]; [1]Weizmann Institute of Science, Israel; [2]Max Plank Institute for Solid State Research, Germany; [3]University of Riga, Latvia

Acceptor-doped $BaZrO_3$ is a promising electrolyte for protonic ceramic fuel cells as it combines high bulk proton conductivity with good chemical stability. The protonic conductivity is achieved by dissociative water incorporation into oxygen vacancies formed by acceptors on Zr^{4+} sites. We have investigated the influence of

dopants, oxygen vacancies, and protons on the macroscopic elastic and electromechanical properties of acceptor-doped $BaZrO_3$ ceramics.
Ceramics of $BaZr_{1-x}X_xO_{3-x/2+\delta}H_{2\delta}$ with X = Ga, Sc, In, Y, Eu and $0.05 \leq x \leq 0.2$ were prepared by solid state reactive sintering and hydration. Ultrasonic pulsed echo time of flight measurements were used to infer the Young's and the shear moduli. Both moduli decrease by up to ~20% due to the presence of dopants and oxygen vacancies that cause local lattice distortions [1,2]. Water incorporation into the vacancies decreases the moduli even further. An unexpectedly large electrostriction coefficient ($M_{33} \sim 10^{-15}$ m^2/V^2) was detected with a capacitive proximity sensor for all dopants introducing a new class of non-classical electrostrictors. M_{33} of the hydrated ceramics exhibits a Debye-type relaxation with the relaxation frequency exponentially increasing with the ionic radius closely matching dielectric relaxation measured by impedance spectroscopy. This implies that the protons are associated with the dopants, and the binding strength decreases from Ga to Y.

8:30 AM ST05.00.04
Strain Induced Enhancement of Hydrogenation Capacity in rGO/Pd/rGO Nanolaminates Dae ho Kim[1], Jinseok Koh[1], ShinYoung Kang[2], Eun Seon Cho[1] and Seung Min Han[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Lawrence Livermore National Laboratory, United States

In this work, rGO/Pd/rGO nanolaminates for metal-hydride hydrogen storage material was studied for the first time that indicated an enhancement in the hydrogen storage capacity due to the mechanical strain imposed on the Pd nanoparticles. Pd nanoparticles were encapsulated by the graphene layers to fabricate rGO/Pd/rGO nanolaminates and reduced graphene oxide (rGO) wrapping induced strain on Pd nanoparticles were then analyzed using high resolution transmission electron microscope (HRTEM). The average strain induced on the Pd nanoparticles in the as synthesized rGO/Pd/rGO nanolaminates was 3.30% in tension, and this value of strain increased to 5.44% upon hydrogenation. The strain increase to 4.94% in Pd and 7.12% in PdH_x nanoparticle if the contracted lattice parameter by nanosize effect was considered. Atomistic simulations were performed to provide further analysis on the effect of surface tension on the reference lattice parameter of Pd nanoparticles to refine the calculated strain from the HRTEM analysis. Hydrogen storage performance indicates a significant improvement, where both kinetics and the hydrogen storage capacity are significantly improved without sacrificing nano-size effects, and this enhancement is due to the tensile strain on the Pd nanoparticles causing a reduction in the activation energy of hydride formation.

8:40 AM ST05.00.05
The Role of Surface Energy in Propagation of Stress-Induced Cracks in Li-Intercalated Hollow-Sphere Silicon Anodes—A Comprehensive Analytical Model Tejveer S. Anand, Jayant Choudhary, Akash Sonkar, Henam S. Devi and Madhusudan Singh; Indian Institute of Technology Delhi, India

Owing to their high theoretical capacity to incorporate substantial amounts of lithium, silicon anodes in lithium-ion batteries undergo significant volumetric changes during charge-discharge cycles, leading to battery failure due to pulverization and fracture of the anode material. We have constructed an analytical model based on concentration-driven diffusion and linear elasticity. This comprehensive model incorporates diffusion-induced stress (DIS), electrochemical (forward) reaction induced stress (RIS), and surface effects associated with a hollow silicon spherical electrode under potentiostatic operation. Also included are various forms of stress - radial, hoop and hydrostatic, coupled with various functional parameters to study variations in stress profiles for low lithium concentrations. Two surface effects are accounted for: a) surface energy , which is the Laplace pressure arising from lithium concentration difference at the silicon interface, and surface elastic modulus. To illustrate the importance of surface effects in this model, we carried out numerical solutions of the coupled problem in its natural geometry - spherical polar coordinates, to study a hollow silicon sphere with inner radius of 200 nm and outer radius of 500 nm. When aforementioned surface effects are ignored, the maximum value of radial stress is found to be 5.3 MPa (tensile) at 318 nm (close to the center of the hollow sphere). When surface

energy and surface modulus are included in the solution, the maximum value of radial stress reduces dramatically by nearly 59% and the location of the maximal stress moves inwards to ~285 nm. This consequently leads to the stress at the outer surface becoming compressive in nature. Further, with a systematic increase in surface energy parameters, radial as well as hoop stress at the outer interface becomes more compressive. Physically, in a manner somewhat analogous to hydrophobic liquids, this shift can be understood as the effect of enhanced surface energy countering the tendency of the system to expand and relieve its increased surface stress by propagating cracks. Unsurprisingly, as the surface to volume ratio increases for smaller hollow silicon spheres, the effect becomes even more discernible for low surface lithium-concentrations ([Li]~ 1 mol / m^3). This suggests that it may be advantageous to use slightly larger electrodes (at the cost of lower capacity), or to employ lower working lithium concentrations. We are currently studying the effect of suitable barrier layers for rational design of anodes with engineered stress profiles, while maintaining high capacity.

Creep-Enabled 3D Solid-State Lithium-Metal Battery Ju Li; Massachusetts Institute of Technology, United States

Existing all-solid-state Li-metal batteries suffer attacks by the chemically aggressive and mechanically stressful Li metal. Li metal is a soft crystal and may exhibit either displacive or diffusive deformation. Here, we describe a class of all-solid-state Li-metal batteries enabled by 3D porous Li-metal hosts made of electrochemically stable mixed Li-ion and electronic conductor (MIEC) and electronic and Li-ion insulators (ELI). Within 3D open porous MIEC/ELI structure, Li metal advances and retracts via interfacial diffusional creep as an ``incompressible working fluid'' with fast stress relaxation and minimal contact with a solid electrolyte (SE), thereby significantly improving the electrochemomechanical stability. In situ transmission electron microscopy corroborated with thermodynamic analyses offers design principles in materials, sizes, and interfaces of the 3D porous MIEC/ELI structures, which are applicable to other alkali-metal batteries. The successful construction of a creep-enabled battery engine opens a new avenue toward high-density, electrochemically and mechanically robust all-solid-state Li-metal batteries. [Nature 578 (2020) 251]

12:10 PM ST05.01.02
Structural Evolution and Failure Modes in High-Performance Silicon-Oxide Based Anode Driven by Electrochemistry and Mechanics Guoyu Qian; Peking University Shenzhen Graduate School, China

High-energy-density silicon oxide-based/ graphite composite anodes are promising to become the next-generation anode material in the lithium-ion battery industry. However, as the vital raw material of the newly designed anodes, micron-sized silicon oxide-based particles exhibit poor cycling stability, which limits its industrialization promotion. Due to the complex amorphous microstructure inside the silicon oxide-based particles, its evolution and failure mechanism during the electrochemical cycling process remains poorly understood.
Accurate sample preparation for the silicon oxide-based particles will be performed by FIB-SEM dual-beam system, so that the chemical compositions and structure in the internal space of silicon oxide-based particles would be characterized. Combining with the different results during the whole electrochemical cycling process,

we would obtain the formation and evolution principles of the internal microstructure for the silicon oxide-based particles.
Moreover, the dramatic volume change, the damage of ion pathway and conductive network inside the particles, the continuous growth and reconstruction of SEI, and the Si-ion loss to the silicon oxide-based particles during hundreds of electrochemical cycles would be comprehensively investigated, in order to summarize the negative factors of the particle failure and capacity loss.
Benefited from the results in this report, more effective strategies would be designed, which could be generalized for the preparation of other silicon oxide-based anode materials. Therefore, the next-generation anodes of Li-ion batteries with excellent cycling stability, high reversible capacity and superior rate performance would be obtained.

12:25 PM *ST05.01.03
Chemo-Mechanics of Battery Transformations Investigated with *In Situ* Imaging Methods Matthew T. McDowell; Georgia Institute of Technology, United States

Pathways to batteries with higher energy density necessarily involve the use of electrode materials that undergo substantial chemo-mechanical transformations in both liquid and solid-state electrolyte environments. Here, I discuss my group's efforts to use *in situ* and *operando* characterization to investigate the interplay between chemistry and mechanics during reactions of high-capacity battery electrode materials. First, our work on using *in situ* transmission electron microscopy (TEM) to investigate reversible void nucleation and growth during delithiation of antimony (Sb) alloy nanocrystals is presented. Sufficiently small Sb alloy nanocrystals were found to form single voids during dealloying rather than undergoing shrinkage, as in larger particles. This voiding behavior during dealloying was a result of the impact of stiff native oxide surface layers that retained their shape. This effect was found to be size dependent, and an analytical model was developed to show that small nanocrystals do not exhibit enough total strain energy during shrinkage of the Li-Sb phase to drive mechanical buckling of the shell. These observations translated to improved electrochemical behavior in battery cells, where the small nanocrystals were observed to exhibit the highest average Coulombic efficiency compared to larger particles. Next, a study on chemo-mechanical degradation of FeS_2 electrode materials reacting with different ions (lithium, sodium, and potassium) is presented. Despite larger volume changes during reaction with Na^+ and K^+, only reaction with Li^+ was observed to cause fracture. Modeling showed that this surprising result was found to be due to the shape of the reaction front as it evolves during reaction, with sharp corners during lithiation resulting in stress concentration and fracture. Finally, our efforts on understanding interphase formation and mechanical contact at solid-state interfaces in all-solid-state batteries is discussed. The reaction of $L_{1+x}Al_xGe_{2-x}(PO_4)_3$ (LAGP) solid-state electrolyte with lithium is found to involve amorphization and volume expansion of ~130%. *In situ* X-ray tomography experiments of operating LAGP-based cells reveal that the growth of the interphase causes fracture, which is the underlying cause of impedance increase within the cell. Together, these studies highlight the controlling influence of chemo-mechanics in high-capacity battery electrolyte materials when used in both liquid and solid-state battery systems.

12:50 PM ST05.01.04
Real-time Control of Dendrites in Rechargeable Batteries Using Smart Feedback Asghar Aryanfar[1,2], Yara Ghamlouche[1] and William A Goddard III[2]; [1]Amrican University of Beirut, Lebanon; [2]California Institute of Technology, United States

The non-uniform growth of the microstructures in dendritic form inside the battery during prolonged charge-discharge cycles causes short-circuit as well as the capacity fade. We develop a feed-back control framework for the real-time minimization of such microstructures. Due to accelerating nature of the branched evolution, we focus on the early stages of growth, identify the critical ramified peaks and compute the effective time for the dissipation of ions from vicinity of those branching fingers. The control parameter is a function of the maximum interface curvature (i.e. minimum radius) where the rate of run-away is the highest. The minimization of total charging time is performed for generating the most packed microstructures which correlate closely with those of considerably higher charging periods, consisting of constant and uniform square waves. The developed

framework could be utilized as a smart charging protocol for the safe and sustainable operation the rechargeable batteries, where the branching of the microstructures could be correlated to the sudden variation in the current/voltage.

Fundamental Understanding of the Coupled Mechanical and Chemical Degradation of Lithium Metal Electrodes Xingcheng Xiao; General Motors, United States

Low cycle efficiency and dendrite growth are two critical barriers for rechargeable batteries using Li metal as negative electrodes, mainly due to the coupled mechanical/chemical degradation of the SEI layer formed on Li metal surface. We have developed a comprehensive set of in situ diagnostic techniques combined with atomic/continuum modeling schemes to investigate and understand the coupled mechanical/chemical degradation of the SEI layer/Li system including fundamentally understanding the surface and interface phenomena. We have found that the mechanical incompatibility between SEI and soft Li leads to the complicated mechanical behaviors of the lithium metal electrode during the plating and stripping process. We systematically investigated the relationship between surface morphology and current density distribution which results in an inhomogeneous Li plating/stripping process. We also investigated the mechanical properties of Li metal electrode at different cycle period, including the stress evolution and deformation mechanism which have been significantly impacted by SEI formation. Based on the fundamental understanding from the integrated in-situ diagnostics, atomic simulation, and continuum framework, we have developed a new coating design strategy to achieve high cycle efficiency/dendrite free and extend the cycle life of lithium rechargeable batteries.

Sodium Metal Mechanics—Temperature and Grain-Rotation Effects on Plasticity and Creep William LePage[1,2], Yuxin Chen[2], Kuan-Hung Chen[2], Andrea Poli[2] and Neil P. Dasgupta[2]; [1]University of Tulsa, United States; [2]University of Michigan, United States

Na-ion and Na-metal batteries are attractive alternatives to Li-ion, as they have the potential to reduce cost and add supply chain stability for energy storage portfolios. The raw materials for Na-based batteries are more readily sourced: Na is much more earth-abundant than Li, Na batteries can utilize aluminum for both current collectors (instead of copper), and they can also readily use cobalt-free cathodes. In order to advance the state-of-the-art for Na-ion and Na-metal batteries, reliable mechanical property data for Na is needed. However, few reports have characterized the mechanical properties of Na, especially in terms of its viscoplastic and creep properties [1]–[3].

In this study, we report the first temperature-dependent measurements of power-law creep of Na. While prior works on the viscoplastic and creep deformation of Na have reported values at room temperature, this work measured the tensile response of Na in inert environments between 273 and 348 K. Furthermore, this work revealed insights about sodium deformation in general that have implications for Na batteries. For example, tests at room temperature utilizing digital image correlation (DIC) were performed inside of an argon glovebox [4] to map the local deformation of Na tensile samples. Local strain and rotation maps from DIC revealed millimeter-scale inhomogeneity that was attributed to plastic grain rotation, due to the large (~1 mm) grain size in the Na. The full calibration of power-law creep behavior from this work is valuable for modeling efforts to understand the fundamental research of Na-based batteries.

Gliding and Microcracking in a Single Crystalline Ni-Rich Cathode Jie Xiao; Pacific Northwest National Laboratory, United States

High energy Ni-rich cathode will play a key role in advanced Li-ion batteries, but it suffers from moisture sensitivity, side reactions and gas generation. Single crystalline Ni-rich cathode has a great potential to address the challenges present in its polycrystalline counterpart by reducing phase boundaries and materials surfaces. However, synthesis of high-performance single crystalline Ni-rich cathode is very challenging, not mentioning a fundamental linkage between over potential, microstructure and electrochemical behaviors in single crystalline Ni-rich cathodes. This talk will discuss the planar gliding and microcracking along the (003) plane in a single crystalline Ni-rich cathode by using in situ AFM and TEM. The formation of microstructure defects is correlated with the localized stresses induced by a concentration gradient of Li atoms in the lattice, providing clues to mitigate particle fracture from synthesis modifications.

2:40 PM *ST05.02.03
Cationic and Anionic Redox Heterogeneity in Layered Battery Cathode Yijin Liu; SLAC National Accelerator Laboratory, United States

Multiscale electro-chemo-mechanical interplay governs the local structural and chemical evolution and is fundamental to the global electrochemical behavior of batteries. Prolonged battery operation under realistic conditions induces state-of-charge (SoC) heterogeneity, builds up mechanical stress, and provokes morphological breakdown. These processes prevail in most battery electrodes and ultimately determine the device-level battery performance. In lithium-rich nickel-manganese-cobalt (LirNMC) layered material, a promising cathode for lithium-ion batteries with superior energy density however suffers from capacity and voltage fade, the coexisting cationic and anionic redox activities further complicate the redox heterogeneity, urging for a comprehensive investigation of at the nano- to meso- scales. In this talk, we will present a systematic study on the mesoscale degradation of the layered battery cathode material. We look into the intertwined lattice, redox, and micro-morphology properties as the cathode is cycled under different conditions. Our results suggest that the cathode particle engineering could be a viable approach for further improving the structural and chemical robustness of the Li-ion battery.

3:05 PM DISCUSSION

3:20 PM ST05.02.05
Unraveling the Role of Primary Particle Size and Morphology During Calcination of Layered NMC Cathodes for Li-Ion Batteries Mark Wolfman[1], Xiaoping Wang[1], Peter Eng[2], Joanne Stubbs[2], Vincent De Andrade[1], Pallab Barai[1], Juan C. Garcia[1], Hakim Iddir[1], Venkat Srinivasan[1] and Tim Fister[1]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States

In modern layered cathodes for lithium-ion batteries, the sizes and morphologies of the primary particles play a key role in governing the electrochemical dynamics during cycling, since the desired charge-transfer reactions

and any competing solid-electrolyte interphases rely on the exposed particle surfaces. Synthesis of layered cathodes is a two-step process. The secondary structure is determined largely by the conditions used in the initial preparation of the transition metal precursor material. The subsequent high-temperature calcination transforms the precursor to the final lithiated cathode while largely preserving the structure of secondary particle agglomerates. Recent research has characterized the crystal structure during this transformation, but has been largely silent on the accompanying morphological changes in the primary particles. Through a combination of in-situ X-ray diffraction and X-ray tomography, the morphology and structure of layered NMC primary particles were tracked during calcination. Comparison with first principles calculations and continuum modeling provided additional insights into the changes in both phase and morphology. These results provide a foundation for a more deliberate design of cathode materials with the necessary performance characteristics to help meet the growing demand for electrochemical energy storage.

3:35 PM *ST05.02.06
Role of Mechanical Deformation on Rate Capability of Electrosorption and Insertion-Type Charge Storage Veronica Augustyn; North Carolina State University, United States

Extremely fast charging and discharging, along with long cyclability, require energy storage materials that respond with minimum mechanical deformation while at the same time storing significant amounts of charge. The coupling of mechanics with electrosorption and insertion leads to fundamental limits in the power capability of materials. During this presentation, I will discuss our use of operando atomic force microscopy to probe the real-time deformation of ion insertion materials at fast (minute and second) timescales. The nanoscale dimensions of the AFM tip allow us to probe not only the deformation but also the heterogeneity of the insertion process. Furthermore, I will share our insights into how understanding mechanical deformation can lead to the design of high power energy storage materials such as tungsten oxides with confined interlayer water.

8:15 PM ST05.03.01
Effect of Li Concentration-Dependent Material Properties on Diffusion Induced Stresses of a Sn Anode Hyeongyun Nam, Chung Su Hong and Seung Min Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Sn is one of promising anode materials with high theoretical capacity for Li ion batteries and has attractive mechanical properties for effective stress relaxation during lithiation. Soft, ductile nature as well as creep at room temperature allow for Sn to effectively relax the generated stress due to the volumetric strain as a result of lithiation. In this study, finite element simulation was used to study the evolution of diffusion induced stresses in Sn micropillar anode with the focus on the effect of concentration-dependent material properties in the diffusion induced stresses. Simulation results using concentration-dependent material properties indicated a different failure mode in comparison to that from simulations results using concentration-independent material properties. When modeled using constant material properties that are independent of Li composition, compressive hoop stress is developed at surface of pillar. If we assume elastic deformation, max hoop stress at the surface is 1000 MPa, but this reduced down to 150 MPa and 40 MPa in compression when plasticity and creep, respectively, is incorporated in simulation model. On the other hand, when concentration-dependent material properties were incorporated in the model, concentration profile of Li in Sn becomes homogeneous as lithiation is proceeded and compressive hoop stress at surface is transformed into tensile hoop stress in the early

stage of lithiation. This hoop stress transition at surface is found to be originated from the increase of diffusivity of Li in the lithiated phases; outer region near the surface that has already transformed to Li rich phases is pushed out as the core of the pillar undergoes lithiation reaction to result in tensile hoop stress at the surface of the micropillar. Development of tensile hoop stress at surface can then trigger the crack formation at the surface of Sn micropillar. In order to experimentally determine the critical dimension for Sn micropillar as a result of lithiation, Sn micropillars of varying sizes were studied which was determined to be 5.3 μm when charged at rate of C/10.

8:30 PM *ST05.03.02
Heterogeneous Damage in Li-Ion Batteries—Experimental Analysis and Theoretical Modeling Kejie Zhao; Purdue University, United States

We assess the heterogeneous electrochemistry and mechanics in a composite electrode of commercial batteries using synchrotron X-ray tomography analysis and microstructure-resolved computational modeling. Morphological defects are visualized at multi-scales ranging from the macroscopic composite, particle ensembles, to individual single particles. Particle fracture and interfacial debonding are identified in a large set of tomographic data of active particles. Mechanical failure in the regime near the separator is more severe than toward the current collector. The active particles close to the separator experience deeper charge and discharge over cycles and thus are more mechanically loaded. The difference in the Li activity originates from the polarization of the electrolyte potential and the non-uniform distribution of the activation energy for the charge transfer reaction. We model the kinetics of intergranular fracture and interfacial degradation to confirm that the various Li activities are the major cause of the heterogeneous damage. The interfacial failure may reconstruct the conductive network and redistribute the electrochemical activities that render a dynamic nature of electrochemistry and mechanics evolving over time in the composite electrodes. We further quantify the influence of the mechanical damage on the metrics of battery performance. We simulate the electrochemical impedance profile to build a relationship between the interfacial debonding and the impedance of electron transport and surface charge transfer. The mechanical failure disrupts the conduction path of electrons and results in significant polarization and capacity loss in batteries.

8:55 PM ST05.03.03
Structural Lithium-Ion Battery Electrodes Based on Branched Aramid Nanofibers Paraskevi Flouda, Suyash Oka, Dimitris Loufakis, Dimitris Lagoudas and Jodie Lutkenhaus; Texas A&M University, United States

Structural energy storage devices combine energy storage and structural functionalities in a single unit, leading to lighter and more efficient electric vehicles. However, conventional electrodes for batteries and supercapacitors are optimized for high energy but suffer from poor mechanical properties. Here, we use Kevlar® nanofibers to fabricate mechanically strong Li-ion battery anodes and cathodes. Specifically, we report on free-standing electrodes consisting of lithium iron phosphate (LFP, cathode) or silicon (Si, anode) particles, reduced graphene oxide (rGO), and branched aramid nanofibers (BANFs). LFP and Si have high theoretical capacity values. rGO has high electrical conductivity, high surface area, high capacitance, and excellent mechanical properties. Recently developed branched aramid nanofibers, nanoscale Kevlar® fibers, are of great interest due to their exceptional mechanical properties, such as ultimate strength and stiffness. rGO and BANFs interact with each other through hydrogen bonding and π-π stacking interactions allowing for load transfer within the electrodes. The composite electrodes were fabricated *via* vacuum-assisted filtration to achieve highly layered structures. Electrical, mechanical, and electrochemical properties for all composite electrodes were evaluated as a function of composition. Overall, we obtained up to two orders of magnitude improvements in Young's modulus and tensile strength compared to commercial battery electrodes while maintaining energy storage capability. The role of BANFs was further investigated using scanning electron microscopy (SEM), x-ray photoelectron microscopy (XPS), and electrochemical impedance spectroscopy (EIS) before and after electrochemical cycling. This work demonstrates an efficient route for designing structural Li-ion battery cathodes and anodes with enhanced mechanical properties. This work is supported by AFOSR under Grant No.

9:10 PM ST05.03.04
High-Density Hydrogen Storage on Zeolite-Templated Carbon Monoliths Seth Putnam[1], Dalton Compton[1], Atsushi Gabe[2], Hirotomo Nishihara[2] and Nicholas Stadie[1]; [1]Montana State University, United States; [2]Tohoku University, Japan

Volumetric hydrogen storage was investigated on compacted monoliths of zeolite-templated carbon, a material with unique mechanical properties allowing for extreme densification. Pellets were prepared by a hot-pressing method between 433-573 K and 50-345 MPa, with densities of up to ~1 g/mL. Hydrogen adsorption measurements were carried out on the so-obtained monolithic samples between 40-298 K and 0.0003-10 MPa, with a focus on volumetric storage and delivery metrics at 77 and 298 K. Under optimal pelletization conditions, a sample was prepared which demonstrates near-ideal stored and delivered quantities of hydrogen when compared to that of ZTC powder compacted to “crystalline” (periodic model) density. The improvement in hydrogen delivery is notable at room temperature, exhibiting a 10% advantage over compression alone. Higher capacities and deliveries could not be achieved with activated carbons owing to mechanical properties prohibitive to the preparation of pellets without the use of excessive binder, highlighting the unique advantage of ZTC as a soft, sponge-like material for high density energy storage applications.

9:15 PM ST05.03.05
Computational Electro-Chemo-Mechanics of Two-Dimensional Energy Materials Dibakar Datta; New Jersey Institute of Technology, United States

Two-dimensional materials (2DM) such as graphene, transition metal dichalcogenides (TMD), MXenes, and their heterostructures are among the most promising energy materials for radically advanced batteries. In this presentation, two important computational aspects of 2DM-based batteries are addressed – (i) 2DM and its heterostructures as anode materials, and (ii) 2DM as van der Waals (vdW) slippery interface. The conventional anode materials have several problems, such as low gravimetric capacity (e.g., graphite – 372 mAh/g) and high volume expansion (e.g., silicon – 300%). Our computational modeling shows that topologically modified 2DM can be utilized as high-capacity anode materials for ion batteries with capacity as high as 1000 mAh/g. However, despite enormous opportunities in 2DM anode, several challenges need to be addressed, such as trapping of adatoms at the defect sites, the effect of defects on the diffusivity of adatoms, mechanical degradation at defect sites during charging/discharging, etc. The second part of the presentation discusses the interface of anode and current-collector (e.g., silicon anode and copper current-collector in Li-ion battery). To combat the issue of high-stress development at the anode-current collector interface during charging/discharging, we propose the usage of the graphene layer over the current collector as a vdW slippery interface that reduces the interfacial stress and enhances the cycle life of batteries. Our computational results are in excellent agreement with the experimental findings.

SESSION ST05.04: Flexible Batteries

Fiber-Based Wearable Energy Storage Devices Zijian Zheng; The Hong Kong Polytechnic University, Hong Kong

Wearable energy storage devices are indispensable cornerstones for future wearable electronics. Current energy

storage technologies are based on materials and devices that are rigid, bulky, and heavy, making them difficult to wear. On the other hand, fibers are flexible and lightweight materials that can be assembled into different textiles and have been worn by human beings thousands of years. Different from conventional two-dimensional thin films and foils, the three-dimensional fiber and textile structures not only provide superior wearing ability but also much larger surface areas. This talk will introduce how our research group makes use of the attributes of fibers for high-performance wearable energy storage devices. We will demonstrate the strategies and discuss the perspectives to modify fibers and textiles for making wearable capacitors and batteries with excellent mechanical durability, electrochemical stability, and high energy/power density.

10:25 PM ST05.04.03
Self-Assembly of Polypyrrole Micro-Foam/Carbon Nanotube Composite Electrodes for Stretchable Self-Sensing Supercapacitor Devices HaoTian H. Shi and Hani E. Naguib; University of Toronto, Canada

Polypyrrole (PPy)-based electrochemical energy storage electrodes have been widely investigated due to its desired pseudocapacitive charge storage capabilities. However, with the inflexible nature of the conducting polymer, its utilization in fully flexible and stretchable supercapacitor electrodes has been hindered. Herein, a surface-modified thermoplastic polyurethane (TPU) was utilized as the flexible substrate, coated with a thin surface layer of carbon nanotubes (CNT) to provide the desired electrical conductivity and allowed better adhesion of the PPy micro-foam (PPyMF) structures. The fabrication process involved density difference induced alignment of surface CNTs for an even surface coating of the conducting carbon layer suitable for PPy polymerization. With the formation of high specific surface area PPyMF, the flexibility of the sandwiched structure was retained, while providing a highly conducting network with extremely porous active PPyMF for charge storage. The as-fabricated TPU/CNT/PPyMF electrodes were shown to produce a high 345 F/g gravimetric capacitance at a scanning rate of 5 mV/s, an exceptional electrical conductivity of 713 S/m, and a retained capacity of 71% after 3000 charge/discharge cycles, which was better than previously reported polypyrrole based electrode systems. The retained flexibility and charge storage capability during bending was tested to show that 78% of capacity was retained at a bending angle of 90 degrees. At the same time, the supercapacitor electrode was also designed to be self-sensing with an ability to sense strain based on resistance changes, allowing further monitoring of supercapacitor stretching and flexing during usage.

Interphase Influence on the Elastic Moduli of Functionalized Reduced Graphene Oxide and Aramid Nanofiber Nanocomposite Supercapacitor Electrodes Tianyang Zhou, James Boyd, Jodie Lutkenhaus and Dimitris Lagoudas; Texas A&M University, United States

Energy storage materials that also provide structural integrity are in need for the weight reduction of electrical automobiles. Structural supercapacitor electrodes consisting of aramid nanofiber (ANFs) and reduced graphene oxide (rGO) nanosheets have shown promising experimental combinations of mechanical properties and capacitance. Further, electrodes including chemically functionalized rGO nanosheets (frGO) has demonstrated even higher experimental moduli than that of the rGO/ANF nanocomposite. The purpose of the present work is to develop a micromechanics model for elastic moduli to analyze the influence of different functional groups and support the development of multifunctional composite electrodes. A three-step micromechanics model was developed to capture the influence of the functional groups on the overall elastic modulus of frGO/ANF composite electrode, as well as the waviness (or curvature) of the respective nanomaterials. The functional

groups on rGO were modeled as a separate phase surrounding the rGO. The interphase was introduced in the nano scale representative volume element (RVE) to form the effective frGO phase. In the microscale RVE, waviness and random orientation was introduced to both ANFs and the frGO. Then, the effective ANF and frGO phases were combined in the mesoscale RVE. Parametric studies on the interphase were carried out. The influence of the interphase thickness and interphase modulus was considered. The in-plane moduli increase significantly with initial interphase modulus increase. However, the increase of in-plane moduli of the composite films will reach a plateau after 30 GPa. Functionalized rGO/ANF composites have lower waviness and a wider waviness distribution per film compared to rGO/ANF composites according to scanning electron microscopy images, which was also captured by the model. Based on the modeling results, the sensitivity of elastic moduli to waviness is higher at lower waviness because of the nonlinear relationship between elastic moduli and waviness which led to the higher standard error of the elastic moduli observed in the experimental results.

10:45 AM *ST05.05.02

Structural Batteries for Mass-Less Energy Storage Leif E. Asp; Chalmers University of Technology, Sweden

Engineering materials that can store electric energy in structural load paths can revolutionise lightweight design across transport modes. Contemporary electric vehicles and aircraft use traditional lithium ion batteries for electrical energy storage. The battery is only providing an electrical energy storage function - adding weight to the system but does not contribute to its structural performance. This paper will present research aimed at the development and demonstration of a multifunctional material that can simultaneously store electrical energy and carry mechanical loads. We have coined this material as the *structural battery composite*. Structural battery composite materials will allow radical weight savings for any electrically powered structural systems, from laptops to cars and aircraft. We foresee that access to structural batteries would allow that practically all the weight of the current monofunctional battery is removed in satellites and significantly reduced in electric cars. Use of structural batteries will provide more energy efficient transport solutions and hence increase competitiveness and save money. As an example, for satellites, a 250 kg weight reduction corresponds to a cost reduction for launch of at least $3.8M.

Over the last decade, Chalmers and KTH have performed research to realise structural battery composites. By this work, the Swedish team has established a position as leaders in the field [1]. Current structural battery composites have demonstrated an energy density of 24 Wh/kg at a Young's modulus of 25 GPa. We are currently in the process of developing and demonstrating the second-generation structural battery composite with an anticipated energy density of at least 50 Wh/kg and a modulus of 70 GPa. This is slightly lower than traditional composites and Li-ion batteries but combined into a multifunctional material providing significant mass savings.

Structural battery composites are made from carbon fibres in a structural battery electrolyte (SBE) matrix material. Neat carbon fibres are used as a structural negative electrode, exploiting their high mechanical properties, excellent lithium insertion capacity and high electrical conductivity. Lithium iron phosphate coated carbon fibres are used as the structural positive electrode. Here, the lithium iron phosphate is the electrochemically active substance and the fibres carry mechanical loads and conduct electrons. The surrounding SBE is lithium ion conductive and transfers mechanical loads between fibres. With these constituents, structural battery cells are realised.

The presented research relates to recent activities funded by EU's Clean Sky II and USAF. It further comprises ongoing research activities to realise the second-generation laminated structural battery composite full cells. The work comprises Multiphysics models for design and analysis of structural battery devices; separators to allow increased charge/discharge rates; highly multifunctional carbon fibre-reinforced positive electrodes; and design and characterisation of multifunctional electrodes/SBE and separator/SBE interfaces.

1. Our paper Fredi G, et al. *Multifunctional Materials*, 1, 2018, 015003 *was appointed among the top-ten breakthroughs in physics in 2018 by the Physics World magazine*.

11:10 AM *ST05.05.03
Modelling Challenges for Structural Supercapacitors E.S. Greenhalgh, S.N. Nguyen, M. Valkova, C. Lee, M.S.P. Shaffer, A. Kucernak and A. Panesar; Imperial College London, United Kingdom

Structural power composites is an important emerging technology which has the potential to address challenges associated with both lightweighting and electrical energy storage for a range of platforms, but particularly transportation. The focus of the work reported here are structural supercapacitors. Although these devices do not offer the high energy densities associated with batteries, they provide a research vehicle to understand the generic development and implementation hurdles associated with structural power. Structural supercapacitors consist of two electrodes (woven carbon fibre plies impregnated with carbon aerogel) which sandwich an electrically insulating (but ionically conducting) separator (spread tow woven glass fibre). This assembly is immersed in a structural electrolyte, which is a biphasic interconnecting network of a structural phase (typically epoxy) and an ionically conducting phase (typically ionic liquid).
Predictive modelling is discipline which could potentially accelerate the progress, but there is a dearth of work into such studies for structural power. This paper describes the modelling efforts which have been undertaken at Imperial College London, focusing on studies at three different lengthscales: *micro*, *meso* and *macro*.
Firstly, at the *micro* lengthscale, topology optimization (TO) methods are being adopted to identify the optimum microstructure of the structural electrolyte and hence maximize the multifunctional performance of the resulting structural power devices. The structural electrolyte needs to provide a balance between mechanical load-bearing and ionic transport functions. TO has been used to find solutions for the ideal microstructures under different loading cases (tension and shear) whilst maximizing ionic conductivity. This has led to the optimum microstructures for given volume fractions of each phase, over a range of weightings (ranging from dominated by mechanical loading requirements to dominated by ionic transport) having been identified. These predictions have been validated against 3D printed unit cells, the mechanical and electrochemical performance of which has been characterized.
At the *meso* lengthscale, a multiphysics numerical model has been developed, using a commercially available finite element code (ABAQUS), to predict both the mechanical and electrochemical response of our devices. Key to this is predicting the consolidation of the device during manufacture, since this will dictate the spacing between the electrodes (hence the electrochemical performance), but also the reinforcement volume fraction (hence the mechanical performance). The consolidated device geometries have been then been modelled to predict their mechanical response but also, using a modified user element, their electrochemical response. The future aspiration is to permit coupling in these models, such that the influence of mechanical cycling or damage on the electrochemical performance can be predicted. Ultimately this model will provide a means to support the certification of structural power components for transport applications.
Finally, at the *macro* lengthscale, is the challenge of multifunctional design: identifying how best to design with and adopt structural power composites. Methodologies have been developed to provide a clear comparison between conventional compartmentalized systems (such as load-bearing structure and conventional batteries) and structural power components. Hence, the energy and power densities need to be achieved in such multifunctional materials to offer a weight saving over existing systems have been determined. Such studies have considered a range of platforms, and provided an insight into target applications for future structural power materials.
It is anticipated that development of predictive models at these different lengthscales will underpin and accelerate the maturation of this emerging technology, and hasten its adoption by end-users.

11:35 AM ST05.05.04
Rational Interfaces Design for Structural Batteries with High Energy Densities and Electrochemical Performance Tianwei Jin and Yuan Yang; Columbia University, United States

In the past decades, lots of efforts are made by researchers to promote the development of structural lithium ion

batteries, which endow energy storage ability to structural parts for vehicle lightweighting. However, the two strategies people normally use nowadays still have major challenges. One method is introducing thick or heavy packaging and mechanically supporting parts to or inside cells, which intrinsically decreases the energy densities of these energy storage devices. The other one is replacing conventional cell parts like electrodes and electrolytes with materials which have strong mechanical properties but poor electrochemical cycling stability, which sacrifice cycling performance of batteries.
By finite element analysis, we find that the reason of unsatisfying flexural behavior of conventional lithium ion batteries is the sliding of separator and electrode layers relative to each other, and it will greatly increase if we can suppress this sliding. The reason is that if layers are bonded together, all components will participate in the resistance of bending rather than slide relatively, which inspires us with a new idea to improve the mechanical behavior of batteries.
Here we propose a straightforward and rational interfacial design to make cell parts of lithium ion batteries robust by applying suitable and strong “binders” to each interface inside. With a thin coating layer of porous PVDF-HFP, which is previously shown without detriment to cycling performance, electrodes can be bonded with PVDF-coated separators tightly by hot pressing. With these techniques, all components in cells can contribute to the overall mechanical strength, which allows the battery with greatly enhanced flexural strength than conventional batteries. On the other side, on account of the chemical simplicity of this strategy, the structural battery in this work can deliver a comparable specific capacity with conventional cells. This work comes up with a new and simple way to design structural batteries, with both mechanical performance and energy density satisfied, and the method can be easily transferred to large-scale production in industry. Thanks to the wide electrochemical stability of PVDF-HFP, nonflammable and fire-retardant electrolytes can also be utilized, once they are compatible with electrodes, to improve the safety of batteries for their practical application as structural parts in vehicles.
In addition, we apply finite element analysis to conduct simulations to compare the contribution of materials' intrinsic mechanical properties and interfacial adhesion strength in flexural behaviors of batteries, which provides a valuable insight into feasible structural batteries with balanced mechanical and electrochemical properties.

11:50 AM ST05.05.05
Reduced Graphene Oxide / Kevlar Aramid Nanofiber Electrodes as a Structural Supercapacitor Platform Jodie Lutkenhaus[1], Dimitris Lagoudas[1], James Boyd[1], Micah Green[1] and Haleh Ardebili[2]; [1]Texas A&M University, United States; [2]University of Houston, United States

Structural energy and power devices combine the mechanical properties of structural composites with the energy storage properties of capacitors or batteries. These multifunctional devices promise to reduce the mass and volume of electric vehicles, aircraft, and spacecraft. Carbon fiber mats have been proposed as platforms due to their high stiffness, but it is a challenge to achieve high specific energy and power because the carbon fiber occupies a large volume/mass and is not as electrochemically active due to its low surface area. In response to this challenge, we have explored composite electrodes containing reduced graphene oxide (rGO) nanosheets and Kevlar aramid nanofibers (ANFs). The rGO nanosheets are conductive, mechanically stiff, and have a high surface area; the ANFs are mechanically stiff and provided bridging among the rGO nanosheets via noncovalent interactions.

This talk will provide an overview of the rGO/ANF structural supercapacitor platform, experimentally emphasizing the role of non-covalent interfacial interactions and computationally emphasizing electrode architecture and interphase effects. We compare nacre-like and open-cell electrode morphologies, in which rGO/ANFs electrodes are made via vacuum filtration and hydrothermal synthesis, respectively. Experiments and COMSOL multi-physics modeling demonstrate tradeoffs among ion transport. Generally, the open cell structure results in poorer mechanical properties but satisfactory capacitance. We also compare different functional groups on chemically functionalized rGO, including dopamine, tannic acid, amine, carboxylic acid, and chelating ions. It is found that the mechanical stiffness increases with increasing non-covalent interaction strength, but this results in denser electrodes and poor ion transport. Further, micromechanical modeling shows

modulus and conductivity variations depending on electrode arrangement and waviness (i.e., curviness) of the rGO nanosheets and ANFs. The interphase, as described by modeling as a proxy for the non-covalent interacting layer, affects modulus and conductivity, as well. Together, these results indicate that rGO/ANF electrodes with good combinations of mechanical stiffness and capacitance should have a layered structure with flattened nanomaterials (not wavy, wrinkled, or curvy) with strong and numerous noncovalent interactions, but these electrodes should also have sufficient porosity to allow for ion access to the electrode's surfaces. Lastly, in comparison to the carbon fiber platform, the rGO/ANF capacitors have higher capacitance, but lower stiffness.

Looking to the future, structural energy and power devices bear tradeoffs among mechanical properties and energy storage performance that still need to be addressed with new materials and platforms. The effect of electrochemomechanical coupling is needed to understand failure modes and long term stability.

Mechanical Modeling of Li-Ion Batteries—From Physics-Based to Data-Driven Juner Zhu, Wei Li, Martin Z. Bazant and Tomasz Wierzbicki; Massachusetts Institute of Technology, United States

Lithium-ion batteries (LIBs) are ubiquitous in modern society with a wide spectrum of applications from consumer electronics to electric vehicles and the future electric aircraft. The basic structure of a commercial LIB cell consists of alternating porous layers (electrodes and separator) and metal foils (current collectors). These solid materials are saturated with a liquid electrolyte. The first part of this talk will cover a comprehensive physics-based modeling program of the LIB structure, based on several key publications of our team. We will then show that conventional computational tools such as finite element simulations gradually lose their effectiveness as the dimensionality of the system increases. We will use the second part of the talk to demonstrate the applicability of physics-guided neural network approaches, both PDE-based and energy-based, in the mechanical modeling of LIBs in a few real-world scenarios.

SESSION ST05.06: Solid State Batteries II

The Electrochemo-Mechanics of Interfaces in All-Solid-State Li-Ion Batteries Yue Qi[1,2], Hong-Kang Tian[2], Aritra Chakraborty[2], A. Talin[3] and Philip Eisenlohr[2]; [1]Brown University, United States; [2]Michigan State University, United States; [3]Sandia National Laboratories, United States

Maintaining the physical contact at the electrolyte/electrode interface and preventing mechanical failure are critical to the performance of all-solid-state batteries (ASSB). The ceramics based solid electrolyte and electrode interface tends to have imperfect contact, which can be worsened due to cycling and improved due to cell stack pressure. The solid electrolyte is also subject to electrochemical decomposition at the interface, causing volume change, in addition to the well-known volume change in the electrodes during lithiation-and-delithiation. These chemical strains generate mechanical stress, which leads to fracture in the highly compliant all-solid-state batteries, especially in 3D ASSBs. In this presentation, new continuum models were developed to capture the highly coupled electrochemical-mechanical phenomena. First, we will present a 1D Newman battery model for a film-type Li|LiPON|$LiCoO_2$ ASSB that incorporated the effect of imperfect contact area with

battery performance by assuming the current and Li concentration will be localized at the contacted area. To establish the relationship between the applied pressure and the contact area, we applied Persson's contact mechanics theory as it uses self-affined surfaces to simplify the multi-length scale contacts in ASSLBs. The model is then used to suggest how much pressures should be applied to recover the capacity drop due to contact area loss. Furthermore, we will introduce a 3D Newman battery model for the experimentally-made 3D Si|LiPON|$LiCoO_2$ ASSB to incorporate the chemo-mechanical strains due to interfacial decomposition of LiPON and the lithium concentration gradient while cycling. This electrochemo-mechanical model could be used for predicting whether and where the fractures would be produced in order to guide the architecture design of 3D ASSB with balanced energy density and mechanical integrity.

Enabling Highly Conductive and Flexible Solid-State Electrolyte Film for All-Solid-State Li-Ion Battery
Zhaoxin Yu, Kiseuk Ahn, Jie Xiao, Jun Liu and Dongping Lu; Pacific Northwest National Laboratory, United States

All-solid-state lithium batteries (ASSLBs) are pursued intensively as a promising next-generation energy storage technology due to their high potentials to achieve superior safety and high energy/power densities.[1] Sulfide solid-state electrolytes (SSEs) are arguably more viable for bulk-type ASSLBs than oxide and polymer-based SSEs, thanks to their higher ionic conductivities at room temperature and lower elastic modulus, which allows fast Li^+ transportation and intimate contact with active materials.[2] However, deployment of sulfide solid-state electrolytes in practical bulk type ASSLBs are hindered by the processing of highly conductive and ultra-thin solid electrolyte films. Most ASSLBs are evaluated using thick sulfide SSE pellets (>300 microns) for appropriate mechanical strength. This method is not realistic since thick SSE pellet causes a serious penalty to energy density at the cell level.[3] Therefore, it is urgent to develop highly conductive and ultra-thin sulfide SSE film with good mechanical properties for the deployment of ASSLBs.
Here, we report an up-scalable method for the preparation of highly conductive sulfide SSE films with a lean amount of polymeric binder. A new polymeric binder/solvent combination, which is compatible with sulfide SSEs, was identified to prepare the ultra-thin SSE film. Under processing, the polymeric binder is well-controlled into filament-shape and builds a 3D-matrix, providing superior confinement for SSE particles with decent flexibility. Effects of the polymeric binder on SSE film have been investigated in terms of film mechanical property, ionic conductivity, and electrochemical properties of Li/SSE/Li symmetric cells. As a result, ultra-thin SSE film with a thickness of 75-100 um was prepared with 2 wt. % of the polymeric binder and demonstrates an overall conductivity of about 1 mS/mcm at room temperature. More details of this research will be discussed at the symposium.

Mechanical Constriction Design of Stabilities for High Performance Solid-State Batteries Xin Li; Harvard University, United States

Mechanical constriction induced various stabilities greatly widen the operational voltage window of solid-state batteries. Bulk and interface stabilities can be modulated to operate at extreme voltages of high voltage cathodes

and Li metal anode. Ab-initio simulations and experimental characterizations are used to unveil chemical, electrochemical and microstructural details to support the unique physical picture of mechanical constriction modulated electrochemical behavior. Based on the design principle, up to 10 mA/cm^2 current density on lithium metal anode and up to 10 V voltage stability of sulfide electrolytes are demonstrated. The potential impact of this effect on the design of high voltage solid state batteries beyond the commercial level will also be discussed.

2:05 PM DISCUSSION

2:20 PM *ST05.06.05
Mechanical Properties of Metal Anodes of Rechargeable Batteries Matt Pharr; Texas A&M University, United States

Metallic anodes have the potential to enable batteries with enormous capacities. Indeed, lithium metal has the highest theoretical capacity, lowest density, and most negative electrochemical potential of known anode materials for rechargeable batteries. However, dendrites of Li can form during cycling, which lead to significant safety issues that have precluded their practical deployment. Sodium metal anodes have similar safety concerns but have recently received increased attention due to their natural abundance, relatively low cost, and potential for grid-scale energy storage. Potassium metal anodes are still very much in a developmental phase but have promise stemming from their potential for simple cell design with cheap fabrication, earth abundance, and relatively low cost. Magnesium metal anodes have enormous volumetric capacities but readily form passivating layers during recharging, and recent studies suggest dendrite formation can occur under certain conditions. While the electrochemistry of these systems has received extensive study, at the heart of many practical issues in these systems lies a mechanics of materials problem. Specifically, as atoms are deposited and stripped during electrochemical cycling, the material deforms, generating stresses under constraint. These stresses can result in fracture, delamination, detachment, and/or unstable deformation (e.g., the formation of dendritic structures) of the electrodes, diminishing their capacity or leading to severe safety issues. Likewise, the stresses in turn may affect the electrode kinetics, the growth morphology under cycling, and/or the integrity of the contact at the anode/solid-state-electrolyte interface. Studies that provide deeper understanding of mechanics in these systems may thus play a key role in mitigating or even preventing many of these issues. For instance, modelling studies have suggested that the mechanical properties of the anode materials (relative to the separators or solid-state electrolytes with which they are in contact) are key in guiding the suppression of dendritic growth during electrochemical operation. Experimental studies have shown that the morphology of Li during electrochemical deposition depends on external pressures applied to battery stacks, as does the propensity for maintaining interfacial contact in all-solid-state batteries. As such, prior to real applications, a comprehensive understanding of the mechanical properties of these materials is vital. To this end, through nanoindentation, microhardness, and bulk testing, this talk will present experimental studies of the mechanical properties of metallic Li, Na, K, and Mg anodes, including how these properties vary with loading rate, representative size scale, and temperature. These properties will be connected to implications in terms of potential battery performance, e.g., in preventing dendritic structures, detachment between solid-state electrolytes and metallic anodes, etc. Overall, this talk will provide insight into guiding the design of battery materials, architectures, and electrochemical (e.g., charging) conditions that mitigate unstable growth of metal anodes during electrochemical cycling.

2:45 PM ST05.06.06
Bioinspired Structural Ion Conductive Membranes for Energy Storage Applications Ahmet Emre, Jinchen Fan, Mingqiang Wang, Volkan Cecen and Nicholas A. Kotov; University of Michigan–Ann Arbor, United States

Bioinspired ion conductive membranes have been widely investigated for beyond lithium-ion battery

applications. The high theoretical specific energy density (2600Wh/kg) and high specific capacity (1675mA/g) along with the natural abundance and low toxicity of sulfur have been attracting significant attention for the development of an alternative battery system to replace traditional lithium-ion batteries which suffer from safety and capacity/energy density limitations in various applications. However, challenges such as polysulfide dissolution and shuttling prevent mass commercialization of metal sulfur batteries. Inspired from biological ion transport mechanisms, we show a practical yet comprehensive approach for the development of high-performance metal sulfur batteries. Aramid nanofiber (ANF) based composite ion conductive membranes not only prevent dendrite formation but also confine polysulfides on the cathode side. ANF composite battery separators provide diverse and opposing properties including high mechanical properties, high ionic conductivity, and high thermal/chemical stability. Moreover, the highly selective ion sieving properties of these strong biomimetic separators provide safe and high-performance structural batteries. Fabrication of such biocompatible, affordable, flexible, and high energy density structural battery is quite crucial in powering next-generation electric vehicles, robotics and electronics including but not limited to portable, wearable, and implantable biomedical devices.

Tropical Rain-Forest Plants—A Source of Bio-Inspired New Materials, New Technologies and New Concepts Nick P. Rowe; Centre National de la Recherche Scientifique (CNRS), France

Tropical rain forests represent some of the most complex and diverse living structures. Plants make up the three-dimensional complexity of these ecosystems not only as trees, but also as creepers, vines, lianas, and epiphytes. This diversity of growth forms has evolved and is adapted for a wide range of physical and mechanical constraints. Big trees are well designed to be mechanically stable under self-loading but are also compliant when the wind blows. Vines and lianas exploit the stature of big trees by attaching and climbing on them towards the light. They show highly specialized properties to reach and attach to supports and then climb by economically, narrow stems which are amazingly flexible and highly resistant to mechanical failure. In this talk we will go on a walkabout of tropical rain forests and visit highly adapted growth forms, their remarkable mechanical properties and also their capacity for movement. In fact, plants, especially climbing plants, do move. Not only rather slowly by growth but also by internally controlled circling, spiraling, waving and oscillating movements - movements by solid materials without muscles. So, our tour will not only be a story about the different materials and structures that exist in these environments—what we might call a static view, it will also be a story with a dynamic view, how plants grow and move adaptively using smart additive processes

(AKA growth), how they can move and position themselves, and how they can explore their environment and mechanically attach to supports.

Nick Rowe is a biologist and Director of Research in the CNRS, at the AMAP research Laboratory in Montpellier, France. He grew up in the southeast of England and was educated in Rochester, Kent. He obtained both his B.Sc. degree in honours botany and Ph.D. degree from the University of Bristol, England. Being British and having worked and lived in France, Germany and Great Britain, his personal outlook and his research interests and collaborations in science remain highly international and multidisciplinary. Originally trained as an evolutionary biologist focusing on the origin and evolution of plants, he became increasingly interested in plant functional biology and biomechanics—how different plant species have evolved and adapted diverse functional and biophysical properties for surviving in a complex world. In recent years, he established a biomechanics laboratory in France, forming a home-base for research into the biomechanics and diversity of plants from the tropical forests of South America, west Africa and southeast Asia. Most recently, his research has focused on the structures and properties we see in today's plant diversity and how this offers a source of inspiration for developing new materials, new technologies and new concepts. His latest projects are exploring the functional, ecological, evolutionary and developmental potential of plants as sources for new innovative technologies including research on climbing plant innovations for soft robotics.

Nanotechnology for Sustainability Yi Cui; Stanford University, United States

One of the most challenging problems human beings are facing during the 21st century is the sustainability due to climate change and environment pollution. Nanotechnology provides new opportunities to address the sustainability issues, including energy and environment. In this talk, I will provide examples of nanotechnology for sustainability, including: 1) Nanomaterials design for reinventing batteries to achieve high energy density, long life, good safety and low cost to be used in the applications of transportation and grids. 2) Reinventing textiles with nanotechnology to control human body infrared radiation for the warming and cooling purpose, which could potentially save building energy consumption by 30%. 3) Air, water and soil nanotechnology for effective removing pollutants and disinfecting biopathogen. I will also discuss how to take these technologies from labs to markets in order to have a sustainability impact to the real world.

Biography
At Stanford University, Yi Cui is Director of the Precourt Institute for Energy, co-director of the StorageX Initiative, and professor of materials science and engineering and of photon science at SLAC National Accelerator Laboratory. A cleantech pioneer and entrepreneur, Cui earned his B.S. degree in chemistry in 1998 from the University of Science & Technology of China and his Ph.D. degree in chemistry from Harvard University in 2002. He was a Miller Postdoctoral Fellow at the University of California, Berkeley, from 2002 to 2005 before joining the Stanford faculty. Cui manages a large Stanford research group, from which alumni have succeeded in academia and businesses. He has founded five companies to commercialize the energy and environment technologies from his lab: Amprius Inc., 4C Air Inc., EEnotech Inc., EnerVenue Inc. and LifeLab Design Inc.

A preeminent researcher of nanotechnologies for better batteries and other sustainability technologies, Cui has published more than 500 studies and is one of the world's most cited scientists. He is an elected fellow of the American Association for the Advancement of Science, the Materials Research Society, and the Royal Society

of Chemistry. He is an executive editor of *Nano Letters* and co-director of the Battery 500 Consortium.

In 2021, U.S. Department of Energy awarded Cui an Ernest Orlando Lawrence Award which honors mid-career scientists and engineers in eight research fields. Other awards include: Materials Research Society Medal (2020), Electro Chemical Society Battery Technology Award (2019), Nano Today Award (2019), Blavatnik National Laureate (2017), and the Sloan Research Fellowship (2010).

How New and old Materials Research and Know-How Extend the Increase in Computation Power Iuliana Radu; imec, Belgium

For the past 20 years, doomsayers have been talking about the end of performance increase in compute because transistor scaling was supposed to end. We all know this was far from true and continue physical and performance scaling of the transistors has enabled continues increase in computing power. Maintaining physical or performance scaling of the switches themselves is becoming more difficult but other options exist and the field of very exciting research. Old concepts with new materials and new concepts with old materials are in the spotlight and materials research is paramount to enabling new growth in computing power and of the society in general.

In this talk, we will cover an old concept but with new materials: transistors with 2D semiconducting channels as these materials are expected to enable further scaling of transistor area and performance. At the other side of the spectrum, we will cover how better-understood materials such as Al, Nb, TiN contribute to better qubit for quantum computing. Uniting the two topics are not only the application of computing, but also the mindset and fundamental need for extreme control of materials and processes involved in fabricating these devices.

Transistors with 2D materials hold the promise for extreme gate length scaling compared to Si as they can be deposited with monolayer precision, and mobility is expected to be almost independent of material thickness. In this presentation, we will discuss imec's work on 2D materials emphasizing channel and dielectrics deposition and how process steps could change device performance. We will cover how device and circuit modelling guides choices in integration schemes and ultimately defines specifications for the materials involved. We will describe how variability analysis can help differentiate between one-off observations and consistent process control and understanding.

Quantum computing is fundamentally different that classical computing but many of the technology challenges are similar to those for building classical systems. In this talk, we will outline how learning and practices from standard semiconductor development can be used to enable quantum computing. We will discuss how materials and process development can improve device performance.

In both topics, we will outline what we believe main materials research directions to be investigated and where fundamental discovery and innovation is key.

Biography

Iuliana P. Radu is Director of Quantum and Exploratory Computing at imec. Her activities include work on beyond CMOS device concepts such as spintronic majority gates and switches with novel channel materials and their possible applications in the semiconductor industry. Quantum computing includes work on qubit devices and the periphery circuits meant to control them. Prior to establishing the Beyond CMOS program at imec in 2013, she was a Marie Curie and FWO fellow at KU Leuven and imec. Iuliana received a Ph.D. degree in physics from Massachusetts Institute of Technology in 2009 where she searched for Majorana fermions in the quest to build very reliable qubits for quantum computing. She has authored over 190 papers in leading peer-reviewed journals and conferences. She has given more than 40 invited talks at international conferences and seminars where she is a frequent speaker on quantum computing and exploratory devices for classical computing. She currently serves as program committee member for ESSDERC and SNW and is an associate editor for IEEE *TNANO*.
