Late News: Ferroelectric Properties and Magnetic-Induced Behavior of Magnetoelectric Multiferroic BiFeO3

Xiang Li, Yongjian Tang, Hyunjea Lee, Joseph Casamento, Antonio B. Mei, Phillip Dang, Zexuan Zhang, Ludi Miao, Debdeep Jena, Darrell G. Schlom, Daniel C. Ralph and Huili Xing; Cornell University, United States

Magnetoelectric multiferroic materials have received increasing attention by the research community since they simultaneously possess magnetization and ferroelectricity and the two order parameters are coupled by magnetoelectric effects. $BiFeO_3$ (BFO), one of the few room-temperature magnetoelectric multiferroic materials, is of special interest. For instance, BFO can be potentially used in the magnetoelectric spin-orbit (MESO) device[1], spin-orbit torque field-effect transistor (SOTFET)[2], etc. However, to date, most studies on BFO have been focused on the electric field induced switching instead of magnetic field driven behavior. Despite difficulties in directly switching ferroelectricity in BFO by an external magnetic field, the exchange interaction between BFO and an adjacent ferromagnetic (FM) material[3] might enable a new way for switching by applying a magnetic stimulus via spin-orbit torque if the materials parameters fall in the right window, as proposed in the modeling work of SOTFET[2]. In this work, a $SrRuO_3$(SRO)/BFO/SRO heterostructure is used to study the ferroelectric properties and magnetic-induced behavior of BFO.
The SRO/BFO/SRO (20/100/20nm) heterostructure was grown epitaxially by molecular-beam epitaxy (MBE) on (110) $DyScO_3$ substrates using similar growth conditions in [4]. No ion irradiation was done post growth. Ti/Pt (5/50nm) was blanket deposited by sputtering, and subsequently patterned into top metal contacts of capacitors by photolithography and ion milling. Large area Ti/Pt top contacts are effectively shorted to the bottom SRO layer thus serving as the opposite electrode of the capacitors.
First, we discovered that these MBE BFO layers are highly insulating, unlike the ones reported in [4], where post-growth MeV-ion irradiation had to be applied to curb the leakage through polarization domains. The low

leakage in these MBE BFO films directly enabled us to study its ferroelectric properties by the positive-up-negative-down (PUND) measurement at both RT and 5 K, a common method to obtain polarization-electric field (P-E) loops by measuring the displacement and switching currents. Conductive AFM was also carried out: very low current level (~10 pA up to 10 V) was measured across the sample and no leakage pattern was observed. The PUND data revealed a saturation polarization (P_S) of 60-80 μC/cm^2 and a coercive field of 0.6-1 MV/cm, but no clear dependence on temperature.
Next, we applied out-of-plane (oop) or in-plane (ip) magnetic fields up to 6 T, respectively, during the PUND measurements, at both RT and 5 K to investigate if an external magnetic field can influence the measured P-E loop in BFO. At RT, the SRO layers serve as simple metal electrodes; while at 5 K, we expect the SRO layers will be polarized by the external magnetic fields since SRO has a ferromagnetic Curie temperature of ~150 K. In this BFO/FM heterostructure, no noticeable shift in the P-E loop is observed at 5 K under the magnetic field condition used in this study. At RT, a systematic shift in the P-E loops was observed; however, after carefully correlating the shift with the order of measurements, we believe the shift arose primarily from the ferroelectric imprint effect not the magnetic field. Overall, these observations are consistent with our modeling predictions[2]. Due to the relatively large thickness (100 nm) and P_S (~70 μC/cm^2), the switching energy barrier in BFO is too high. If the coupling strength between the two order parameters remains the same or increases, it is more likely to observe magnetic-induced behavior in thin La-doped BFO with reduced P_S.

Magnetocaloric Study of $Mg_{0.5}Zn_{0.125}A_{0.375}Fe_2O_4$ (A = Co, Cu, and Ni) Ferrites Dipesh Neupane[1], Jeotikanta Mohapatra[2], Surendra Dhungana[1] and Sanjay R. Mishra[1]; [1]The University of Memphis, United States; [2]The University of Texas at Arlington, United States

Magnetic refrigeration (MR) is a crucial subject as a future cooling technology based on magnetocaloric effect (MCE) that replaces the conventional vapor compression technique for energy saving, high efficiency, minimal environmental impact, and reliability. MR of magnetic materials is based on the change in entropy when the materials are subjected to the field. Therefore for more efficient, materials should have large entropy changes. Spinel ferrites are one of the essential magnetocaloric materials that consist of transition metal ions (MFe_2O_4, M = Mn, Zn, Co, Ni, Cu, and Mg). Among different spinel ferrites, the Mg-Zn spinel ferrite is considered necessary due to its remarkable magnetic and electrical properties. The MCE in ferrite is observed ~ 1.36 at 350K. The current effort is to broaden the MCE operating temperature. In view of the above, in this study, a comparative study of magnetocaloric effect (MCE) in $Mg_{0.5}Zn_{0.125}A_{0.375}Fe_2O_4$, A = Co, Cu, and Ni is reported. The samples were prepared via auto-combustion method and heat-treated in the air at 1100ºC for 12 h. The phase identification of the powders performed using x-ray diffraction shows that all the samples exhibit a high-purity cubic spinel structure. The lattice parameter is affected due to different ionic radii of substituted elements. With Co and Ni substitution, a gradual shift in the peaks to the left as compared to Cu is observed that showed a decrease in lattice parameters from 8.510 Å to 8.356 Å due to smaller ionic radii of Co^{2+} ion (0.65 Å), Ni^{2+} ion (0.69 Å) than Cu^{2+} ion (0.73 Å). Morphology and size of the $Mg_{0.5}Zn_{0.125}A_{0.375}Fe_2O_4$, A = Co, Cu, and Ni particles were investigated by scanning electron microscopy (SEM). SEM shows the particle diameter was ~ 40 – 170 nm, indicating that the nanoparticles were polycrystalline. Magnetic measurements were performed using a Quantum Design Superconducting Quantum Interference Device (SQUID) magnetometer. The magnetization as a function of the temperature for all sample, under an applied magnetic field of 100Oe, were measured to see the phase transition. When the temperature decreased, the samples exhibited a paramagnetic (PM) - ferromagnetic (FM) transition at the Curie temperature (T_C). The transition temperatures increased from 550 K to 600 K for Cu to Co. Ni substituted sample showed transition temperature in between Cu and Co. Saturation magnetization for $Mg_{0.5}Zn_{0.125}A_{0.375}Fe_2O_4$, A= Cu, Ni, and Co reached 23 emu/g, 27emu/g, and 33 emu/g at 10K. Large magnetic properties for Co is due to the superexchange interaction and magnetic coupling.

To evaluate the MCE of the samples, the isothermal magnetization curves were collected at different fixed temperatures ranging from 300 to 700 K. the temperature measurements are at intervals T=10K. The magnetic entropy change ΔS_M has been calculated from the M–H curves using the Maxwell relation. The maximum entropy change $|-\Delta S_M^{Max}|$ as a function of temperature increases from 1.25 $J.Kg^{-1}K^{-1}$ to 3.16 $J.Kg^{-1}K^{-1}$ under an applied magnetic field of 5T Cu to Co substitution. The peak position of ΔS_M vs. T curve was independent with applied fields for the same material, whereas the peak shifted towards lower temperature as for Cu sample and higher temperature for Co sample compare to Ni sample. This magnetocaloric behavior is mainly due to superexchange interaction between Fe – Fe ions and particle size. These values are relatively high and comparable to other ferrite systems. Arrot plots showed the positive slope of the curve for all samples indicating a second-order phase transition. Cooling efficiency can be calculated from the peak position of ΔS_M called relative cooling power (RCP). The RCP was found to be 51 to 126 J/Kg for Cu, 62 to 135 J/kg for Ni, and 76 to 165 J/kg for Co sample calculated from 0.5T to 5T, respectively. Significantly higher ΔS_M^{Max} and curie temperature make our compounds promising materials for magnetic refrigeration technology for higher temperatures.

Late News: Ferroelectricity and Enhance Energy Storage Density in 0.70Pb(Zr0.52Ti0.48)O3-0.30Pb(Fe0.5Nb0.5)O3 Nanoscale Ferroelectric Thin Film Prepared by Pulsed Laser Deposition Technique Karuna K. Mishra, Ivan Castillo and Ram Katiyar; University of Puerto Rico, United States

Highly (001) oriented 0.70Pb($Zr_{0.52}Ti_{0.48}$)O_3-0.30Pb($Fe_{0.5}Nb_{0.5}$)O_3(0.70PZT-0.30PFN) magnetic ferroelectric thin films were deposited on $La_{0.67}Sr_{0.33}MnO_3$ (LSMO) buffer layer coated on $(LaAlO_3)_{0.3}(Sr_2AlTaO_6)_{0.7}$ (001) substrates by following two subsequent laser ablation processes in oxygen atmosphere employing pulse laser deposition technique. The 0.70PZT-0.30PFN films were found to grow in tetragonal phase with orientation along (001) plane as inferred from x-ray diffractometry analysis. The temperature dependent dielectric measurements (80-750 K) were performed on metal-ferroelectric-metal heterostructure capacitors in the frequencies range of 10^2–10^6 Hz was observed to be diffused over a wide range of temperature 400–700 K and exhibits high dielectric constant ~2200 at room temperature. The well saturated slim loop of thin films capacitors suggesting nano-scale ferroelectric behaviors (relaxor type) of 0.70PZT-0.30PFN thin films in line with diffuse dielectric response results. An excellent high energy storage density (Ure) ~51 J/cm3 with efficiency ~62 % was estimated at applied voltage 1.5 MV/cm. High DC breakdown strength, larger dielectric constant and high restored energy density values of our 0.70PZT-0.30PFN ferroelectric thin films indicate its usage in high energy storage applications. These results will be presented in details at the meeting.

Realizing New Multiferroic Double Perovskites for Photovoltaic Applications—First-Principles Approach Neda Rahmani[1,2], Mohammad E. Ghazi[2], Morteza Izadifard[2], Alireza Shabani[1], Biplab Sanyal[3] and Jost Adam[1]; [1]University of Southern Denmark, Denmark; [2]Shahrood University of Technology, Iran (the Islamic Republic of); [3]Uppsala University, Sweden

Clean and renewable solar energy is regarded as one of the most reliable and abundant sources to tackle the prevalent energy crisis. The photovoltaic effect, directly converting sunlight into electricity, is an important way to harvest solar energy, and many efforts have been devoted to the development of photovoltaic technology. Toward the next-generation photovoltaics, multiferroic materials (MFs), with the coexistence of ferroelectricity and magnetism in the same phase, show promise as candidates for harvesting energy, especially from sunlight. The spontaneous polarisation of such type of non-centrosymmetric materials is the origin of charge carrier separation. On the other hand, magnetic ordering induces a small bandgap, typically due to electronic states of the magnetic atom in the Fermi energy region. One method to find these rare materials is to employ double perovskites (DPs) with general formula $A_2BB'X_6$, in which one of the sublattices is magnetic, and the other one is ferroelectric. This study intends to develop and apply theoretical tools to predict and improve the photovoltaic properties in new double perovskites with multiferroic properties. In that light, the structural, magnetic, electronic, and photovoltaic properties of new MF-DPs A_2MnBO_6 (A=Sn, Bi and B=V, Ta, Ti) using ab initio

simulations based on DFT method are systematically investigated. The electronic band structure and density of states demonstrate the semiconducting behaviour of these double perovskites with the values of band gaps falling within the desired range for optimal photovoltaic performance. Structural calculations, including distortion parameters and bond angles, indicate that these DPs undergo a significant octahedral tilting and distortion which may result in a considerable value of electric polarization and hence, may be suggested as potential multiferroic materials. In the MnO_6 octahedra, Jahn-Teller effect, which is related to the Mn^{3+} electron configuration, distorts the Mn-O bonds. Whereas, in $Ta(Ti)O_6$ octahedra, the Second Order Jahn-Teller effect originating from d^0 electron configuration of $Ta^{5+}(Ti^{4+})$ is responsible for the off-centering displacement of Ta(Ti) atoms and the distortion of $Ta(Ti)O_6$ octahedra. Optical properties, including absorption coefficient (α) calculations, show that the value of α in the visible region is in the order of 10^5 cm^{-1}, comparable to the absorption coefficient of some well-known photovoltaic materials. These results draw an intense theoretical research interest to explore the photovoltaic properties of new multiferroic double perovskites to characterize them as potential solar materials.

PVD TiN Development to Improve Ferroelectric Properties of HZO Films in MFM Capacitors David Lehninger, Konstantin Merstens, Lukas Gerlich, Maximilian Lederer, Tarek Ali and Konrad Seidel; Fraunhofer Institute for Photonic Microsystems (IPMS), Germany

The discovery of ferroelectricity in doped hafnium oxide thin films revived the interest in ferroelectric (FE) memory concepts [1]. Compared to other dopants, zirconium doped hafnium oxide (HZO) crystallizes at low temperatures (e.g. $T_{cryst.} < 400°C$), which makes this material ideal for the implementation of ferroelectric functionalities into the Back-End-of-Line (BEoL) [2]. For this approach, metal-ferroelectric-metal (MFM) capacitors are very interesting. Integrated in the BEoL, they can be connected either to the drain- or gate-contact of a standard logic located in the Front-End-of-Line (FEoL) to realize ferroelectric random access memories (FeRAMs) or ferroelectric field effect transistors (FeFETs), respectively. It is beneficial to deposit the top electrode of the MFM stack by physical vapor deposition (PVD) processes like sputtering. It is fast, can be done at room temperature, and is a low-cost and reproducible process.
Here, we present the impact of the top TiN electrode, deposited by reactive magnetron sputtering using a metallic titanium (Ti) target and nitrogen / argon plasma, on the ferroelectric properties of HZO films embedded in MFM capacitors. By using different nitrogen (N2)- and argon (Ar) flows, TiN film with various compositions (measured by X-ray-photoelectron spectroscopy) and thicknesses (measured by ellipsometry) have been realized. The crystallinity and different phases have been determined by X-ray diffraction (GI-XRD). The influence of the mentioned parameters on the ferroelectric properties of the HZO film are discussed by taking additional effects like film stress into account. Furthermore, the low temperature PVD TiN is compared with high temperature chemical vapor deposited (CVD) TiN.

Cross-Domain Optimization of Ferroelectric Parameters for Negative Capacitance Transistors Sai Surya Kiran Pentapati[1], Rakesh Perumal[2], Sourabh Khandelwal[3], Michael Hoffmann[4], Sung Kyu Lim[1] and Asif Khan[1]; [1]Georgia Institute of Technology, United States; [2]NVIDIA, United States; [3]University of South Florida, United States; [4]NaMLab gGmbH, Germany

Field Effect Transistors with a ferroelectric gate stack provide a negative capacitance (NC) effect and show a sub 60mV/decade sub-threshold slope (SS) [1—3]. This improves the cell delay and total power (using supply voltage scaling) without traditional Moore's law scaling. [4—5] study the impact of the ferroelectric properties (coercive field E_c and polarization P_0) at transistor, gate, and full-chip level. Using a wide range of non-hysteresis $E_c(1, 4)MV/cm$, $P_0(10, 40)\mu C/cm^2$ values, we introduce the idea of optimality of ferroelectrics (those within 5% of the lowest achievable power at given voltage while meeting target delay). An open-source 15nm

FinFET with 0.8V supply voltage is used for target delay baselines and to generate the NCFET librarues.

Transistor Level analysis at V_{DD}=0.4V shows sub-threshold slope(SS) and I_{on} improves as the (E_c, P_0) is closer to hysteresis boundary (this is the curve beyond which NCFETs have hysteretic behavior). NC effect increases as we move closer to the boundary, and higher I_{on} and SS do not coincide as a strong NC effect also has a smaller range of operation in terms of V_{gs}. So, a steep SS caused by large NC effect saturates quickly, while a slightly smaller slope remains active for a longer range of V_{gs} achieving higher I_{on}. Gate level analysis inverter provides of power and delay metric evolution.

Gate Level: The voltage amplification effect [1] of NCFET decreases the V_{th} and devices go to saturation at a smaller $|V_{gs}|$. This increases the saturation mode of operation to a wider range of V_{gs} and the voltage transfer curves become smoother. So, short-circuit current is higher at large SS, and gate capacitance ($\propto I_{on}$) is higher when I_{on} is large. At low V_{DD}, the NC effect does not saturate for V_{gs} within the operation range (0, V_{DD}) and the effects at hysteresis boundary vary due to this. NC saturation also causes the delay to increase with V_{DD} in extreme cases counter-intuitive to the traditional delay-V_{DD} curves. The optimality region also changes with V_{DD} as a higher NC effect is required to meet target delay when VDD is decreased for NCFETs. At iso-delay, we achieve 92% reduction in total power using a V_{DD}=0.2V and a high NC effect ferroelectric. The same NCFET creates 87% reduction (best observed) in full chip power analysis as well.

Not all benefits at gate level translate to a full-chip level. Using various types of cells in full chip optimization, the NCFETs that lie out of the optimal range in gate-level analysis can be within the wider optimal range of full-chip. While a subset of the optimal range in full-chip can be estimated using inverter level analysis, different cells behave differently with NC effect, and a full chip design with a large number of cells and good variation in types of cells gives a detailed optimal NCFET ranges for a given supply voltage and technology.

Impact of FeFET Drain Current Variation in Processing-in-Memory Architectures Nathan E. Miller, Zheng Wang, Saurabh Dash, Asif Khan and Saibal Mukhopadhyay; Georgia Institute of Technology, United States

We analyze the impact of drain current (I_{DS}) variation in 28 nm high-K metal-gate Ferroelectric FET devices on FeFET-based processing-in-memory (PIM) deep neural network accelerators. Non-Normal variation in I_{DS} is observed due to repeated read operation on two devices with different channel dimensions at various read frequencies. Device-circuit co-analysis using the measured current distribution shows a 1 to 3 percent accuracy degradation of an FeFET-based PIM platform when classifying the Fashion-MNIST dataset with the LeNET-5 DNN model. This accuracy drop can be fully recovered with variation-aware training methods, showing that FeFET current variation is not prohibitive to the design of DNN accelerators.

Ferroelectric-HfO2 FeFET for 3D High-Density Memory Application Masaharu Kobayashi; The University of Tokyo, Japan

In the research field of memory devices, ferroelectric memory has been attracting much attentions because of the newly discovered ferroelectric HfO2 (FE-HfO2) material which is fully CMOS compatible [1]. Ferroelectric memory device can inherently operate at high-speed and low-power. One-transistor memory, ferroelectric FET (FeFET), has a small footprint and non-distructive read-out [2], which is promising for high-density storage memory application. Recently, 3D stacked FeFET has been proposed and demonstrated[3], which can possibly compete with NAND flash memory in terms of memory capacity and power consumption.
There are, however, several challenges to realize such 3D stacked FeFET using conventional poly-Si channel. Poly-Si channel has low mobility and forms a low-k interfacial layer which causes voltage loss and reliability degradation by charge trapping. In this work, we propose to use amorphous oxide semiconductor (AOS), IGZO [4,5], as an alternative channel material. IGZO channel provides high mobility as a deposited channel and prevent low-k interfacial layer formation. IGZO has been already in production for flat panel display, and high reliability has been already proved.
We fabricated FE-HfO2 capacitor by capping with IGZO layer. IGZO layer works as preferable capping for HfZrO2 and induces ferroelectric orthorhombic phase. Electrical characerization shows sharp hysteresis and large spontaneous polarization charge, which can be explained by process-induced strain by IGZO capping. FE-HfO2 capacitor with IGZO capping also shows wake-up free endurance characteristics, which can be due to the engineered itnerface between the FE-HfO2 and IGZO layer avoiding interface defect such as oxygen vaccancy [6]. Then we fabricated FeFET with IGZO channel, in which we introduced back gate. Back gate can help to fix the IGZO body potential so that the elecric field is effectively applied to the FE-HfO2 layer for erase operation. The field-effect mobility is as high as 10cm2/Vs, which is the same as Hall mobility and the mobility of transistor with SiO2 gate insulator. There is no mobility degradation with FE-HfO2. DC I-V sweep and pulse write operation both show >0.5V memory window with almost ideal subthreshold swing. This subthrshold characteristics is attributed to the low interface trap (<1011cm2) and bulk defect, and junctionless operation. These results are promising for high-density and low power storage memory application.

Ultrathin HfO_2-Based Ferroelectric Tunnel Junctions on Silicon Nirmaan Shanker[1], Suraj Cheema[1], Cheng-Hsiang Hsu[1], Adhiraj Datar[1], Jongho Bae[1], Daewoong Kwon[1] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Ferroelectric materials offer significant promise for nonvolatile memories and low-power logic transistors [1] due to stable polarization states which can be reversed under an applied electric field. With the recent discovery of ferroelectricity in HfO_2 [2], fluorite-structure binary oxides have attracted considerable interest as they are compatible advanced semiconductor processes, unlike prototypical perovskite-structure ferroelectrics. Accordingly, ultrathin HfO_2-based ferroelectrics have received significant attention in charge-based

ferroelectric random-access memory (FeRAM), ferroelectric field-effect transistors (FeFETs), and even negative capacitance FETs [3]. Meanwhile, resistive-switching materials have emerged as promising candidates for novel beyond-CMOS computing paradigms [1]. In this context, ferroelectric tunnel junctions (FTJs) present a promising energy-efficient resistive switching memory as FTJs exploit the polarization-dependent tunneling barriers across thin ferroelectric barriers. However, a critical requirement for FTJs is to achieve a sufficiently high tunneling current while still exhibiting a large ON/OFF ratio (tunneling electroresistance), which requires robust ferroelectricity as the tunneling barrier is reduced to the ultrathin limit, presenting a materials challenge preventing realistic FTJ-based memories.

In this work, we demonstrate FTJs with ultrathin Zr-doped HfO_2 (Zr: HfO_2) ferroelectric barriers down to a thickness corresponding to two unit cells, grown by atomic layer deposition on silicon [4,5]. These tunnel junctions exhibit large polarization-driven electroresistance (19000 %), the largest value reported for HfO_2-based FTJs. In addition, due to the ultrathin ferroelectric barrier, these junctions provide large tunneling current (> 1 A cm^{-2}) at low read voltage, orders of magnitude larger than reported thicker HfO_2-based FTJs. Furthermore, the data retention (>10^4 s) and endurance characteristics (> 10^3 cycles) in these ultrathin HfO_2-based FTJs are comparable to those obtained with much thicker HfO_2-based ferroelectric layers. Scanning probe microscopy techniques – piezoresponse force microscopy (PFM) and conductive atomic force microscopy (C-AFM) – help establish polarization-driven switching is indeed responsible for the observed resistive switching. Thus, the ultrathin ferroelectric barriers not only allow robust memory operation, but also enable simultaneous occurrence of large electroresistance and large current, critical for practical applications.

Performance Comparison of Negative Capacitance in Si Nanowire and Nanosheet Field Effect Transistors Md. Azizul Hasan, Fahimul I. Sakib and Mainul Hossain; University of Dhaka, Bangladesh

The superior electrostatic control and high scalability of nanowire (NW) and nanosheet (NS) gate-all-around field-effect-transistors (FETs) make them promising alternatives to FinFETs in advanced technology nodes. Negative capacitance (NC) effect, originating from a ferroelectric (FE) material in the gate stack, can provide an elegant solution for the much-needed voltage scaling in these aggressively scaled devices. In this work, a comparative analysis on the performance of NC-NWFETs and NC-NSFETs is presented through fully calibrated, three-dimensional TCAD simulations. For the same layout footprint (LF), both single channel NC-NSFETs and those, with vertically stacked NSs, have been considered. Single channel NC-NSFET exhibits 9% lower subthreshold swing (*SS*) and 35% higher ON-current (I_{ON}) than NC-NWFET of comparable device dimensions. In contrast to NC-NWFET, capacitance matching between the FE and the underlying metal-oxide-semiconductor (MOS) capacitance is achieved with a thinner FE layer in NC-NSFET. This is particularly significant, since a thinner FE layer enables further scaling of these NC devices. In addition, NC-NSFET, with vertically stacked NSs, can achieve 4× higher I_{ON} and ~50% lower *SS* than NC-NWFET, owing to higher effective width and better capacitance matching. A high I_{ON}/I_{OFF} ratio of 10^6, with low operating voltage (V_{DD} = 0.2V), is obtained for the NC-NSFET. The significantly higher I_{ON} in NC-NSFET also results in faster switching, with significantly lower power consumption, at V_{DD} < 0.3 V. The performance of stacked NC-NSFETs can be optimized by tuning the width and thickness of the NSs. Negative differential resistance (NDR)

is found to be more pronounced in NC-NSFET, enabling these devices to attain a stronger drain-induced-barrier-rising (DIBR) and steeper *SS* for gate lengths (L_G) as small as 10 nm. The results presented here pave the way for performance optimization of NC-NWFETs and NC-NSFETs, in ultra-scaled and high-density logic applications, for 10 nm and beyond technology node.

Low Voltage Operating Ferroelectric Memory Transistor with MoTe2 Channel and P(VDF-TrFE)
Yongjae Cho, Ji Hoon Park and Seongil Im; Yonsei University, Korea (the Republic of)

$MoTe_2$ channel-based P(VDF-TrFE) ferroelectric nonvolatile memory is fabricated, which operates at minimum switching pulse voltage and minimum drain voltage. For the minimum switching voltage of 8 V, bottom-gate architecture is employed and its advantages are investigated. By using bottom-gate structure, we could avoid a dead layer formed at the interface between thermally-deposited Al and P(VDF-TrFE) at top-gate architecture. A dead layer in top-gated ferroelectric memory transistors increases the coercive voltage so as the switching pulse voltage. And, for the minimum drain voltage, a novel method of H_2O_2 treatment is developed. By oxidizing the source/drain area of $MoTe_2$ surface by H_2O_2 solution, Ohmic contact between Pt and $MoTe_2$ is achieved even without thermal annealing which would have a destructive effect on the crystal quality of P(VDF-TrFE). To demonstrate the benefit of our memory transistor in aspect of power saving, it is integrated into an OLED operating circuit.

Impact of Interfaces and Dopants on Ferroelectric Properties of Epitaxial HfO_2 Films Tingfeng Song, Saúl Estandía, Jike Lyu, Jaume Gàzquez, Ignasi Fina and Florencio Sanchez; Instituto de Ciencia de Materiales de Barcelona (ICMAB-CSIC), Spain

Ferroelectric HfO_2 is a promising material for new memory devices, but the microstructure of the films needs to be better controlled and some properties, mainly endurance, need to be improved. Research on ferroelectric HfO_2 has been focused mainly on polycrystalline films. In contrast, epitaxial films, of great interest to understand properties and prototyping devices, are scarcely investigated. The recently achieved stabilization of the orthorhombic ferroelectric phase in epitaxial $Hf_{0.5}Zr_{0.5}O_2$ films on perovskite $La_{0.7}Sr_{0.3}MnO_3$ electrodes has allowed to, among other results, control the crystalline polymorphs through substrate selection, achieve high polarization, endurance and retention in sub-5 nm films, and fabricate epitaxial ferroelectric tunnel junctions. Studies on epitaxial films are still in a nascent state, and little is known about the effects of dopants and interfaces, whose critical influence has been demonstrated in polycrystalline films. We will show the relevance to the stabilized phases and ferroelectric properties (polarization, endurance and retention) in epitaxial HfO_2-based capacitors of i) substrates and electrodes, and ii) chemical composition of the HfO_2-based films.

8:40 AM EL09.10.02
Impact of the Interface Layer on the Wake-Up Behaviour of Hafnium Oxide Maximilian Lederer, Konstantin Merstens, Alireza Kia, Jennifer Emara, Ricardo Olivo, Yannick Raffel, David Lehninger, Tarek Ali, Kati Kühnel, Konrad Seidel and Thomas Kämpfe; Fraunhofer Institute for Photonic Microsystems, Germany

Ferroelectric field effect transistors based on hafnium oxide have become a viable option as embedded non-volatile memory solution due to its high coercive field as well as its compatibility to complementary metal-

oxide-semiconductor (CMOS) processes [1]. In comparison to ferroelectric capacitors, these devices comprise an additional interface layer, which impacts the electrical field distribution in the gate stack and yields a depolarization field counteracting the polarization of the ferroelectric, affecting properties like endurance and retention [2,3]. In consequence, this is expected to affect the wake-up behaviour of the hafnium oxide layer. Additionally, this layer is already present during the crystallization of the ferroelectric at high temperature. As diffusion processes cannot be excluded at these temperatures, influences on the crystallization behaviour are expected.
Here, we present the impact of different annealing temperatures on the layer stack. Diffusion processes inside the layer stack during the crystallization anneal were investigated using time-of-flight secondary ion mass spectroscopy (ToF-SIMS). For high annealing temperatures, changes in the chemical composition of the interface layer were observed. Furthermore, electrical characterization of the ferroelectric properties revealed a strong impact of the annealing temperature, which resulted in an increased presence of the wake-up effect for lower annealing temperatures. Additional transmission Kikuchi diffraction (TKD) analysis revealed strong differences in the microstructure and crystallographic texture, which are most likely responsible for the observed behaviour.

Influence of Antiferroelectric-Like Behavior on Tuning Properties of Ferroelectric HZO-Based Varactors Sukhrob Abdulazhanov, Maximilian Lederer, David Lehninger, Tarek Ali, Jennifer Emara, Ricardo Olivo and Thomas Kämpfe; Fraunhofer Institute for Photonic Microsystems, Germany

With the progress in wireless networks, including the upcoming 5G and Internet of Things, there is a high concern in exploring of materials for passive or active RF devices. The main criteria are good CMOS-compatibility, low tuning voltage, low chip size and low power consumption. Ferroelectric materials, like barium strontium titanate (BST) [1] have been widely used as tunable capacitors - varactors. However they lack CMOS compatibility and require relatively high tuning voltages. Hafnium zirconium oxide (HZO) is a fully CMOS-compatible material [2], with a good back-end-of-line integration possibility due to its low thermal budget [3]. It is a good candidate for varactor applications [4], with a high miniaturization possibility [5],[6]. Here, we investigate the capacitance-voltage (CV) characteristics of $Hf_xZr_{1-x}O_2$ MFM thin film capacitors with various Zr doping, thicknesses and annealing temperatures. The impact of field cycling during the wake-up on the tunability was analyzed and an optimized bias region for the maximum tunability was determined. Additionally, the effect of antiferroelectric-like (AFE) behavior on tuning was investigated. The superposition of ferroelectric and AFE regime shows an interesting behavior, where less bias for tuning is needed, but tunability is reduced. A usefulness of such a behavior for varactor application was also examined. We have also investigated the ferroelectric and antiferroelectric-like properties at elevated temperaures. It was shown that with increase of temperature tunability deteriorates. Temperaure measurements also comply with recent studies of ferroelastic nature of AFE behavior [7].

Rethinking Reliability of Ferroelectric Transistors for Memory and Logic Applications Nicolo Zagni[1], Kamal Karda[2], Francesco Maria Puglisi[1], Paolo Pavan[1] and Muhammad A. Alam[2]; [1]Università degli Studi di

Modena e Reggio Emilia, Italy; [2]Purdue University, United States

Introduction Despite the remarkable development in ferroelectric FETs, endurance and reliability of these devices still represent serious concerns in both memory and logic applications. In this work, we present recent results discussing the reliability of HfO_2-based FeFETs [1] employed as either non-volatile memory elements or as steep-switching NCFET logic transistors. For FeFET, we analyze the role of interface and bulk trap generation on memory window closure leading to limited endurance. For NCFET, we discuss the beneficial role of negative capacitance (NC) effect in reducing the persistent reliability issue of negative bias temperature instability (NBTI). We utilize a common theoretical framework based on the Landau Theory to describe ferroelectric energy landscape that allows capturing: *i*) the hysteretic I-V characteristics of FeFETs when employed for memory applications; and *ii*) the NC effect when aiming at steep-slope (hysteresis-free) switching for logic transistors [2].

Endurance Limits of FeFETs Endurance is the total number of repeated program/erase cycles after which the states of a memory become indistinguishable. One of the main factors limiting the endurance of FeFETs is the generation of traps at the interfacial layer inserted in the gate stack between the ferroelectric and semiconductor body. In [3], we developed an experimentally validated analytical model to describe the effects of aging on the memory window (MW). This model captures the degradation of programmed/erased states depending on the amount of generated traps that in turn is related to the amplitude and duration of the writing pulses. As such, the analytical model could serve either as an add-on to traditional techniques or as a stand-alone method to characterize generated defect densities under a variety of stress conditions. For instance, it is possible to estimate the net generated traps from the MW expression derived in [3], thus allowing to correlate MW measurements with generated traps. The estimation drawn from the simple analytical model can be helpful to develop next-generation FeFETs with improved endurance.

NBTI Suppression In NC-FETs The primary mechanism for NBTI-induced degradation in MOSFETs is the increase in interface trap density with stress time. The NBTI degradation can be fully compensated by adding a ferroelectric (FE) layer of proper thickness for stabilized NC operation. This enables steep-slope, hysteresis-free operation needed for switching. NBTI reduction comes from the extra capacitance given by the parasitic source/drain overlap regions that cause the capacitance matching (between the negative capacitance and the intrinsic MOSFET gate capacitance) to improve over stress time. Since achieving an optimum FE layer thickness needed for obtaining NBTI-free operation can be challenging, we performed simulations for various thicknesses to find that even for relatively thin FE (e.g., 7 nm) NBTI degradation is reduced [4]. In other words, even if the FE thickness needs to be determined exclusively by process integration and capacitance matching constraints, it would still lead to NBTI reduction.

Conclusions Reliability aspects in ferroelectric FETs for both memory and logic applications were investigated by means of either analytical models or self-consistent numerical simulations based on the framework based on Landau Theory. The modeling approach presented in this work allows gaining useful insights into how to improve reliability of ferroelectric FETs and accelerate the path towards widespread commercialization.

Acknowlegments Authors thank prof. L. Selmi (Univ. of Modena and Reggio Emilia) for useful discussion. This research has received partial funding from the European Commission's Horizon 2020 BeFerroSynaptic project, grant agreement n°871737 via the IU-NET consortium.

CMOS Backend Compatible Ferroelectric Tunnel Junction Memory Device Keerthana S. Nair[1,2], Marco Holzer[1,2], Sourish Banerjee[1], Catherine Dubourdieu[1,2] and Veeresh Deshpande[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

Ferroelectric tunnel junction (FTJ) memories have gained prominence among emerging non-volatile memories due to low power consumption, high switching speed, and potential for neuromorphic applications [1]. Recent development of doped hafnium oxide ferroelectric layer enables integration of FTJ memory devices with CMOS technology. In FTJ devices, the tunneling current is directly dependent on the remnant polarization of

the ferroelectric layer. While the tunneling current is higher across a thin ferroelectric layer (around 1-4 nm), it is challenging to have a high remnant polarization in these layers and simultaneously achieve a high tunneling electro resistance (TER) ratio. FTJs with a composite stack of Metal-Ferroelectric-Dielectric-Metal, allow the use of a thick ferroelectric layer (~10 nm) while obtaining high TER, as demonstrated recently [2, 3]. However, the crystallization of the ferroelectric layer is carried out at high temperatures (500-600°C) which are incompatible with the CMOS back-end-of-line. In this work, we demonstrate a highly CMOS backend compatible FTJ stack with a 400°C crystallized $Hf_{0.5}Zr_{0.5}O_2$ (HZO) ferroelectric layer and TiN-Al_2O_3-HZO-W stack. Such a stack with a TiN bottom metal and a W top metal allow seamless integration with the CMOS back-end-of-line, particularly at contact level and has not yet been explored. The FTJ devices show on-current and TER that are comparable to the state-of-the-art. The devices also show multi-level resistance behavior necessary for neuromorphic applications. We will also discuss a detailed investigation of the switching transients, voltage, and device resistance dependence on switching cycles. As the composite stack is similar to those used in the study of negative capacitance, the polarization switching behavior of the device is of importance to a broader community. Furthermore, we will also discuss device characteristic dependence on dielectric thickness and identify parameters to improve the TER, on-state current and retention.

11:45 AM *EL09.11.01
Hafnia-Based Ferroelectric Devices—A Singlular Type of Switching P. Nukala[1,2], D. Carbone[3], M. Ahmadi[1], Y. Wei[1,4], Sylvia Matzen[5] and Beatriz Noheda[1,1]; [1]University of Groningen, Netherlands; [2]Indian Institute of Science, India; [3]Lund University, Sweden; [4]École Polytechnique Fédérale de Lausanne, EPFL, Switzerland; [5]University Paris-Saclay, CNRS, France

Hafnia-based films are changing the way we think of ferroelectric switching. Ferroelectricity in these materials arises from metastable phases that are easier stabilized at the smallest dimensions. In addition they present low leakage as well as CMOS compatibility [1], making them ideal candidates for memory and logic devices. In addition, their switching takes place, quite uniquely, without involving domain wall motion, which allows experimental access to negative capacitance states[2]. Multiferroic tunnel junctions (MTJs) fabricated with (La,Sr)MnO_3 electrodes and ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ barriers show both tunneling magnetoresistance (TMR) and tunneling electroresistance effect (TER), displaying four resistance states by magnetic and electric field switching[3]. Moreover, under electric field cycling, the TER effect can reach values as large as 10^6%. Experiments indicated that polarization switching alone cannot be responsible for those changes[4]. In this talk we will show direct evidence, by means of *operando* transmission electron microscopy[5], as well as synchrotron x-ray diffraction experiments with *in-situ* application of electric fields[6], of the mechanisms that come into play during electric field switching in hafnia-based devices, as well as their relative importance determining the properties of these devices.

***In Situ* Transmission Electron Microscopy of Field-Induced Polarization Switching in Antiferroelectric Zirconia** Sarah Lombardo[1], Christopher Nelson[2], Kisung Chae[3,3,4], Sebastian E. Reyes-Lillo[5], Mengkun Tian[1], Nujhat Tasneem[1], Zheng Wang[1], Michael Hoffmann[6], Kyeongjae Cho[4], Andrew Kummel[3], Josh Kacher[1] and Asif Khan[1,1]; [1]Georgia Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States; [3]University of California, San Diego, United States; [4]The University of Texas at Dallas, United States; [5]Universidad Andres Bello, Chile; [6]NaMLab/TU Dresden, Germany

Ferroelectric and antiferroelectric oxides have gained attraction in recent years for use as gate oxides in field effect transistors (FETs), along with potential applications toward random access memories and high-density energy storage, owing to their hysteretic charge-voltage characteristics and negative capacitance phenomena. Exploiting this negative capacitance can lead to lower operating voltages, and therefore, operation of transistors beyond their current limits. The origin of negative capacitance is thought to stem from the energy barrier of first order field-induced phase transitions. In the case of antiferroelectric materials, interesting non-linearities in their polarization-voltage characteristics (i.e. double hysteresis loops) are observed and attributed to an electric field-induced first-order, structural phase transition between a non-polar, parent phase and a polar active phase. However, direct observation and identification of such phase transitions and their relation to ferroelectric/antiferroelectric properties has yet to be unanimously determined, leaving significant gaps in our fundamental understanding of the microstructure-property relationship of such materials. Since polarization correlates with microstructure, the application of an electric field alters the microscopic features, enabling electrical properties suitable for non-volatile memory, analog synapses, and artificial neurons, but also poses significant challenges to performance such as variability, reliability, and endurance.
The first step in identifying the crystallographic pathways involved in polarization switching of antiferroelectric ZrO_2-based thin films is the direct imaging of the polarization switching at the atomic scale with applied bias via *in situ* transmission electron microscopy (TEM). *In-situ* TEM characterization can provide simultaneous biasing and imaging of atomic structure in real time. Field-induced phase transitions and microstructural evolution of antiferroelectric zirconia are investigated via high resolution, in-situ TEM biasing, coupled with DFT-calculated atomic models, to identify the origin of antiferroelectricity in these materials. Such characterization techniques highlight the ability of advanced electron microscopy to provide insight into structure-property relations of fluorite-type binary FE/AFE oxides, thereby improving our fundamental understanding of the microscopic mechanisms behind device performance for the advancement of logic and memory technologies.

Late News: Atomic Scale Crystal Field Mapping of Polar Vortices in Oxide Superlattices Sandhya Susarla[1,2], Pablo García-Fernández[3], Colin Ophus[1], Pablo Aguado-Puente[4], Sujit Das[2], Peter Ercius[1], Lane W. Martin[2], Ramamoorthy Ramesh[2,1,2] and Javier Junquera[3]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Universidad de Cantabria, Spain; [4]Queen's

University, United Kingdom

Polar vortices in oxide superlattices exhibit complex polarization topologies. In this presentation, I will talk about using a combination of energy loss near-edge structure analysis, crystal field multiplet theory, and first-principles calculations to probe the electronic structure within such polar vortices in $[(PbTiO_3)_{16}/(SrTiO_3)_{16}]$ superlattices, at the atomic scale. The peaks in Ti -edge EEL spectra shift systematically depending on the position of the Ti^{4+} cations within the vortices i.e., the direction and magnitude of the local dipole. First-principles computation of the local projected density of states on the Ti orbitals, together with the simulated crystal field multiplet spectra derived from first-principles are in good agreement with the experiments. This combined experimental and theoretical approach can serve as a fundamental basis to study macroscopic properties such as chirality and circular dichroism.

12:40 PM EL09.11.04
Atomic-Scale Design of Negative Capacitance in Ultrathin HfO_2-ZrO_2 Ferroic Heterostructures on Silicon Suraj Cheema[1], Nirmaan Shanker[1], Cheng-Hsiang Hsu[1], Yu-Hung Liao[1], Shang-Lin Hsu[2,2], Steven K. Volkman[1], Vladimir Stoica[3], Zhan Zhang[4], John Freeland[4], Padraic Shafer[2], Jim Ciston[2], Mohamed Mohamed[5], Chenming Hu[1] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The Pennsylvania State University, United States; [4]Argonne National Laboratory, United States; [5]Lincoln Laboratory, Massachusetts Institute of Technology, United States

Negative capacitance [1] has emerged as a promising solution to overcome fundamental energy-efficiency limits in conventional electronics, in which internal ferroelectric order within the gate stack of a field-effect transistor can enable low-power operation [2,3]. Thus far, negative capacitance has been primarily demonstrated in thick perovskite- and fluorite-structure ferroelectric thin films, but integration into advanced semiconductor technology nodes will require stabilization at the ultrathin regime. Here, we present evidence of negative capacitance in atomic-scale HfO_2-ZrO_2 heterostructures [4] down to two-nanometers thickness, leveraging our recent work examining the 2D limits of fluorite-structure ferroelectricity on silicon [5-7]. HfO_2-ZrO_2-HfO_2 trilayers on Si-SiO_2 demonstrate sub-7 Å effective oxide thickness (EOT) without having to scavenge the SiO_2 interlayer, in stark contrast to conventional high-κ metal gate (HKMG) technology. Accordingly, in comparison to industrial HKMG benchmarks, these SiO_2-buffered ferroic heterostructures boast the lowest reported leakage for such aggressively-scaled EOT gate oxides, possible via negative capacitance.

In contrast to previous reports of negative capacitance in thicker ferroelectric HfO_2-based films [8], the microscopic origin of negative capacitance in these ultrathin HfO_2-ZrO_2 multilayers arises from mixed ferroelectric-antiferroelectric order. Remarkably, this fluorite-structure family fosters the stabilization and competition of such ferroic order at the atomic-scale regime [5-7]. We first demonstrate ultrathin ferroic order – a crucial requirement for negative capacitance – down to one-nanometer in doped-HfO_2 films [5,6] and five-angstroms in conventionally-antiferroelectric ZrO_2 films [7]. To establish polarization switching in these ultrathin films, hysteretic characterization – via scanning probe, electrical tunnel junction and dielectric measurements – in various device geometries (in-plane, out-of-plane) diagnose competing antiferroelectric-ferroelectric order. In conjunction, electron microscopy and synchrotron X-ray characterization monitor structural signatures of the competing ferroic phases. These results indicate not only the absence of a ferroelectric critical thickness, but also ultrathin-enhanced polar distortion in fluorite-structure thin films [5,7], critical breakthroughs towards exploiting ferroic-based phenomena at ultra-scaled dimensions. Finally, pulsed electrical measurements and Landau phenomenology help explain the underlying origins of negative capacitance in this mixed-ferroic system. Therefore, this work not only broadens the ferroic origins of negative capacitance beyond ferroelectricity, but also allows one to design negative capacitance in atomic-scale HfO_2-ZrO_2 heterostructures on silicon [4], paving the way towards realistic ferroelectric-based computing.

12:55 PM EL09.11.05
Ferroelectric HZO Capacitor with W/TiN Bottom Electrode with No Wakeup Harshil Kashyap[1], Mahmut S. Kavrik[1], Chenghsuan Kuoo[1], Ajay Yadav[2] and Andrew Kummel[1]; [1]University of California, San Diego, United States; [2]Applied Materials, Inc., United States

Ferroelectric HfO2 is being investigated for neuromorphic computing and back-end memory due to its scalability and compatibility with the current CMOS processing. However, for low power operation, low switching voltage (sub +/-1V) is desired. To achieve this, thinner FE HZO films are required along with no interfacial oxide/dead layers. In this study, Ni(top)/HZO/W/TiN MIM capacitors grown at high temperature were explored to achieve low voltage operation. Sputtered W/TiN bottom electrodes were deposited on a Si wafer. Samples were annealed in-situ prior to deposition in UHV at 350oC for 30 min in homebuilt ALD tool. HZO was deposited using TDMAH, TDMAZ and H2O ALD precursors at 350°C substrate temperature. 50 nm Ni top electrodes were deposited using thermal evaporation. Oxide thickness was measured using ellipsometry on a Si witness sample. Samples were annealed at 450°C in N2 for 2min. Electrical characterization was performed using a Keithley 4200A-SCS characterization system.

A sample with 200 cycles HZO (12 nm) was fabricated and characterized. Cross sectional TEM measurements revealed an oxidized W film which is reduced at the W/HZO interface; this was confirm by EDS (not shown). This results in abrupt W/HZO interface and low voltage switching because there is no interfacial dielectric layer which inducing a voltage drop as observed in other electrode materials such as TiN and Si. The sample shows steep switching and high 2Pr of 41μC/cm^2 at +/-5V. To reduce the operating voltage, the device was scale. 100 cycles of HZO were deposited; ellipsometry was used to confirm the thickness as 6 nm. Endurance test was performed at 1MHz +/-1.8V (~3 MV/cm) to study the device performance over time.

The device showed a 2Pr = 39 uC/cm2 at +/-1.8V (3MV/cm) and a maximum 2Pr = 62 uC/cm2 at +/- 3.1V along with sharp switching I-V. The voltage scaling with thickness, as shown by the comparison of two devices is consistent with the absence of interfacial oxides. The endurance performed is superior to typical TiN/HZO/TiN structures and is sufficient for many applications. Furthermore, the devices do not show any wake-up which is beneficial since this complicates operation in a practical circuit. The absence of wake-up is consistent with the absence of oxygen vacancies at the W/HZO interface because the HZO ALD was performed on oxidized W film which was reduced to W metal during high-temperature ALD; confirmed by EDS (not shown). It is well known that oxygen vacancies at the electrodes result in the pinning of FE grains which reduces Pr. By operating with subloops with less than full Pr, +/-1V operation can be achieved and this will further increase the endurance.

Directly Connecting Local Chemistry and Structure to Relaxor Properties Using Scanning Transmission Electron Microscopy James M. LeBeau; Massachusetts Institute of Technology, United States

Relaxor ferroelectrics are characterized by diffuse dielectric and piezoelectric properties, which distinguishes them from traditional ferroelectrics. To formulate models of local polar behavior, the structural and chemical complexity in relaxor systems have largely been probed with diffuse scattering using X-rays, neutrons, and electrons. These techniques, however, provide a measure of the average global and local structure across a relatively large volume of the material. Consequently, the origin of relaxor properties continues to be debated although these materials have been studied extensively. In this talk, I will discuss how aberration corrected scanning transmission electron microscopy (STEM) can be used to directly separate nanoscale structural and chemical inhomogeneities in relaxors. Here, we apply these techniques to $Pb(Mg_{1/3}Nb_{2/3})O3$-PbTiO3 (PMN-PT). Through simultaneous acquisition of images that are sensitive to chemistry (angle annular dark-field STEM) and light elements (integrated differential phase contrast STEM), we directly connect nanoscale chemical order regions, distorted oxygen octahedra, and local polarization. We find that the degree of chemical order smoothly varies within ordered domains and approaches a minimum at anti-phase boundaries, as well as regions of correlated oxygen octahedral titling are found to be anti-correlated with regions of maximal chemical order. Comparing with the projected polarization, we observe that the regions of greatest variation in polarization correspond to the regions of maximum chemical order and maximum octahedral distortion. Based on these results, we show that both structural and chemical inhomogeneities act as a barrier for polarization rotation and thus frustrate long range polar order.

Status and Outlook for Ferroelectric Hf-Based Films and Devices Robert Clark; TEL Technology Center, America, LLC, United States

The recent discovery that with certain dopants hafnium oxide can be crystallized in a form that exhibits ferroelectricity has opened up a range of device possibilities(1). We chose to work within the Hf/Zr system for our initial studies. The advantages of the Hf/Zr doping system include the similarity in precursors which can enable several running modes for the ALD process including a co-pulsing scenario, as well a cycle ratio scenario for controlling the Zr doping. In addition, the relative range of doping for which a strong remnant polarization is observed is much broader for the Hf/Zr system than for other dopants such as Al, Si, etc. which means this system should be more tolerant of small variations in composition, temperature and thickness than the other doping schemes. These factors along with a relatively low thermal budget suggest the CMOS-friendly Hf/Zr system could provide the basis for a number of ferroelectric memory devices. Other potential uses for these films include the possibility to create multi-domain ferroelectric FETs that can be used within a neuromorphic device to mimic synapse behavior. This talk will review and update our work to date on these films and their potential uses. References: 1. T. S. Böescke, J. Müller, D. Bräuhaus, U. Schröder and U. Böttger, in *Technical Digest of the International Electron Devices Meeting*, p. 24.5.1 (2011).

Scaling FeFET Towards 7nm Node—A TCAD Perspective Gihun Choe, Jae Hur and Shimeng Yu; Georgia Institute of Technology, United States

Ferroelectric materials have been explored for device structures such as ferroelectric random-access memory, ferroelectric tunnel junction, and ferroelectric field-effect transistors (FeFETs) [1]-[3]. Among the device structures, the FeFETs have been considered as one of the most versatile devices to implement the non-volatile memory and in-memory compute. It has low write energy as it is electric field driven, non-destructive read-out

mechanism and relatively fast program/erase speed [3]. The discovery of ferroelectric material based on doped HfO_2 has made FeFETs more attractive. Hafnia based ferroelectric material has good compatibility with the complementary metal-oxide-semiconductor (CMOS) fabrication process. Even more, its ferroelectric properties could be controlled depending on the dopant materials and doping concentration, which enables fine-tuning of FeFETs' performance.

Industrial development of FeFETs stays at 28nm/22nm today [4] [5], primarily because high voltage (~3V) is required to program the polarization states in the conventional ferroelectric gate MFIS stack (metal/doped HfO_2/interfacial layer/silicon). The unmatched charge between the Fe-cap and MOS-cap creates enhanced electric field in the interfacial layer, resulting in trap generation, reliability degradation and exacerbated variability.

Making FeFETs compatible with 7nm FinFET-like structure, if successful, could enable the emerged memory-logic circuit designs that take the advantages of high-performance 7nm logic transistors. Scaling down the ferroelectric layer thickness while maintaining ferroelectric properties is especially critical. In a recent research [6], 1~2 nanometers of the hafnia-zirconia-based ferroelectric layer were demonstrated. GlobalFoundries prototyped high-k/metal-gate bulk FeFETs at 28 nm [4] and fully-depleted SOI (FDSOI) FeFETs at 22 nm using silicon doped HfO_2 based material [5].

In this work, we simulated FeFETs from 22 nm node of FDSOI to 7 nm node of ferroelectric FinFET (Fe-FinFET) using a Sentaurus TCAD to assess its scalability. Simulation parameters including ferroelectric properties were fitted with experimental results of a 22nm FDSOI FeFET for accurate expectation and future suggestion. Quasi-static I-V characteristics of the FeFET were modeled using the multi-domain Preisach model built in TCAD and domain phase variations were considered. Eventually, the design guideline for 7 nm technology node of Fe-FinFET was suggested with an aim to optimize the write voltage below 1.5V. The memory window of Fe-FinFET could be enhanced using innovative gate stack design and/or employing higher-k materials for an interlayer oxide.

DFT Modeling of Scaling Limits in FEFETs Kisung Chae[1,2], Andrew Kummel[1] and Kyeongjae Cho[2]; [1]University of California, San Diego, United States; [2]The University of Texas at Dallas, United States

Atomic stack models in ferroelectric (FE) hafnium-zirconium oxide (HZO) based on density functional theory have been developed to elucidate the atomic and electronic structure level origin of fatigue behavior, i.e., deteriorating memory window with field cycling. Stack models to mimic metal-FE-metal (MFM) capacitor and metal-FE-semiconductor FE field effect transistor (FEFET) were developed. There were three key findings. (1) For a metal in direct contact with the FE layer, the field inside the FE is eliminated and local potential profile inside the FE is unchanged upon polarization switching. Conversely, the field inside the FE is not completely eliminated by a relatively less polarizable semiconductor electrode, and there is an asymmetric potential profile

due to polarization switching. (2) When a DE interlayer is placed at the interfaces in MFM and FEFET stacks, a significant internal field is induced in both cases. Strength of the field is dependent on the thickness of the FE layer, decreasing for thicker FE layers, and for ultrathin films (<4 nm) can exceed the breakdown voltage, consistent with difficulty in synthesizing FE HZO films thinner than 5 nm. (3) Since the field within the FE layer is reversed each time the polarization switches, this will promote charge-compensating defect generation. With a significant accumulation of defect density, most likely O vacancies, the FE phase of HZO would become thermodynamically unstable, and transition to a non-polar phase losing the spontaneous polarization. This would explain the fatigue behavior of the FE devices. The suggested mechanism would be more significant for a FEFET due to the lower polarizability of semiconductor vs metal electrodes and the spontaneous formation of insulating oxide DE interlayers, for example silicon oxide on silicon, which is consistent with unsatisfactory endurance for FEFET devices compared to MFM capacitors. The atomic models have developed a fundamental understanding to enable experimental optimization strategies for desired device performance.

Multidomain Ferroelectric Switching Dynamics Studied with a Physics-Based Circuit Compatible Model for Phase-Field Simulations Chia-Sheng Hsu[1], Sou-Chi Chang[2], Dmitri Nikonov[2], Ian Young[2] and Azad Naeemi[1]; [1]Georgia Institute of Technology, United States; [2]Intel Corporation, United States

The multidomain nature of ferroelectric (FE) polarization switching dynamics has recently attracted a great deal of research attention due to the discovery of the doped hafnium oxides as an FE material compatible with transistor fabrication processes. To study Zr-doped hafnium oxides (HZO), we develop a physics-based circuit compatible model for phase-field simulations, where the 3-dimensional time-dependent Ginzburg–Landau (TDGL) equation and Poisson's equation are self-consistently solved with the SPICE simulator. Systematically calibrated based on the experimental measurements of metal–ferroelectric–metal (MFM) capacitors, the model well captures transient negative capacitance (NC) in pulse switching dynamics, with domain interaction and viscosity being the key factors. The influence of pulse amplitudes on voltage transient behaviors is found to be attributed to the fact that the FE free energy profile strongly depends on how the domains interact. In addition, we extract the domain viscosity dynamics during polarization switching according to the experimental measurements. For the first time, a physics-based circuit-compatible SPICE model for multidomain phase-field simulations is established to reveal the impact of microscopic domain interaction on the NC effect. The findings of this article may have important implications for the charge boost induced by the stabilization of NC in an FE/dielectric (DE) stack at a specific operating voltage or frequency.

MIT Virtual Source Ferroelectric FET (MVSFE) Model—Application to Scaled-L_g FeFET Analog Synapses Ahmad Zubair, Ujwal Radhakrishna, Mark Theng, Dimitri Antoniadis and Tomas Palacios; Massachusetts Institute of Technology, United States

Conventional multi-purpose hardware based on von-Neumann architecture does not satisfy the energy efficiency requirements of large-scale implementations of deep neural networks (DNN). Hardware accelerators that reduce data movement are therefore key to improve the power efficiency of many big data applications based on deep learning, such as image classification and speech recognition. Emerging non-volatile memory devices such as resistive random-access memory, phase change memory, floating gate memory and ferroelectric field effect transistors (FEFETs) are potential candidates for these DNN accelerators due to their synaptic functionality *i.e.* analog conductance modulation.
FeFET analog synapses are 3-terminal devices that have been proposed to improve the classification accuracy and yield low latency in non-volatile memory-based DNN accelerators. This is due to their high conductance ratio, operation capability with sub-100 ns pulse [1] and seamless integration with CMOS process flow.
This work presents a simulation framework to evaluate novel ferroelectric and anti-ferroelectric devices, such as doped HfO_2 ferroelectric-transistors, and their impact in system-level neuromorphic applications. The study uses a new, comprehensive, physics-based compact Verilog-A model, the MIT Virtual Source Ferroelectric FET (MVSFE) model that describes transistors with ferroelectric (FE)-oxides in their gate-stack. We expanded

physics-based MIT Virtual Source model benchmarked against scaled 45nm [2] MOSFET to capture the physics of ferroelectric oxide using VDST-P [3,4]model calibrated against experimental FE HZO characteristics. The model captures underlying FET incorporating ballistic transport and charges for advanced technology node FeFETs (with or without internal gate). Our model extends the scope of [1] to the highly scaled L_g required for energy efficient system-level implementation of DNN [5] We also use the framework to show that engineering the device with multiple t_{FE}/V_T elements along width direction engineering is effective to improve system-level performance metrics (i.e. linearity and classification accuracy) of DNN built using analog synapses. The results provides insight on improved device design, and its system-level performance impact in a multilayer perceptron neural network.

First-Principles Theory and Insights of Two-Dimensional Ferroelectric Semiconductors and Semimetals
Xiaofeng Qian; Texas A&M University, United States

Nanoscale ferroelectric materials hold great promises in miniaturized device applications such as ferroelectric capacitor, transducers, actuators, sensors, photovoltaics, etc. Here we present first-principles theoretical predictions and understandings of three materials classes of two-dimensional ferroelectrics, including (a) semiconducting 2D group IV monochalcogenides [1], (b) semiconducting 2D multiferroic semiconductors in monolayer transition metal phosphorus chalcogenides (TMPCs) with coexisting ferroelectricity and ferromagnetism [2], and (c) semimetallic few-layer WTe_2 [3,4]. We show that monolayer group IV monochalcogenides hold highly anisotropic and large ferroelectric polarization with visible-spectrum excitonic gap and sizable exciton binding energy and strain-tunable ferroelectric transition barrier. We will further discuss our study and understanding of domain wall, phase transition and domain switching in 2D ferroelectric group IV monochalcogenide using first-principles based machine-learning force field developed in our group. In contrast to group IV monochalcogenides, monolayer TMPCs hold coexisting ferroelectricity and ferromagnetism where Cu atoms spontaneously move away from the center atomic plane and result in out-of-plane electric dipole moment, suggesting the possibility of controlling electric polarization by external vertical electric field. Finally, we will present our study of ferroelectric polarization in semimetallic few-layer WTe_2 where small interlayer sliding induces ferroelectric transition with small kinetic barrier, enabling facile ferroelectric switching upon electric gating and ferroelectric nonlinear anomalous Hall effect demonstrated in experiment very recently [4].

9:00 PM *EL09.14.01
Polycrystalline Ferroelectric $HfZrO_2$-Based Negative Capacitance FETs with Polarization Phases and Domains Min-Hung Lee; National Taiwan Normal University, Taiwan

The integrating ferroelectric gate stack into FETs with negative capacitance (NC) effect [1][2] for subthreshold swing (SS) improvement has attracted lots of attention due to hafnium (Hf)-based oxide with ferroelectricity. The prospect of ferroelectric Hf-based oxide by ALD (Atomic Layer Deposition) has been wide and intensive studied due to lots of applications. The HfO_2 with suitable dopants and annealing for ferroelectric (FE) transition would be studied, and demonstrated NC effect for steep-slope FET (SS-FET) and memory applications [3][4].
Pursuing steep-SS with accompanying hysteresis is a challenge for NC-FET development, as well as the issue of asymmetric SS of bi-directional sweep [5][6]. Furthermore, the reduced NC onset voltage is another issue to boost steep SS at low operation bias [7]. The antiferroelectric (AFE) $Hf_{1-x}Zr_xO_2$ with adopting as gate would overcome partial issues and make comparison with ferroelectric $Hf_{1-x}Zr_xO_2$ [8][9]. Note that the FE and AFE characteristics of $HfZrO_2$-based is achieved by Zr incorporation content by ALD supercycle.
Device dimension scaling down, such as FinFET and GAA, to comparable with domain size of polycrystalline ferroelectric $HfZrO_2$ (HZO) is evaluated for SS and drain-induced barrier lowing (DIBL) [10][11]. The multi-domain modeling of polarization randomly located in HZO and the probability with Gaussian distribution HZO are confirmed by measurement data within limitation polarization, and presented NC effect for voltage amplification with opposite direction of E-field in FE and IL. The experimental data of FinFET and planar FET are used to validate the simulation results and the direction effect of domain quantity.
The compatible CMOS process and scaling film thickness are the advantages to integrate into semiconductor industry by comparison with perovskite material. The high scalability and CMOS-compatibility of ferroelectric Hf-based oxide is a key technology enabler for energy-efficient computing to serve for smart power management in IoT applications.

Late News: Low Temperature (350 °C) Annealing for Ferroelectric Hf0.5Zr0.5O2 Thin Films Zhouchangwan Yu, Balreen Saini, Fei Huang, Wilman Tsai and Paul McIntyre; Stanford University, United States

HfO_2-based ferroelectric thin films are promising for memory and neuromorphic applications. Compared to conventional perovskite-structure ferroelectric materials, HfO_2-based ferroelectrics have excellent CMOS compatibility, and they are better able to meet back-end-of-line (BEOL) thermal budget requirements. In this work, we demonstrate that high polarization ($P_r > 20\ \mu C/cm^2$) $Hf_{0.5}Zr_{0.5}O_2$ (HZO) thin films are achieved by a

rapid thermal anneal (RTA) at a very low temperature (350°C). Orthorhombic phase formation of HZO is studied as a function of RTA time.

In the ferroelectric HZO capacitor structure, 10 nm HZO is sandwiched between 10 nm top and bottom TiN electrodes. The HZO film is deposited by a plasma-enhanced atomic layer deposition (PE-ALD) process at 250°C. The bottom and top TiN are deposited by reactive sputtering of Ti in N_2 atmosphere. After top TiN deposition, the capacitors are annealed by RTA at 350°C in N_2 atmosphere from 30 to 600 seconds. Finally, Pt contacts are deposited on the TiN top electrodes to facilitate for electrical measurements. Capacitor areas are defined by etching Pt/TiN stack in SC1 solution.

All HZO capacitors display polarization switching after annealing at 350°C, even after only 30 s anneal. The remnant polarization (P_r) increases as the RTA time increases from 30 s to 120 s, and the P_r saturates for longer RTA times ($P_r > 20$ $\mu C/cm^2$). For all devices, there is no evidence of an anti-ferroelectric hysteresis loop observed even in the as-processed (pristine) state, and no significant polarization "wake-up" effect is observed during voltage cycling. Grazing incidence X-ray diffraction (GI-XRD) is performed to analyze the phase evolution of the HZO thin film in this low temperature anneal process. The observed O(111) peak is consistent with formation of the orthorhombic phase. HZO films annealed for longer RTA time display higher O-phase peak intensities. Also, weak peaks indexed as the monoclinic phase begin to appear as the RTA time increases. Synchrotron XRD are performed for quantitative analysis on the phase evolution structure as a function of RTA time.

The ALD temperature used in deposition of the HZO film is a key factor enabling a low RTA thermal budget. HZO deposited at 200°C required a higher temperature for formation of films exhibiting a programmable polarization (> 500°C). Also, significant wake-up behavior is observed during voltage cycling, suggesting that the tetragonal phase and orthorhombic phase co-exist in the pristine state for films deposited at this lower ALD temperature, later transforming to the orthorhombic phase during cycling. Possible structural origins of this ALD temperature-induced change in phase formation sequence will be discussed.

9:40 PM EL09.14.03
High-Performance and High-Endurance Hafnia-Based Ferroelectric Field Effect Transistor with 3-Dimensional Structural Approach Taeho Kim, Junghyeon Hwang, Giuk Kim, Minhyun Jung and Sanghun Jeon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Since the discovery of fluorite-structure oxides with ferroelectricity, especially doped-HfO_2, the ferroelectric field effect transistor (HfO_2-FeFET) has attracted huge attention as an emerging memory device. One of the serious challenges of the HfO_2-FeFETs is their limited endurance, which has been attributed to the degradation of the interface layer before the polarization fatigue of the HfO_2-ferroelectric layer. The main mechanisms of the interface layer degradation of FeFETs represented by metal-ferroelectric-insulator-semiconductor (MFIS) are charge injection/trapping and interfacial defect generation, which is mainly induced by high electric field through the interfacial dielectric layer. In this work, we propose strategies to minimize the interfacial electric field by approaching from two viewpoints of ferroelectric material properties and device structure. In this study, we present a structural approach and ferroelectric characteristics of a device that can have a larger dielectric capacitance compared to ferroelectric capacitance to improve the memory window and reliability characteristics. When it comes to 1T-1C type FeRAM, material and process are designed to have a high spontaneous polarization (Ps) value. However, for large memory window and reliable 1T type FeFET, it requires a certain value of spontaneous polarization value. We found that MFMIS (metal-ferroelectric-metal-insulator-semiconductor) FeFET with a three-dimensional channel structure is very effective to improve the memory window and reduce the electric field through the interfacial layer. In particular, the latter contributes greatly to improving reliability characteristics.

9:55 PM EL09.14.04
Architecture Dependent Ferroelectric Material Considerations in Planar and Nanowire Transistors

Sandeep Semwal and Abhinav Kranti; Indian Institute of Technology Indore, India

Negative capacitance field effect transistors (NCFET) have the potential to lower the subthreshold swing below 60 mV/decade at room temperature. This can be achieved through an internal amplification for which the magnitude of ferroelectric capacitance (C_{FE}) must be lower than the oxide capacitance (C_{OX}) i.e. $|C_{FE}| < C_{OX}$ [1]. Since the transistor architecture has evolved from traditional planar to nanowire, the geometrical considerations for C_{FE} and C_{OX} have become relevant in the choice of ferroelectric material [2]–[3]. Our analytical investigation for a long channel metal–ferroelectric–insulator–semiconductor (MFIS) NCFET has shown that the circular cross-section of the nanowire yields more negative ferroelectric capacitance along with a higher oxide capacitance than that exhibited by the planar device. Also, $|C_{FE}|$ increases significantly as compared to C_{OX} in a cylindrical geometry as compared to planar NCFET, which translates into the requirement of a thicker ferroelectric layer (T_{FE}) to sustain the internal amplification and the associated sub-60 mV/decade current transition. In order to mitigate the above condition of using a relative thicker T_{FE}, a ferroelectric material with a higher coercive field or lower remnant polarization is more suited for nanowire architecture. For an interfacial oxide layer of 1 nm, a double gate NCFET with Al-HfO_2 [2], Y-HfO_2 [4], Gd-HfO_2 [5] and HZO [4] requires a minimum T_{FE} of 5 nm, 8 nm, 12 nm, and 21 nm, respectively, to sustain internal amplification. However, for a cylindrical nanowire NCFET, the minimum T_{FE} values increase to 7 nm, 11 nm, 23 nm, and 69 nm, respectively. This difference between the minimum values of T_{FE} is least (~2 nm) for Al-HfO_2 (exhibits a high coercive field) and highest (48 nm) for HZO based NCFET. This difference between the minimum ferroelectric thickness of a planar double gate and a nanowire NCFET is governed by the coercive field and remnant polarization of the ferroelectric material. Since nanowire architecture can effectively suppress short channel effects, the maximum possible nanowire diameter should be selected so as to further limit the minimum T_{FE} for sustaining the internal amplification. For a thinner interfacial oxide layer thickness, the minimum T_{FE} for cylindrical NCFET can also become comparable to that required for a planar NCFET. The above mentioned inferences indicate the suitability of a ferroelectric material with a higher coercive field (or lower remnant polarization) along with thinner interfacial oxide or larger nanowire diameter for nanowire transistor architecture.

Analysis of Ferroelectric Negative Capacitance—Hybrid MEMS Actuator Using Energy Landscape

Raghuram Tattamangalam Raman, Arvind Ajoy and Revathy Padmanabhan; Indian Institute of Technology Palakkad, India

Electrostatic MEMS (Micro Electro Mechanical System) actuators are widely used in various applications like RF (Radio Frequency) MEMS, Digital Micromirror Devices etc. These devices inherently consume low-power. However, they demand high operating voltages. A novel method proposed to mitigate this large voltage requirement, is to connect a ferroelectric capacitor, exhibiting negative capacitance, in series with the MEMS actuator thereby forming a hybrid MEMS actuator[1]. This technique is adapted from the emerging and recently reported use of ferroelectric negative capacitance in realizing steep slope (Subthreshold Swing SS < 60 mV/decade) low-voltage transistors. The response of the electrostatic MEMS actuator depends heavily on the applied input (static and dynamic inputs). Hence, it is necessary to develop a physics-based unified framework that facilitates an easy analysis of the hybrid MEMS actuator for different inputs.

We propose an energy-based framework to systematically analyze the statics and dynamics of the hybrid MEMS actuator. The proposed method uses graphical energy-displacement and phase portrait plots to

investigate static pull-in, dynamic pull-in and pull-out phenomena of the hybrid MEMS actuator. The ferroelectric capacitor is governed by the Landau-Khalatnikov equation, which relates the voltage across the ferroelectric to its charge. The MEMS actuator, however, is governed by the nonlinear force-balance differential equation, expressed in terms of the electrode displacement. Therefore, we employ a coordinate transformation from the charge to the displacement, to obtain the Hamiltonian of the hybrid MEMS actuator in terms of its displacement. A mapping function, based on the MEMS capacitor charge-voltage relationship, is used for this transformation[2].

Using this framework, we show that the static pull-in, dynamic pull-in and pull-out voltages of the hybrid actuator are significantly reduced due to the ferroelectric negative capacitance, as compared to the standalone MEMS actuator. The results obtained are in agreement with the numerical SPICE (Simulation Program with Integrated Circuit Emphasis) simulations of the hybrid MEMS actuator[3]. The framework is unified because the same Hamiltonian is used for examining the static pull-in, dynamic pull-in, and pull-out phenomena. Since the proposed framework uses only graphical plots for the analysis, it eliminates solving intricate nonlinear differential equations that govern the dynamics of the hybrid actuator. Therefore, this serves as a quick analysis tool to predict the pull-in and pull-out voltages of the hybrid MEMS actuator. The proposed energy-based framework also has the capacity to include the adhesion between the contacting surfaces. We model the adhesion using Van der Waals force and illustrate the reduction in the pull-out voltage in the hybrid MEMS actuator due to the presence of adhesion. The proposed framework could be further enhanced to include other phenomena such as fringing field capacitance. It could also be used for different MEMS structures by suitably modifying the mapping function, used for the coordinate transformation.

SESSION EL09.15: On-demand
Wednesday Morning, April 14, 2021
EL09

8:00 AM EL09.15.01
Physical Investigation and Modeling of the Dynamic Hysteresis in Ferroelectric-based Negative Capacitance FET Chang Su[1], Kaifeng Wang[1], Liang Chen[1], Zhongxin Liang[1], Mengxuan Yang[1], Qianqian Huang[1,2] and Ru Huang[1,2]; [1]Institute of Microelectronics, Peking University, China; [2]National Key Laboratory of Science and Technology on Micro/Nano Fabrication, China

While power consumption density significantly increases with scaling down of MOSFETs, novel low power devices have triggered lots of interest, among which ferroelectric-based negative capacitance (NC) FET is regarded as a promising candidate due to its capability of sub60 subthreshold swing (SS) and high on current. Up to now, although domain nucleation and growth theory is reasonable to explain experimental phenomena observed such as steep SS in NCFET and V-drop in R-FE circuit, the physical mechanism of hysteresis in FeFET lacks a thorough analysis, making it difficult to unambiguously determine the contribution of domain switching to hysteresis. Besides, the specific model aimed at hysteresis is missing, while the conventional method relies on extraction from pre-existing transfer curve, which is too time-consuming to approximate and systematically offer the explicit guideline with high efficiency. In this work, an accurate efficient quantitative model of hysteresis in multi-domain FeFET is proposed, based on modeling of FE polarization switching dynamics mediated by domian nucleation and growth, including history effect, minor loop operation, voltage and time dependence. The proposed model can accurately capture the dynamic mechanism of hysteresis without

time-consuming iteration process, unveiling its non-monotonic dependence on voltage sweeping rate, coupled with sweeping range, which is also briefly discussed in physics. Moreover, the FE material-related parameters impact on hysteresis in FeFET is investigated by model and physically analyzed to draw a comprehensive conclusion. Furthermore, we re-evaluated the prerequisite of NC origin and requirement of hysteresis-free, showing that there exists a fundamental challenge of FeFET for high-speed and low-voltage operation as a logic device.

8:10 AM EL09.15.02
The Impact of Body Biasing on Externally-Connected Al:HfO_2-Based Ferroelectric Field Effect Transistor Yejoo Choi, Seungjun Moon, Jaemin Shin and Changhwan Shin; Sungkyunkwan University, Korea (the Republic of)

Since the physical dimension of integrated circuit device (especially, memory device) has been aggressively scaled down over the past a few decades, it has been faced with a few critical/technical issues such as ever-increasing power dissipation and even incommensurate integration density because of the physical scaling limit [1]. As one of the promising solutions, ferroelectric field effect transistor (FeFET) has been emerged as a candidate for future nonvolatile memory (NVM) device because of its scalability and compatibility to CMOS (complementary metal oxide semiconductor) technology. In real, among various ferroelectric materials, HfO_2-based ferroelectric material doped with various dopants such as Zr, Al, and Si are being adopted in FeFET. Al-doped HfO_2 (HAO) shows its stable ferroelectricity in thermal process (e.g., 500 °C ~ 900 °C). Moreover, by modulating various conditions of fabrication process, the ferroelectricity of HAO can be optimized. This indicates that HAO can be widely used for future FeFETs.
In this work, the performance of HAO-based ferroelectric capacitor is presented with various fabrication conditions since the ferroelectricity of ferroelectric material requires appropriate conditions for crystallization. To explore many fabrication options for HAO-based ferroelectric capacitor, following conditions are taken into account and modulated: 1) the doping concentration of HAO (i.e., the cycle ratio of ALD deposition); 2) oxygen exposure time in ALD deposition process; 3) ALD substrate temperature; 4) annealing temperature. Then, the HAO capacitor is externally connected to the gate stack of the baseline MOSFET to electrically form a FeFET. Note that 500nm-long-channel MOSFET (metal oxide semiconductor field effect transistor) is fabricated to explicitly analyze the effect of the body biasing as well as to avoid short channel effects [2]. The modulation of memory window (MW) by body biasing in FeFETs with HAO-ferroelectric capacitor are experimentally investigated.

Developing Electrocatalysis Systems for CO2 Reduction Edward Sargent; University of Toronto, Canada

I will update on progress in energy utilization and carbon balance in electrochemical reduction of CO2 to ethanol and ethylene. I will discuss key advances in both system design and catalyst design, synthesis, and realization.

8:25 AM EN01.01.02
Optimizing the CO_2-to-CO Electrochemical Conversion From 2D Silver Nanoprisms via Superstructure Assembly Kun Qi, Yang Zhang, Ji Li and Damien Voiry; University of Montpellier, France

Electro-reduction of CO_2 in a highly selective and efficient manner is a crucial step toward the utilization of CO_2 but still requires the development of novel fabrication strategies for improving the activity of the selectivity of the catalytic materials. The catalytic properties are largely dictated by the electronic structure because the performance of catalysts follows the Sabatier principle, which predicts that interactions between reactants (and intermediates) and the catalyst surface must be ideally balanced[1]. Owing to their reduced dimensionality, two-dimensional (2D) materials have emerged as interesting platforms for studying electrocatalysis[2].
In this context, nanostructured Ag catalysts have been found to be effective candidates for CO_2 to CO conversion[3]. However, the ambiguous determination of the CO_2 reduction active sites and the maximization of the density of exposed active sites has greatly limited the use of Ag towards the realization of practical electrocatalytic devices. Herein, we report a superstructure design strategy prepared by the self-assembly of two-dimensional Ag nanoprisms for maximizing the exposure of active edge ribs[4]. The self-assembled Ag nanoprisms allow exposing > 95% of the edge sites which translates into high selectivity and activity towards the production of CO from CO_2. Our first principle calculations combined with electrocatalytic measurements point out the reduced binding energy of COOH* intermediate on the low-coordinated Ag surface atoms at the corner and edges ribs of the nanoprisms. Electrochemical measurements on individuals nanoprisms and the corresponding superstructures allowed us to identify the edge ribs as the active sites with a onsetpotential for the CO2RR reaction of 190 mV and a turnover frequency of $5.2 \times 10^{-3} \pm 2.8 \times 10^{-3}$ s^{-1} at an overpotential of 0 mV. When tested in an H-cell, the Ag superstructure demonstrates a selectivity over 90% for 100 hours together with a current retention of ≈ 94% at -600 mV vs. RHE.

Electrocatalytic CO2 Reduction on Green Synthesized Copper Nanoarchitectures to C_2 and C_{2+} Value-Added Products Supported Over Gas Diffusion Layers Venkata Siva Rama Krishna Tandava[1], Sebastian Murcia[1] and Joan Ramon Morante[1,2]; [1]Catalonia Institute for Energy Research (IREC), Spain; [2]Universitat de Barcelona, Spain

Circular economy of CO_2 is nowadays a hot issue for our society. Nevertheless, its successful implementation still requires a lot of new knowledge of reliable systems. Electrochemical CO_2 reduction (ECO_2R) is one of several promising strategies to mitigate CO_2 emissions. Developing novel advanced functional nanostructured catalyst materials and systems for electro conversion of CO_2 to alternative fuels or value-added products in order to meet the global energy needs and so as a means to curb the increasing amounts of CO_2 in the atmosphere is of utmost importance. To date, Copper (Cu) and Copper-based materials are the only heterogeneous catalyst systems that have shown a propensity to produce valuable hydrocarbons and alcohols such as ethylene and ethanol.
Copper nanoparticles were synthesized by a simple wet chemical reduction method at mild temperatures using *L*-Ascorbic acid, a widely used green reducing agent, and different additives for the morphological control. X-Ray Diffraction studies revealed the presence of Cu_2O particles with varied crystallographic orientation, which can be selective towards ethylene and C_{2+} products, while SEM analysis showed the formation of specific morphologies such as cubes, cuboctahedrons, and truncated octahedron morphologies. The as-synthesized nanoparticles were directly drop cast on 3D porous substrates (e.g., carbon Toray and copper foam). The electrodes were evaluated in conventional H-type and flow filter-press cells with Gas Diffusion electrodes under neutral and alkaline electrolyte conditions. A clear correlation between working voltage, structural electrocatalyst properties, pH, and product distribution was observed, with higher selectivity towards ethylene generally obtained at intermediate potentials. Other aspects such as hindering the Hydrogen Evolution Reaction and evaluating the role of halide species were also considered. The results and both selectivity favoring and limitation factors were discussed and potential solutions were addressed here.

8:55 AM *EN01.01.04
Novel Materials for Oxygen and Carbon Monoxide Electrocatalysis Maria Escudero-Escribano; University of Copenhagen, Denmark

The design and development of active, stable, and selective electrocatalysts for renewable energy conversion reactions is key for the transition towards a decarbonised future. This talk will present some recent strategies aiming to understand and engineer the interfacial structure and properties for oxygen and carbon monoxide/carbon dioxide electrocatalysis.
The first part will be focused on the development of self-supported high surface area nanostructured catalysts for the oxygen reduction and evolution reactions (ORR and OER, respectively). In the second part, I will present our recent work on Cu-based well-defined electrodes in contact with different electrolytes aiming to understand the structure sensitivity for CO_2 and CO reduction. We show how model studies are essential to understand the structure-property relationships and design efficient electrocatalysts for sustainable energy conversion.

9:20 AM EN01.01.06
Late News: Au Decorated Cu(OH)2 Nanoneedle Catalysts for Electrochemical CO2 Reduction Kim R. Gustavsen, Erik A. Johannessen and Kaiying Wang; University of South-Eastern Norway, Norway

The industrialization of the planet has created an increasing demand for energy which unfortunately has been linked to rising levels of carbon dioxide (CO_2) in the atmosphere. Thus, incentives to utilize alternative methods of energy generation is becoming more and more important. While renewable energy technologies are developing rapidly, they still suffer from intermittency. They will therefore be dependent on the development of new energy storage technologies if the transition to a renewable energy economy should be successful.

Electrochemical CO_2 reduction is a promising candidate for energy storage since it can generate valuable chemicals and fuels (such as hydrocarbons) while at the same time close the carbon cycle. The only metal catalyst capable of efficient hydrocarbon production is copper, despite being unselective and known to generate a wide range of products simultaneously. This greatly reduces the efficiency of the desired product, and much effort has been aimed at tuning the selectivity of copper-based catalysts. However, a highly selective Cu based catalyst that is functional over a prolonged period without suffering deactivation is yet to be found.

Copper hydroxide has shown great promise for CO_2 reduction reaction (CO_2RR), and have a greater affinity towards C_2 products such as ethylene at the cost of methane formation [1]. Similar to oxide-derived Cu (OD-Cu), the oxidation state of the surface is believed to play an important role in the enhanced selectivity towards ethylene. However, the existence of sub-surface oxide during reaction conditions is a controversial topic, and factors like increased surface roughness is also suggested as being responsible. Nevertheless, while favorable C-C coupling energetics are observed for $Cu(OH)_2$ based catalyst compared to polycrystalline Cu, the Faradaic efficiency (FE) for ethylene is still relatively low (38.1%) [2].

In this work we attempt to further enhance the C_2 selectivity of $Cu(OH)_2$ nanoneedles by depositing a thin Au coating. The Au sites will generate CO, which can be transferred to adjacent Cu sites by either readsorption or surface diffusion to undergo further reduction. The $Cu(OH)_2$ nanoneedles were synthesized by anodizing Cu foils in 3M KOH at a constant current density (~3.2 mA/cm^2) for 10 minutes. Subsequently, the $Cu(OH)_2$ nanoneedles were decorated with Au using DC magnetron sputtering. The catalyst performance was evaluated in an H-cell and the gaseous products were quantified by gas chromatography in an on-line configuration .

From Organic Electronics Towards Bio-Organic Systems for CO_2 Recycling Niyazi Serdar Sariciftci; Johannes Kepler Universität Linz, Austria

Organic photovoltaic cells are maturing from the academic research into the industrial development, entering the markets. Pure organic nanostructures and organic/inorganic hybrid nanostructures are comparatively studied

for such devices. This talk gives an overview of materials' aspect and devices.
In order to account for a sustainable future, the application of biodegradable and biocompatible systems for organic optoelectronics are needed. The use of cheap electronic devices in a large scale will introduce a "consumable electronics" into the market of "consumer electronics". Therefore environmentally friendly materials are important to use. This is a next great challenge to material science in organic electronics. New developments of bio-inspired and/or bio-origin, bio-compatible materials from our institute will be reported. Such materials can also be used to interface the biological and biomedical research with the organic electronics field.
Last but not least the conversion of CO_2 to methane (or other synthetic fuels) using solar energy is an important step to make an efficient, large scale energy storage. At the same time this will make a cyclic and sustainable CO_2 economy. We report organic as well as bio-organic catalysts which can be used in photo-electro-catalytic conversion devices. Such bio-catalysts can be enzymes as well as living bacteria immobilized on electrodes. Selectivity of such bio-catalysts is very high and combined with the room temperature operation of such bio-electro-catalytic systems makes them industrially highly attractive.

10:55 AM *EN01.02.02
Chiral molecules and the Electron's Spin—New approach to Spin Controlled Chemistry Ron Naaman; Weizmann Institute of Science, Israel

Spin based properties, applications, and devices are commonly related to magnetic effects and to para or ferro magnetic materials. However, we found that chiral organic molecules act as spin filters for photoelectrons transmission, in electron transfer, in electron transport. The effect, termed Chiral Induced Spin Selectivity (CISS), [[1],[2]] lead to the discovery that when chiral molecules are charge polarized, there is a transient spin polarization [[3]]. At each electrical pole, the (partially) unpaired electron is spin polarized with opposite polarization at the positive and negative poles. Which spin is associate with which pole depends on the handedness of the molecule. This finding sheds new light on enantio-specific interactions and it allows to construct novel methods for enantio-separation.[[4],[5]] It also opens new ways to induce spin polarization in semiconductors and to obtain temperature activated ferromagnetism in chiral matallo-organic crystals [[6]].

11:20 AM EN01.02.03
Late News: Electrochemical- Thermally-Activated Chemical (E-TAC) Water Splitting Hen Dotan[1,2], Avigail Landman[2,1], Gideon Grader[2,1] and Avner Rothschild[2,1]; [1]H2Pro, Israel; [2]Technion--Israel Institute of Technology, Israel

Electrolytic hydrogen production faces technological challenges to improve efficiency, economic value and

rapid scale up. In conventional water electrolysis, the water oxidation and reduction reactions are coupled in both time and space, as they occur concurrently at an anode and a cathode in the same cell. This introduces challenges such as product separation, and sets strict constraints on material selection and process conditions. Another major challenge is to improve efficiency, which is limited by the large (> 400 mV) overpotential loss of the four-electron oxygen evolution reaction (OER).
The Electrochemical – Thermally-Activated Chemical (E-TAC) water splitting cycle decouples these reactions by dividing the process into two stages; an electrochemical (E) stage that reduces water at the cathode and charges (oxidizes) a nickel hydroxide ($Ni(OH)_2$) anode to nickel oxyhydroxide (NiOOH), followed by a chemical (TAC) stage that reduces the charged anode (NiOOH) spontaneously (without applied bias) back to its initial state ($Ni(OH)_2$) by oxidizing water. This chemical reaction is accelerated at elevated temperatures (60-100°C), providing a handle to control the evolution of oxygen in the cell so as to avoid mixing with hydrogen. The E-TAC cycle enables overall alkaline water splitting at an average cell voltage of ~1.5 V in a membraneless cell architecture that offers potential for cost reduction by eliminating membranes and sealing components, and supports high-pressure hydrogen production. High electrolytic efficiency of 98.7%$_{HHV}$ is achieved by dividing the four-electron OER into four one-electron reactions wherein four Ni(II) sites are charged (oxidized) to Ni(III). The operational challenges that arise from swinging between the E and TAC stages and the material challenges that arise from the finite capacity of the nickel (oxy)hydroxide anode will be discussed in the talk.

11:35 AM EN01.02.04
Catalyst Optimization for Electroreduction of Nitrates to Ammonia Marcelo E. Chavez, Sebastian Murcia and Joan Ramon Morante; Catalonia Institute for Energy Research, Spain

A combination of the increased awareness about nitrogen-oxyanions contamination in waters and the value of certain nitrogen-based products as key commodities, potential fuel or chemical precursors, have opened a novel approach line within the circular economy, framed in the development of both: novel materials and optimal processes for nitrate electroreduction to ammonia as main reaction product. The vast literature in the field of water denitrification points to the most promising materials for nitrate electroreduction. Pure transition and noble metals, in combination with organic and inorganic substrates have been tested in this process with different outcomes, among which the most remarkable are the catalytic activities of copper, gold, silver and iron. However, most of the materials that showed excellent properties for one step of the complete reduction of nitrate, did not show good results in terms of faradaic efficiencies towards most of the nitrogen-based valuable products. In this work, ammonia is presented as main product given its essential role in modern agriculture and as a potential energy carrier. In this context, in a sustainable process, not only the catalytic activity defines the ideal material, but its combination with the faradaic efficiency and stability of the electrocatalyst. Having copper as the most active material for nitrate electroreduction, it is important to combine it with a substrate that provides stability, resistance to operative conditions, and selectivity to ammonia. The reasons stated above have conducted the research to define materials for nitrate electroreduction as copper nanoparticles supported by carbon-based and titanium structures. Copper nanoparticles obtained by electroless reduction and deposited on 3D carbon and metallic substrates, combined with the optimal electrochemical conditions of working potential, nitrate concentration and ammonia recovery system are presented in this work to open a potential alternative route to the traditional high energy consuming Haber-Bosch process for ammonia production.

11:50 AM EN01.02.05
Late News: Selective Hydrogen Catalysis via Carbon Nanotube Encapsulation and Oxide Layer Deposition Samuel S. Hardisty, Kobby Saadi and David Zitoun; Bar-Ilan University, Israel

Catalysts undergo poisoning and degradation during their utilization in many different fields. Common examples are the CO poisoning of Pt, or the degradation of Pt/C catalysts during start-stop procedures, both occurring in polymer electrolyte fuel cells (PEMFCs). Another energy technology that features prominent catalyst degradation is the hydrogen bromine redox flow battery (H_2-Br_2 RFB). H_2-Br_2 RFBs are a cheap and efficient solution to large scale energy storage. The main hinderance of the technology is the poisoning of the hydrogen evolution reaction/hydrogen oxidation reaction (HER/HOR) catalyst by bromine species which have

crossed over the proton exchange membrane. Without a revolution in membrane development, this crossover appears unpreventable. Therefore, we sought to protect the catalyst locally. Two possible solutions were found to impart catalyst active site selectivity: Pt encapsulation in single walled carbon nanotubes (SWCNTs) and metal oxide deposition on catalysts via atomic layer deposition (ALD).
Platinum nanoparticles were synthesized within the internal cavities of small diameter SWCNTs, through a simple impregnation and drying procedure. High resolution transmission electron microscopy (HRTEM), atomic force microscopy (AFM) and scanning tunneling electron microscopy (STEM) were used to characterize the particles and demonstrate that they were confined within the SWCNTs. The typical hydrogen under potential deposition peaks were observed on a cyclic voltammogram of the sample, whereas the oxide region was heavily suppressed compared to Pt/C. Some diffusion limitation was observed during the HOR, indicating that the electrolyte diffusion pathway is through the SWCNTs, but the same mass transport limited current was attained. The oxygen reduction reaction (ORR) mass transport limited current was much lower than expected for Pt (2 mA cm^{-2}), indicating a transport selectivity for hydrogen over oxygen. The stability of these platinum nanoparticles in the presence of bromide/tribromide solution was vastly increased compared to the standard 50% Pt/C catalyst, shown by x-ray photoelectron spectroscopy (XPS) and electrochemistry. It is proposed that this effect is caused by steric and electrostatic repulsion of the large tribromide ion by the SWCNT cavity (internal diameter of 2 nm). The encapsulated platinum also features a vastly higher mass activity when cycled in a cell, indicating better Pt utilization due to the small particle size. This opens a new route for imparting selective access to active sites of a catalyst, hence increasing the stability of the catalyst, a potential solution to many problems faced by technologies that rely on catalysts.
Another possible solution to prevent catalyst poisoning is through a protective oxide coating on its surface. ALD was chosen due to its highly controllable, conformal deposition, but also as it can be applied to a wide range of commercial catalysts, making it highly applicable for real world applications. Different thicknesses of vanadium oxide were deposited on a commercial 50% Pt/C catalyst. XPS and HRTEM confirmed the ALD process had deposited vanadium oxide species on the catalyst. The HOR was unaffected by this deposition, indicating diffusion of hydrogen could occur through the oxide layer. Stability of the material in the presence of bromide/tribromide solution was superior to the uncoated commercial catalyst, showing the oxide coating successfully protected the catalyst. Again, whilst it has been demonstrated for bromine poisoning of Pt, this approach should be applicable to many poisoning problems facing other catalysts/applications.

12:05 PM EN01.02.06
Late News: The Relationship Between Energy Levels of Polymeric Organic Semiconductors and Their Reactivity Towards the Oxygen Reduction Reaction Alexander Giovannitti, Tyler Mefford, William C. Chueh and Alberto Salleo; Stanford University, United States

We present the development of electron-transporting polymeric organic semiconductors as a new class of metal-free electrocatalysts for the oxygen reduction reaction in aqueous electrolytes. The polymeric organic semiconductors are based on conjugated polymers with large electron affinities (equivalent to materials with low lying lowest unoccupied molecular orbital (LUMO)), where polar side chains are attached to the backbone to process materials from solution and to improve the ionic charge transport properties.[1] This design concept results in fast charging polymer electrodes where volumetric charging of thick electrodes (> 1 μm) is achieved due to the balanced ionic and electronic charge transport properties of the polymer. The outstanding mixed ionic/electronic transport properties also enable the utilization of single-phase electrodes where no additives or binders are needed for the electrode to function in aqueous electrolytes.
We will further explain the working principle of the polymeric electrocatalyst, for which the polymeric organic semiconductor is first activated by an electrochemical doping reaction (reduction, n-type doping) that increases the reactivity of the material towards molecular oxygen. By employing in-situ spectroelectrochemical measurements and rotating ring disk electrode (RRDE) measurements, we find that the polymer achieves its highest performance when charged to the polaronic, singly charged, state. The polymers predominantly yield hydrogen peroxide through the 2-electron reduction of oxygen. The selectivity towards peroxide and water (4-electron product) is influenced by electrolyte pH. We hypothesize that chemically tuning the polymer's energy levels and side chains will pave the way for the successful development of low-cost, metal-free, and solution-

processable electrocatalysts for energy conversion technologies.

Conducting Biopolymers as Metal-Free Electrocatalysts Philipp Stadler[1,1], Halime Coskun[1], Abdalaziz Aljabour[1], He Sun[1,1] and Tsukasa Yoshida[2]; [1]Johannes Kepler Universität Linz, Austria; [2]Yamagata University, Japan

The most active and efficient catalysts for the electrochemical hydrogen evolution reaction rely on noble metals, a fact that increases the cost of producing hydrogen and thereby limits the widespread adoption of this fuel. Here we present metal-free polydopamine and polyguanine as selective organic hydrogen electrocatalysts[1–3]. The conducting functional polymers incorporate selective hydrogen-affine hydrogen bonds that possess a similar hydrogen binding energies and work function as e.g. platinum or palladium. We report the synthesis of hydrogen-selective electrocatalytic polyguanine and polydopamine and demonstrate the enhancement of the rate-determining step in the proton reduction. We further present mechanistic spectral IR-operando studies on the catalytic hydrogen bonded motifs and showcase the surface tunability between hydrogen evolution and hydrogen electrosorption including steps towards scaling the material for continuous electrolysis for several 100 hours/cycles without notable degradation.

12:25 PM EN01.02.08
Synthesizing a Novel Janus Carbon Nano-Onions Modified as a Catalyst Support for Oxygen Reduction Reaction Angelica Del Valle-Perez, Armando J. Nieves-Carrasquillo and Lisandro Cunci; Universidad Ana G. Mendez, Puerto Rico

Carbon materials have been awakening scientific interest for research because it allows chemical functionalization for multiple applications in the sciences, especially in energy applications. Carbon Nano-onions (CNO) are spherical structures composed of multilayers of fullerenes, these layers are connected in a way that shows the shape of an onion. Its development begins with the use of nano-diamonds, a carbon material of strong structure which it forms in a very violent environment. The nano-diamonds are taken to a furnace at a temperature of 1650°C to finally obtain the CNO. Janus particles are receiving increasing attention because of their dual properties, where each side can be functionalized to have distinctive characteristics. The modifications on the surface of these nanoparticles can provide different chemical and physical properties. The interesting properties of Janus nanoparticles are that they have different sizes and shapes which have now been able to be studied in more detail. The purpose of this project is to use asymmetrically modified CNO as a support for metal nanoparticles to avoid agglomeration and, thus, increase their surface area and efficiency. Janus nanoparticles will be designed by a Wax-paraffin Pickering Emulsion process using CNO on its surface. The deposition of Platinum (Pt) was carried out by a chemical process using sodium borohydride. The removal process of the paraffin involves the dispersion of the wax-paraffin/CNO-Pt particles in Chloroform, repeating the process by six times and rinse with isopropanol to finally obtain the amphiphilic nanoparticle. The differences on the surface of the particles before and after removing the paraffin were observed by Scanning

Electron Microscopy (SEM). The Energy-Dispersive Spectroscopy was used to validate the elemental information of the particles and assure the deposition of 20% of Pt on the surface of the particles. Transmission Electron Microscopy (TEM) provided us with information on the dispersion of Pt on the surface of CNO. Through X-ray diffraction (XRD) and Raman Spectroscopy, we were able to confirm the paraffin removal and presence of Pt in these particles. Cyclic Voltammetry was used to characterize the proposed catalyst and comparison with the commercial catalyst Pt/Vulcan. The Pt-CNO/CNO catalyst was tested for its performance for the Oxygen Reduction Reaction (ORR) using the Rotating Ring Disk Electrode (RRDE). Polarization curves of ORR were obtained with RRDE rotations at 0,100,400,900,1600 and 2500rpm in a O_2-saturated 0.1M KOH solution.

Mechanistic Studies of the Electrochemical CO_2 Reduction on Single Site, Metallic and Hybrid Electrocatalysts Peter Strasser; Technische Universität Berlin, Germany

In this talk, I will highlight some recent advances in our understanding of the catalytic reaction mechanism of the direct electrochemical reduction of CO_2 and of related mixed feeds into value-added fuels and chemicals on smooth polycrystalline metallic surfaces, on non-metallic, single metal-site electrocatalysts, and on metallic/non-metallic tandem catalyst schemes. Methods used include in situ X-ray analytical techniques and time-resolved Differential Electrochemical Mass Spectrometry (DEMS) conducted in novel capillary flow cells. The DEMS flow cells enable milli-second resolved analysis of reaction products under stationary and transient conditions, providing access to accurate onset potentials of a wide variety of reaction products.

1:25 PM EN01.03.02
Combinatorial Investigation of Metal Based Compounds as Electrolyzers for Oxygen Evolution Reaction Hannah N. Barad[1], Gerardo Salinas[2], Eran Oren[1], Mariana Alarcon-Correa[1], Florian Peter[1], Alexander Kuhn[2] and Peer Fischer[1]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Universite de Bordeaux, France

Combinatorial materials science (CMS) is a highly promising method for fast discovery of new functional materials, such as low T_c superconductors, shape-memory alloys, and photoabsorbers. CMS has been used to form thin films with composition and thickness gradients, consequently, synthesizing, on a single substrate, a range of samples with systematically varying properties, which is the first step in finding new materials and device structures. Apart from the composition or thickness, film morphology and nanostructuring can be especially important for an assortment of applications ranging from catalysis and photovoltaics to magnetic materials, as morphology governs the chemical reactivity, determines the surface area, and is important for charge mobility and recombination processes. However, heretofore CMS research did not encompass film morphology as a study parameter.
Here we describe how we vary nano-scale morphology and material composition at the same time using an adapted shadow growth method based on glancing angle deposition (GLAD), which eliminates the commonly used wet chemical steps for nanostructure synthesis. In a one-step well-controlled growth we quickly obtain a large number of nano-columnar structures, including nanorods, nanohelices, and nano-zigzags, with varying material compositions. Adapting GLAD and introducing it into CMS, with accompanying high-throughput characterization, constitutes an integrated approach for discovering new materials and structures for a multitude of applications in many scientific fields.
We use this method to fabricate a multi-component nanocomposite electrolyzer and study its compositional and

structural variations. The system is a multinary elemental metal-based library, where each material has an impact on the resulting nanostructure as well and the chemical composition and state. After investigating the physical and chemical properties of the library, it is then examined as an electrocatalyst for oxygen evolution reaction (OER). The OER activity shows a dependence on the nanostructuring of the library as well as on the chemical and compositional variation. By using CMS and high-throughput analysis, we are able to gain insights that the standard experimental techniques would not be able to achieve, thus indicating the importance and impact CMS has in the field of electrolyzers for the future.

Hydrazine Oxidation Electrocatalysis on Multi-Doped Carbons—Who Does What? David Eisenberg; Technion–Israel Institute of Technology, Israel

Electrocatalysis of hydrazine oxidation, a promising non-carbon fuel, is both a practical goal, and a scientific paradox. Hydrazine is a famous reductant in chemical synthesis, yet the onset potential for its electro-oxidation reaction is highly dependent on the catalytic surface. Some excellent catalysts have been developed in recent years towards direct hydrazine fuel cells. Most of these catalysts, however, are either prohibitively expensive (e.g. Pt-based ones), or easily deactivated (e.g Ni-based ones).

We have recently discovered a family of multi-doped carbons with record-breaking electrocatalytic activity towards hydrazine oxidation in alkaline pH.[1,2] They contain many components, all of which postulated to be possible candidates for hydrazine oxidation active sites: from Mo-doped Fe_3C nanoparticles, to the N-doped, graphitic, hierarchically porous carbon. They provide the first example of hydrazine oxidation on carbides. Moreover, they are stable, efficient, and easy to make on a large scale.

In our quest to understand the source of activity in these fascinating materials, we launched a systematic study into each of the component, and into their combination. On the way, we discovered how Mo-doping is actually unnecessary, and how Zn and Cu direct the nanostructure by different mechanisms.[2] Furthermore, we demonstrated that the carbon matrix itself is highly active toward the reaction.[3] At this point, we raised even larger questions: are the carbide nanoparticles even participate in the reaction? What does it really take for a carbon material to electro-oxidize hydrazine? To answer these questions, we combined electrochemical measurements, broad scope material characterization, and mechanistic quantum-mechanical calculations.[4]

In this talk I will present unpublished and recently published results, clearing the field of hydrazine oxidation on doped carbons, and explaining the individual catalytic, cooperative and structural roles of each component. While much remains to be understood about the activity and selectivity of these elusively simple material, and their excellent performance makes this challenge both technologically and scientifically appealing.

Enhancing Hydrogen Evolution Reaction Assisted by Metal-Free Hot Electron Driven Electrode Hyun Uk Chae, Ragib Ahsan, Jun Tao and Rehan Kapadia; University of Southern California, United States

To pull through the emerging energy crisis, cost-effective, stable, and highly active electrocatalysts are required. Hydrogen evolution reaction (HER) is one of the electrochemical processes which allows direct conversion of electrical energy to chemical energy. However, the efficiency of this conversion process is limited by the overpotential required to reach a high enough current density. Up to date, transition metals such as platinum having the narrow d-orbital have been treated as a good electrocatalyst. They enable the activation energy to be reduced by lowering the energy of the transition state via strong interaction between the adsorbed hydrogen

atoms and the energy states of the catalyst. However, the high cost as well as low abundance in the Earth has been limiting their widespread use in commercial electrocatalysis. Herein, we show that the turn on voltage of the electrochemical reaction can be adjusted in a semiconductor-insulator-plasma etched graphene (SIEG) device. O_2 plasma etched graphene was introduced as a top electrode to increase the number of electrochemical active sites. This breaks the limitation of the catalytic property of pristine graphene limited by its large hydrogen adsorption energy and lack of electrochemically active sites. The Oxide-semiconductor layer plays a role to tune the hot electron population by biasing the graphene-semiconductor junction. The shift of the onset potential of HER can be achieved up to ~0.8V while reaching a current density of 90 mA/cm^2 at an overpotential of -0.5V vs RHE. Importantly, this occurs without the assist of any noble metal catalyst and uses only abundant elements such as silicon, aluminum, and carbon. This potentially introduces a new pathway in which electrocatalysts could be engineered through control over the number of active sites and electron distribution.

Lattice Oxygen Evolution Reaction and Its Role in Electrochemical Stability of Iridium Oxides Vitaly Alexandrov; University of Nebraska–Lincoln, United States

Electrocatalytic water splitting has received a great deal of attention as an attractive way of storing energy in the form of pure hydrogen. RuO_2 and IrO_2 catalysts are archetypical materials used for the anodic oxygen evolution reaction (OER) in acidic media, but even for the most stable oxides the long-term stability represents a critical issue. Theoretical analysis based on the use of Pourbaix diagrams have emerged as a powerful tool to identify acid-stable materials for electrocatalysis. Despite the great utility of these diagrams, they do not capture the whole complexity of reaction conditions that may affect materials stability such as highly oxidizing non-equilibrium conditions of the OER. For example, it has been recently demonstrated by both simulations and experiments for a number of complex oxides including rutile IrO_2 that stability of a catalyst can suffer from the active participation of lattice oxygen in the OER. In this work we employ density functional theory (DFT) calculations to investigate the thermodynamics of the OER through both the conventional and the lattice oxygen evolution reaction mechanisms across a series of iridium-oxide based catalysts. We show that lattice oxygen participation should be attainable for a number of iridium-oxide phases that are predicted to be thermodynamically stable based on the Pourbaix diagrams. These results suggest that lattice oxygen evolution reaction should be taken into account when analyzing electrode stability under electrochemical conditions. The obtained theoretical results will be discussed in the context of available experimental data.

2:25 PM EN01.03.06
Mechanistic and Experimental Insights Towards Laser-Ablated Holey Nanocarbons in Single-Atom Catalysis (SAC) via Fundamental Dangling Bond Concepts Kishwar Khan[1], Zhengtang Luo[1] and Khalil Amine[2]; [1]The Hong Kong University of Science and Technology, Hong Kong; [2]Argonne National Laboratory, United States

Single-atom catalyst (SAC) is a key player in catalysis these days owning a tiny amount of metal atoms could increase its intrinsic activity towards efficient catalyst in numerous reactions. However, it is the remaining challenge and questionable to control its stability, benchmark performance, superior energy consumption during the complex synthesis process, and above the average temperature that encourages single metal atoms to become agglomerate. Herein we report a new approach based on laser ablation techniques to make laser irradiated doped holey graphene support (LGO), and subsequently make it hetero-doped laser irradiated macroporous graphene (NLG). Used the fundamental dangling bonds concept of nanocarbons to trap the metal atoms from Iron and Cobalt foams. We applied the optimized process conditions so that M^0 could transfer electrons to NLG via dangling oxygen groups to become $M^{\sigma+}$. These dangling surface bonds of oxygen synchronizes with $M^{\sigma+}$ to make metal-oxide (M-O) bonds. Dry the material at ambient conditions to make stronger dangling bonds between M-O, and then sonicate it afterwards to take away metal atoms from bulk counterparts to metal single atoms (MSA) anchored on the NLG via dangling bonds associated with oxygen groups. This new synthesis approach for making SAC is easy, economical, and sustainable as the metal foam is

working here like photocopying machine, and we can use the same foam for a long time as a metal precursor. Furthermore, we demonstrated this idea on the synthesis of two catalysts, namely Co-SAC@NLG towards hydrogen evolution reaction (HER) and Fe-SAC@NLG for oxygen reduction reaction (ORR) electrocatalysts. The morphology was experimentally verified by different tools, including aberration-corrected scanning transmission electron microscopy (AC-STEM). At the same time, bonding states, and surrounding environment of MSA are dually confirmed by X-ray absorption near edge structure (XANES) and extended X-ray absorption fine structure (EXAFS). For mechanism understanding, first-principle calculation density functional theory (DFT) was applied to justify its working mechanism in detail based on thermodynamics using grand canonical potential kinetics (GCP-K) quantum mechanics to obtain for various overpotentials to get minimum free energy using Legendre transformation (LT) to relate applied voltage and net charge of the structure. Apart from the demonstration of a new synthesis approach, the detailed experimental insights, and understanding the theoretical mechanism from this study will expand the existing knowledge in the field of heterogeneous single-atom catalyst towards different reactions.

2:40 PM EN01.03.07
Control of Oxygen Vacancies to Tune the Electronic Structure and OER Activity of Orthorhombic SrIrO3 Matthew Sweers, D. Bruce Buchholz and Linsey Seitz; Northwestern University, United States

Human-induced climate change, driven by rising levels of carbon dioxide in the atmosphere, is one of the greatest challenges humanity has ever faced. Electrolysis holds the potential to be a valuable option for carbon-free energy storage especially when coupled with renewable electricity sources. Hydrogen produced by electrolysis can be used to generate electricity in a fuel cell or as a feedstock for vital chemicals. Current electrolysis technology lacks the necessary efficiency to be economically viable at an industrial scale due to the lack of adequate catalysts for the Oxygen Evolution Reaction (OER), the more complex of the necessary half-reactions, in acidic environments.
The best catalysts for the OER in acid are iridium- and ruthenium-based. By pushing these compounds to higher performance, we can identify which material properties are responsible for high OER activity. From recent literature on cobalt-based OER catalysts in alkaline conditions, increased covalency of the metal-oxygen bond results in involvement of lattice oxygen in the reaction and decreased formation energies for intermediate oxygen species, both resulting in higher activity. We examine whether similar effects of metal-oxygen bond covalency occur in the analogous system of iridium-based catalysts in acidic environments, recognizing that Ir and Co are both group 9 transition metals. We build upon this test by tuning the O 2p band through manipulation of the anion sub-lattice of the exceptionally active perovskite catalyst, orthorhombic SrIrO3 (SIO). Precise control and variation of the concentration of oxygen vacancies allows us to perturb the electronic structure, compare the results with a concurrent DFT study, and measure the resulting changes in catalytic activity of SIO. This study first requires a reliable deposition method, which has been achieved by investigating factors that control the growth, crystallinity, and composition of the films.
We developed a consistent method for depositing atomically smooth thin films of SIO via pulsed laser deposition. The films have been extensively characterized using x-ray diffraction, spectroscopy methods, and multiple forms of microscopy, revealing several trends that highlight key deposition parameters. For example, the x-ray photoelectron spectroscopy of the Ir4f peaks signifies an unexpected but critical dependence of the film's iridium content on the position of the substrate within the vapor plume during deposition. This phenomenon is likely due to the relative masses of the vaporized species. This revelation, along with other trends, led to the consistent deposition protocol that provided a platform to vary oxygen content in SIO films. Deliberate formation of oxygen vacancies typically includes doping with foreign cations, which may result in unintended changes to electronic structure and catalytic activity, overshadowing the effect of the oxygen vacancies. Thus, we investigate alternative routes to control oxygen content without introduction of foreign species: 1) varying the oxygen partial pressure during deposition, and 2) annealing films in mixtures of O2 and N2 post-deposition. Characterizing the oxygen-deficient films, such as with x-ray absorption spectroscopy, in conjunction with electrochemical OER testing allows us to investigate the electronic structure changes and their effects on catalytic activity. For example, a clear relationship has been identified correlating decreased oxygen content with increased Ir4f binding energy, making plain the influence of anion stoichiometry on electronic

structure. Exploring these relationships enhances our understanding of the drivers of OER catalytic activity and helps in the development of better catalysts. Improvement of OER technology will enable electrolysis to become a financially viable option for energy storage and sustainable chemical production, aiding in our fight against climate change.

Electrochemical Analysis of Au and Cu Surface Alloys During Hydrogen and CO_2 Reactions In Aqueous Media Emily M. Marquez, Kim Hong Kue, Diana Godoy and Hadi Tavassol; California State University, Long Beach, United States

We report on electrochemical analysis and stress measurements of hydrogen and CO_2 reactions on Au and Cu surfaces in aqueous solutions with different pHs. Hydrogen and CO_2 reactions are important for the production of chemical fuels using water electrolysis and reduction of CO_2 to CO or small hydrocarbons. However, room temperature electrocatalysis of H_2 production and CO_2 reduction on earth-abundant surfaces remain challenging. Hydrogen reactions ($2H^+ + 2e^- \leftrightarrow H_2$) are efficient on Pt and Pd surfaces but are not as feasible on many earth-abundant transitions metal surfaces particularly at higher pHs. CO_2 reduction is slow on even most active surfaces and requires transfer of multiple electrons and protons ($CO_2 + 2H^+ + 2e^- \rightarrow CO + H_2O$). Interestingly, surfaces with high activity toward CO_2 (*e.g.* Au and Cu) are not active toward hydrogen reactions. Here, we explore the reaction mechanism and early stages of catalysts activation during hydrogen and CO_2 reactions on these surfaces using electrochemical analysis and *in-situ* stress measurements.
Well-defined Au and Cu surfaces are prepared using evaporation and atomic layer electrochemical deposition. Electrochemical analysis shows changes in surface reactivity toward HER and CO_2 reduction as the surface composition and structure is altered. Our stress analysis shows that hydrogen activation on surfaces causes a compressive stress, that can be used as a signature for activity toward hydrogen reactions. Interestingly, *in-situ* stress measurements of Au surfaces do not show proton activation even at low pHs. However, our analysis reveals stress responses corresponding to CO_2 interaction with Au surface at low pHs. The CO_2 stress responses are evident at *ca.* 0.2-0 V *vs.* RHE. The stress response is different from what is observed for hydrogen activation on surfaces. We will particularly discuss how these signature features of hydrogen and CO_2 reactions changes as a function of solution pH. We also use rate dependence of stress response to identify surface charge effects of primary activation steps. Our studies show that at higher pHs water is involved in the hydrogen reactions even on Pt surfaces. We will discuss how CO_2 activation changes surface charge dynamics during activation steps. These studies will provide insight into activity and selectivity descriptors for hydrogen production and CO_2 reduction reactions in aqueous media.

Metal-Organic Framework based Cobalt Oxide and Cobalt Sulfide as Efficient Electrocatalysts and High-Performance Supercapacitors Jonghyun Choi, Tenzin Ingsel, Khamis Siam and Ram Gupta; Pittsburg State University, United States

The increasing global population and advancement in energy-dependent devices have caused increased energy use in consumer and industrial appliances, electronic devices, and automobiles, creating an urgent need for clean and renewable energy sources. Electrochemical water-splitting is one of the greenest ways to generate clean and high-performance fuel. Water-splitting produces hydrogen and oxygen gases. The generated hydrogen gas can be used as fuel, whereas evolved oxygen gas can be used in metal-air batteries or released in the

atmosphere as a clean gas. The electrocatalytic properties of most of the materials for water splitting depend upon several factors such as morphology, phase purity, defects, etc. Additionally, electrochemical energy storage devices garner considerable research interest because of their high storage energy and long lifecycle; supercapacitor's global market reached $2 billion in 2015. This project has synthesized metal-organic framework (MOF) derived cobalt oxide and cobalt sulfide using a facile method. 2-methyl imidazole and cobalt nitrate hexahydrate were used for the synthesis of MOF-derived cobalt oxide and MOF-derived cobalt sulfide electrodes. The electrode with MOF-derived cobalt oxide went through a solvothermal process while the electrode with MOF-derived cobalt sulfide was sulfurized hydrothermally. The structural and electrochemical properties of these electrodes were studied in detail. The MOF-derived cobalt oxide and sulfide's electrocatalytic activities were studied in 1M KOH solution for oxygen evolution reaction and 3M KOH solution for capacitive behaviors and storage capabilities. MOF-derived cobalt oxide showed an overpotential of ~375 mV to achieve a current density of 10 mA/cm^2. A significant improvement in electrocatalytic properties was observed with the electrode that went through sulfurization. MOF-derived cobalt sulfide displayed an overpotential of ~278 mV at 10 mA/cm^2. The specific capacitance obtained by the cobalt sulfide-based electrode (MOF-derived) was ~2537 F/g at 1A/g while the cobalt oxide-based electrode (MOF-derived) was ~484 F/g at 1 A/g. Our results suggest that a facile method of sulfurization of the MOF-derived compound is a way to achieve high electrocatalytic activities for oxygen evolution reaction in the water-splitting process and increased capacitive capabilities.

4:30 PM EN01.04.03
How Strain Modifies the Electrochemical CO_2 Reduction Pathway on Cu Taewoo Kim, Rishi Kumar, Jeffrey A. Brock, Eric E. Fullerton and David Fenning; University of California, San Diego, United States

Copper is an attractive electrocatalyst for CO_2 conversion to valuable carbonaceous products. However, the poor selectivity remains as a challenge to achieve high energetic efficiency. In this work, using model Cu (001) surfaces, we clarify how tensile strain influences CO_2 reduction reaction pathway, shifting products selectivity away from single-carbon to value-added, multi-carbon products.
We establish varying built-in tensile strain on epitaxially grown Cu (001) surfaces on single-crystal Si substrate by changing film thickness. With decreasing film thickness, we observe increasing in-plane tensile strain at the surface that shifts the Cu *d*-band center toward the Fermi level, in good agreement with *d*-band theory. In CO_2 electrolysis at moderate overpotential, we find a suppression of single-carbon products with this upshifting *d*-band center. The change in selectivity indicates a change in adsorption energy for reaction intermediates and perhaps the promotion of hydrogenation of *CO-to-*CHO, one of the key descriptors for CO_2 conversion to multi-carbon products. These findings provide direct experimental evidence that strain can tune the CO_2 conversion reaction pathway to produce energy dense products, providing new opportunities to design efficient and selective catalysts even without changing catalyst composition.

4:45 PM DISCUSSION TIME

5:00 PM EN01.04.05
Late News: Direct Electrosynthesis of Pure Aqueous H2O2 Solutions up to 20% by Weight Using a Solid Electrolyte Yang Xia and Haotian Wang; Rice University, United States

Hydrogen peroxide (H_2O_2) is a crucial chemical with a wide range of applications in civil and industrial fields. It is currently produced from the industrial energy- and waste-intensive anthraquinone process. Its centralized feature also makes it rely heavily on the storage and transportation of H_2O_2, which is unstable and hazardous. Electrocatalytic oxygen reduction reaction (ORR) to H_2O_2 provides an alternative to realize green and delocalized production, with the only inputs from renewable electricity, water and air. However, this route still faces two challenges: 1) lack of catalysts which selectively drive the $2e^-$ ORR towards H_2O_2 (instead of H_2O); 2) generated H_2O_2 are typically in mix with solutes in traditional electrolyzers, which necessitates complicated separation processes to recover pure H_2O_2 solutions for applications.

To make the electrochemical route more reliable in the future scaling-up, we reported a direct and continuous production of pure H_2O_2 solutions for the first time, through rational design of both catalyst and reactor. Here, we report a direct electrosynthesis strategy that delivers separate hydrogen (H_2) and oxygen (O_2) streams to an anode and cathode separated by a porous solid electrolyte, wherein the electrochemically generated H^+ and HO_2^- recombine to form pure aqueous H_2O_2 solutions. By optimizing a functionalized carbon black catalyst, we achieved over 90% selectivity for pure H_2O_2 at current densities up to 200 mA cm^{-2}, which represents a H_2O_2 productivity of 3.4 millimoles per square centimeter per hour (3660 moles per kilogram of catalyst per hour). A wide range of pure H_2O_2 concentrations up to 20 wt.% could be obtained by tuning the water flow through the solid electrolyte, and the catalyst retained activity and selectivity for 100 hours. The as-generated H_2O_2 solutions were also demonstrated to reduce the Total Organic Carbon (TOC) level of local rainwater to that of drinking water.

5:15 PM EN01.04.06
Size-Composition Catalytic Activity Maps for Alloy Nanoparticles Liang Cao and Tim Mueller; Johns Hopkins University, United States

We present the use of *ab-initio* calculations to calculate the coverage-dependent catalytic activity of alloy nanoparticles with realistic sizes (5 nm-10 nm) by explicitly predicting atomic-scale structures and adsorbate binding energies. We demonstrate our approach using Pt–Ni nanoparticles as catalysts for the oxygen reduction reaction (ORR). We achieve our results by constructing a quaternary Pt-Ni-OH-Vacancy cluster expansion model to explicitly predict OH adsorption energies on nanoparticles of varying shape, size, and atomic structure. The OH coverage-dependent ORR activity is calculated through a kinetic Monte Carlo (KMC) simulation. This model enables us to accurately investigate the catalytic activity of various surface sites with different coordination numbers and local atomic environments. Using this model, we evaluate how different parameters affect the ORR activity of Pt-Ni nanoparticles, including size (2 nm-10 nm), Pt composition (60%-100%), and shape. Through the use of KMC-enabled kinetic simulations of structural evolution we evaluate how the activities of the particles change due to Ni dissolution. Our approach identifies OH coverage at the atomic scale and provides theoretical insights into how to tune the structures of alloy nanoparticles to optimize catalytic activity.

5:30 PM EN01.04.07
Late News: Structural Dynamics of Nanoalloy Catalysts for Fuel Cells by In Situ Total X-Ray Scattering Valeri Petkov; Central Michigan University, United States

Many catalysts for energy related applications, in particular metallic nanoalloys, readily undergo atomic-level changes during electrochemical reactions. The origin, dynamics and implications of the changes for the performance of the catalysts inside operating devices though are not well understood. This is largely because they are studied on model nanocatalysts under controlled laboratory conditions. We will present results from combined x-ray specroscopy and total scattering studies on the dynamic behavior of Pt/Pd-3d transition metal nanoalloys inside an operating proton exchange membrane fuel cell [1]. The results indicate that the catalysts change profoundly under the erosive conditions inside the cell, including leaching of transition metal species and continuous re-alloying leading to the emergence of structure states with an improved activity and stability.

1. V. Petkov et al. *Nanoscale* 11 (2019) 5512.

5:45 PM EN01.04.08
Characterization of CeO_x-Decorated Pd/C Catalysts Synthesized By Controlled Surface Reactions for Hydrogen Oxidation in Anion Exchange Membrane Fuel Cells Richard Andres Ortiz Godoy[1,1,2], Jasna Jankovic[1,1,2] and Mariah Batool[1]; [1]University of Connecticut, United States; [2]Center for Clean Energy Engineering, United States

The sluggish kinetics of hydrogen oxidation reaction (HOR) at the anode in alkaline electrolytes are one of the

biggest hurdles in the development of next generation non-Pt catalyst for anion Exchange Membrane Fuel Cells (AEMFCs) having an efficient HOR catalyst[1–3]. Lately, Pd has been extensively used because of the need of developing HOR electrocatalysts based on more abundant and cheaper elements than Pt. Additionally, in order to increase the HOR kinetics of Pd, previous studies focused their efforts on the development of Pd-CeO_2 composites because CeO_2 is an oxygen-deficient compound that allows for a fast OH^- saturation. Lately, Pd has been extensively used because of the need of developing HOR electrocatalysts based on more abundant and cheaper elements than Pt. Additionally, to increase the HOR kinetics of Pd, previous studies focused their efforts on the development of Pd-CeO_2 composites because CeO_2 is an oxygen-deficient compound that allows for a fast OH^- saturation. Controlled Surface Reactions (CSR) process has been used to selectively deposit different atomic ratios (0, 0.24, 0.38 and 0.59 at. ratio ICP-AES Measured bulk Ce/Pd) between CeO_x onto carbon supported Pd catalysts nanoparticles with the main goal of improving the efficiency of HOR catalysts expecting a homogenous distribution of CeO_x nano-islands preferentially attached to Pd nanoparticles (NPs) in order to achieve highly active CeO_x-Pd/C catalysts for HOR[4]. In recent years, when it comes to study the relationship between morphology and structure of nanoparticles that constitute the fuel cells catalyst and the correlation to their electrocatalytic activity, Transmission Electron Microscopy (TEM) has become the state-of the art characterization technique. Here I present a comprehensive characterization approach for the synthesized highly active catalyst, and correlate obtained structural/compositional parameters to the performance. The characterization of the catalysts was carried out via Inductively Coupled Plasma-Atomic Emission Spectroscopy (ICP-AES), High-Resolution Transmission Electron Microscopy (HR-TEM), Scanning Transmission Electron Microscopy (STEM) - Energy Dispersive Spectroscopy (EDS), Electron Energy Loss Spectroscopy (EELS), and X-ray Photoelectron Spectroscopy (XPS) to confirm the bulk composition, phases present, morphology, elemental mapping, local oxidation state and surface chemical states, respectively. The HRTEM images indicated that Pd NPs were uniformly distributed on the carbon support with only some minor agglomeration. Additionally, the achieved high interfacial contact between CeO_x and Pd acquired on single NPs was, for the first time, segmented and calculated using High-resolution STEM-EDS maps and Image J processing program by measuring the overlap intensities between Pd and Ce NPs; the results clearly showed that CeOx NPs were in intimate contact with Pd and their interfacial contact area increased with the addition of CeOx, reached a maximum at a ratio 0.38 CeOx -Pd/C, then decreased due to the formation of large CeOx islands upon the further addition of CeO_x. The attained interfacial contact area also seems to be much higher than other previously reported Pd-CeO_2 catalysts synthesized by other methods[4–7].

Late News: Oxygen Reduction Reaction Activity of Nanocolumnar Pt Thin Film Electrocatalyst Deposited on Carbon Support by High Pressure Sputtering

Assem Basurrah[1,2], Busra Ergul[1], Zhiwei Yang[3], Ranjitha Hariharalakshmanan[1] and Tansel Karabacak[1]; [1]University of Arkansas at Little Rock, United States; [2]University of Jeddah, Saudi Arabia; [3]Raytheon Technologies Research Center, United States

Proton-exchange membrane fuel cell (PEMFC) is one of the most important sources of clean energy especially for automotive applications, which currently utilizes platinum nanoparticles dispersed on carbon (Pt/C) as a catalyst. However, the catalyst activity and durability need to be improved and the cost of the fuel cell need to be reduced for successful commercialization. Extensive research has been done to improve the catalyst activity and durability, reduce the amount of platinum used and reduce its manufacturing cost. Continuous thin film layer approach is a promising candidate for non-conventional catalysts to address these challenges. For this purpose, nanocolumnar Pt thin film (Pt-TF) layers supported on carbon was fabricated by high pressure sputtering (HIPS) and investigated as oxygen reduction reaction electrocatalysts for PEMFCs. HIPS is a simple physical vapor deposition method that is scalable and easily applicable to industrial sputter deposition systems, in which atoms come to the substrate surface with oblique angles and form columnar structures. Different Pt-TF/C weight ratios ranging from 5% to 20% and Pt: Ni (1:3) TF/C were studied. Weight loading was controlled

by changing the sputter deposition time. X-ray diffraction analysis revealed the existence of Pt and formation of the Pt: Ni alloy on carbon support. Electrochemical characterization of the carbon-supported Pt-TF samples was conducted by cyclic voltammetry and rotating disk electrode measurements in an aqueous perchloric acid electrolyte. The electrochemically active surface area, mass activity and specific activity of the Pt-TF/C samples were found to be increasing as the Pt-TF/C ratio was increased.

5:55 PM EN01.04.10
Late News: Catalytic Performance of Porous Yb2O3 Sesquioxide Alina Aftab, Richard Blair, Katerina Chagoya and Nina Orlovskaya; University of Central Florida, United States

Ytterbium Oxide (Yb_2O_3) is a rare earth oxide that has been used in various applications, including sensor and laser technology, sintering aid and doping of different ceramics, and catalytic applications. Although Yb_2O_3 has been considered a potential catalyst for reactions such as vapor phase catalytic dehydration, to the best of our knowledge, there is no reported research for the use of Yb_2O_3 in the hydrogenation of syngas in Fisher-Tropsch chemical reactions. In order to add to the current state of knowledge, the possibility of using porous Yb_2O_3 as a catalyst for converting syngas ($CO+H_2$) into liquid hydrocarbons using the Fischer-Tropsch process was explored. 99.99% pure Yb_2O_3 ceramic powder was pressureless sintered at 900 °C for four hours in the air to create cylinders with an average porosity of 45%. The crystal structure and lattice parameters of Yb_2O_3 were then measured using neutron diffraction and Yb_2O_3 was confirmed to be cubic (*Ia*-3) with c=10.43731 Å lattice parameter. The spectral vibrational signature of Yb_2O_3 attained by micro-Raman spectroscopy corresponded fully to the one published in the literature. Two plug flow catalytic experiments, at temperatures of 250 °C and 500 °C, were performed for the catalytic studies. It was found that Yb_2O_3 is catalytically active and can be used to convert syngas into useful hydrocarbons. Production of methane, ethene, and ethane was detected in the catalytic experiment at 500 °C, but propane, propene, butane, and methanol were also detected in the experiment at 250 °C. It was concluded that more data points are required to be collected to determine if the products' mass distribution followed Flory-Schulz's distribution. Raman spectroscopy and neutron diffraction were also performed on samples used in the catalytic experiment. The crystal structure did not change during the catalytic experiment and the lattice parameter was c=10.43582 Å. A slight shift in the Raman active peaks was detected in the Raman spectra and an extra peak had to be added to obtain the curve fitting.

Redox Catalytic Energy Conversion Through an Electrochemical-Chemical Cycle Qing Wang; National University of Singapore, Singapore

Conventionally, the operation of electrochemical energy conversion and storage devices is inherently dictated and constrained by the redox reactions at electrode-electrolyte interface. The redox-mediated process, a chemical reaction between an electrolyte-borne redox species electrochemically generated on electrode and a material (either soluble or insoluble in electrolyte) off the electrode, provides additional flexibility in circumventing the constraints intrinsically confronted by the conventional electrochemical devices. One example is the redox-mediated hydrogen and oxygen evolution reactions (HER & OER) for spatially decoupled water electrolysis. The concurrent electrochemical-chemical cycle enables continuous reactions between an electrolyte-borne redox mediator and a HER/OER catalyst loaded in a fixed-bed reactor spatially separated from the cell, which is believed to be advantageous to enhanced safety, operation flexibility and H_2 purity. Another example is redox-mediated nitrogen reduction reaction (NRR) for ammonia synthesis. Judiciously selected

redox species serve both as electron and proton carriers circulating between the cell and N_2-filled catalyst bed and present considerably promoted NRR reaction yield. In this talk, I will report our latest progress in the above areas. In addition, I will briefly introduce some other studies on redox-mediated reactions, such as redox targeting-based battery for low-grade waste heat harnessing based on a thermal-electrochemical cycle.

9:00 PM EN01.05.04
Size-Dependent Activity for N_2 Electroreduction on Metal Nanocatalysts Xiaofeng Feng; University of Central Florida, United States

Electrochemical reduction of N_2 to NH_3 has recently received considerable attention, because it may enable sustainable, distributed production of NH_3 when powered by solar- or wind-generated electricity. However, typical catalysts show a low activity and selectivity for N_2 reduction reaction (NRR) due to the barrier for N_2 activation and the competing hydrogen evolution reaction (HER). A rational design of NRR catalysts relies on our understandings of structure-activity relationships and active sites for the NRR, and such study requires model catalysts with well-defined structures. Here we present a study of size-dependent activity for the NRR on Ru nanoparticle catalysts. We first tried colloidal synthesis method with polyvinylpyrrolidine (PVP) as a surfactant to control the size of Ru nanoparticles, while the derived Ru catalysts showed negligible activity for NRR, which was attributed to residual surfactant molecules that blocked catalyst surfaces. Therefore, we used atomic layer deposition (ALD) method to prepare Ru nanoparticles with controlled sizes and clean surfaces. We also quantified the electrochemical active surface areas of Ru samples and measured surface-area-normalized activity for the NRR. Consequently, the effect of Ru nanoparticle size on the NRR activity and Faradaic efficiency was revealed, which can provide insights into the active sites for the NRR and guidance on the design of NRR catalysts via surface site engineering.

Late News: An Experimentally Verified LC-MS Protocol Towards an Economical, Reliable and Quantitative Isotopic Analysis in Photo(Electro)Catalytic Nitrogen Reduction Reactions Sandra E. Saji; The Australian National University, Australia

To substitute the energy-intensive Haber-Bosch process for the synthesis of ammonia, some labile techniques, such as photocatalysis, electrocatalysis, photoelectrocatalysis, and photothermocatalysis, have emerged and attracted intense research interest. However, the contamination of the reaction system is one of the major concerns on how to reliably and accurately evaluate the performance of these catalysts, which is why various control studies are involved. Isotopic labelling studies are one of the most reliable control strategies in nitrogen fixation experiments, to ensure the fact that N_2 is exclusively the source of the generated ammonia. As a convenient, sensitive and accurate technique distinguished with a quantitative atomic mass resolution, liquid

chromatography-mass spectrometry (LC-MS) has been extensively employed for the detection of ammonia in aqueous electrolyte systems. However, the previously reported protocols for $^{15}N_2$ isotopic analysis using LC-MS either involved hazardous procedures which could potentially damage the instrument, or lacked in their experimental verification using real samples. In this work, we present a safe, reproducible and economical protocol for the detection of ammonia using LC-MS, exhibiting an exponentially steep progressive detectivity of ^{15}N abundance, which was well verified with a series of experimental results for nitrogen reduction reactions. This is expected to provide a prudent, cost-effective and sustainable gateway into isotopic analysis.

Late News: Understanding the Interaction of Solvents and Biogenic Impurities with Heterogeneous Catalysts Haseena K V and M. A. Haider; Indian Institute of Technology Delhi, India

The integration of chemo and biocatalysis for the sustainable production of high-value chemicals and fuels from bio-renewable resources like lignocellulosic biomass has attained notable attention in the past decade. The catalytic reactions for transforming platform chemicals obtained from fermentation are often carried out in the liquid phase. Catalyst deactivation caused by the biogenic impurities such as amino acids and proteins arriving from the fermentation media is a key challenge in this line. To understand the role of solvents and biogenic impurities, the hydrogenation reaction of fermentation-derived 6-amyl-α-pyrone (6PP) was explored. Reactions using pure 6PP was carried out in solvents with different dielectric constants. Cyclohexane was found to be the best solvent providing >99% 6PP conversion and 79% DDL yield in 10 min using (10%) Pd/C. Further, the same reaction was carried out at different temperatures and almost complete conversion was obtained at 433 K. With an increase in temperature 6PP conversions increased along with DDL yield. However, reactions using fermentation-derived 6PP showed reduced conversion and product yield. Experiments revealed that even trace quantities of biogenic impurities such as amino acids and proteins from the fermentation media interact with the catalyst and cause significant deactivation of the catalyst. DFT simulations using the Vienna ab initio simulation package (VASP) was employed to unravel the interaction of amino acids on the catalyst surface. Amino acid Methionine (Met), bound through sulfur atom in its most stable adsorption mode with a binding energy=-186 kJ/mol, and it underwent C-S bond cleavage to form SCH_3 species with an activation barrier E_a =136 kJ/mol. This species was found to be stable on the surface. A plausible mechanism for the dissociation of Met on Pd (111) surface is proposed capturing the energetics of the dissociation steps. Much stronger adsorption and relatively lower dissociation barriers were found in the case of Cys on the same surface. Interestingly the observed experimental trend in deactivation also aligns well with simulation results. A combined experimental and computational approach is used to develop deeper insights into the interaction of solvents and biogenic impurities in heterogeneous catalysis.

9:45 PM EN01.05.08
Late News: Metal/organic Hybrid Electrocatalyst for CO2 Reduction by Reductive Conversion of CuSCN / Neutral Red Hybrid Thin Film Yuki Tsuda[1], Tensho Nakamura[1], Philipp Stadler[2] and Tsukasa Yoshida[1]; [1]Yamagata University, Japan; [2]Johannes Kepler Universität Linz, Austria

Reducing atmospheric carbon dioxide (CO_2) is one of the most important challenges for sustainable society. Electrocatalysis for CO_2 reduction reaction (CO_2RR) to energy-rich chemicals has been intensively studied. The catalyst needs to be developed out of earth-abundant elements and should be efficient, fast and selective for useful product.
Recently, Coskun et al. have reported high catalytic activity of metal-free polydopamine towards CO_2RR [1]. Aside from its conductivity, its hydrogen-bonding nature is supposed to be important for stabilization of reaction intermediates. Among traditional electrocatalytic metals, copper (Cu) is outstanding to yield useful hydrocarbons, although its product selectivity is limited. If we can now combine both of them, namely, by introducing hydrogen-bonding organic molecules into Cu, selective production of hydrocarbon such as methane may be achieved by forming concerted catalytic sites.
In this study, the above-mentioned hybrid catalyst has been aimed by employing electrochemical self-assembly (ESA) of CuSCN / neutral red (NR) hybrid thin films. Minor addition of NR, one of phenazine dyes bearing

many amino groups in its structure, to the bath for cathodic electrodeposition of CuSCN resulted in ESA of red-colored and nanostructured CuSCN/NR hybrid thin films, which is then electrochemically transformed into Cu/NR hybrid by electrolysis at -1.0 V vs. Ag/AgCl in an aqueous 0.1 mol dm^{-3} KCl under N_2. Formation of metallic Cu and remainder of NR have been confirmed by XRD and FT-IR, respectively.
Thus prepared thin film electrodes were tested for CO_2RR in an aqueous 0.1 mol dm^{-3} KCl (pH 6.8) While nanostructured Cu made by reductive conversion of NR-free CuSCN showed a reasonable activity to achieve -1.3 mA cm^{-2} at -1.2 V (vs. Ag/AgCl) under CO_2, about 3 times enhanced from that under N_2, the Cu/NR hybrid showed a unique feature to reduce potential (for -0.75 mA cm^{-2}) from the initial -1.01 to -0.73 V upon 10 times repetition of voltammetric potential scanning, indicating its activation for CO_2RR. It is possible that NR molecules re-organize to form catalytic sites during the electrolysis.
At this stage, we haven't identified the products and their selectivity. These preliminary results, however, already indicate successful strategy to obtain hybrid electrocatalyst to combine Cu and hydrogen-bonding organic molecules to enhance the activity for CO_2RR.

9:50 PM EN01.05.09
Atomic Probing of Defects Engineered Nanocarbon Support Concurrence with Bimetallic Atoms Towards Electrocatalysis and Zn-Air Batteries Kishwar Khan[1], Zhengtang Luo[1] and Khalil Amine[2]; [1]The Hong Kong University of Science and Technology, Hong Kong; [2]Argonne National Laboratory, United States

The mechanistic understanding of defects engineering in nanocarbons, and its hybrid with single metal atoms towards electrocatalysis are vital to study in-depth, and still its remains very challenging. Herein, we advocate the fundamental understanding of the nature of active sites in ample edge defects nitrogen-doped graphene (DG) fascinated with specific coordination of carbon atoms rings. The concept of defect mechanism revealed that the topological defect (*e.g.* multiple edge pentagon, pentagon—octagon—pentagon or pentagon—heptagon—pentagon rings) appeared correspondingly in the combination of carbon atoms that avoided random dislocations and disclinations that brought active sites during reactions. We anchored Ni and Fe isolated single metals on DG support towards enhanced O_2 response. X-ray absorption spectroscopy evidences the embedding nature of NiFe metal atoms within the DG surface. The precise structural characterizations using high-resolution transmission electron microscopy/high-angle annular dark-field (HAADF) images in scanning transmission electron microscopy (STEM) techniques to probe the atomic level understanding of such defects, its different coordination of atoms. Density functional theory (DFT) further trust these specific grouping of carbon atoms and frilling of NiFe single atoms on the tip-enhanced local electric field of the carbon support that active upsurge sites and promotes the kinetics for ORR and OER. This study offers new prospects and underscores the importance of identifying topological defects in nanocarbons with the addition of single metal atoms towards the active species for multiple reaction catalysts.

Hybridization of Molecular and Metallic/Semiconductor Materials for CO_2 Catalytic Reduction Marc Robert; Université de Paris, France

Reduction of carbon dioxide has as main objective the production of useful organic compounds and fuels - renewable fuels - in which solar energy would be stored. Molecular catalysts can be employed to reach this

goal. They may in particular provide excellent selectivity thanks to easy tuning of the electronic properties at the metal and of the ligand second and third coordination sphere. Hybridization of these catalysts with conductive or semi-conductive materials may lead to enhance stability and new catalytic properties. This approach bridges between homogeneous and heterogeneous, and it raises new fundamental questions that may further lead to breakthrough in CO_2 reduction chemistry.
Our recent results in this area will be discussed. [1-5]

8:25 AM *EN01.06.02
Operando Insight into the CO_2 Electrocatalytic Reduction Reaction Beatriz Roldan Cuenya; Fritz Haber Institute of the Max Planck Society, Germany

The efficient electrochemical conversion of CO_2 (CO_2RR) to valuable fuels and feedstocks is a highly sought process towards the minimization of the carbon footprint. However, higher selectivity towards C_{2+} products must be achieved before a broad industrial use can be envisioned. Better efficiency can be attained by tuning the morphology (size, shape, dispersion), oxidation state, composition of the catalysts, NP/support interactions, and by a rational selection of the electrolyte. In addition, understanding the changes that a catalyst may experience on its surface during a reaction is crucial in order to stablish structure/composition-reactivity correlations. Here, mechanistic insight into CO_2RR will be provided by using as target materials size- and shape-controlled mono and bimetallic NPs including Cu, Cu_2O, Zn, Cu-Zn, Cu-Ag NPs with spherical, cubic and triangular-base prism shapes, and Cu_2O cubes decorated with monodispersed Ag nanoparticles on the surface.
A synergistic combination of spectro-electrochemical methods, *in situ* microscopy (EC-AFM, L-TEM), *operando* X-ray absorption spectroscopy (XAS), *operando* high-energy X-ray diffraction (HE-XRD), *operando* Raman spectroscopy and *quasi in situ* X-ray photoelectron spectroscopy (XPS) were used to gain insight into the morphological, structural, and chemical transformations undergone by the NPs during CO_2RR. I will illustrate that the as-prepared state of the mono and bimetallic NPs is drastically different from the structure and surface composition of the working catalyst. Thus, our study gives a comprehensive insight into C_{2+}-forming state of Cu-based catalysts and sheds light into the selectivity-determining catalyst properties for CO_2RR.

9:05 AM EN01.06.04
Design and Mechanistic Understanding of Earth-Abundant Metal Chalcogenide Electrocatalysts for Selective Electrosynthesis of Hydrogen Peroxide Hongyuan Sheng, Aurora N. Janes, J. R. Schmidt and Song Jin; University of Wisconsin-Madison, United States

Hydrogen peroxide (H_2O_2) is a versatile and green oxidant with a variety of distributed applications such as environmental remediation, disinfection, and household sanitation, but its centralized chemical production via the anthraquinone process poses significant cost, energy, and safety concerns. Decentralized electrosynthesis using renewable electricity to selectively reduce O_2 to H_2O_2 via the two-electron oxygen reduction reaction ($2e^-$ ORR) could better satisfy end-user demands on-site, yet robust, earth-abundant catalysts that are active and selective in acidic (or neutral) solutions are lacking. Here we present our recent joint efforts combining theory and experiments to establish rational design rules for selective and stable acidic $2e^-$ ORR electrocatalysts based

on earth-abundant metal chalcogenide compounds. We first showed that pyrite-type cobalt disulfide (CoS_2) selectively catalyzes the acidic $2e^-$ ORR at low overpotentials due to the spatial separation of active metal sites by anions, which kinetically suppresses the scission of O-O bond in OOH* adsorbate and the undesired $4e^-$ ORR. We further established both pyrite- and marcasite-type cobalt diselenide ($CoSe_2$) polymorphs as more stable and leaching-resistant acidic $2e^-$ ORR catalysts because of the much weaker binding of O* adsorbate to Se sites. This stability allows for the bulk accumulation of practically useful 547 ppm H_2O_2 and the effective electro-Fenton degradation of organic pollutant for on-site environmental remediation. Building on the new mechanistic understanding, our ongoing developments and future perspectives of earth-abundant metal compound-based $2e^-$ ORR electrocatalysts will also be discussed.

9:20 AM EN01.06.05

Late News: Highly Active Co–Fe–P Nanoparticles Decorating Carbon Fibers Electrodes for the Oxygen Evolution Reaction María Isabel Díez García, Guillem Montaña Mora, Andreu Cabot Codina and Joan Ramon Morante; Institut de la Recerca de la Energia de Catalunya, Spain

Electrocatalytic decomposition of water is a promising route for hydrogen production, which nowadays is one of the best candidates as energy vector for a future carbon-free economy. The involved catalysts must have high electrocatalytic activity (and high selectivity) for lowering the applied voltage to the cell and long-term stability for the durability of the device. Apart from that, the materials should be composed by Earth-abundant elements and be environmentally friendly. Besides, the synthetic route should be cheap and scalable for industrial production. For the oxygen evolution reaction (OER), the Ir/Ru oxides show excellent electrocatalytic performance for water oxidation in alkaline media, however, the scarcity of these metals and their high cost are detrimental for practical applications. Fueled by a growing interest in new materials that could be advantageous against precious metal-based catalysts, metal phosphides have attracted particular attention. Most of them exhibit good catalytic properties toward hydrogen evolution reaction (HER) and OER and a high conductivity compared with the corresponding metal oxides/hydroxides. In this work, we investigate CoFeP nanoparticles supported on two different 3D electrodes, nickel foam and carbon felt substrates. Electrodes using nickel foam display higher current densities due to a lowered Tafel slope and higher conductivity of the substrate. For CoFeP deposited on nickel foam, overpotentials lower than 300 mV are achieved for 10 mA/cm^2. The influence of the Co/Fe ratio, particle size, morphology and structure of CoFeP nanoparticles deposited on the electrode supporting materials have been investigated and compared with the monometallic phosphides emphasizing the role of the use of bimetallic based systems combined with the advantageous expected role of the phosphides.

9:35 AM EN01.06.06

Ultrathin Bismuth Oxyiodide Nanosheets for Photocatalytic Ammonia Generation from Nitrogen and Water Under Visible to Near-Infrared Light Mohammadjavad Mohebinia[1], Chunzheng Wu[2], Guang Yang[1], Shenyu Dai[3], Alireza Hakimian[1], Tian Tong[1], Hadi Ghasemi[1], Zhiming Wang[2], Dezhi Wang[1], Zhifeng Ren[1] and Jiming Bao[1,1,1]; [1]University of Houston, United States; [2]Institute of Fundamental and Frontier Sciences, University of Electronic Science and Technology of China, China; [3]Sichuan University, China

Artificial photosynthesis of ammonia using atmospheric nitrogen and water is a sustainable but challenging alternative to the Haber-Bosch process. Bismuth oxyiodide (BiOI) is a promising candidate due to its superior light absorption capability (bandgap of around 1.8 eV) and abundant surface oxygen vacancies. However, its improper band edge positions made it inactive for overall water-splitting and N_2 fixation. In this work, ultrathin BiOI nanosheets were synthesized through a simple surfactant (PVP) assisted hydrothermal route. The nanosheets split pure water into H_2 and O_2 and converted nitrogen and water into ammonia under visible or near-infrared light. PVP capping not only reduced the thickness of BiOI sheets but also upshifted its band edge positions due to the surface electric dipole induced by polyvinyl pyrrolidone molecules on the BiOI surface, thus enabling the water oxidation and nitrogen reduction half-reactions simultaneously.

SESSION EN01.07: Sustainable 3D-Metal Electrocatalysis
Session Chairs: Marc Robert and Philipp Stadler
Friday Morning, April 23, 2021
EN01

11:45 AM *EN01.07.01
Power-to-X Technologies—Bioinspired Catalyst and Device Design Mathias Smialkowski[1], Kai Junge Puring[1], Kevinjeorjios Pellumbi[2,1], Lucas Hoof[2], Daniel Siegmund[2] and Ulf-Peter Apfel[1,2]; [1]Ruhr University Bochum, Germany; [2]Fraunhofer UMSICHT, Germany

The efficient reduction of protons and CO_2 under mild conditions is a current challenge for modern society. Nature utilizes enzymatic machineries that comprise iron- and nickel- containing active sites to perform these transformations.[1] Recently, we reported on the formidable HER activity of bulk $Fe_{4.5}Ni_{4.5}S_8$ electrodes revealing similar structural and functional properties of the enzymes.[2,3] We herein set out to explore the influence of the Fe : Ni ratio on the performance of the electrocatalyst.[4] Using linear sweep voltammetry, we show that the increase in the Fe or Ni content, respectively, lowers the activity of the bulk electrocatalyst towards HER. Additionally, with increasing Se content in $Fe_{4.5}Ni_{4.5}S_{8-x}Se_x$, the HER performance is significantly lowered.[5,6] Thus, specific Fe-Ni interactions seem to be the key for materials reactivity.
In addition, we show that a temperature increase leads to a significant decrease of the overpotential. Furthermore, due to the resemblance of such sulfides with CO_2 converting enzymes, we likewise investigated $Fe_{4.5}Ni_{4.5}S_8$ electrodes to perform CO_2 reduction.[7] In non-aqueous conditions as well as in supercritical CO_2, this material is indeed a potential catalyst affording CO or formic acid, respectively, as main product with high Faradaic yields.
Notably, the reactivity of the pentlandite materials can be further tuned by the reactor environment as well as the electrodes shape which was found to be equally important as the catalyst.

FeP/C 3D Cathodes as Highly Efficient Electrodes for Hydrogen Production María Isabel Díez García, Sebastian Murcia and Joan Ramon Morante; Catalonia Institute for Energy Research (IREC), Spain

The deployment of carbon-free energy technologies that could compete with the price of fossil fuels is expected to be a key factor for sustaining the future energy requirements of the world population. In this regard, H_2 is a promising energy vector that could be produced using solar energy, and one of the approaches consists on coupling an electrolyzer to a photovoltaic cell. Among electrode materials used as cathodes, iron phosphide has

engaged interest in the last years. Apart from the fact that it is composed of two elements highly abundant in the Earth crust, the new synthetic routes are making its synthesis simpler and cheaper. In this work, a 3D electrode composed by FeP directly deposited on carbon fibers is fabricated by a simple impregnation method and subsequent heat treatment. The intermediate iron species are converted to FeP by in situ PH_3 generation at 300-400 °C, leading to a highly porous electrode with a high surface area. Electrodes are optimized by exploring different synthetic conditions, such as heat treatment temperatures or catalyst loading. The intermediate Fe species are found to influence the final FeP/C configuration. Optimized FeP/C electrodes exhibit high activity towards hydrogen evolution reaction (HER) in both acidic and alkaline electrolytes displaying low overpotentials and excellent stability. Additionally, the doping with some particular metals is also studied, unveiling the role of the dopant in the HER activity. A further demonstration of performance in a flow cell is presented, confirming the feasibility of our electrodes as cathodes for HER in continuous operation.

12:25 PM EN01.07.03
Late News: Topological Engineering of Pt-Group-Metal-Based Chiral Crystals Toward High Efficiency Hydrogen Evolution Catalysts Qun Yang and Claudia Felser; Max Planck Institute for Chemical Physics of Solids, Germany

It has been demonstrated that topological nontrivial surface states can favor heterogeneous catalysis processes such as the hydrogen evolution reaction (HER), but a further decrease in mass loading and an increase in activity are still highly challenging. The observation of massless chiral fermions associated with large topological charge and long Fermi arc (FA) surface states inspires the investigation of their relationship with the charge transfer and adsorption process in the HER. In this study, it is found that the HER efficiency of Pt-group metals can be boosted significantly by introducing topological order. A giant nontrivial topological energy window and a long topological surface FA are expected at the surface when forming chiral crystals in the space group of $P2_13$ (#198). This makes the nontrivial topological features resistant to a large change in the applied overpotential. As HER catalysts, PtAl and PtGa chiral crystals show turnover frequencies as high as 5.6 and 17.1 s^{-1} and an overpotential as low as 14 and 13.3 mV at a current density of 10 mA cm^{-2}. These crystals outperform those of commercial Pt and nanostructured catalysts. This work opens a new avenue for the development of high-efficiency catalysts with the strategy of topological engineering of excellent transitional catalytic materials.

12:40 PM EN01.07.04
Mesoporous $NiFe_2O_4$ with Tuneable Pore Morphology for Electrocatalytic Water Oxidation Christopher Simon[1], Jana Timm[1], David Tetzlaff[2,3], Jonas Jungmann[1], Ulf-Peter Apfel[2,3] and Roland Marschall[1]; [1]University of Bayreuth, Germany; [2]Ruhr-University Bochum, Germany; [3]Fraunhofer Institute for Environmental, Safety, and Energy Technology UMSICHT, Germany

Electrocatalytic water splitting using renewable energies to form green hydrogen and oxygen has attracted a widespread interest to replace fossil fuels as major energy carrier. Currently, the oxygen evolution half reaction (OER) is regarded to be the major bottle-neck of water splitting due to its hampered kinetics involving a multi-step proton and electron transfer. Noble metal electrocatalysts, such as RuO_2 and IrO_2 are widely used for OER, however, their prohibitive scarcity and cost limit their potential widespread use in electrolyzers.
Among multiple transition metal oxides, ferrites with the general formula $M(II)Fe_2O_4$ (M = Ca, Zn, Mg, Ni, Co, Mn etc.) have gained considerable attention due to their compositions made up from earth-abundant elements and widespread application fields including electrocatalysis.[1-4] Especially nickel ferrite has been considered as efficient OER electrocatalyst, with outstanding high stability in alkaline media, excellent redox properties, and ferromagnetism facilitating the catalyst separation from solution. [5]
We will report on the successful synthesis of mesoporous $NiFe_2O_4$ materials with narrow pore size distribution for the oxygen evolution reaction. The materials are prepared by a soft-templating strategy using citric acid and the optional addition of the commercially available block copolymer Pluronic® P-123, followed by calcination. The mesopore evolution during thermal treatment is examined systematically giving insights into the formation process of mesoporous $NiFe_2O_4$. The formation of intermediate carbonate species induced by the use of citric

acid in the synthesis plays a key role in the formation mechanism of the templated mesoporous structure. Furthermore, citric acid is also crucial to obtain phase-pure $NiFe_2O_4$.
Detailed nitrogen physisorption analysis including desorption scanning experiments will be presented to reveal the exceptional accessibility of the mesopores generating surface areas of up to 200 m2/g. The ability of the $NiFe_2O_4$ powders to perform electrocatalytic oxygen evolution reaction under alkaline conditions was investigated, highlighting the advantages of mesopore insertion. The performance was ascribed to be dependent of the electrochemical surface area, which increased with the relative surface area of the prepared materials. In general, the highly accessible mesoporous and amorphous structure with large surface areas seem to be key parameters for OER, whereas high crystallinity turns out to be not beneficial.

12:55 PM EN01.07.06
Late News: Synthesis, Properties and Electrocatalytic Activity of Phosphorus-Rich 3D Metal Phosphides
Edward G. Gillan; University of Iowa, United States

Transition-metal phosphides (MP_x) have received significant scrutiny as water splitting electrocatalysts, particularly those with nanostructured morphologies that facilitate the electrocatalytic hydrogen evolution reaction (HER). The most synthetically accessible structures are those from the metal-rich side of metal-phosphorus phase diagrams (e.g., FeP, CoP, Ni_2P, or Cu_3P). Our group has developed a solvent-free chemical exchange synthesis for metal phosphides that can directly produce both crystalline metal-rich and less-studied phosphorus-rich metal phosphides at moderate temperatures near 500 °C. This reaction relies on the direct insertion/exchange reaction between metal halides and elemental phosphorus to form PCl_3 and the MP_x products. In some cases, addition of a tin flux facilitates redox processes and MP_x growth along with $SnCl_2$ byproduct formation. Single metal phosphides from the 3d metal group can be targeted through changes in synthetic conditions to form metal-rich and phosphorus-rich crystalline materials such as FeP versus FeP_2, CoP versus CoP_3, and Ni_2P versus NiP_2 or NiP_3. The synthesis and characterization of different compositions in the Fe/Co/Ni phosphide families will be described.

Several of the MP_2/MP_3 phases show hydrogen evolution reaction (HER) activity analogous to that observed for their metal-rich counterparts despite lower metal content. Even for 3d metal catalysts, a decrease in metal content without large corresponding loss in surface catalytic activity is desirable for sustainable catalytic solutions. The P-rich structures appear to resist (electro)chemical degradation in acidic environments during electrocatalytic HER experiments over extended 18-hour periods. In contrast to the metal-rich phosphides with extensive metal-metal bonding, MP_2/MP_3 structures contain polyphosphide anions that may better encapsulate metal centers and can enable electrocatalytically useful polyphosphide anion redox activity. Comparisons of local structure and properties and their possible impact on surface reactions in electrocatalytic HER will be described.

Late News: Topological Materials as Electrochemical Catalysts Guowei Li and Claudia Felser; Max Planck Institute for Chemical Physics of Solids, Germany

Exotic electronic states are realized in various topological phases, from topological insulators to recently reported Weyl/Dirac semimetals, nodal line semimetals, and magnetic semimetals. They strongly influence the surface electronic structures of the investigated materials and could serve as a good platform to gain insight into the catalytic mechanism of surface reactions. Topological Semimetals such as $PtSn_4$ and $Co_3Sn_2S_2$ adopt quasi-

two-dimensional structures and could expose the crystal surfaces constructing by transition metal atoms. Topological non-trivial surface states are observed at the crystal surfaces, which are located near the Fermi level. These topological surface states can act as both electron acceptors or donators for small adsorbed molecules, consequently tailoring the adsorption energy and Gibbs free energy in the electrochemical catalytic reactions.

Enhanced Water Splitting Performance of MoS_2 and $PdSe_2$ Using Heterostructuring Edward A. Baker, Joe Pitfield and Steven P. Hepplestone; University of Exeter, United Kingdom

Two dimensional materials, such as the transition metal dichalcogenides (TMDCs) are a good candidate for water splitting catalysts [1,2], as they often have larger band gaps than their bulk counterparts. However, this had to be balanced by the thin layers having a small absorption cross section and difficulties in mounting on a suitable substrate. $PdSe_2$ is being suggested as a potential water splitting candidate [3]. However its bulk band gap is too small for water splitting [4]. We propose to use this structure as a surface coating to a second TMDC with a larger band gap such as MoS_2 and use this as an example of how such heterostructures could function.

Using density functional theory, implemented in the Vienna Ab-initio Simulation Package, we have investigated the surfaces of TMDC monolayers MoS_2 and $PdSe_2$, and a Hetero-bilayer of the two, for their potential application as photocatalytic water splitters. The different functional groups involved in the Hydrogen and Oxygen evolution reactions have been added to the monolayers and the hetero-bilayer to determine their energetics. In addition to this, we have looked at how stable these materials are, to both adsorptions and substitutions, in both air and water environments.

Molecular Engineering of Metal Phthalocyanine Electrocatalysts for the Carbon Dioxide Reduction Reaction Yongye Liang, Zhan Jiang and Huan Li; Southern University of Science and Technology, China

Molecular electrocatalysts are attractive due to their well-defined structures and easy regulation of chemical properties. However, in heterogeneous systems, molecular electrocatalysts are usually inferior to noble metal based materials in terms of activity and stability, and the molecular engineering of electrocatalytic performance remains a grand challenge. Herein, we present our recent work on the development of molecularly dispersive electrocatalysts (MDEs) and their molecular engineering regulation strategies for the carbon dioxide reduction reaction. These MDEs were constructed by anchoring metal phthalocyanine molecules on side walls of carbon nanotubes, which could effectively overcome the issues of poor electrical conductivity and molecular aggregations. The electrocatalytic performance could be further improved by tuning metal centers and

substitution groups on phthalocyanine. The designed nickel phthalocyanine MDE system exhibited high selectivity and good stability for the conversion to carbon monoxide at high current densities in gas-diffusion electrodes, setting new records of noble-metal-free and molecule-based electrocatalysts. The cobalt phthalocyanine MDE system could catalyze the six-electron reduction of carbon dioxide to methanol with high selectivity and good stability, which had not been achieved by molecular electrocatalysts. The MDEs with well-defined active centers also facilitated understanding the underlying mechanism on structural factors affecting electrocatalytic performance with the help of in-situ/operando characterizations and theoretical calculations. These studies pave a new path for the development of high-performance electrocatalysts.

5:55 PM EN01.08.04
Unzipping 2D Transition Metal Dichalcogenides for Hydrogen Evolution Reaction Catalysis Suchithra Padmajan Sasikala; KAIST, Korea (the Republic of)

Discovery of 2D atomic structures, including graphene, transition metallic dichalcogenides (TMDs), *h*-boron nitride, phospherene, and mxene, has unveiled new possibilities in materials science. Unzipping of the basal plane is a general issue to uniquely control the material signatures of the 2D materials, as evidenced by the effective transformation of intrinsically metallic graphene into semiconductors, while unzipped into few-nanometer-wide graphene nanoribbons. Nonetheless, reliable unzipping has been reported for graphene and phosphorene thus far. Single elemental nature of those materials allows straightforward understanding of chemical reaction and property modulation involved with such geometric transformations. Here we present spontaneous linear ordered unzipping of bi-elemental 2D MX_2 transition metal chalcogenides as a general route to synthesize 1D nanoribbon structures. Strained metallic phases (1T′) of MX_2 are found to undergo highly specific longitudinal unzipping owing to the self-linearized oxygenation at chalcogenides. Stable dispersions of 1T′ MoS_2 nanoribbons with widths of 10-120 nm and lengths up to ~4 μm are produced in water. Edge abundant 1T′ MoS_2 nanoribbons reveal the hidden potential of idealized elecrocatalysis for hydrogen evolution in a competitive level with precious Pt catalyst.

6:10 PM EN01.08.05
Designing Polymorphic Nanoporous Iridium Oxides for Oxygen Evolution Catalysis SangSeob Lee, Giyeok Lee and Aloysius Soon; Yonsei University, Korea (the Republic of)

Oxygen evolution reaction (OER) is the key anodic catalytic reaction for many important clean energy processes. To date, the search for an active, selective, and stable electrocatalysts has not ceased and a detailed atomic-level design of the OER catalyst remains an outstanding (if not, compelling) problem. Only recently, a computational high-throughput study of iridium oxides (for both IrO_2 and IrO_3) has highlighted the role of polymorphism and stoichiometry to precisely engineer iridium oxides for efficient and stable OER catalysis. However, it seems surprising that nanoporous (i.e. crystal structures containing nanopores and nanochannels) iridium oxides – which have been proposed in various experiments – were not examined in that study. In this work, we have further extended the previous computational report to include many metastable nanoporous iridium oxide polymorphs – inspired both from experiments and also analogous crystal structures from manganese oxides. Using van der Waals corrected density-functional theory calculations, we investigate the thermodynamic stability, intercalation properties, and electronic structure of these nanoporous iridium oxides. We focus on understanding how the charge, size, and concentration of the intercalation ions (e.g. K^+, Ca^{2+}, etc.) may be taken advantage of for engineering the desired OER descriptor – the ratio of Ir^{3+}/Ir^{4+} in these intercalated polymorphs, for the neoteric OER electrocatalysts.

6:15 PM DISCUSSION TIME

6:30 PM EN01.08.07
High-Throughput Data-Mining of Transition Metal Carbides and Nitrides for Promising Conductive Low-Cost Heterogeneous Catalyst Supports Giyeok Lee[1], Taehun Lee[1,2] and Aloysius Soon[1]; [1]Yonsei University, Korea (the Republic of); [2]Princeton University, United States

Transition metal carbides and nitrides are suggested as promising candidates for conductive low-cost heterogeneous catalyst supports given their superior structural durability and electronic structure to effectively promote charge transfer across the catalyst interface. To architecture the most optimal carbide and/or nitride for conductive supports, we consider a range of group VI and V metal carbides and nitrides (in their rock-salt bulk phase) and perform high-throughput first-principles density-functional theory (DFT) calculations using the Vienna *Ab initio* Simulation Package (VASP) within our automated high-throughput in-house python code via the Atomic Simulation Environment (ASE). Namely, from the low Miller-index surfaces of these carbides and nitrides, we calculate and analyze their surface thermodynamic stability, surface work function modulations, and electronic structure analysis to examine the magnitude/origin of charge transfer across the catalyst interface. Furthermore, we introduce point defects at the pristine surfaces of these carbides and nitrides to inspect the variations in surface work functions and electronic structure to anticipate a wider range of tunability of their support properties in heterogeneous catalysis. Through these high-throughput DFT calculations, we have successfully screened out the most promising candidates and propose an *ab initio* design rule to engineer the next-generation hybrid heterogeneous catalysts.

6:35 PM EN01.08.08
Single Ni Atom Decorated Networked Carbon for pH-Universal Oxygen Electroreduction for Fuel Cell Application Alekha Tyagi[1], Kamal K. Kar[1,1] and Hiroyuki Yokoi[2]; [1]Indian Institute of Technology Kanpur, India; [2]Kumamoto University, Japan

In the present era of depleting conventional energy resources, it is urgent to inspect and develop substitutional fuel resources and suitable energy storage and conversion systems for their exploration. Further, in light of the increasing pollution concerns, it is desirable that the alternative systems are suitable for environment-friendly energy conversion. Polymer electrolyte membrane fuel cell (PEMFC) and the metal-air batteries are the prospective devices, which need dedicated research efforts to overcome the shortcomings and reach commercialization. The major performance limiting factor is the sluggish reaction kinetics of the oxygen reduction reaction (ORR) at the cathode. Noble metal nanoparticles supported on carbon are employed as cathode catalyst to enhance the reaction rate. But, these catalysts are not economical and suffer from poisoning and fuel-crossover issues. Suitable cost-effective, highly active and durable catalyst system are very much needed to enhance the rate of the ORR.

Here, we are presenting an atomic Ni decorated N, S doped hierarchical porous networked carbon synthesized by employing an optimized inert pyrolysis followed acid-treatment strategy. Nickel nitrate and guanidine thiocyanate are chosen as precursors for metallic entity and doped porous support, respectively. The catalyst possesses a novel morphology with atomically dispersed Ni atoms and nickel sulfide entities on networked N, S-doped carbon backbone.

The sample synthesized at 750 ºC, which is further treated with 1 M HCl (Ni-GT-750-A) exhibit superior pH-universal ORR performance with an onset potential (V_{Onset}) = 0.91 V (0.1 M KOH) and 0.89 V (0.1 M $HClO_4$) versus reversible hydrogen electrode (RHE). The excellent current stability (95.0 and 60 %) and resistance to methanol poisoning (90.6 and 80.3 %) are observed through chronoamperometric studies as comparison to the state-of-the-art catalyst (Pt/C) (65.0, 27, -33.0 and 16.5 %) in alkaline and acidic media, respectively. This electrochemical performance marks the suitability of the proposed catalyst in wide range of electrolytic media.

The observed ORR performance of the prepared electrocatalyst is attributed to the localized single-metal atom type ORR active sites over carbon matrix, which decreases the potential barriers for intermittent reactions due to enhanced atom utilization efficiency, which in turn increases the ORR kinetics. These atomic species are visualized using high-angle annular dark field- scanning transmission electron microscopy (HAADF-STEM). The hierarchical porous morphology as confirmed through N_2 adsorption-desorption isotherms and pore size distribution in addition to the defects in the carbon support owing to the present heteroatoms as can be visualized by Raman studies also contributed in the overall ORR performance in a synergistic manner. The

explored physicochemical traits and ORR activity of Ni-GT-750-A paves the way for exploration of its catalytic activity for other electrochemical reactions and as electrode material for energy storage devices.

Metal and Semiconductor Photocatalysts for Selective Carbon Dioxide Reduction Harry A. Atwater; California Institute of Technology, United States

Recent work has shown intriguing possibilities for non-equilibrium carrier generation in metal nanostructures at semiconductor interfaces to modify the rates and pathways for photochemical reactions at the nanoscale, suggesting that light can play a new role as an agent of photocatalytic selectivity – beyond its traditional role of charge carrier generation. Key open questions in this field include: i) how hot are the hot carriers? ii) how hot carriers are transported and whether they modify interfacial reactions? iii) ultimately, how efficiently can these processes generate chemical products from sunlight? We show that hot carrier photocatalytic reactions at the Au/p-GaN and Cu/NiO nanoparticle interfaces alter the Faradaic efficiency for carbon dioxide reduction relative to dark electrocatalysis. Notably, at both of these interfaces, charge carrier separation occurs via photoexcited hot hole injection into the p-type wide bandgap semiconductor, localizing electrons in the metal catalyst nanoparticles. An exciting new result is the observation of self-sustaining, unassisted photocatalytic gas phase carbon dioxide reduction in metal/p-GaN structures, where the CO_2 reduction reaction is balanced by water oxidation on gallium nitride. In this work, we have address carrier generation, transport and interface dynamics with first-principles theory, and experimental observation of carrier dynamics via hot-carrier

photocurrent spectroscopy, ultrafast transient absorption spectroscopy, and photoelectrochemical measurements.
Another key future photocatalyst challenge for solar fuels from carbon dioxide reduction is design of earth-abundant tandem photocatalysts with both appropriate bandgaps and sufficiently high photovoltages to efficiently drive carbon dioxide reduction reactions at solar photocurrent densities, with validated durability and long lifetime. We survey options for photocatalysts comprised of metal oxide, metal nitride and tandem heterostructure components.

Calculations of the Electrochemical Reduction of CO2 and the Competing Hydrogen Formation Hannes Jonsson; University of Iceland, Iceland

Results of theoretical calculations of electrochemical CO2 reduction to formate, hydrocarbons and alcohols will be presented. The mechanism for the formation of various products is established and the rate evaluated and compared with experimental measurements. The rate of the main side reaction, the hydrogen evolution reaction, is also estimated. The calculations are based on a detailed atomistic model of the electric double layer (metal slab and water layer) and density functional theory calculations to evaluate not only the free energy of intermediates as a function of applied voltage but also the activation energy for each elementary step, both Heyrovsky and Tafel reactions [1]. Comparison is also made with calculations using an implicit solvation model [2]. A range of close packed metal surfaces are compared, including Cu, Ag, Au, Ni, Fe, Rh, Ir and Pt. The resuls are in remarkably good agreement with the available measurements. A two parameter descriptor is established that can help identify improved catalysts for this important reaction. The elucidation of the reaction mechanism of CO2 electroreduction to hydrocarbons and alcohols as well as the competing hydrogen evolution reaction is an important step towards the design of a selective and energy efficient catalyst for small scale, decentralized fuel production using renewable energy sources and CO2 as reactant.

Electrocatalytic CO_2 Reduction on CuZnAl-Based Oxide Catalysts—Tuning of the H_2/CO Ratio Hilmar Guzmán[1,2], Daniela Roldán[1], Adriano Sacco[2], Micaela Castellino[1], Marco Fontana[2], Nunzio Russo[1] and Simelys Hernandez[1,2]; [1]Politecnico di Torino, Italy; [2]Istituto Italiano di Tecnologia, Italy

Electrochemical Reduction of CO_2 (ER-CO_2) is a very attractive alternative to tackle Global Warming.[1] Cu-based materials have shown increased yields of hydrocarbon and oxygenate products, while its selectivity towards CO is low.[2] Inspired by the thermocatalytic process, a traditional co-precipitation method was employed to synthesize CuZnAl-based oxide catalysts with a mesoporous structure. This CuZnAl catalyst was tested for the first time for the ER-CO_2 under ambient conditions. The Physico-chemical properties of the catalysts were studied by several characterization techniques (e.g., XRD, XPS, BET, SEM, TEM) and electrochemical impedance spectroscopy at different applied-potentials to understand the role of the modification of the catalyst components during operation in the final selectivity and activity. Results revealed that adding amphoteric metal oxides like ZnO and Al_2O_3 to the CuO-based catalyst contributed to promote CO formation over H_2. XPS measurements on the fresh samples revealed that the ternary CuZnAl catalyst presented a lower percentage (5%) of $Cu^0 + Cu^{1+}$ mixture on the surface than the other catalysts, being mainly constituted by Cu^{+2}. This material reached a Faradaic efficiency towards syngas of almost 95% at -0.89 V vs. RHE. Nevertheless, the highest production rate of syngas was obtained at the most negative applied potential (~ 17 $\mu mol\ h^{-1}\ cm^{-2}$ at -1.14 V vs. RHE).). A tunable H_2/CO ratio was achieved by applying different potentials, reaching lower values by increasing applied negative potential (CO current density increased). In fact, a syngas with a H_2/CO ratio of ~2 was obtained at -0.89 V vs. RHE, which is a suitable raw material for further methanol synthesis. The enhanced performance for syngas production of the developed CuZnAl catalyst is

demonstrated to be attributed to its surface properties (i.e., alkalinity and the oxidation state on the surface, its lowest diffusional mass transfer resistance, its highest total pore volume, and the lowest Cu crystals size among the prepared catalysts.

12:20 PM EN02.01.04
Late News: Immobilization of a Molecular Re Complex on MOF Derived Hierarchical Porous Carbon for CO2 Electroreduction in Water/Ionic Liquid Electrolyte Domenico Grammatico[1,2], Huan Ngoc Tran[3], Yun Li[3], Silvia Pugliese[3,2], Laurent Billon[1], Bao-Lian Su[2] and Marc Fontecave[3]; [1]University of Pau and Pays del'Adour, France; [2]University of Namur, Belgium; [3]Collège de France, France

The development of molecular catalysts for CO_2 electroreduction within electrolyzers requests their immobilization on the electrodes. Several methods have been explored for the heterogenization of homogeneous complexes, we here report a novel approach using a hierarchical porous carbon material, derived from a Metal Organic Framework, as a support for the well-known molecular catalyst [Re(bpy)$(CO)_3$Cl] (bpy = 2,2'-bipyridine). This cathodic hybrid material, named Re@HPC, has been tested for CO_2 electroreduction using a mixture of an ionic liquid (1-Ethyl-3-methylimidazolium tetrafluoroborate, EMIM) and water as the electrolyte. The present study reveals that thanks also to the hierarchical porosity and structure of the porous carbon, the Re@HPC is a remarkable catalyst, enjoying excellent activity (high current densities and high turnover numbers) and good stability. Interestingly, it catalyzes the conversion of CO_2 into a mixture of carbon monoxide and formic acid, with a selectivity that depends on the applied potential. These results emphasize the advantages of integrating molecular catalysts onto such porous carbon materials for developing novel, stable and efficient, catalysts for CO_2 reduction.

12:25 PM EN02.01.05
Dynamic Surface Structure of Cu Thin-Film Electrode Under CO_2 Reduction Conditions from *In Situ* X-Ray Characterization Soohong Lee[1], John C. Lin[2,3], Apurva Mehta[3], Ryan C. Davis[3], Thomas Jaramillo[2,3], Christopher Hahn[3] and Walter Drisdell[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Stanford University, United States; [3]SLAC National Accelerator Laboratory, United States

Identifying the chemical state of the catalytic surface at the electrode-electrolyte interface is of significant interest, but the *in situ* characterization of the active surface during the CO_2 reduction reaction (CO_2RR) remains challenging due to the formation of bubbles from gaseous products and mass transport limitations. These hurdles limit state-of-art *in-situ/operando* techniques from characterizing catalyst surfaces under the reaction conditions. In particular, there is great interest in whether Cu oxide species exist at the surface or near-surface of Cu-based CO_2RR catalysts under these conditions, and if such species play a role in the catalytic pathway to multi-carbon products.
Here, we conducted *in-situ* characterization of the atomic and electronic structure of the near-surface of a Cu thin-film using synchrotron X-ray methods under the high current CO_2RR conditions relevant for device operation. The structural evolution of the near-surface region of polycrystalline Cu electrodes under *in situ*

conditions was investigated through a combination of grazing incidence X-ray absorption spectroscopy (GIXAS) and X-ray diffraction (GIXRD). The *in situ* GIXAS shows that the surface oxide is fully reduced to metallic Cu before the onset potential for CO_2RR, and the catalyst surface retains the metallic state across the potentials relevant to the CO_2RR. In addition, *in-situ* GIXRD results showed that potential-dependent surface reconstruction from polycrystalline Cu to a Cu(100)-like surface was observed only in the presence of CO_2 reactants. Previously believed to be a soley potential-induced effect, our findings suggest that surface reconstruction is increased by the CO_2RR chemistry and that this reconstruction occurs across the macroscopic (mm-scale) surface. These findings show that the surface of Cu electrocatalysts is dynamic during the CO_2RR, and underscore the need for *in-situ* studies to accurately understand the catalyst surface state during catalysis.

12:45 PM EN02.01.06

Carbon Dioxide Capture and Electrochemical Conversion with Ionic Liquids Alessia Fortunati[1], María José Rubio[1], Boyan Iliev[2], Nunzio Russo[1] and Simelys Hernandez[1]; [1]Politecnico di Torino, Italy; [2]Iolitec Ionic Liquids technologies GMBH, Germany

The exponential increase in the concentration of greenhouse gasses in the atmosphere is considered one of the most important reason for climate change. Carbon Dioxide is the most significant anthropogenic gas that contributes in global warming.
CO2 capture and storage (CCS) has been proposed as one of the most important invention to mitigate CO2 emissions. Moreover, conversion of carbon dioxide into energy-rich chemicals is a viable approach to reducing the global carbon footprint. The most common techniques to remove CO2 from gas streams are the chemical and physical adsorption by liquid solvents. Traditionally, aqueous amine solutions have been used as chemical solvents because of their high selectivity, high reactivity and low price. Unfortunately, they present also many disadvantages associated with the high energy demand required for the solvent regeneration, corrosion issues and loss of solvent because of their high volatility. Hence, in the need to find more efficient solvents for CO2 capture and conversion, Ionic Liquids (ILs) have been highlighted as very good alternatives to common amine solution. (1)

Within this field lies this research, which in turn is part of a much broader European project called SunCoChem. For this project we are testing the stability and performance of various ionic liquids, provided by Iolitec Ionic Liquids technologies GMBH, and in particular their ability to capture and electrochemically convert a pure CO2 stream to CO with high efficiencies.

The ionic liquids were tested in a two-compartment H-type electrochemical cell. In the anodic chamber a nickel mesh electrode was immersed in a solution of potassium hydroxide and in the cathodic one a silver foil cathode was employed in a solution of CH3CN and ionic liquid. An organic solvent was used to favor the dissolution of the ionic liquid and the homogenization of the solution. The Ionic Liquids (ILs) tested so far have a cationic part based on imidazole, which is expected to stabilize and lower the activation energy for the reduction of CO2, namely [BMIM][BF4], [BMIM][CH3CO2], [BMIM][CF3CO2] and [BMIM][CF3SO3]. This trend was confirmed by a shift to more positive potentials of the onset (~ 0.5V) for the CO2 reduction reaction in the presence of these Ionic Liquid.
During the CP studies, some ILs evidenced a decrease in the applied potential indicating the increase of the electrolyte conductivity on difference to the behavior of the most commonly used [BMIM][BF4] IL in the same organic solvent.

Our results evidence relevant current density values, a good stability during chronopotentiometry (CP) tests and a high selectivity towards the target product: CO, which however change depending on the used IL.

Influence of Sonication on Co-Precipitation Synthesis of Copper Oxide Catalyst for CO_2 Electroreduction

Daniela Roldán[1], Hilmar Guzmán[1,2], Nunzio Russo[1] and Simelys Hernandez[1,2]; [1]Politecnico di Torino, Italy; [2]Center for Sustainable Future Technologies, Italy

The need to reduce greenhouse gas emissions and increase our energy supply makes the electrochemical reduction of CO_2 (CO_2R) a very attractive alternative to produce non-fossil-based fuels or chemicals. Copper-based catalysts is one of the catalyst that most efficiently promote the formation of species with one or more carbon-carbon bonds from the electrochemical reduction of CO_2 [1]. Because the catalyst preparation method has an influence on the physicochemical properties and on the electrocatalytic performance[2], in this work, it was decided to evaluate the effect of the ultrasound application (US) on the shape and size of the particles obtained, its electrocatalytic activity and its selectivity to products of interest. For this purpose, sonication was carried out at different percentage amplitudes of ultrasonic power (23, 30 and 37%) during the aging time of the synthesis. Physical characterization was carried out by using different techniques including X-ray diffraction, BET and filed-emission scanning electron microscopy (FESEM). Electrochemical tests for CO_2 reduction were done under ambient conditions. Regarding the physical characteristics, we found that pore size distribution is narrower by increasing the US amplitude. On the other hand, there is no significant difference in morphology and dimension of particles. However, the surface area increased with the use of ultrasound, this is attributed to a better dispersion created by acoustic cavitation. Ultrasound has also an effect on Copper-based catalysts performance; in this case, the selectivity towards H_2 and C_1 products (CO and formate) was enhanced. In addition, an increase in productivity of CO_2R products was obtained with respect to the synthesized catalysts that were not assisted by ultrasound (> 3-fold). These results motivate us to further explore in what other ways acoustic cavitation phenomenon can influence the physical characteristics of the catalysts and, in turns, their performance for the electrochemical reduction of CO_2.

Copper-Based Systems for CO_2 Reduction—From an Electrochemical to a Photoelectrochemical Approach

Jonathan Albo; University of Cantabria, Spain

To reverse the impact of increasing CO_2 emissions would need not only curbing the reliance on fossil fuels but also developing effective strategies to capture and utilize CO_2. There are also increasing attempts to consider CO_2 as a resource and a business opportunity rather than a waste with a cost of disposal. Among the several available strategies, the electrochemical reduction of CO_2 to produce value-added chemicals becomes a feasible mechanism of storing intermittent renewable energy that is entering the stage of gradual implementation [1]. When electrochemical reduction integrates a light source to provide energy for redox reactions, we have a

photoelectrochemical device, which have attracted an intense attention in recent years [2]. In principle, such integration enables higher energy efficiency by reducing the requirements of external energy and by reducing losses in transporting electricity to the electrolysis cell. Ideally, these systems may be completely operated under the sun without the need of an external bias between cathode and anode compartments, which may additionally reduce system capital costs [3].

Since CO_2 is a thermodynamically stable molecule, its multistep reduction confronts many fundamental technical hurdles. The kinetics for CO_2 reduction are also, in general, more sluggish than the thermodynamically favorable two-electron H_2 evolution reaction, which competes with CO_2 reduction. The electro-and-photoelectro-chemical processes are thus highly dependent on the development of efficient materials capable of selectively reducing CO_2 at low overpotentials. Of the myriad cathode materials that have been used, copper and copper oxides are regarded unique with both intermediate hydrogen overpotentials and CO adsorption [4] allowing further reduction of CO_2 to fuels and commodity chemicals such as methanol [5] or ethylene [6] at moderate reaction rates.

With this communication, the author presents the research activities in the electro-and-photoelectro-chemical conversion of CO_2 to alcohols and hydrocarbons at copper-based systems in the DePRO research group of the University of Cantabria, to provide new insights and guidance to the field. A filter-press dual-chamber cell is used for the continuous conversion of CO_2 under different phases involved (i.e. gas or liquid-phase), electrode/cell designs (e.g. GDE, MEA or photoanode/photocathode) and key operating conditions. Many of these factors are often intertwined, which complicates advances in the field, but with continued research efforts these sustainable technologies for CO_2 conversion might become technically and economically feasible in the near future.

ACKNOWLEDGEMENT

The author gratefully acknowledge the financial support from the Spanish Ministry of Science and Innovation (MICINN) through the project PID2019-104050RA-I00 as well as Ramón y Cajal programme (RYC-2015-17080).

Optimizing Organic Electrosynthesis Through Electrochemical Engineering Approaches and Bayesian

Machine Learning Miguel A. Modestino; New York University, United States

The chemical industry propelled human progress by using energy from fossil fuels and, in the process, inadvertently contributed to anthropogenic climate change. This industry outputs >70,000 products (1.2 billion tons in total), impacts more than 25% of the US GDP, and is responsible for ~5% of the US primary energy consumption (4.5 Quads). Thermochemical processes in this industry account for >93% of this energy consumption (>87% in the form of fossil-fuel-derived heat). Decarbonization of this industry would represent a giant step towards mitigating global warming. This urgent transition must integrate renewable energy sources with chemical manufacturing, ultimately resulting in the electrification of this industry *via* large-scale implementation of electrochemical manufacturing. Currently, however, two major challenges prevent the deployment of electrosynthesis reactors at scale: their low selectivity and their low production rates. This presentation will discuss reaction engineering opportunities to enhance the performance of organic electrosynthesis reactors. Specifically, I will present our work on understanding and improving the electrohydrodimerization process for the production of adiponitrile (ADN), a precursor to Nylon 6,6. Although this model reaction is the largest and most successful organic electrosynthesis implemented in industry, it faces many challenges owing to its limited energy conversion and selectivity. Through a combination of experimental electroanalytical characterization and Bayesian machine learning, we elucidate guidelines for the optimal operation of ADN electrosynthetic reactors. Our results provide insights into mass transport limitations that affect the selectivity of organic electrosynthesis processes and on how to dynamically control electrode processes to mitigate them.

Mass Transport Considerations for High Performance CO_2 Electrolysers Wilson Smith[1,2]; [1]National Renewable Energy Laboratory, United States; [2]University of Colorado Boulder, United States

Electrocatalytic CO_2 reduction has the dual-promise of neutralizing carbon emissions in the near future, while providing a long-term pathway to create energy-dense chemicals and fuels from atmospheric and waste CO_2. The field has advanced immensely in recent years, taking significant strides towards commercial realization. Gas diffusion electrodes (GDEs), composed of solid electrocatalysts on porous supports positioned near the interface of a conducting electrolyte and CO_2 gas, have been able to demonstrate the substantial current densities needed for future commercialization. These higher reaction rates have often been ascribed to the presence of a three-phase interface, where solid, liquid, and gas provide electrons, water, and CO_2, respectively. Conversely, mechanistic work on electrochemical reactions implicate a fully two-phase reaction interface, where gas molecules reach the electrocatalyst's surface by dissolution and diffusion through the electrolyte. Here, we first outline the macro, micro and atomistic phenomena occurring within a gas-diffusion electrode to provide a focused introduction to the architecture of the often-discussed three-phase region for CO_2 electrolysis. In addition, we use a 2-D model to examine the concentration gradients in the gas and electrolyte flow channels across a GDE, which provides longitudinal information along the length of a flow cell. In doing so, we quantify the extent of concentration overpotentials and ohmic drops throughout the catalyst layer across a range of applied potentials and flow rates. Various process parameters were modified to explore the effects on the CO_2 mass transfer-limited current density, conversion, and outlet concentrations of CO_2, CO and H_2. Our model suggests that ohmic losses largely determine the current density distributions at low conversion rates where small gradients in concentration exist. However, as the concentration profiles become less uniform (e.g. high conversion rates), the non-electrochemical consumption of CO_2 starts to overtake electrochemical conversion, and leads to non-uniform performance across the electrode. In addition, while higher flow rates allow the ability to substantially increase current density, this comes at the expense of ohmic drops and losses in selectivity, which become more prominent at high conversion rates. The ability to understand the interplay between process conditions and local environment will be necessary to further develop the science and technology of electrochemical CO_2 reduction.

Nanoporous Au and Cu Gas Diffusion Electrodes for Selective, High Current Density Carbon Dioxide Reduction Aidan Q. Fenwick[1,2], Alex J. Welch[1,2], Ian Sullivan[2] and Harry A. Atwater[1,2]; [1]California Institute of Technology, United States; [2]Joint Center for Artificial Photosynthesis, United States

Nanoporous (NP) transition metals offer a high surface area and edge-rich catalytic environment capable of selective electrolysis of carbon dioxide (CO_2) when utilized as a catalyst in a gas diffusion electrode (GDE). While the copper and gold have been extensively explored as catalysts for the carbon dioxide reduction reaction (CO_2RR) in both aqueous and vapor fed electrolyzes, a fully nanostructured catalytic environment remains unexplored. Here, we report the development and electrochemical performance of NP gold and copper GDEs deposited on a carbon or polytetrafluoroethylene (PTFE) microporous layer (MPL). NP GDEs are synthesized by vapor deposition of an alloy onto the MPL followed by a chemical or electrochemical dealloying process that yields a continuous porous electrode with nanoscale dimensions forming a NP catalyst layer. The average ligament and pore sized can be tuned by varying the temperature, solvent and length of the dealloying process. We observe that carbon paper-based, NP GDEs are prone electrolyte flooding due to the hydrophilicity of the bare metal surface. The contact angle of the NP GDE can be tailored from 40º to 150º via a 2 step application of 1) Nafion ionomer and 2) Nafion:carbon black mixture applied to the NP GDE. This system is capable of electrochemical generation of carbon monoxide with a partial current density of 650 mA/cm^2 in a 250mM $KHCO_3$ electrolyte that can be maintained for over 48 hours of continuous electrolysis. We will also report results of experiments of NP Cu/Au on PTFE and the effects of ligament thickness, pore size, catalyst structure and hydrophobicity on CO_2RR. These studies demonstrate that nanoporous catalyst environments can play an important role in governing the product selectivity and achievable current density of CO_2RR in a GDE.

Stabilization of Local pH Gradient and Separation of Product Gases by Buoyancy-Driven Fluid Dynamics in Solar-Driven Water Splitting Keisuke Obata and Fatwa F. Abdi; Helmholtz-Zentrum Berlin, Germany

In order to achieve a sustainable society driven by the abundant solar energy, the intermittency of sunlight needs to be overcome. One attractive solution is to store solar energy in the form of chemical fuels, e.g., the generation of hydrogen and oxygen in solar-driven water splitting. To this end, tremendous efforts have been devoted to developing efficient semiconductors and electrocatalysts, which resulted in a significant improvement of the reported solar-to-fuel efficiency in the last couple of decades. As the next stage, designing device architectures that are scalable and efficient is paramount in order to fully translate the developed materials towards practical applications. Indeed, it has been shown that major performance losses can be obtained from ineffective design,[1,2] especially when scaling-up devices to larger area. A key component of the device operation is the fluid dynamics, as it plays an important role to determine the mass-transport phenomena in the device and the resultant energy efficiency. In this study, we highlight the buoyancy effects driven by (photo)electrochemical reactions and evaluate their influences on the ion distribution in the electrolyte solutions and product separation.

In the first part, pH changes during water splitting in a stagnant electrochemical cell with near-neutral electrolyte are monitored in-situ by a pH-sensitive fluorescence sensor foil placed between the anode and cathode. Electrolyte close to the anode and cathode gets more acidic and more alkaline, respectively, in unbuffered and buffered neutral-pH conditions. A closer look at the pH distribution within the cell further reveals that natural convection is generated by the electrochemical reactions under non-stirred conditions. Specifically, at low current densities ($\leq$ 2 mA/cm^2), the acidic and alkaline regions move to the top and bottom of the cell, respectively. Based on this observation, we develop a model that considers natural convection driven by buoyancy forces due to local changes in the density of the electrolyte, which reveals that buoyancy-driven convection significantly helps to stabilize local pH gradients. Our extended simulations further predict the great contribution of buoyancy-driven convection towards the production of value-added aqueous chemicals even at high current density range.

Buoyancy-driven fluid dynamics is also considered in terms of product separation in a solar-driven water splitting device. We consider a membrane-less flow cell as an attractive technique to separate gaseous products through the electrolyte flow without having any membrane-associated complexity and losses. We introduce Euler-Euler multiphase fluid dynamics simulations, which calculate the volume fraction of liquid and gas phases, to investigate the crossover in the presence of gas bubbles. We specifically consider realistic implementation of solar-driven water splitting device by taking into account the tilt orientation of the device. Our simulations reveal that gas bubbles, often ignored in previous studies,[2,3] contribute more to the crossover rather than dissolved gases. We also extensively evaluate various important parameters that affect the overall product crossover, e.g., the device tilt angle, bubble diameter, bubble formation efficiency, etc. For example, smaller gas bubbles are found to suppress the crossover due to the stronger momentum exchange between the liquid and gas phases. This suggests the potential benefit of using surfactants, which are known to decrease the bubble diameter, for efficient product separation in membrane-less devices. Overall, our study highlights the critical importance in understanding and controlling the bubble formation under operating conditions to design efficient membrane-less water splitting devices.

3:20 PM ORAL Q&A

3:40 PM EN02.02.07
Strategies for improving GDE Performance by a Uniform Dispersion of Catalyst Nanoparticles and an Optimal Nafion Content Federica Zammillo[1], Hilmar Guzmán[1,2], Nunzio Russo[1] and Simelys Hernandez[1,2]; [1]Politecnico di Torino, Italy; [2]Istituto Italiano di Tecnologia, Italy

In the context of the strategies needed to mitigate CO_2 emissions and combat climate change, the electrochemical CO_2 reduction represents a promising alternative. Among the different reactors, GDE-based ones are widely studied systems: here, the limitations shown by configurations with CO_2 dissolved in electrolyte solutions can be overcome by feeding CO_2 directly in gaseous form. In this work, the manufacturing process of the Cu-based gas diffusion electrode, namely the catalytic ink deposition on a porous carbon paper support, was carried out both by airbrushing (manual) and by spray-coating (automated) techniques. The characterization of the electrodes was performed by using X-Ray Diffraction, X-Ray Photoelectron Spectroscopy and Field Emission Scanning Electron Microscopy techniques. To assess electrodes behavior, cyclic and linear sweep voltammetry techniques were conducted. When comparing the achieved current densities at the highest applied potential, the electrode obtained with the spray coater displayed a better electrocatalytic activity (~10 mA/cm^2 higher at about -2.5 V vs Ag/AgCl), with respect to that fabricated with the airbrush. A thorough study of the GDEs performance was accomplished, testing the so obtained electrodes and thereby evaluating the effect of a variation of Nafion content in the productivity and selectivity results toward the desired products. A promising outcome was achieved when boron (B) has been incorporated in the Cu-catalyst material: indeed, in this case, the hand-made GDE revealed a FE of about 6% toward alcohols (mostly ethanol). The catalyst layer dispersion is a critical aspect of electrochemical CO_2 reduction and, confirming previous studies on the different deposition methods, a more uniform distribution of the catalyst particles enabled the spray coated GDEs to outperform the hand-made ones. Furthermore, the variation of Nafion content on the GDE structure had a relevant effect on the electrode performance, allowing to considerably reduce the side-production of hydrogen and increasing at the same time the CO generation. Finally, the role of local pH was taken into account: a preliminary model highlighted that a higher pH on the electrode surface may promote the hydration of CO_2 to carbonate and bicarbonate species, thus lowering CO_2 concentration at the triple-phase-boundary and hindering liquid products formation.

Late News: Nitrogen Vacancy Enhanced Ni3N/Ni Catalyts for Si Photocathodes with High Activity and Stability Doudou Zhang; The Australian National University, Australia

Magnetron sputtering is a scalable and eco-friendly approach of developing high-performance non-noble electro(co)catalysts with strong adhesion for durability. Herein, a 3D triangular pyramid nickel nitride with tunable nitrogen vacancies was created through magnetron sputtering, which is different from conventional nitridation process with high temperature and hazardous resource. Continuous sputtering the Ni_3N/Ni catalysts with poor-crystalline and good wettability delivered 99 mV overpotential at 10 mA cm^{-2}, a Tafel slope of 28 mV dec^{-1} and durability 75 hours, which is approximate to Pt sputtering on FTO and exceeds the other reported catalysts on the plannar substrates in alkaline media. Based on the theoretical calculations, it is further verified that the presence of nitrogen vacancies effectively enhances the adsorption of water molecules and ameliorates the adsorption-desorption behavior of intermediately adsorbed hydrogen, which leads to an advanced HER activity of Ni_3N/Ni. Then, the Ni_3N/Ni grown on c-Si photocathode showed the current density of 37.3 mA cm^{-2} at 0 V RHE with 0.6 V onset potential, and applied bias photon-to-current efficiency (ABPE) 8.9% toward PEC-HER with stability in strong media 50 hours including the power on-off and continuous reaction. DFT calculations verified the surface structure with N-vacancies surface and high HER activity of the Ni_3N/Ni catalyst under working conditions. The demonstration has showed the potential for practical, large-scale manufacturing of the nitrides cocatalysts for composite photoelectrodes.

Electrolyte Effects on the Electrochemical Reduction of CO_2 Chong-Yong Lee, Jinshuo Zou and Gordon Wallace; University of Wollongong, Australia

Electrochemical reduction of CO_2 offers an eco-friendly recycling strategy in producing economically valuable fuels and chemical feedstocks. This process is readily tuned by employing suitable electrocatalysts, electrolytes, and electrochemical cell configurations to achieve preferred products. The nature of the anions and cations used in the electrolyte, could either having neutral, promoting or detrimental effect on the CO_2 electroreduction; underlying the complexity of such electrocatalytic reaction. This talk will present two recent studies on how the electrolytes could significantly influence the CO_2 electroreduction performance. The dramatic influence of electrolyte alkalinity in widening the potential window for CO_2 electroreduction in a flow-cell system utilized SnS catalyst will be discussed. Alkaline electrolyte was found suppressing the H_2 evolution across all potentials particularly at the less negative potentials, as well as suppress CO evolution at more negative potentials. This in turn widens the potential window for formate conversion. Mechanistic aspects of the role of alkalinity in widening the electrochemical potential window will be elucidated. In another study, seawater was employed as an electrolyte for CO_2 electroreduction. Under the applied cathodic potential and in the presence of CO_2, calcium ions in the seawater resulting in detrimental effect of calcium carbonate deposition onto the catalyst surface. We proposed a strategy in preventing calcite deposition onto the catalyst, hence enabling seawater to be used as a viable electrolyte for CO_2 electroreduction.

10:30 AM *EN02.03.01
Selectivity Tuning of CO_2 Electroreduction Catalysts Under Dynamic Reaction Conditions Beatriz Roldan Cuenya; Fritz Haber Institute of the Max Planck Society, Germany

The utilization of fossil fuels as the main energy source gives rise to serious environmental issues, including global warming caused by the continuously increasing level of atmospheric CO_2. The electrochemical conversion of CO_2 (CO_2RR) to chemicals and fuels driven by electricity derived from renewable energy has been recognized as a promising strategy towards sustainable energy.
In my talk I will provide examples of the dynamic transformations undergone by well-defined CO_2RR catalysts (e.g. Cu single crystals, Cu nanocubes) under reaction conditions and their influence on the catalyst selectivity. In particular, I will discuss how important morphological motives and chemical sites can be created and regenerated in potentiodynamic (pulsed) electrochemistry experiments. Additionally, the determining role of the electrolyte in the surface restructuring, reaction activity and selectivity will be illustrated.
In situ and *operando* characterization methods (e.g. EC-AFM, Liquid-TEM, LEEM/XPEEM, XAS, XPS, XRD) will be used to gain in depth understanding on the structure- and electrolyte-sensitivity of real CO_2RR catalysts under working conditions. Our results are expected to open up new routes for the reutilization of CO_2 through its direct selective conversion into higher value products such as ethylene and ethanol.

10:55 AM EN02.03.02
Influence of Fe-Dopant Clustering on the Activity and Selectivity of MoS_2 Towards Nitrogen Reduction Reaction Akash Jain[1], Maya Bar-Sadan[2,2] and Ashwin Ramasubramaniam[1]; [1]University of Massachusetts Amherst, United States; [2]Ben-Gurion University of the Negev, Israel

The Haber-Bosch process is widely used in the fertilizer industry for ammonia (NH_3) production, but it depends heavily on fossil fuels and involves very high temperatures and pressures. The electrochemical nitrogen reduction reaction (NRR) when combined with renewable sources of energy potentially offers a sustainable and fossil-fuels-free route for NH_3 production at moderate temperatures and pressures. However, for scalable NRR, a highly active, selective, and low-cost electrocatalyst is still needed, which motivates the search and rational design of NRR electrocatalysts. Recently, molybdenum disulfide (MoS_2), a layered transition metal dichalcogenide, has attracted significant interest as an NRR electrocatalyst, because of its highly catalytically active edges and defect sites on the basal plane. Yet, MoS_2 shows overall poor NRR activity and selectivity because of the high thermodynamic energy barriers, sluggish reaction kinetics, and relatively unfavorable thermodynamics than the competing hydrogen evolution reaction (HER). Here, we show that substitutional doping of MoS_2 monolayer with iron (Fe) dopants can improve significantly its NRR activity and selectivity. Using density functional theory (DFT) calculations, we study the influence of isolated Fe-dopant and clusters of Fe-dopants on the stability and local structure of MoS_2 basal plane and edges. Also, we study the thermodynamics of three competing reactions: NRR, HER, and electrochemical desulphurization reaction on the basal plane, and edges of undoped and Fe-doped MoS_2 monolayers. Key finding from our study is that Fe-doping promotes the formation of S-vacancy (V_S) sites on MoS_2 and clustering of Fe-dopants in the basal plane results in the spontaneous (thermodynamically favorable) formation of Fe-dopants and S-vacancy defect (Fe-V_S) complex. The Fe-V_S complex renders Fe and Mo atoms available for NRR reaction intermediates and substantially suppresses HER, increasing the NRR selectivity of MoS_2. Overall, our DFT calculations highlight the role of Fe-dopants in improving the NRR activity and selectivity of MoS_2 and rationalize the observations of recent experiments on Fe-doped MoS_2 nanoflowers that display significantly improved NRR faradaic efficiency and yield compared to undoped MoS_2 nanoflowers.

11:00 AM EN02.03.03
Electronic Structure Based Intuitive Design Principle of Single-Atom Catalysts for Efficient Electrolytic Nitrogen Reduction Ritesh Kumar and Abhishek K. Singh; Indian Institute of Science, India

As an alternative to the cost-and energy-intensive Haber-Bosch process, the implementation of electrolytic ammonia synthesis from the dinitrogen molecule has been a long-sought goal. State-of-the-art electrocatalysts for nitrogen reduction reaction (NRR) face not only activity but also selectivity problems with the competitive hydrogen evolution reaction (HER). Recently, single-atom catalysts (SACs) have emerged as promising for various reactions as they combine the best of homogeneous and heterogeneous catalysts. The reason for their high activity compared to their bulk and nanoparticle counterparts are yet to be completely understood. Inspired by the structure of the nitrogenase FeMo cofactor, we studied 13 transition metals anchored on MoS_2 monolayer at Mo-top positions, as possible electrolytic NRR catalysts using first-principles methods. Employing the implicit solvation model, we calculated free energy barriers for proton abstraction by N_2 molecule in end-on configuration and adsorption free energy of hydrogen on all SACs. Based on these two parameters, Fe, Co, and Ru were found to be the most active and highly selective electrolytic NRR catalysts. Compared with other mechanisms, the limiting potentials (and hence activity) for enzymatic mechanisms were found to be higher on these three SACs, with Ru SAC having a very low overpotential of 0.38V versus Standard Hydrogen Electrode (SHE). Bader charge transferred from transition metal to N_2 molecule and group number of transition metals correlate strongly with the NRR activity and hence emerge as two key descriptors for catalytic activity. These intuitive principles for rational designing of promising alternatives to the currently used bulk Ru(0001) catalyst could accelerate the search for highly efficient and selective SACs for electrolytic NRR.

11:05 AM EN02.03.04
Mechanistically Understanding of PEC Self-Improving Si/GaN Photocathode Using Suite of Advanced Characterization Techniques and First-Principle Calculation Guosong Zeng[1], Tuan Anh Pham[2], Srinivas Vanka[3], Guiji Liu[1], Zetian Mi[3], Tadashi Ogitsu[2] and Francesca Maria Toma[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Lawrence Livermore National Laboratory, United States; [3]University of Michigan–Ann Arbor, United States

To advance the application of solar water splitting for renewable energy, tremendous works have been put on the development of state-of-the-art protective coatings for long-term stability and high efficiency, whereas more effort needs to be focused on the fundamental study of materials' stability/degradation mechanisms. In this work, we report Si/GaN photocathodes for sustained hydrogen production via a self-improving mechanism. By employing state-of-the-art characterization techniques, we show the presence of an oxynitride-like layer, which behaves similarly to electrocatalyst for better mediating charge transfer. DFT simulation shows that replacing the nitrogen atoms by oxygen to form oxynitride can not only passivate the surface for further stability, but also provide more active sites for HER. This work also sets a prototype for fundamental understanding of stability mechanism of protective layers in PEC water splitting application, and the gained knowledge provides feedback for development of further improved design of durable and efficient photoelectrode.

11:10 AM EN02.03.06
Late News: Operando Spectroelectrochemical Observation of Surface States and Active Sites in Chalcopyrite Photocathodes for Solar Water Reduction Yongpeng Liu, Néstor Guijarro and Kevin Sivula; Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland

Photoelectrochemical (PEC) water splitting is emerging as a technology that could potentially sustain a low-carbon hydrogen-based economy. Among the different photoactive materials suitable for operation in a PEC device, $Cu(In,Ga)S_2$ (CIGS) is drawing increasing attention as a photocathode owing to its outstanding optoelectronic properties and tunable band gap. However, serious bottlenecks for the implementation of this material arise from the costly fabrication of PV-grade thin-films using non-scalable vacuum techniques, and the need for overlayers/catalysts to extract charges and perform the hydrogen evolution reaction.

Recently, we reported an all-solution-processed CIGS photocathode that demonstrates a significant and stable photocurrent response towards water reduction, even in the absence of overlayers or co-catalysts. Although the photocurrent onset potential is substantially negative with respect to the flat-band potential, the bare CIGS photocathode offers an intriguing system for gaining fundamental insights. Motivated by its intrinsic catalytic

properties and unsatisfactory photovoltage, we combined three complementary operando spectroelectrochemical techniques including photoelectrochemical impedance spectroscopy (PEIS), intensity-modulated photocurrent spectroscopy (IMPS) and operando Raman spectroscopy with density-functional theory (DFT) calculations to understand the fate of photogenerated charge carriers. Through PEIS, photoluminescence spectroscopy and DFT calculations, we resolved atom-specific surface trapping states that restrict the photovoltage of CIGS. In addition, we performed the first operando Raman study on CIGS photocathodes where we identified the catalytically active sites. Computational methods further confirm these sites requiring the least free energy to adsorb protons for hydrogen evolution reaction. Overall, these fundamental findings suggest the composition of an improved surface for defect passivation and active sites exposure, which paves the way for rational design of this material for PEC water reduction.

Late News: Electronic Excitations of α-Fe2O3Thin Films Measured by Resonant Inelastic X-Ray Scattering at the Fe LIII-Edge—Momentum, Temperature and Dopant Dependence David S. Ellis[1], Ru-Pan Wang[2,3], Deniz Wong[4], Jason K. Cooper[5], Christian Schulz[4], Yi-De Chuang[5], Yifat Piekner[1], Daniel Grave[1,6], Markus Schleuning[7], Dennis Friedrich[7], Frank M. de Groot[8], Roel Van de Krol[7] and Avner Rothschild[1]; [1]Technion–Israel Institute of Technology, Israel; [2]University of Hamburg, Germany; [3]Deutsches Elektronen-Synchrotron DESY, Germany; [4]Helmholtz-Zentrum Berlin für Materialen und Energie, Germany; [5]Lawrence Berkeley National Laboratory, United States; [6]Ben-Gurion University of the Negev, Israel; [7]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; [8]Debye Institute, Utrecht University, Netherlands

Hematite (α-Fe_2O_3) is a promising candidate for a photoanode material for photo-electrochemical hydrogen production, meeting several key criteria. A photoanode's performance depends on optical absorption and electronic transport, which are manifestations of its electronic structure. In spite of hematite's Earth abundance and deceptively simple chemical formula, the electronic and magnetic interactions arising from its Fe d^5 orbitals and neighboring oxygens, and longer range interactions, is surprisingly intricate. Here we interrogate hematite's electronic structure with Resonant Inelastic X-Ray Scattering (RIXS). After a brief introduction to the technique, we present our Fe L_{III}-edge RIXS spectra of heteroepitaxial hematite thin films, both undoped and variously doped, measured for several momentum transfers (**q**), at both low temperature (T=14K) and room temperature. Although there could be some weakly dispersive excitations present in the spectra, a possible sign of charge transfer excitations, we conclude that the bulk of the observed L_{III}-edge RIXS intensity in the visible range originates from ligand-field d-d excitations, which is corroborated with the help of spin-multiplet simulations. The temperature dependence, which showed some highly temperature-sensitive features, identically for undoped, 1% Sn-doped, and 1% Zn-doped samples, is discussed.

Late News: Electronic Structure Modulation of ManganeseIncorporated Ni2P Leading to Enhanced Activity for Water Splitting Lakshay Dheer; Jawaharlal Nehru Centre For Advanced Scientific Research, India

The cornerstone of the emerging hydrogen economy is hydrogen production by water electrolysis with concomitant oxygen generation. Incorporating a third element in metal phosphides can tune the crystalline and electronic structure, hence improving the electrocatalytic properties. In this work using first-principles theoretical calculations, Mn-substituted Ni2P has been explored as an excellent catalyst for water splitting. The catalytic activity of Ni2P improves drastically on Mn-substitution for hydrogen evolution reaction as we obtain a close to optimum ΔGH (-0.14 eV) and the work function of Ni1.5Mn0.5P which falls just below the hydrogen reduction potential. The oxygen evolution activity of Ni2P is also explored upon Mn-substitution. We find a 32% reduction in the overpotential (η) towards OER for Ni1.5Mn0.5P. The effect of surface oxygen (metal-

oxides) species on the catalytic performance of Ni1.5Mn0.5P is further studied and the η further reduces thus improving the OER activity of the catalyst. We show that substitution of a second metal species in metal phosphides alters the electronic structure and induces synergistic interactions in the system leading to an enhanced catalytic activity towards water splitting.

Understanding Charge Transport in Transition Metal Oxides with Novel First-Principles Computational Methods Marco Bernardi; California Institute of Technology, United States

Advances in first-principles calculations enable accurate predictions of charge carrier mobility and scattering mechanisms in semiconductors. However, many transition metal oxides of technological interest remain an open problem as they exhibit soft phonon modes due to structural phase transitions, strong electron-phonon (e-ph) interactions leading to polaron effects, and electron correlation due to open *d* shell, or combinations of these features.

This talk will present a range of new ab initio approaches for treating e-ph interactions and charge transport in oxides. We will first present methods to address soft phonon modes and large-polaron effects, and demonstrate their application to SrTiO3 perovskite as a paradigmatic case. A recent study of a wide range of oxides with room temperature mobilities ranging from low to high will then be presented, highlighting materials design rules for high mobility. The second part of the talk will focus on recent progress, including studies of e-ph interactions in the frameworks of DFT+U and dynamical mean field theory, and their application to understanding the transport properties of various transition metal oxides. If time permits, we will briefly discuss a new approach to predict the formation of self-localized (small) polarons in oxides with inexpensive e-ph calculations.

EN02

1:00 PM *EN02.04.01
Modeling, Design and Optimization of Robust Photoelectrodes Sophia Haussener; EPFL, Switzerland

Photoelectrochemical (PEC) approaches for the processing of solar fuels and materials are interesting, provided they can be efficiently, stably, scalably, and sustainably implemented.
There is still significant process required on the development of earth abundant and efficient but also stable and robust materials. The rapid identification of novel and promising photoelectrode materials or components is needed in order to provide a faster turnover of potential novel candidate materials (and different synthesis processes). Identifying and quantifying the key parameters limiting the efficiency and the stability of the photoelectrodes is fundamental to providing material and mesostructural design guidelines. This quantification is experimentally not accessible given by the multi-physical nature of the processes taking place in the photoelectrodes. Computational modeling can provide the necessary insights but requires the detailed knowledge of material parameters that are often unknown for new photoelectrode materials and requires to account for the complex mesostructured of the photoelectrode.
First, I will discuss versatile and validated computational models that allow for the material characterization, material parameters optimization, and mesostructural optimization of photoelectrodes. I will distinguish between involved multi-dimensional and multi-scale models and rapid screening models based on analytical

correlations. I will then show how models can be extended to incorporate degradation (specifically photocorrosion) processes in order to understand and increase stability. I will show how important the local reaction environment is for the stability of a component, and how heterogeneity in the operating variables (current density, species concentration, temperature, etc.) affect degradation. I will end with providing general guidelines on materials and component integration into efficient and stable photoelectrodes and full devices, while also discussing the robustness of material and device efficiency and stability when exposed to varying, non-design-point operating conditions (such as will be expected in on-sun operation).

Recent Progress on Oxide-Based Tandem Devices for Solar Water Splitting Roel Van de Krol[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; [2]Technische Universität Berlin, Germany

Practical photoelectrochemical devices for solar water splitting should generate photovoltages in excess of 1.7 V to reach viable efficiencies. Currently, the only practical way to achieve this is to combine two or more absorbers in a tandem configuration. With silicon being a nearly ideal candidate as a bottom absorber, the main challenge is to find a suitable top absorber material that combines good chemical stability with a bandgap of around 1.9 eV. I will discuss recent progress on $Cu_5V_2O_{10}$, b-$Cu_2V_2O_7$, α-$SnWO_4$, and $CuBi_2O_4$, all of which have a bandgap that is close to the ideal value. We have synthesized all these materials with pulsed laser deposition in an attempt to obtain films of high electronic quality. Although all these materials show relatively modest photocurrents, some show surprisingly high photovoltages and reasonable stability under certain conditions. The opportunities for these materials and challenges that have to be addressed will be critically discussed. In the second part, I will show several examples of tandem water splitting devices. One is an all-oxide device based on p-$CuBi_2O_4$ and W:$BiVO_4$, the second is based on a top absorber of nanostructured WO_3/$BiVO_4$ with a flat silicon wafer as a bottom absorber. I will finish with some considerations on the scale-up of these devices and show some recent results on the importance of natural convection near electrode surfaces.

1:50 PM EN02.04.03
High Throughput Evaluation of Multi-Element, Multi-Functional Coatings for Improved Photoanodes and Photocathodes Joel Haber[1], Zemin Zhang[2], Guiji Liu[2], Aniketa Shinde[1], Lan Zhou[1], Dan Guevarra[1], Ryan Jones[1], Kevin Kan[1], John Gregoire[1], Francesca Maria Toma[2] and Jason K. Cooper[2]; [1]California Institute of Technology, United States; [2]Lawrence Berkeley National Laboratory, United States

The development of efficient, stable photoanodes and photocathodes remains a primary materials challenge in the establishment of a scalable technology for artificial photosynthesis. The typical photoelectrode architecture consists of a semiconductor light absorber coated with a metal oxide that serves a combination of functions, including corrosion protection, electrocatalysis, light trapping, carrier transport, and elimination of deleterious surface recombination sites. We describe high throughput investigations of the variation in performance and photo-response of integrated photoanode and photocathode libraries. The photoanode assembly libraries consist of uniform $BiVO_4$ light absorbers coated with films varying in composition and loading and evaluated at pH 9 and 13. The photocathode assembly libraries, for example, consist of uniform $CuBi_2O_4$ light absorbers coated with film libraries varying in composition and loading. Photoelectrode assemblies based on promising coating compositions and loadings were characterized in detail.

Late News: Semi-Monolithic Tandem Solar Cell Architecture for Photoelectrochemical Water Splitting Kai C. Outlaw-Spruell, Joshua Crunk, Wilman Septina and Nicolas Gaillard; Hawaii Natural Energy Institute, United States

Tandem devices are necessary architectures for unassisted photoelectrochemical water splitting because of their ability to maximize the power conversion efficiency and provide a high photo-voltage necessary to drive the

reaction. The traditional tandem integration process involves a monolithic tandem stack where the wide bandgap top cell is grown onto the narrow bandgap bottom cell, which places limitations on material selection and fabrication processes due to restrictions such as deposition techniques and temperature. To overcome this challenge and provide flexibility in material selection and manufacturing processes, a semi-monolithic tandem device architecture is investigated.

The semi-monolithic tandem device architecture is a novel approach of tandem cell manufacturing aimed at providing cost-effective, scalable photoelectrochemical water splitting technology. This technique employs a lift off and transfer method to combines two independently processed cells into one cell architecture using a transparent conductive adhesive (TCA) to create a multi-junction photovoltaic stack. This allows combination of materials which a standard deposition technique would not allow due to bottom cell degradation during deposition.

In this communication, we report of our latest results to integrate wide bandgap chalcopyrite absorbers into semi-monolithic tandem devices for PEC water splitting. Being an essential steppingstone in the semi-monolithic tandem manufacturing process, characterization of the relative conversion efficiency of a single junction solar cell before and after the lift off process was investigated. The cell was exfoliated using a soda lime glass substrate and a TCA that exhibited ~90% transmittance from 300-2000 nm as well as an out-of-plane series resistance on the order of 10^{-1} Ω-cm^2 (comparable to that of molybdenum in $Cu(In,Ga)Se_2$ solar cells). Using a 1.8 eV $CuGa_2Se_5$ cell integrated with CdS, ZnO and ITO, our results showed that approximately 100% of the baseline efficiency, short-circuit photocurrent density and open-circuit voltage was preserved after exfoliation. Then, the wide bandgap device was integrated with a 1.1eV narrow bandgap silicon solar cell using our lift-off/transfer technique to create a semi-monolithic tandem device. An open circuit voltage (Voc) of 1.2V was obtained, corresponding to over 83% of the sum of the sub-cells Voc. These promising results confirm the viability of the semi-monolithic approach to create efficient tandem devices for PEC water splitting.

2:00 PM EN02.04.06
Multifunctional $CoMoO_4$ for Supercapacitors, Oxygen Evolution and Methanol Oxidation Tenzin Ingsel, Felipe de Souza, Ram Gupta and Khamis Siam; Pittsburg State University, United States

The depletion of nonrenewable fossil fuels and its adverse impact on the environment has intensified the search for alternative, sustainable, and clean energy sources for the last several decades. Concurrently, the researchers have focused on designing and developing innovative materials to convert and efficiently store energy. Oxides and sulfides of transition metals have become the state-of-the-art material for energy conversion and storage, mainly attributed to their rich faradic reaction in electrode-electrolyte interface. These materials' potential applications have been extensively studied for electrode material in batteries, supercapacitors, electrocatalyst for water splitting, and fuel cell applications. In this project, metal molybdate $CoMoO_4$ was prepared via two different methods, binder-free/in situ and dip coating. The two different $CoMoO_4$ electrodes' specific capacitance was calculated at different current densities and scan rates. Sharp differences between the two electrodes were observed regarding how much specific capacitance they can deliver based on various current densities and scan rates. The in-situ electrode displayed a specific capacitance of 2853 F/g, whereas the dip-coated achieved 357 F/g, both recorded at 1 mV/s. When the OER performances of $CoMoO_4$ in situ and dip-coated electrodes were compared, in situ $CoMoO_4$ required a lower overpotential of 324 mV whereas, dip-coated electrodes exhibited 381 mV, both at 10 mA/cm^2. In situ $CoMoO_4$ showcased faster kinetics with a more downward Tafel slope of 70 mV/dec compared to dip-coated electrode with 90mV/dec. With the introduction of 0.5 M methanol in the 1M KOH electrolyte, an improved current density signal was observed in both the electrodes. A current density signal of 200 mA/cm^2 (@20 mV/s) and 25 mA/cm^2 (@20 mV/s) with and without 0.5 M methanol were observed in dip-coated $CoMoO_4$. With 0.5 M methanol in electrolyte, an improved current density signal of 135 mA/cm^2 was obtained in the binder-free electrode from an initial current density signal of 30 mA/cm^2 (@20 mV/s). Such findings indicate the facile construction of molybdate-based electrocatalysts for methanol oxidation.

2:25 PM *EN02.04.07
The Optical Properties and Electronic Structure of $CuBi_2O_4$ and the Spatiotemporal Dynamics of Photoexcited Plasmonic Gold Nanospheres for Applications in Light Driven Chemistry Jason K. Cooper[1,2,3]; [1]Joint Center for Artificial Photosynthesis, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Liquid Sunlight Alliance, United States

The economies of the future and the sustainability of the planet's ecosystems will rely on green energy technologies such as through the capture of sunlight to drive chemical transformations. In particular, light-harvesting photoelectrodes dictate the generation of photovoltage and photocurrent so understanding the underlying physics governing performance and stability limitations are critical to advance related technologies. Specifically, $CuBi_2O_4$ is a natively p-type semiconductor with 1.5 – 1.8 eV optical bandgap; as a photocathode it has been demonstrated to have a photocurrent onset potential greater than 1 V_{RHE} yet remains limited to about 1.5 mA cm^{-2}. In this investigation we characterize the electronic structure (valence and conduction band orbital composition) of the material using a suite of advances spectroscopic techniques in conjunction with DFT modeling. These results suggest the limited electron polaron diffusion length of 45 nm is related to charge localization at Cu 3d states in the conduction band. Photoelectrodes made of plasmonic nanostructures are interesting for energy conversion applications due their dual function acting both as catalytic centers and light absorbers thus localizing the light energy directly at the catalytic site. Hollow-gold nanospheres (HGNs), thin shells of gold which can be readily dispersed in water, have a plasmon resonance absorption which can be tuned from 520 nm to the near infrared based on the shell dimeter and thickness making them excellent structures to harvest a large portion of the terrestrial solar flux. After the plasmon is excited, the energy is rapidly converted to heat the particle. In this study, through a combination of transient absorption (TA) spectroscopy and full scale molecular dynamics (MD) on 30 nm particles surrounded by water, the spatiotemporal temperature and pressure profiles reveal that photoexcitation of the HGN creates a high temperature and high-pressure environment particularly suited for thermal catalysis. These studies taken together identify an unique opportunity for coupled reaction micro-environments to take advantage of photoelectrochemical and photothermal reaction mechanisms.

Application of Photocorrosive Metal Sulfide Photocatalysts to Artificial Photosynthetic Reactions Akihide Iwase; Meiji University, Japan

Artificial photosynthesis including water splitting and CO_2 fixation using photocatalysts is an attractive research field toward realizing sustainable society. The metal sulfides with narrow band gaps are a promising material group as a photocatalyst for hydrogen evolution under visible light irradiation. Although the metal sulfide is a favorable material for visible light absorption, the metals sulfide itself is oxidized by photogenerated holes (photocorrosion). We have successfully utilize metal sulfide photocatalysts in Z-schematic water splitting and CO_2 reduction upon using a reduced graphene oxide as a solid-state electron mediator.[1-3)] In the present study, we will present the successfully developed and improved Z-scheme systems using the metal sulfides prepared by a flux method with various alkaline chloride salts.
A single phase of metal sulfides was successfully prepared by a solid-state reaction and a flux method with various flux alkaline chloride salts. The particle size and aggregation degree depended on the preparation temperature in the flux method. Highly crystalline large particles were obtained at high temperature. The

particle size was smaller than that of a solid-state reaction. All samples showed photocatalytic activity for sacrificial H_2 evolution under visible light irradiation. The metal sulfides prepared by the flux method showed the higher activity for sacrificial H_2 evolution than that prepared by a conventional solid-state reaction. The metal sulfide prepared by the flux method also functioned as a H_2-evolving photocatalyst in the Z-scheme systems with a reduced graphene oxide as an electron mediator. The solar water splitting activity was higher than that using the metal sulfide prepared by a solid-state reaction.[4)] The Z-scheme system was also active for CO_2 reduction under visible light irradiation.
Thus, we successfully developed and improved Z-scheme systems for water splitting and CO_2 reduction using photocorrosive metal sulfide photocatalysts under visible light irradiation.

8:40 PM *EN02.05.02
Electrolyte Engineering for Water Splitting Tatsuya Shinagawa; The University of Tokyo, Japan

Converting the water molecule that sits at the bottom of the free energy landscape into hydrogen can serve as a core-technology in the future sustainable society, if driven by renewable energy sources. Photocatalytic and photoelectrochemical water splitting falls in this category of technologies, which proceeds, upon the irradiation of light, via a complex photophysical and electrocatalytic process involving photon absorption, exciton separation, carrier diffusion, carrier transport, surface reaction, and mass-transport.[1,2] Achieving solar hydrogen production at a high efficiency thus requires these steps to function efficiently and simultaneously despite of their differing time scales, however, the complex reaction network hinders its quantitative understanding and thus rational designing. Notably, by decoupling the steps, the photophysical and electrocatalytic events during water splitting can be independently addressed, which would shed light on the system and pave a way for its development. [1,2]
This contribution describes the electrocatalytic water splitting at near-neutral pH levels, whose milder condition than the extreme pH counterparts is compatible with photocatalytic and photoelectrochemical systems, with a particular focus placed on the electrolyte.[3-7] Electrocatalytic water splitting at the near-neutral pH levels experiences a reactant-switching.[3] The hydrogen evolution reaction (HER) proceeds as the reduction of proton at smaller reaction rates, which switches to that of the water molecule at higher reaction rates due to the diffusional constraints of the proton. Likewise, the oxygen evolution reaction (OER) proceeds as the oxidation of the hydroxide ion and the water molecule at lower and higher reaction rates, respectively. Adding the buffering species, e.g., phosphate, into the solution mitigates such local pH alteration by in-situ providing the proton and hydroxide ions, although beyond this simple buffering action, the added buffering species plays a variety of decisive roles.[3-6] For instance, the molality of the buffering species needs to be sufficiently high to attain improved buffering capacity for maintaining the local pH levels, which however is counterbalanced by the enlarged viscosity at high molalities, resulting in a slowed mass-transport flux of the buffering species.[3.4] Also, the identity of ions, either kosmotropic or chaotropic, has similarly large influences on the electrolysis. Particularly, at molalities higher than 0.1 mol kg^{-1}, the mean activity coefficient of the added ions is no longer unity, and the association of the ions need to be taken into account that is determined by the identity and combination of the ions.[3,5] All in all, looking at the electrolysis from the viewpoint of electrolyte quantitatively elucidates the bottleneck of the water splitting at the near-neutral pH levels and provides the guideline to improve its performance, highlighting the significance of *electrolyte engineering*.[3] The aspect of electrolyte engineering detailed herein can be extended to the regulation of the gas cross-over during water splitting and quantitative understanding of mass-transport during photocatalytic water splitting.

Rational Design of Photoelectrocatalytic Materials for CO_2 Reduction Guiji Liu; Lawrence Berkeley National Laboratory, United States

Due to the rapid depletion of fossil fuels and related environmental issues, developing technologies for producing renewable, clean fuels for our future is of great importance. Artificial photosynthesis via CO_2 reduction offers an attractive and cost-effective route to achieve this goal. However, the uncontrollable chemical transformations of existing photoelectrocatalytic materials under operating conditions greatly limit their applications for artificial photosynthesis technologies. Understanding their chemical transformations is a prerequisite to achieve sustainable energy conversion and storage into chemical bonds. Herein, we unravel the transformation mechanisms of photoelectrodes by systematic chemical and photoelectrochemical analysis and consequently provide an efficient protection scheme for light driven CO_2 reduction, using cuprous oxide as a model system.

9:25 PM EN02.05.05
Hierarchical Bimetallic Phosphide of Ni_2P-Cu_2P on Ni-Foam-Graphene-CNTs Substrate—Efficient and Super-Stable Electrocatalyst for Overall Water Splitting Sk Riyajuddin[1], Mansi Pahuja[1], Sushil Kumar[1], Takahiro Maruyama[2] and Dr Kaushik Ghosh[1]; [1]Institute of Nano Science and Technology, India; [2]Meijo University, Japan

The depletion of fossil fuels and the increase in environmental pollution have quest the scientific society to develop renewable and environment-friendly resources that can fulfill the needs of energy demands. Amidst all the existing clean energy resources, hydrogen energy is the most economical and has already captured a prime place in recent technological developments. Having high energy density, hydrogen can stand as an alternative to traditional fossil fuels. Water splitting via the electrochemical process to generate hydrogen for a fuel cell is an economic and green approach to resolve the looming energy and environmental crisis. It involves two half-cell redox reactions i.e. cathodic hydrogen evolution reaction-HER ($2H^+ + 2e^- H_2$) and anodic oxygen evolution reaction-OER ($4OH^- O_2 + 2H_2O$) but due to their sluggish kinetics, its desires to develop highly active electrocatalysts to accelerate the electron transfer process. So far, the precious noble metals like Pt (for HER) and RuO_2/IrO_2 (for OER) have been proven to be the best electroactive catalyst but their extortionate cost and dearth restrain the industrial-grade applications. Besides that, these noble metals (Pt, RuO_2, IrO_2) are incompetent to make their position in the same electrolyte for continuous overall water splitting. Developing cheap, stable, scalable, and efficient electrocatalyst is in need to explore the suitable cost-effective replacement of noble metal-based electrocatalyst for future scale-up industrial viability. Herein, we report a rationally design seamless super-hydrophilic homogeneous bimetallic phosphide of Ni_2P-CuP_2 on Ni-foam-Graphene-CNTs heterostructure using facile electrochemical metallization followed by phosphorization without the intervention of metal oxides or hydroxides. The bimetallic phosphide shows extraordinary water electrolysis activity in terms of ultra-low overpotential (HER-12 mV@10 mA/cm^2, 124 mV@100 mA/cm^2 in acid medium and OER-140 mV@20 mA/cm^2, 190 mV@50 mA/cm^2 in basic medium) and high turn-over frequency ($1s^{-1}$@100 mV for HER and $1s^{-1}$@310 mV for OER). The excellent stability at least for 10 days at a high current density of 500 mA/cm^2 without much deviation, infers the practical utilization of the novel catalyst towards green fuel production. The low Tafel slope (41 mV/dec for both HER and OER), low charge transfer resistance (18 ohm-HER), large electrochemical active surface area (959 cm^2-HER, 630 cm^2-OER), and large active site density ($4.26x10^{-4}$ mol/cm^2-HER, $2.12x10^{-4}$ mol/cm^2-OER) indicating super electrocatalytic properties. The versatility

of the catalyst has been observed when it shows remarkable performance in overall water splitting with a very low cell voltage of 1.45 V @10 mA/cm^2 in 1M KOH solution and long-term stability up to 40 hours with minimum loss (3%) of current density. The theoretical density functional study reveals that H-binding energy distribution among P-sites of CuP_2 and Ni_2P and d-band sifting among metal atoms in the heterostructure (Ni_2P-CuP_2) favour the HER and OER activity, respectively. Besides, the catalyst demonstrates an alternate transformation of solar energy to green H_2 production using a standard silicon solar cell. This research unveils a new avenue to design and synthesize highly stable electrocatalyst against an attractive paradigm of commercial water electrolysis for renewable electrochemical energy conversion.

Late News: Electrochemical Methane Conversion with CuO/CeO2 Catalysts Jaehyun Lee, Jiwoo Yang and Jun Hyuk Moon; Sogang University, Korea (the Republic of)

The oxidation of methane, driven by electrochemical potential, is desirable as a strategy to overcome the low selectivity in thermochemical catalytic reactions, but improving productivity remains a challenge. We demonstrate the electrochemical conversion of methane to methanol in a CuO/CeO_2 oxide catalyst. We confirm the highest methane oxidation activity at Cu:Ce=6:4. we achieve the highest production rate of 752.9 μmol/g_{cat}/hr (6 hr reaction) at ambient pressure; Among the oxygenates, a CH3OH selectivity of 79% is obtained. In a high pressure reaction at 10 bar, productivity of 1,832.2 μmol/g_{cat}/hr and 21,986.6 μmol/g_{cat} is achieved. We confirm the formation of methanol by oxidation of methane by active oxygen on the catalyst, and also present a side reaction pathway by further oxidation of methanol.

9:50 PM *EN02.05.08
Molecular-Semiconductor Hybrid Systems for Photocatalytic and Electrochemical CO_2 Reduction
Takeshi Morikawa; Toyota Central R&D Labs., Inc., Japan

For the development of systems to convert CO_2 into useful energy-rich chemicals under sunlight or electrical energy, the use of metal-complex catalysts is one of attractive approaches because CO_2 selectivity and reaction rates can be controlled by ligand modification [1]. The combination with semiconductor photosensitizers is also one of promising approaches to promote the reaction under photoirradiation. To realize a CO_2 reduction system which utilizes water molecule as an electron donor in the CO_2 reduction reaction (CO_2RR), we previously proposed the a hybrid molecular-catalyst/semiconductor system for the visible-light driven CO_2RR, and demonstrated systems of particulate photocatalyst and photoelectrode utilizing Ru-bipyridine complex polymer catalysts linked with semiconductors of N-doped Ta_2O_5[2], GaP:Zn[3], InP:Zn[4], $(CuGa)_{0.8}Zn_{0.4}S_2$[5], $(AgIn)_{0.22}Zn_{1.56}S_2$[4], ZnS:Ni[4], etc. The photoelectrode system demonstrated a monolithic tablet-formed device, and it generated formate with a solar-to-chemical conversion efficiency (E_{solar}) of 4.6 % in an aqueous solution [4]. DFT calculation and related experiments clarified that the very low onset potential (-0.18 V vs RHE) for CO_2 reduction at the Ru-bipyridine complex is dependent on combination of carbon support and K^+ in solution, which enabled the demonstration of the monolithic device [6].
One recent topic is a visible-light-driven Z-schematic CO_2 reduction using H_2O as an electron donor in aqueous particulate suspension which can be operated in a simple mixture of [Ru(4,4'-diphosphonate-2,2'-bipyridine)$(CO)_2Cl_2$] ([Ru(dpbpy)] modified $(CuGa)_{1-x}Zn_{2x}S_2$ (CGZS) hybrid photocatalyst as a CO_2 reduction, $BiVO_4$ photocatalyst as a water oxidation and Co-complex as an electron mediator [7]. The CO_2 reduction activity was significantly dependent on the composition of CGZS, and utilization of [Ru(dpbpy)]/CGZS at x=0.7 (E_g = 2.36 eV) showed the highest Z-schematic CO_2 reduction activity for CO and $HCOO^-$ production accompanying O_2 generation under visible-light irradiation. The very high CO_2 reduction selectivity exceeding 90 % under visible light irradiation as the aqueous particulate suspension suggests that particulate Z-schematic reaction is also applicable to the highly selective and efficient photocatalysis for solar fuel generation by CO_2

fixation.
As for the electrochemical system, our recent approach is the use of earth-abundant elements. As well as lowering system costs, reduction in CO_2 emissions from raw materials mining to final catalyst synthesis further confirms the feasibility of this earth-abundant systems. A silicon photovoltaic cell (Si-PV) was connected to a [Mn-bpy] cathode for CO_2RR [5] and an β-FeOOH anode combined with Ni hydroxide for OER [8, 9]. The system operated in a one-compartment reactor filled with pH 6.9 aqueous solution saturated with CO_2 [10], and exhibited E_{solar} of over 10 % in production of mixture of CO and H_2 as syngas.

α-$SnWO_4$ Photoelectrodes Prepared by Pulsed Laser Deposition—An Overview of the Recent Progress
Patrick Schnell, Moritz Kolbach, J. Mark C. M. Dela Cruz, Markus Schleuning, Keisuke Obata, Rowshanak Irani, Ibbi Y. Ahmet, David E. Starr, Roel Van de Krol and Fatwa F. Abdi; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Direct photoelectrochemical hydrogen production is a promising route towards a clean and sustainable energy supply. To obtain high solar-to-hydrogen (STH) efficiencies, a suitable semiconducting material with a band gap of 1.7 to 1.9 eV is needed as the top absorber in tandem solar water splitting devices [1]. An interesting candidate is α-$SnWO_4$, a ternary metal oxide with an ideal band gap of 1.9 eV and a flatband potential of ~0 V vs. RHE. Several deposition methods have been used for the deposition α-$SnWO_4$ thin films. The highest reported photocurrent so far of 0.75 mA/cm^2 has been achieved by pulsed laser deposited (PLD) α-$SnWO_4$ films covered with an NiO_x overlayer [2].
In this study, we provide an overview of our current understanding of α-$SnWO_4$ films prepared by pulsed laser deposition. First, although the deposition of NiO_x is crucial to obtain the above-mentioned record photocurrent, it limits the photovoltage as observed from the cyclic voltammetry and open circuit potential analysis (OCP). This suggests that the interface between α-$SnWO_4$ and NiO_x is not ideal, and understanding this interface is important to improve the performance further. We therefore present a thorough α-$SnWO_4$/NiO_x interface investigation by means of synchrotron-based hard X-ray photoelectron spectroscopy (HAXPES). These data are complemented with OCP analysis and Monte-Carlo-based photoemission spectra simulation. Our study reveals that the deposition of NiO_x with PLD introduces a strong upwards band bending (~400 meV) at the interface, which is favorable for charge separation. However, significant oxidation of Sn^{2+} to Sn^{4+} can be simultaneously observed at the interface with increasing NiO_x layer thickness. Our photoemission spectra simulation indicates that this can be attributed to the formation of SnO_2 at the interface. Control experiments show that such a layer

can indeed be responsible for the reduction of photovoltage; its formation has to therefore be avoided to overcome the photovoltage limitation of α-$SnWO_4$. In the second part of this study, a systematic investigation of the photoelectrochemical stability of α-$SnWO_4$ is performed in electrolytes with a broad pH range (2 – 13) at various applied potentials. Inductively coupled plasma optical emission spectroscopy (ICP-OES) is combined with X-ray photoelectron spectroscopy, X-ray diffraction and electron microscopy to reveal the mechanisms behind the stability or degradation at respective pH and applied potential. Finally, we show the operation conditions in which a self-limiting passivation layer is formed on α-$SnWO_4$. While this layer blocks further charge transfer, such a self-limiting process relaxes the requirement for the protective overlayer, i.e., it allows for the presence of a limited number of pinholes. Overall, this overview suggests that despite the previously reported challenges, α-$SnWO_4$ is a promising material for photoelectrochemical water splitting. Further performance improvements can be achieved by optimizing the interfacial properties between α-$SnWO_4$ and the overlayer as well as taking advantage of the beneficial self-passivation mechanism.

Late News: Rational Design of Photoelectrochemical Perovskite-BiVO4 Tandem Devices for Selective Syngas Production Virgil Andrei, Geani M. Ucoski, Motiar Rahaman, Chanon Pornrungroj, Esther Edwardes Moore, Bertrand Reuillard, Qian Wang, Demetra S. Achilleos, Robert A. Jagt, Chawit Uswachoke, Hannah J. Joyce, Robert Hoye, Judith L. MacManus-Driscoll, Richard H. Friend and Erwin Reisner; University of Cambridge, United Kingdom

Metal halide perovskites have recently emerged as promising alternatives to commonly employed light absorbers for solar fuel synthesis.[1,2] These semiconductors enabled photoelectrochemical (PEC) perovskite-$BiVO_4$ tandem devices which can perform unassisted water splitting,[3,4,6] as well as the more challenging CO_2 reduction to syngas.[5,7] While the bare perovskite light absorber is rapidly degraded by moisture, recent developments in the device structure have led to substantial advances in the device stability, from seconds to days.

In this contribution, we give an overview of the latest progress from the field of perovskite PEC devices, introducing design principles to improve their performance and reliability. For this purpose, we will discuss the role of charge selective layers in increasing the device photocurrent and photovoltage, by fine-tuning the band alignment and enabling efficient charge separation. A further beneficial effect of hydrophobicity is revealed by comparing devices with different hole transport layers (HTLs). A threefold increase in the lifetime of perovskite photocathodes is obtained by replacing a hydrophilic PEDOT:PSS HTL with an inorganic NiO_x HTL.[3] A further leap in stability up to 96 h can be demonstrated by introducing a hydrophobic PTAA HTL, which acts as an additional barrier to lateral moisture infiltration while further increasing the onset potential for H_2 evolution to approximately 1.0 V vs. RHE.[6]

On the manufacturing side, we will provide new insights into how appropriate encapsulation techniques can extend the device lifetime to a few days under operation in aqueous media.[3,5] Many prototypes rely on low melting alloys as encapsulants, however the demand on rare elements can be detrimental for the overall cost and scalability of the tandems, whereas metals can suffer from chemical corrosion. To avoid these drawbacks, we introduce graphite epoxy paste as a conductive, hydrophobic encapsulant.[6,8] This abundant, metal-free composite can reduce the device cost[6] while enabling a more facile integration of perovskite devices with inorganic,[6,7] molecular[5] and bio-catalysts.[4] The combined advantages of these approaches are demonstrated in a perovskite-$BiVO_4$ tandem configuration, leading to selective unassisted CO_2 reduction to syngas.[7]

Manufacturable Processes for Si-Based Metal-Insulator-Semiconductor Photoanodes for Solar-Driven Water Oxidation Soonil Lee[1], Li Ji[2] and Edward Yu[1]; [1]The University of Texas at Austin, United States; [2]Fudan University, China

Si-based photoelectrodes have attracted substantial interest due to their potential for cost-effective conversion of water into clean fuel using solar energy. However, Si-based photoanodes for the oxygen evolution reaction (OER) are still challenging due to the requirements of large overpotential and low stability in alkaline solutions. To achieve high efficiency and long-term stability, metal-insulator-semiconductor (MIS) structures have been widely explored. In Si-based MIS photoanodes, the insulator needs to prevent Si corrosion in alkaline solutions and also transport carriers efficiently. In this work, we demonstrate a series of highly manufacturable processes for fabricating Ni/SiO_2/Si MIS photoanodes with SiO_2 insulating layers up to 90nm thick and localized, non-lithographically fabricated Ni catalyst contacts. The resulting photoanode structures show high efficiency and long-term stability in alkaline solutions. Specifically, a Ni/SiO_2/n-Si photoanode yielded onset potential and photocurrent density of ~1.0 V versus RHE and ~25 mA/cm^2, respectively, while a Ni/SiO_2/p^+n-Si photoanode yielded an onset potential of 0.7 V versus RHE and saturation current density of 32 mA/cm^2, all in 1 M KOH alkaline solutions. Moreover, in stability testing in 1 M KOH aqueous solution, a constant photocurrent density of ~15.5 mA/cm^2 was maintained at 1.3 V versus RHE for 48 hours. This approach yields an enhancement in OER performance of Si-based MIS photoanodes with highly manufacturable fabrication processes that are amenable to large-scale commercial fabrication.

8:40 AM EN02.06.05
Chances and Challenges of Thermally Coupled Solar Water Splitting Moritz Kolbach[1], Kira Rehfeld[2] and Matthias M. May[3]; [1]Helmholtz-Zentrum Berlin für Materialen und Energie, Germany; [2]Ruprecht-Karls-Universität Heidelberg, Germany; [3]Universität Ulm, Germany

Hydrogen is a versatile energy carrier. When produced by water splitting using renewable energy sources, it is a greenhouse gas-free alternative to fossil fuels. The industrialization process of this technology is currently dominated by electrolyzers powered by electricity from wind turbines or photovoltaic solar cells. This approach is, for now, the most advanced and feasible. However, there are indications that the long-term goal to produce Hydrogen on a TW-scale only by wind power could face physical limitations,[1] not present for the solar route, which we will discuss.
Furthermore, it is debated in the community whether more integrated device designs for solar water splitting

can optimize hydrogen production due to lower balance of system costs and a smarter thermal management.[2,3,4] Such a more integrated device–with the photoabsorber immersed in the electrolyte or not–offers the opportunity to thermally couple the absorber and the electrolyte. In this way, heat losses in the photoabsorber can be turned into an efficiency boost for the device via simultaneously cooling the absorber, enhancing the catalytic performance of the water splitting reactions, and decreasing the ohmic losses.[5]
However, the complex influence of different weather and climate conditions on the efficiency of such a thermally coupled device is poorly understood. Here, we introduce an open-source Python-based model that combines solar cell physics, electrochemistry, thermal fluxes, and climate data as part of the "YaSoFo" environment.[6] This model allows us to find suitable device configurations and quantify the efficiency-benefits for multi-junction photoelectrochemical devices. In addition, we scrutinize our predictions under idealized laboratory conditions. Our modelling and experimental results give important insights into the chances and challenges for thermally coupled water splitting.

Electrocatalytic CO_2 Reduction to C_{2+} Products on B-Doped CuO Catalysts Hilmar Guzmán[1,2], Daniela Roldán[1], Nunzio Russo[1] and Simelys Hernandez[1,2]; [1]Politecnico di Torino, Italy; [2]Istituto Italiano di Tecnologia, Italy

Since the industrial revolution, anthropogenic activities have impacted the planet's carbon cycle by the emissions of large amounts of greenhouse gases (GHGs), shifting the equilibrium of human history. The electrocatalytic CO_2 reduction (EC CO_2R) is an interesting technology because, driven by renewable energy sources, can be used to store both renewable electricity and CO_2 in added-value products such as liquid fuels (ethanol and other high-octane alcohols (>C_2)).[1] To date, researchers have focused on observing the effects of surface modification (e.g., nano-structuring and surface tailoring) on catalyst selectivity and activity to produce C_{2+} products. Nonetheless, it still remains an ongoing challenge due to high C-C coupling barriers. Among these studies, incorporation of the light element boron (B) into the Cu catalyst has been reported to induce the formation and stabilization of Cu^{+1}/Cu interfaces and reduce the barrier of the *CO dimerization, promoting a high activity for EC CO_2R towards C_2 products.[2] We have developed a B-doped Cu oxide catalyst by the ultrasound-assisted co-precipitation method and B_2O_3 impregnation, which were tested for this technology. The catalyst materials have been fully characterized by different Physico-chemical methods like X-ray diffraction, BET, porosimetry, filed-emission scanning electron microscopy (FESEM), among others, before and after the catalytic tests. The results revealed that for producing C_{2+} alcohols, the catalyst must overcome the 1° RDS of *CO formation, and then this *CO can be converted by dimerization to superior products. Thus, Faradaic efficiency towards alcohols (> 95% selectivity to ethanol) increases, and B-doping reduces H_2 production up to an optimum B amount. Therefore, under the optimum synthesis condition, a partial current density of about 3 mA cm^{-2} for alcohols was reached. The physical and chemical properties of the nanostructures synthesized materials define concerted efforts that can be manipulated to tune the performance of the electrochemical reaction. These interesting results could help find a suitable electrocatalyst to establish this technology at the industrial level.

Facile and Scalable Synthesis of Cu_2O-SnO_2 Catalyst for the Photoelectrochemical CO_2 Conversion

Maddalena Zoli[1,2], Daniela Roldán[1], Hilmar Guzmán[1,2], Simelys Hernandez[1,2], Angelica Chiodoni[2], Katarzyna Bejtka[2] and Nunzio Russo[1]; [1]Politecnico di Torino, Italy; [2]Istituto Italiano di Tecnologia, Italy

The conversion of the atmospheric CO_2 to value-added compounds is more and more attractive to the scientific community, since natural sink cannot keep up with the constant anthropogenic emission and amplification processes. Recently, CO_2 concentration in the atmosphere exceeds 410 ppm, and its growth has remained constant since the 50s[1]. Renewable and green approaches to CO_2 recovery are aimed to minimize the worrying impact of its emission to the environment, and to drive the transition to a new circular economy approach in chemistry and energy production. Within the depicted scenario, electrochemical and photoelectrochemical CO_2 reduction are being widely investigated as promising methods to transform CO_2, under mild reaction conditions, into useful chemicals or fuels. For instance, alcohols, CO and HCOOH that can be exploited as renewable energy sources or as key intermediates for the chemical industry.
Among the non-precious metal oxides, Cu_2O is a cheap, abundant and intrinsically p-type semiconductor. Due to its narrow band gap (~ 2 eV) and the suitable positioning of conduction and valence bands, Cu_2O is an ideal photocatalyst for CO_2RR. Simultaneously, SnO_2 is an n-type direct band-gap semiconductor with noticeable electron mobility together with an intrinsic stability. It openly transpires the dual role of Cu_2O, as photoabsorber and forming a p-n junction with tin oxide.
In this work, the synthesis of photoactive copper-tin-oxide-based catalyst was optimized by a co-precipitation method[2], employing $Cu(NO_3)_2 3H_2O$ and $SnCl_4 5H_2O$ into a stirred and heated reactor. A solution of Na_2CO_3 was added as a precipitant agent, while $NaBH_4$ as the reducing one[3], in order to promote the Cu_2O formation. The work-up protocol, based on copious MilliQ water washings, was implemented and finally optimized. The characterization step included Field Emission Scanning Electron Microscopy (FESEM), Energy Dispersive X-ray Analysis (EDX) X-rays Diffraction Analysis (XRD), UV-Visible Spectroscopy analysis, among others, and allowed the morphological assessment, the porosity value estimation and the crystalline phase evaluation. With the latter, it has been found a correspondence to the cubic crystalline phase (cuprite) of Cu_2O and consequently confirmation that the reduction process has been successfully carried out.
The so obtained catalyst was then deposited it onto a GDL (Gas Diffusion Layer) and FTO-based substrates by spray coating of an ink containing: the catalysts, Vulcan carbon (to increase the electrode conductivity), Nafion as binder and Isopropanol as carrier. The photo-electrochemical activity for the CO_2 reduction reaction was tested in the dark and under sunlight simulated conditions by means of Linear Sweep Voltammetry (LSV) and Chrono-Potentiometry (CP) analyses. Relevant current density (j) values of up to 40 mA/cm^2 were observed, and from the products analysis during the CP a high Faradaic Efficiency to CO was obtained. The influence of the ink composition was accurately investigated in terms of interaction among all the components and with respect to the employed substrate, taking into account sun-light activity and stability of the prepared electrodes towards their future utilization in a device for the sun-driven CO_2 conversion to high-added value products.

Extraction of Mobile Charge Carrier Photogeneration Yield Spectrum in Metal Oxide Photoelectrodes
Daniel Grave[1], David S. Ellis[2], Yifat Piekner[2], Moritz Kolbach[3], Hen Dotan[2], Asaf Kay[2], Patrick Schnell[3], Roel Van de Krol[3], Fatwa F. Abdi[3], Dennis Friedrich[3] and Avner Rothschild[2]; [1]Ben Gurion University, Israel; [2]Technion–Israel Institute of Technology, Israel; [3]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

In conventional solar cell materials, above-bandgap photon absorption generates free electrons and holes, which travel freely through the material and contribute to the photocurrent. In metal oxides, however, light can excite electrons and holes into a variety of different electronic states, some of which are, or can eventually become mobile charge carriers, while others do not contribute to photocurrent. For example, the visible absorption spectrum of hematite (α-Fe_2O_3), one of the leading photoanode candidates for solar water splitting, is thought to be composed of both ligand-to-metal charge transfer (LMCT) bands which are responsible for the photocurrent and more localized *d-d* bands which do not generate free charge. As a result, much of the optical absorption is wasted. Since both the LMCT and *d-d* bands span the visible spectrum, the photogeneration yield, defined as the probability of an absorbed photon to generate mobile charge carriers, depends strongly on wavelength. Here, we introduce a new method to empirically extract the mobile charge carrier photogeneration yield spectrum of semiconductor photoabsorbers using optical and external quantum efficiency measurements of ultrathin films. We apply this method to hematite photoanodes in photoelectrochemical cells under *operando* conditions and show agreement between the extracted photogeneration yield spectrum and the photoconductance spectrum measured by time-resolved microwave conductivity. We demonstrate that mobile charge carrier generation fundamentally limits the conversion efficiency of hematite photoanodes, and provides an upper limit to the achievable photocurrent that is lower than that predicted by its bandgap. We then extend the analysis more generally to other photoelectrode materials and demonstrate its value towards understanding optical absorption mechanisms and charge carrier generation in complex materials.

Semi-Permeable Oxide Coatings for Selective (Photo)electrocatalysis Daniel Esposito; Columbia University, United States

Conventional electrocatalysts used in fuel cells, electrolyzers, and photoelectrochemical systems are typically comprised of metallic nanoparticles that lower energy barriers for electrochemical reactions at the electrocatalyst/electrolyte interface. Typically, these nanoparticles are partially or fully exposed to a liquid phase that contains the reactants and products of interest. In contrast, this presentation describes an emerging

class of (photo)electrocatalysts for which the active electrocatalyst sites are completely encapsulated by ultrathin layers of permeable oxides that can exhibit membrane-like properties. These so-called membrane coated electrocatalysts (MCECs)[1] offer many potential advantages over conventional electrocatalysts, including the ability to simultaneously mitigate degradation,[2] alter reaction selectivity,[3] and improve reaction kinetics at the buried interface between the overlayer and active catalyst.[4] This talk will focus on describing recent case studies of silicon oxide (SiO_x) and titanium oxide (TiO_x)-encapsulated Pt electrocatalysts that demonstrate the ability of nanoscopic overlayers to greatly modulate reaction selectivity, even in cases where the thermodynamics and/or kinetics of the undesired reaction are highly favored compared to the desired reaction. By systematically changing the properties of well-defined oxide overlayers, this work uncovers design principles that can be used to tune reaction selectivity for a wide range of electrochemical reactions of interest for the sustainable production and use of fuels and commodity chemicals.

Novel Approach to Extract Reaction and Recombination Rates of the Photoelectrode Peter Cendula[1], Prangya P. Sahoo[2], Gabriel Cibira[1] and Pavel Simon[1]; [1]University of Zilina, Slovakia; [2]Slovak Academy of Sciences, Slovakia

Semiconductor/electrolyte interfaces attract intense interest to convert solar energy to chemical fuels. Although many analytical models describing the photocurrent-voltage response of these devices exist, they have difficulty to reproduce full numerical simulations under small anodic bias.
We recently derived an analytic model of a weakly absorbing n-type semiconductor/electrolyte interface with a slow rate of water oxidation reaction, fast recombination rate and under small voltage bias [1]. Excellent overlap of our model was demonstrated with full numerical simulations. Our model enabled us to simplify calculation of the impedance of the semiconductor/electrolyte interface derived in the work of Bertoluzzi et al[2]. The comparison of analytic and measured impedance allows to extract the reaction rate for redox reaction from the dark impedance and the direct bulk recombination constant of the semiconductor from the impedance under illumination.
This work provides easy-to-use recipe for the quantitative comparison of the recombination and reaction properties of the various semiconductor photoelectrodes by impedance spectroscopy.

Heterostructures of Cadmium Chalcogenide Quantum Dots and MoS_2 Nanoplatelets Prepared by Linker-Assisted Assembly—Influence of Ligand Properties on Excited-State Charge Transfer and Photocatalysis Arianna Rothfuss, Nuwanthi Suwandaratne and David Watson; University at Buffalo, The State University of New York, United States

Heterostructures of semiconductors can achieve photoinduced charge separation for a wide variety of applications in photocatalysis, including photoelectrochemical (PEC) water splitting. Heterostructures comprised of quantum dots (QDs) and MoS_2 nanoplatelets have demonstrated potential as architectures for PEC water splitting and hydrogen generation.[1] Linker-assisted assembly (LAA) is a promising synthetic method for these heterostructures. In LAA, colloidal QDs are pre-synthesized, affording substantial control over size and energetics, and then interfaced with the nanoplatelets. Moreover, charge-transfer properties of the heterostructures can be tuned with properties of the bridging ligand.
This presentation will focus on the effects of varying the length of molecular linkers between QDs and MoS_2 on the dynamics of charge transfer and the efficiency of redox photocatalysis. Mercaptoalkanoic acid ligands, ranging from 3 to 16 carbon atoms, as well as cysteine were used to attach the QDs to MoS_2. We hypothesized that tuning the alkyl chain length of the ligand would modulate the rate of electron transfer, due to the variable spatial separation between the components. LAA-derived QD/MoS_2 heterostructures were initially synthesized with cysteine as the linker and exhibited rapid electron transfer from the QDs to MoS_2 due to the type-II energetics. These heterostructures also produced oxidative photocurrent and demonstrated photoelectrochemical and photocatalytic hydrogen generation. The LAA-derived QD/MoS_2 heterostructures with mercaptoalkanoic acid linkers also exhibited dynamic quenching, relative to free QDs, in time-resolved emission experiments, which provided evidence for excited-state charge transfer.
Measured electron-transfer rate constants for the heterostructures were tunable over three orders of magnitude by varying the alkyl chain length. LAA-derived heterostructures oxidized lactic acid to pyruvic acid, and oxidative photocurrents varied by approximately 4-fold with the length of the bridging ligand. These results highlight the extent to which the properties of bridging ligands affect excited-state charge transfer and photocatalysis within QD-MoS_2 heterostructures, and, more generally, provide insight into the design of materials architectures for PEC water splitting.

Probing the Photoelectrochemical Properties of Fe_2TiO_5 Using Epitaxial Thin-Film Photoanodes Motoki Osada[1,2,2], Kazunori Nishio[1,2,3], Kyuho Lee[1,2], Harold Hwang[1,2] and Yasuyuki Hikita[1]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States; [3]Tokyo Institute of Technology, Japan

Recently, Fe_2TiO_5 has emerged as a promising photoanode material for water photo-oxidation due to its suitable bandgap of 2.1 eV, high chemical stability, and scalability consisting of earth-abundant elements [1]. It has been reported that photoelectrochemical (PEC) performance is enhanced in heterostructure forms such as Fe_2TiO_5/α-Fe_2O_3 or Fe_2TiO_5/TiO_2 [2,3]. However, these investigations have been limited in polycrystalline nanostructures that hinders the elucidation of the intrinsic PEC properties of Fe_2TiO_5.
Building on our successful fabrication of single-phase Fe_2TiO_5 epitaxial thin films using pulsed laser deposition [4], here we report the comprehensive characterization of the intrinsic PEC properties of Fe_2TiO_5 using the most well-defined surface and bulk structures available. We demonstrate that Fe_2TiO_5 exhibits highly efficient charge transfer efficiency of 20% at the Fe_2TiO_5-electrolyte interface at 1.23 V vs. RHE, while it is only 1% for α-Fe_2O_3. This excellent surface property is further corroborated by forming heterostructures with α-Fe_2O_3 epitaxial thin films, in which the photocurrent enhances by an order of magnitude and the onset potential improves by ~300 mV compared to a pure α-Fe_2O_3 photoanode. Details of the epitaxial photoanode fabrication, photocurrent-voltage curves, transient photocurrent analysis, and impedance spectroscopy will be discussed in the presentation.

Late News: Effect of Varying Magnetic Field on the Alignment of Tandem Semiconductor Microparticles for Unassisted Water-Splitting Saumya Gulati and Josh Spurgeon; University of Louisville, United States

There has been a vast improvement in photovoltaic (PV) technology in the last couple of decades; however, solar PV technology has a lot of drawbacks, including that it is intermittent, broadly dispersed, and non-transportable. Hence, cost-effective solar energy storage is critical for widespread implementation of solar energy as the primary energy source. My project focuses on the development of tandem semiconductor microparticles which when placed in water under 1 Sun condition could spontaneously split water into hydrogen and oxygen with solar-to-hydrogen efficiency of >10%.
In the present work, we have acquired customized microwire array structures made on silicon (Si) wafer by deep reactive ion etching method and formed a diode on these particles via a doping process. We have also been able to produce a TiO2 tandem junction for additional photovoltage. Nickel, which serves multiple purposes in the design, has been deposited on Si via an electroless photo-deposition process. It acts as a hydrogen evolution catalyst while protecting the Si from oxidation. Secondly, owing to its ferromagnetic property, an electromagnet can orient these particles to achieve current-matching, in the series-connected Si and TiO2. This is hypothesized to achieve higher efficiency.
For proof-of-concept, the magnetic alignment analysis has been done on Ni coated Si microwire particles. Future work aims at replicating similar analyses for tandem microwire particles and testing its effect on the eventual solar-to-hydrogen efficiency.

Recent Developments in Understanding Ternary Oxide Photoelectrodes Using $BiVO_4$ as a Model System Dongho Lee, Ann Lindberg and Kyoung-Shin Choi; University of Wisconsin–Madison, United States

Oxide-based photoelectrodes recently have been at the forefront of research for photoelectrochemical water splitting. While most oxide-based photoanodes suffer from severe electron-hole recombination, $BiVO_4$ photoanodes are known to achieve exceptionally high electron-hole separation efficiencies. However, an understanding of what features of $BiVO_4$lead to this desired property is currently lacking. In this study, we sought to elucidate these features by investigating $PbCrO_4$, which has electronic and structural similarities to $BiVO_4$. For this goal, we prepared $PbCrO_4$ as a high-quality photoanode and compared its photoelectrochemical properties and stability with those of $BiVO_4$. In this presentation, we will discuss the photoelectrochemical similarities and differences between $PbCrO_4$ and $BiVO_4$ in detail, which can provide useful guidelines to develop high-performance oxide-based photoanodes. Another topic to be discussed in this presentation is the effects of surface termination/composition of a ternary photoelectrode on the interfacial energetics. For ternary oxide photoelectrodes, there exist numerous ways to terminate the surface even for the same facet and their surface composition can be different from their bulk composition. However, the effects of surface termination/composition on a ternary oxide photoelectrode have not been systematically studied. In this presentation, we will compare $BiVO_4$ photoelectrodes with V-rich and Bi-rich surfaces and demonstrate that the surface composition has a considerable effect on the surface energetics and photocurrent generation of $BiVO_4$ even for the same facet. We will also discuss the atomic origin of the impact that the surface of photoelectrodes has on their surface energetics and photoelectrochemical properties.

With High-Performance Two-Electron, Dendrite-Suppressing Zinc Anodes in Hand, Time for Battery Cathodes to Catch Up Debra R. Rolison[1], Samuel Kimmel[2,1], Christopher Rhodes[2], Christopher N. Chervin[1], Brandon J. Hopkins[3], Nathaniel L. Skeele[1], Jeffrey W. Long[1] and Joseph F. Parker[1]; [1]U.S. Naval Research Laboratory, United States; [2]Texas State University, United States; [3]NRL-NRC Postdoctoral Associate, United States

Although lithium-ion batteries are today's go-to high-energy battery technology, the inherent safety issues of Li-ion remain a persistent challenge, especially when Li-ion battery packs are required, as in electrified vehicles and distributed microgrids. The monolithic three-dimensional (3D) zinc "sponge" developed at the U.S. Naval Research Laboratory (NRL) solves long-standing performance limitations for zinc anodes and paves the way for next generation Ni–Zn batteries competitive with the specific energy of Li-ion systems plus adding improved safety inherent to aqueous, nonflammable electrolytes. However, the current performance of β-$Ni(OH)_2$ composite electrodes does not provide sufficient performance or energy density to match that of Zn sponge anodes and represents a critical bottleneck to Ni–Zn batteries with high energy density. We are investigating Ni-based cathodes redesigned as architectures to wire the electrode volume in 3D while building on Texas State's microwave synthesis of multi-substituted α-$Ni(OH)_2$ to increase the capacity, minimize the parasitic oxygen evolution reaction, and provide stable multi-electron cycling of the active material.

Covalent Organic Framework Cathodes for Zinc-Ion and Metal-Sulfur Batteries Aninda J. Bhattacharyya, Ruth Gomes and Akshatha Venkatesh; Indian Institute of Science, India

This presentation discusses the application of covalent organic frameworks (COFs) as cathodes in battery chemistries beyond the Li-ion viz. non-aqueous liquid electrolyte-based Li/Na-S and aqueous Zn-ion batteries.

We have designed covalent organic framework nanosheets over end-opened multi-walled carbon nanotubes (CNT-CON) and explored their role as sulfur host in metal sulfur batteries. The carbon nanotubes provide the conductivity and confine the elemental sulfur, whereas the covalent organic nanosheets layer acts as a porous (chemical) trap to prevent polysulfide dissolution electrolyte. Numerous experimental methods investigated the crystallinity, porosity, and framework composition of the cathode material. The molecularly designed covalent organic framework viz. the CNT-CON/S when employed as the cathode in Li-S and Na-S battery exhibited a significant improvement in electrochemical performance (specific capacity and cycling efficiency) as compared to CNT/S and COF/S cathode. All these studies convincingly show that COFs grafted on to conducting carbon structures can serve as alternative (organic) electrodes for high-performance metal-sulfur battery systems (Ruth Gomes et al. *ACS Sustainable Chem. Eng.* 2020).

The second part of the lecture will discuss a redox-active two-dimensional COF and its graphene oxide composite (COF-GOPH) as a cathode in an aqueous rechargeable Zn-ion battery (ZiB). Zinc metal anode and varying concentrations of Zn^{2+}-ion and Li^{+}-ion electrolytes were used in the cell with COF-GOPH cathode. The best battery performance was obtained when the composition of the Zn and Li-based electrolytes are 1:1. Combination and X-ray photoelectron spectroscopy and conductivity measurements reveal that optimum concentration of Li^{+} ions in the mixed-ion electrolyte was beneficial for better facilitation of Zn^{+2} diffusion into the electrode, providing superior electrochemical performance. The COF-Zn aqueous mixed-ion system offers a better alternative to conventional aqueous organic batteries with a single type of ions. It ensures excellent electrochemical performance in cycling stability reversibility and capacity retention (Akshatha Venkatesh et al. *submitted*, 2021).

The above examples of employing COF in battery chemistries beyond the Li-ion further broadens the potential of COFs. The work clearly demonstrates that COFs can be used in the development of new and efficient battery systems that are safe, cost-effective, eco-friendly, and, most importantly, providing a sustainable future.

WITHDRAWN-NO REG (EN03.01.03) Biosourced Sepia Melanin as Universal Organic Cathode for Post-Li-Ion (Zn2+, Al3+) Aqueous Rechargeable Batteries Abdelaziz M. Gouda and Clara Santato; Polytechnique Montréal, Canada

The increasing demand for energy especially from renewable and intermittent resources (e.g. sun and wind) along with the colossal demand for portable electronics and the growing popularity of electric vehicles, push the community to be more dependent on energy storage technologies, especially Lithium-ion battery (LIB)). Concurrent with this booming LIB technology, an emerging topic of research has been dedicated to curtailing the environmental concerns, the Li mining geopolitical issues, as well as providing other cost effective and environmental benign alternatives. Rechargeable zinc and aluminum aqueous batteries hold promise owing to the affordability, high capacity and safety [1, 2]. Eumelanin is the most common form of the pigment melanin in the human body, with diverse functions including photoprotection, antioxidant behavior, metal chelation, and free radical scavenging [3]. Sepia Melanin is a natural eumelanin extracted from the ink sac of cuttlefish. The poor solubility of melanin in most of organic solvent combined with the density of metal-binding catechol groups that reversibly bind mono and multivalent metal ions, constitutes the foundation and stability for its use in energy storage systems [4, 5]. In this work, we report on the use of sepia melanin with reduced graphene oxide (as conductive binder) grafted on carbon paper as a highly stable, biosourced, environmentally benign and biocompatible cathode for Zn^{+2} and Al^{+3} aqueous rechargeable batteries. This stable, environmentally benign and bio compatible cathode will enable applications from biomedical devices to grid storage.

Analysis of MoS_2 Coatings on Zn-Anode for High Efficiency Zn-Ion Rechargeable Battery Gerardo Gamboa, Sanket Bhoyate and Wonbong Choi; University of North Texas, United States

Zn-ion battery is an increasingly attractive alternative energy storage system compared to traditional Li-ion batteries due to their low cost, high theoretical capacity, and increased safety. However, dendrite formation limits the stability of the Zn metal anode and restricts the practical use of Zn-ion batteries. In our early work, MoS_2 via electrodeposition has been proven to be an effective barrier to Zn dendrite growth, however, the growth of such MoS_2 thin films has not been well studied. For this study, a series of tests on the deposition of MoS_2 on Zn of different grain size proved that Zn grain boundaries are favorable sites for the start of MoS_2 growth. The Zn coated anodes were then tested for their efficiency in symmetrical cell testing. The MoS_2 layer, as thin at 50 nm, increased the anodic diffusion of Zn ions and improved overall battery performance. The structure-property relations of MoS2 coatings on Zn has been studied systematically. The Zn ion conductivity of the MoS_2 coated anode with the variation of the coating thickness and morphology of MoS2 also has been studied. This study further reinforces the possibility of creating practical Zn-ion batteries as next generation energy storage systems.

9:35 AM EN03.01.06
Investigating Magnesium Ion Insertion in WS_2 Cathodes and Mg-CNT Composite Anodes Mayukh Nandy, Todd Houghton, Srivatsan Swaminathan, Arjun Modi and Hongbin Yu; Arizona State University, United States

Today, Lithium ion batteries are often the primary means of providing electrical power to a diverse ecosystem of devices, from mobile phones to electric vehicles. However, while capacity, cost, and reliability of Li-ion chemistries have steadily improved over the past two decades, limitations of the technology have become increasingly apparent. Indeed, despite considerable investment in LIBs, it is not clear the technology will reach optimal energy density and per-cell cost targets, laid out in industry and government-sponsored roadmaps, by the year 2030 at its current rate of progress. Furthermore, cost fluctuations in the price of raw materials used to fabricate LIBs and environmental impacts caused by both production and disposal have yet to be fully addressed.

Given the present and anticipated limitations of LIBs, investigations into alternative divalent metal-ion battery chemistries which utilize magnesium or zinc have continued to gain traction within the scientific and engineering community. Mg-ion cells offer a theoretical volumetric capacity which exceeds that of lithium while utilizing an element more abundant in the earth's crust. Mg anodes are also dendrite free, allowing greater practical capacitates than what is currently achievable with intercalation-type anodes used for LIBs. However,

Mg-ion battery cells consisting of sulfur-containing chalcogenide cathodes and Mg metal anodes must utilize unconventional and often volatile electrolyte solutions to inhibit anode surface passivation.

Here, the electrochemical behavior of WS_2 cathodes and Mg-CNT composite anodes in contact with a conventional EC/PC polymer-gel (PVDF-HPF) electrolyte is investigated within the context of Mg-ion insertion. Indeed, the atomic structure and interlayer spacing of WS_2 is similar to other Mg-insertion cathodes such as TiS_2 and MoS_2, while Mg-CNT composite anodes have demonstrated compatibility with perchlorate-containing electrolytes. Analysis of WS_2 cathodes via cyclic voltammetry shows a reversible redox reaction involving Mg species at the cathode/electrolyte interface, indicating a possible intercalation mechanism. Additional cathode and anode surface data is provided by XPS, Powder XRD, and Raman Spectroscopy. Cell fabrication details and analysis of reacted cathodes and anodes in the context of Mg-ion intercalation will be discussed.

SESSION EN03.02: Solid State Batteries

11:45 AM *EN03.02.01
Solid Electrolyte-Modified 4V Layered Cathodes for High-Voltage and Solid-State Lithium Batteries
Yuan Yang; Columbia University, United States

The development of next-generation energy storage demands electrode materials with higher capacity. One potential solution is to charge layered oxides, such as $LiCoO_2$ and $Li(Ni_xCo_yMn_z)O_2$ (NCM) cathodes, to a higher electrode potential so that more Li+ ions can be removed. However, this is often impeded by performance degradation arising from following phenomena: 1) phase transition in the bulk electrode, 2) surface reconstructions, and 3) electrolyte oxidation. In this talk I will present our recent studies on using ceramic electrolyte-based coatings to alleviate these issues. With a thin layer of $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP) coating, phase transition and surface reconstruction of $LiCoO_2$ are suppressed. Consequently, LAGP protected $LiCoO_2$ shows a discharge capacity of 196 mAh g^{-1} at 0.1 C when charged to 4.5 V vs. Li^+/Li. The capacity retention is 88% over 400 cycles . The LAGP coating also suppresses electrolyte oxidation when layered oxides are combined with polyethylene oxide (PEO)-based solid polymer electrolytes. While PEO is easily oxidized above 4 V vs. Li^+/Li when it is in contact with bare $LiCoO_2$ and NCM523, it is stable up to 4.3-4.4 V vs. Li^+/Li with a LAGP coating. When charged to 4.3 V, capacity retention of 89.7% over 200 cycles, and 93.8% over 100 cycles are achieved in LAGP-LiCoO2/PEO/Li cells and NCM523/PEO/Li cells, respectively. The corresponding average coulombic efficiencies are ~99.8%. These studies show that solid electrolyte coating is an effective approach to enhance interfacial stability of 4V layered oxide cathodes with various electrolytes at high electrode potentials.

12:10 PM EN03.02.02
Zeolite-Templated Carbon—A Model Framework Solid for Beyond Lithium-Ion Battery Cathodes
Romain J. Dubey[1,2], Erin E. Taylor[3], Kostiantyn Kravchyk[1,2], Maksym Kovalenko[1,2] and Nicholas Stadie[3]; [1]ETH Zürich, Switzerland; [2]Empa, Swiss Federal Laboratories for Materials Science & Technology, Switzerland; [3]Montana State University, United States

Beyond lithium-ion battery (LIB) chemistries demand new electrode materials exhibiting unique features to accommodate the larger and/or multivalent active ions. Zeolite-templated carbon (ZTC) is an ordered microporous carbon scaffold that is molecularly thin, electrically conductive, and connected in three dimensions. Its narrow pore size distribution is centered at 1.2 nm, permitting the controlled introduction and

ultrafast conduction of a wide range of molecular guests. We report methodological studies of the serviceability of ZTC as a stable cathode material across wide voltage ranges for both bulky, polyatomic anions (as in dual-ion electrochemistries) and divalent cations (as in magnesium-ion electrochemistries) in high energy density and high power density electrochemical cells. Charge storage proceeds by a purely capacitive mechanism at the cathode, mated with the faradaic mechanism of metal plating and stripping at the anode. Solid-state NMR spectroscopy sheds insight into the roles of the ion and solvent in charge/discharge cycling within the microporous framework of ZTC, with intuitive trends revealed based on ion size, solvent size, and solvent viscosity.

12:25 PM EN03.02.03
Comparison of Hong versus von-Alpen Type Nasicon Membranes for Use in a Rechargeable Seawater Battery Jeffrey B. Wolfenstine[1], Wooseok Go[2], Jeff Sakamoto[3] and Youngsik Kim[2]; [1]Solid Ionic Consulting, United States; [2]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); [3]University of Michigan–Ann Arbor, United States

The rechargeable seawater battery (SWB) is one of the potential candidates as a large-scale energy storage system due to its low cost and eco-friendliness compared to Li-ion batteries. However, the current seawater battery using a Hong Nasicon ($Na_3Zr_2Si_2PO_{12}$) [H-NASICON] Na-conducting membrane suffers from high ohmic polarization as a result of its low ionic conductivity. One way to reduce to this polarization is to use a Na-conducting membrane with higher ionic conductivity than H-NASICON. In this regard von-Alpen type NASICON ($Na_{3.1}Zr_{1.55}Si_{2.3}P_{0.7}O_{11}$) [VA-NASICON] was investigated as a possible replacement membrane for use in a SWB. The electrical, mechanical, chemical stability and SWB cell testing of VA-NASICON and H-NASICON were evaluated and compared. It was observed that VA-NASICON exhibited both a higher bulk and grain boundary conductivity leading to a total ionic conductivity of 3 times higher than that for H-NASICON. The results will be explained in terms of the difference in structure and microstructure between the two materials. The difference in the mechanical properties; hardness, fracture toughness and fracture stress between the two materials will be explained based on their microstructural differences. The ionic conductivity, structure and microstructure of VA-NASICON were unchanged after testing in seawater, suggesting it is chemically stable in seawater. Testing of VA-NASICON in SWB coin cells revealed it exhibited about 1.5 x the power compared to H-Nasicon. This value is in close agreement the lower ohmic resistance of VA-NASICON compared to H-NASICON. The results of this study suggest that of the two materials evaluated, VA-NASICON is the better choice for a Na-ion conducting electrolyte in a SWB than the current H-NASICON.

12:40 PM DISCUSSION TIME

12:55 PM EN03.02.05
Tuning Ionic Conductivity in Argyrodite Solid Electrolytes with Pseudohalides Annalise E. Maughan; National Renewable Energy Laboratory, United States

All-solid-state batteries hold the potential to transform electrochemical energy storage technologies. Replacing the flammable liquid electrolyte with a solid-state ion conductor can improve battery safety and may further increase battery energy density when paired with lithium metal anodes. However, widespread implementation of all-solid-state batteries is hindered in part by the fact that candidate solid-state electrolytes typically exhibit ionic conductivities that are several orders of magnitude lower than liquid electrolytes, which typically results in slow charge/discharge rates. While there are a multitude of candidate electrolyte materials for all-solid-state batteries, rapid advancements in this field necessitate a fundamental understanding of the relationships between composition and ionic conductivity. These design principles may then be leveraged to identify and target new materials with ionic conductivities that are competitive with existing liquid electrolyte technologies. One such family of materials is the argyrodites of the general formula Li_6PS_5X (X = halide or pseudohalide), as they can achieve ionic conductivities that are nearly competitive with liquid electrolytes. Because the X-site can be occupied by either halides or larger pseudohalides, these materials provide an exciting system to understand the underlying relationships between structure, composition, and ion conduction in candidate solid electrolytes. In

this work, I have prepared new argyrodite materials with pseudohalides at the X-site and have determined the structure-property relationships that contribute to low activation barriers and high ionic conductivities in these materials. This work highlights an exciting approach to tuning ionic conductivity in new electrolyte materials for potential applications in all-solid-state batteries.

1:10 PM EN03.02.06
Anharmonic Phonons, Superionic Diffusion and Ultralow Thermal Conductivity in Argyrodite Cu_7PSe_6
Mayanak K. Gupta[1], Jingxuan Ding[1], Dipanshu Bansal[1], Douglas Abernathy[2], Georg Ehlers[2], Naresh Osti[2], Wolfgang Zeier[3] and Olivier Delaire[1,1,1]; [1]Duke University, United States; [2]Oak Ridge National Laboratory, United States; [3]Justus-Liebig-University, Germany

We present a combined experimental and theoretical investigation of atomic dynamics in the superionic compound Cu_7PSe_6, rationalizing the atomistic diffusion mechanism and the impact of host lattice dynamics. Inelastic neutron scattering (INS) and quasi-elastic neutron scattering (QENS) were performed as a function of temperature and were complemented with ab-initio molecular dynamics extended to long time scales with the use of machine-learned potentials (MLMD). INS data reveal characteristic changes at the onset of superionic behavior, providing insights into the role of the host lattice dynamics, while QENS probes the superionic Cu diffusion via the jump length, residence time, and diffusion constant. The MLMD simulations reveal that the long-range Cu diffusion is limited by an inter-cluster hopping step, which is strongly coupled to the host phonon dynamics. Further, MLMD simulations enable us to capture the ultralow lattice thermal conductivity within the Green-Kubo framework. These results supersede the traditional quasiharmonic phonon picture to capture the strong anharmonicity in this superionic system.

This research was supported by the U.S. DOE.

1:25 PM EN03.02.07
Late News: Recycling Li7La3Zr2O12 (LLZO) and Li1.5Al0.5Ge1.5(PO4)3 (LAGP) -Based Electrolyte Composites Using the Cold Sintering Process Yi-Chen Lan and Enrique D. Gomez; The Pennsylvania State University, United States

The anticipated commercialization of all-solid-state lithium batteries highlights the urgent need to develop recycling strategies for solid-state electrolytes. Garnet type, $Li_7La_3Zr_2O_{12}$ (LLZO), and NASICON-type, $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP) electrolytes are particularly promising because of their high conductivity and good chemical stability against lithium metal and air, respectively. Here, we use cold sintering process to recycle degraded electrolytes with poor structural integrity. The low temperature allows co-sintering of composites, which still remains challenging for conventional sintering. Two model systems, LLZO with polypropylene carbonate (PPC) and lithium perchlorate ($LiClO_4$), and LAGP with bis(trifluoromethanesulfonyl)imide (LiTFSI) salts, are studied. LLZO-PPC-$LiClO_4$ shows a reprocessibility for eight times with ionic conductivities in excess of 10^{-4} Scm^{-1} at room temperature and relative densities of 76~80%, which are comparable with the values of pristine sample. LAGP-LiTFSI reprocessed composites exhibit high relative densities of around 90% and ionic conductivities above 10^{-5} Scm^{-1} at room temperature. Thus, we demonstrate the use of cold sintering to recycle ceramic-salt and ceramic-salt-polymer integrated electrolytes.

5:15 PM *EN03.03.01

Multi-Electron Intercalation Cathodes M. Stanley Whittingham; Binghamton University, The State University of New York, United States

The Olivine lithium iron phosphate cathode provides a very stable and high rate cathode for lithium and lithium-ion intercalation batteries. However, its energy density is much lower than that of the NMC layered oxides. This can be helped by switching to lithium manganese phosphate, which has an 0.5 V higher cell potential. To achieve energy densities approaching those of the layered oxides, it will be necessary to achieve a two-electron reaction per redox center. In principle, the anode can be lithium, sodium, magnesium or calcium. Vanadium is one of few suitable transition metal centers where a two-electron can be achieved, as vanadium can readily undergo between the +5 and +3 oxidation states, and in some cases to the +2 state. The earliest two-electron cathode was vanadium diselenide, VSe2, [1] with relatively low cell potentials as the reaction uses the +4 to +2 oxidation states. VS_2 would be expected to have more attractive potentials. Vanadium phosphates are found to readily and reversibly intercalate both two lithium or two sodium ions [2,3], with the former having cell potnetials around 4 and 2.5 volts. The challenges facing these systems will be discussed [4].

5:40 PM *EN03.03.02
The Effect of Crystal Structure on the Activity of Cu in Na-Ion Cathode Materials Enyuan Hu[1], Qinchao Wang[1], Yiman Zhang[2], Jue Liu[2] and Xiao-Qing Yang[1]; [1]Brookhaven National Laboratory, United States; [2]Oak Ridge National Laboratory, United States

Sodium-ion batteries are important for energy storage because sodium is much more abundant than lithium which is the fundamental element for lithium-ion batteries. From chemical point of view, sodium-ion cathodes open up opportunities for utilizing novel electrochemistries that are not possible in lithium-ion cathodes. For example, Fe^{3+}/Fe^{4+} and Cu^{2+}/Cu^{3+} redox cannot be utilized in lithium-ion cathode because of structural disorder or/and exceedingly high voltage that is incomptabile with currently available electrolyte. In sodium-ion cathodes, structural ordering enabled by the large size of sodium ion, the diversity of structures, and the relatively low voltage make it possible to utilize the Fe^{3+}/Fe^{4+} and Cu^{2+}/Cu^{3+} redox couples. This talk will focus on the latter one. Two kinds of materials with the same stoichiometry ($Na_{2/3}Cu_{1/3}Mn_{2/3}O_2$) but different structures (P2 and P3) are synthesized and characterized to understand the structure-property relationship in these materials. Synchrotron and neutron scattering as well as DFT calculations are used to understand the bulk structural changes during electrochemical cycling. Synchrotron-based hard and soft x-ray spectroscopies are used to understand the chemistries both in the bulk and at the surface in these two materials. The effect of crystal structure on the activity of Cu will be explained and the possibility of O activity will also be discussed.

6:05 PM EN03.03.03
Hierarchical Intercalant Orderings in Layered Oxides for Na- and K-Ion Battery Electrodes Jonas Kaufman and Anton Van der Ven; University of California, Santa Barbara, United States

Layered transition-metal oxides have been successfully employed as electrode materials for Li-ion batteries, however, intercalating Na or K instead often introduces effects that can diminish reversibility and rate capability. Within these materials, Na and K tend to stabilize additional host crystal structures accessed via topotactic phase transitions and display a stronger preference for ordering within the intercalation layers to minimize electrostatic energy. In some cases, rather than discrete orderings appearing at some particular intercalant concentrations, the stable orderings within a concentration range form a continuum, or a "Devil's staircase," of hierarchical orderings based on some underlying motifs. Using a first-principles statistical mechanical approach, we have identified several such sets of orderings in common layered oxides intercalated

with Na or K, within the O3/P3/O1 structure family. An important set of orderings appears in the P3 structure at intermediate concentrations, in which variants of one particular ordering are separated by periodically spaced antiphase boundaries. The overall density of boundaries in this case determines the average composition. Another notable set of orderings is predicted for K intercalation at high concentrations, where alternating regions of octahedrally and prismatically coordinated K exist in the same intercalation layer. This mixed coordination leads to significant distortions of the host structure. We discuss these sets of orderings in the context of phase stability predictions for several systems and compare our results to experimentally observed voltage profiles and structural evolution during cycling. We also explore ramifications for ion diffusion and electrode performance.

6:20 PM EN03.03.04

Origins of Irreversibility in Layered $NaNi_xFe_yMn_zO_2$ Cathode Materials for Sodium Ion Batteries Eric Gabriel[1], Changjian Deng[1], Paige Skinner[1], Sungsik Lee[2], Pete Barnes[1], Chunrong Ma[1], Jihyeon Gim[2], Miu Lun Lau[1], Eungje Lee[2] and Hui (Clair) Xiong[1]; [1]Boise State University, United States; [2]Argonne National Laboratory, United States

Layered $NaNi_xFe_yMn_zO_2$ cathode (NFM) is of great interest in sodium ion batteries due to its high theoretical capacity and utilization of abundant, environmentally-friendly elements. However, the evolution of the local bonding of the transition metals (TMs) beyond the first charge/discharge cycle is not well understood. In this work, we investigate the reversibility of TM ions in layered NFMs with varying Fe contents and potential windows after multiple cycles. Utilizing *ex situ* synchrotron X-ray absorption near edge spectroscopy (XANES) and extended X-ray absorption fine structure (EXAFS) of pre-cycled samples the valence and bonding evolution of the TMs are elucidated. Our results indicate that Fe redox (Fe^{3+}/Fe^{4+}) is active in the first several cycles in these $NaNi_xFe_yMn_zO_2$ samples, but on the 5th cycle Fe no longer participates in charge compensation. Manganese was found to be inactive for all cycles. The Ni redox couple contributes most of the charge compensation for NFMs beyond the 1st cycle. Ni redox is quite reversible in the cathodes with less Fe contents. However, the Ni redox couple shows significant irreversibility with high Fe content of 0.8, suggesting an interaction between Ni and Fe bonds. The electrochemical reversibility of the NFM cathode becomes increasingly enhanced with the decrease of either Fe content or with lower upper charge cutoff potential.

6:35 PM DISCUSSION TIME

6:50 PM *EN03.03.06

Open-Framework Polyanionic Compounds as Potassium Insertion Host Shinichi Komaba[1], Tomooki Hosaka[1], Shahul Hameed[1,2], Mirai Ohara[1], Tetsuya Takahashi[1], Kei Kubota[1,2] and Ryoichi Tatara[1,2]; [1]Tokyo University of Science, Japan; [2]Kyoto University, Japan

We reported the high working voltage of K-ion battery (KIB) comparable to Li-ion and higher than Na-ion batteries based on the fact that the standard potential of potassium is lower than those of lithium and sodium in nonaqueous electrolyte [1,2]. In 2015, our group reported a graphite negative electrode delivering >250 mAh g^{-1} with excellent reversibility [1]. Furthermore, a Prussian blue analogue (PBA) of $K_2Mn[Fe(CN)_6]$ demonstrated highly reversible potassium insertion/extraction and 4 V operation, realizing a 4 V-class $K_2Mn[Fe(CN)_6]$/graphite full cell [3]. The previous studies revealed that a three-dimensional open framework structure of PBAs is suitable for insertion/extraction of large K^+ ion. In addition to the PBAs, polyanionic compound and metal organic phosphate open framework (MOPOF) materials are potential positive electrode materials for KIBs due to their open framework structure and inductive effect. In this talk, our recent studies on potassium insertion into various polyanionic compounds and MOPOFs, such as orthorhombic $KFeSO_4F$ (o-$KFeSO_4F$), $KFePO_4F$, $K_6(VO_2)(V_2O_3)_2(PO_4)_4(P_2O_7)$ (K6V6P6), and $K_2[(VOHPO_4)_2(C_2O_4)]$ [4,5], will be presented to give a perspective of potassium insertion material design.
We have reported a reversible potassium extraction and insertion into o-$KFeSO_4F$, which has $KTiOPO_4$-type structure providing large channels for K^+ ion diffusion. In this study, potassium insertion mechanism of $KFe(III)PO_4F$ having the same crystal structure was examined and compared with that of o-$KFe(II)SO_4F$.

$KFe(III)PO_4F$ exhibited reversible potassium insertion and extraction based on the Fe^{3+}/Fe^{2+} redox couple. In addition to the $KTiOPO_4$-type structure materials, other open-framework materials of K6V6P6 and $K_2[(VOHPO_4)_2(C_2O_4)]$ were investigated. K6V6P6 delivered a reversible capacity of ca. 60 mAh g^{-1} with a plateau at 4.0 V. $K_2[(VOHPO_4)_2(C_2O_4)]$ exhibited a large discharge capacity of >100 mAh g^{-1} and excellent rate capability due to the facile migration of K^+ ions in the framework. From these results, we will present our future insight into electrochemical potassium insertion chemistry for battery applications.

The Ultimate Intercalation Limit in Disordered Rock Salt Electrodes Shyue Ping Ong, Haodong Liu, Zhuoying Zhu, Ping Liu and Xingyu Guo; University of California, San Diego, United States

Rechargeable lithium-ion batteries with high energy density that can be safely charged and discharged at high rates are desired for electrified transportation and other applications. In this talk, I will report the discovery of a disordered rocksalt (DRS) Li3V2O5 anode with near-optimal intercalation potentials for safe, fast-charging batteries. In particular, we will demonstrate that the outstanding electrochemical performance of these DRS electrodes can be attributed to a hitherto undiscovered redistributive lithium intercalation reaction with low energy barriers. Beyond the immediate practical applications, the discovery of this novel high-rate intercalation reaction opens a completely new space for the search of metal oxide electrodes for fast-charging, long-life lithium-ion batteries. Further, I will discuss a statistical analysis of the ultimate limits of intercalation into DRS type materials.

8:40 PM *EN03.04.02
Computational Study on the Intercalation Energy Storage Mechanism of Transition-Metal-Carbide MXene by Quantum-Classical Hybrid Simulation Yasunobu Ando[1,2]; [1]AIST, Japan; [2]Kyoto University, Japan

Two-dimensional transition-metal carbide MXenes has been known as a promising material of high-performance electrode for energy storage applications with both non-aqueous and aqueous electrolytes because it has electronic conductivity, ion capability in interlayer nanospace, and the redox activity of Ti. Especially, as an electrode of electrochemical capacitors, MXenes have a unique dependence of capacitance on intercalated cation species and a distinctive behavior that is both capacitive and pseudocapacitive depending on the electrolyte. To better understand electrochemical mechanism of these behaviors, we performed a microscopic theoretical analysis of the electric-double layer (EDL) in the interlayer nanospace of the MXene electrode by combining first-principles calculations based on density functional theory (DFT) and classical implicit solvation theory named three dimensional reference-site interaction model (3D-RISM) method [1]. By using the quantum-classical hybrid simulation, solvation effect at the interlayer nanospace of MXene electrode was taken into consideration appropriately with low computational cost comparable with conventional DFT simulation.

For the unique dependence of capacitance on intercalated cation species, our simulation results showed that the capacitance of EDL capacitors can be enhanced by a factor of 1.8, when the water molecules are strongly confined into the two-dimensional nanoslits of titanium carbide MXene electrode. This is because that dipolar polarization of strongly confined water overscreens an external electric field applied on the EDL and enhances capacitance with a characteristically negative dielectric constant of a water molecule [2, 3].

Another investigated feature is the distinctive behavior that is both capacitive and pseudocapacitive depending on the electrolyte. As a result of their electronic states simulated via the quantum-classical hybrid simulation, it was found that the hydration shell of intercalated ions prevents orbital coupling between MXene and the intercalated ions, which leads to the formation of an EDL and capacitive behavior. However, once the cations are partially dehydrated and adsorbed onto the MXene surface directly, because of orbital coupling of the cation states with the MXene states, particularly for surface-termination groups, charge transfer occurs and results in a pseudocapacitive behavior [4].

9:05 PM EN03.04.03
Correlating Crystallinity of Nb_2O_5 Fibers with Electrochemical Performance as Sodium-Ion Battery Electrode Carla G. Real[1], Davi Marcelo Soares[2], Gurpreet Singh[2] and Hudson Zanin[1]; [1]University of Campinas - UNICAMP, Brazil; [2]Kansas State University, United States

Research on niobium pentoxide (Nb_2O_5)-based electrodes for electrochemical energy storage devices is gaining traction because of its ability to store charge at high rates despite its wide bandgap and low electronic conductivity—a phenomenon not observed in other widely studied transition metal oxides electrode materials. Crystalline form of Nb_2O_5— orthorhombic and pseudohexagonal phases— also presents superior electrochemical stability and rapid ion transport of alkali-metal ions throughout the a–b plane. This work investigated the effect of different crystalline structures of Nb_2O_5 in micro/nano fibermat geometry as working electrode in sodium half-cells. The micro/nano fibermat geometry promoted Na-ion de/intercalation reactions combined with capacitive reactions. Results show that these materials present excellent cycling stability and specific capacity within 0 to 2.25 V potential window. Orthorhombic Nb_2O_5 outperform amorphous Nb_2O_5 and many other traditional high capacity metal oxide-based electrodes such as birnessite such as MnO_2 and RuO_2.

The Architectures for the Si and Li-Metal Anode Based Batteries with High Performances In Kim[1,2], Cary Hayner[1] and Xin Li[2]; [1]NanoGraf Corporation, United States; [2]Harvard University, United States

Currently, pure electric vehicles (EV) are produced from many car makers. And it is becoming more popular with the public. However, an additional increase of driving range with long life and high safety is necessary to make EV popularized completely. Also, aviation service such as air-taxi will be commercialized soon. Therefore, the application of new materials such as Si and Li-metal anode is essential to increase energy density dramatically at this moment. And proper electrode engineering has brought Si-based anode materials closer to commercialization from consumer applications. However, Si technology has not yet been significantly commercialized due to a number of shortcomings. In particular, cycle life and irreversible capacity losses due to side reactions continue to be issues that plague their widespread use. Thus, the addition of only thimbleful silicon is possible right now for practical batteries, and it is difficult for the dramatic increase of energy density of batteries.
In this presentation, we can check the current status of approaches for commercialization of Si anode based batteries. Also, newly developed advanced architecture with offering higher battery capacity and faster rate performance, all while being produced via a low-cost solution chemistry-based manufacturing process will be introduced. This scalable manufacturing procedures of silicon-based anode can lead to significantly improved performance of next-generation batteries, which have high energy density, long-term cycling stability, and fast

charging ability.
In the case of Li-metal, the electrode structure is going to be porous rapidly and the growth of Li dendrite is going to be generated rapidly. And those lead short cycle life performance, low safety and poor reliability. Thus, Li-metal anode is not possible to be applied to EV, and it is tested for the application of drones that have low requirement for life and safety.
In this presentation, we are going to introduce hybrid Li-metal battery, having high energy density (-800 Wh/L, -360 Wh/kg), high safety and long cycle life performance, which is applicable to practical EV. We applied hybrid Li-metal anode technologies and additional support from safe materials to retard thermal runaway.

10:00 PM *EN03.04.05
Phase Evolution and Interfacial Strain in Electrode Materials for Energy Storage Dong Su; Institute of Physics, Chinese Academy of Sciences, China

Advanced (scanning) transmission electron microscopy ((S)TEM) techniques have been intensively applied to study the reaction kinetics of electrode materials for secondary ion batteries. With/Combining different TEM techniques, including in-situ TEM and diffraction, HAADF-STEM, and STEM-electron energy-loss spectroscopy, researchers are able to probe local structural and chemical information of electrode materials at atomic resolution. This talk will focus on using in-situ and analytical TEM to characterize the oxide electrode material for lithium ion batteries. After reviewing the recent advances of in-situ TEM investigations on both anode and cathode, we will discuss the dynamical study on the phase evolution, strain effect and passivation layer of conversion-type Fe_3O_4, aiming to understand how reaction pathways affect the batteries performances [1-3]. In addition, this talk will present our investigations on effects of defects on capacity fade of Ni-rich Li(Ni, Mn, Co)O_2 cathode [4].

Enabling Low-Temperature Operation of Alkali Metal Anodes through Electrolyte Design Akila C. Thenuwara, Pralav P. Shetty and Matthew T. McDowell; Georgia Institute of Technology, United States

Low temperature (< -20 °C) operation of conventional Li-based secondary batteries is severely hindered by increased cell polarization, which can be attributed mainly to the low ionic conductivity of electrolytes and sluggish solid-state diffusion in graphite. Additionally, charging of graphite-based Li-ion batteries under low-temperature conditions can cause undesirable Li plating; thus, there is a substantial need for next-generation anodes that can operate over a wide temperature range. In this regard, the Li metal anode has previously shown some promise for ultra-low temperature operation; however, it generally exhibits limited cycling capability and low Coulombic efficiency. Here, we develop advanced electrolyte formulations (which consist of dual salts and/or dual solvents) and show that these formulations can substantially improve the Coulombic efficiency (CE) of both Li and Na metal anodes down to -60 °C.[1-2] For example, we show that pure ether based electrolytes exhibit CE < 50 % for Li cycling at -40 °C, but using FEC additives increases CE to over 90 %. The origins for this improved performance are primarily due to beneficial alterations of the solid-electrolyte interphase (SEI) at low temperatures when these additives are used. We perform cryo-transmission electron microscopy (TEM) and X-ray photoelectron spectroscopy to link SEI chemistry and structure as a function of temperature to cycling performance. Furthermore, we investigate the solvation structure of Li^+ and Na^+ in the electrolyte and relate solvation structure to SEI formation. Our results provide important guidance for designing electrolytes and interfaces for efficient operation of high-energy batteries at low temperatures.

High Valent Redox for Li and Na-ion Electrodes William C. Chueh; Stanford University, United States

High-valent redox at the positive electrodes are required to achieve high-energy density in intercalation lithium and sodium-ion batteries. Yet, high-valent redox is usually accompanied by strong structural irreversibility and hysteresis. In this talk, I will present a unified understanding of high valent redox that integrates redox chemistry with point defect chemistry and coulombic interaction. I will draw examples from lithium-ion electrode chemistries based on 3d, 4d and 5d transition metals.

10:55 AM *EN03.05.02
Stacking-Fault Enhanced Lattice Oxygen Redox in Layered Cathode Materials Yan-Yan Hu[1,2]; [1]Florida State University, United States; [2]National High Magnetic Field Laboratory, United States

Many layered Li and Na cathode materials deliver additional capacity via lattice oxygen redox reactions. However, its origin is under debate. The irreversibility and hysteresis of lattice oxygen redox limit its practical applications. With combined magnetic resonance spectroscopy and computational studies, we have discovered that layered structures with stacking faults can afford additional removal of lithium accompanied by lattice oxygen redox. The insights gained in this work may inspire materials design which employs structural disorder for achieving high-capacity stable cathode materials.

11:20 AM *EN03.05.03
Anionic Redox Chemistry in Layered Chalcogenide Cathode Materials for Sodium Batteries Zulipiya Shadike[1], Tian Wang[2], Ding-Ren Shi[2], Enyuan Hu[1], Zheng-Wen Fu[2] and Xiao-Qing Yang[1]; [1]Brookhaven National Laboratory, United States; [2]Fudan University, China

The discovery of anionic redox chemistry in layered compounds was traced back to ligand-hole chemistry in chalcogenides, in which the redox of S_2^{2-}, Se_2^{2-} or Te_2^{2-} ions in layered structures might be involved. In recent years, investigation of oxygen redox chemistry in cathode materials has attracted a lot of attention based on the potential to increase the energy density of Li-ion batteries. The reversible oxygen redox reactions in layered cathode materials such as Li-rich NMC and $Li_2Ru_{0.5}Mn_{0.5}O_3$ are considered to be responsible for their extraordinary specific capacity. Similarly, the reversible sulfur redox reaction in layered chalcogenides is considered a promising approach to increase the specific capacities in sodium-ion batteries. However, only a limited number of studies on the nature of anionic redox chemistry in layered chalcogenides have been reported in the literature. Issues about whether the redox mechanism is based on reversible formation/decomposition of S-S dimers or formation of electron holes on S are still under debate. We have designed and synthesized a series of layered cathode materials such as $NaCrS_2$, Ti substituted $NaCrS_2$ and Se substituted $NaCrS_2$ for a systematic

investigation about the nature of anionic redox chemistry of sulfur, including the formation of localized electron holes, anionic dimers, and disulfide-like species during the charging process. The charge compensation mechanisms and structural evolution of these cathode materials have been investigated using synchrotron-based multi-model characterization techniques such as in situ/ex situ x-ray absorption spectroscopy, x-ray diffraction, x-ray pair distribution function analysis as well as spatially resolved x-ray fluorescence mapping combined with DFT calculation. These results provided valuable information for the development of high energy cathode materials based on the anionic redox reaction for sodium batteries.

Mechanism of Non-Hysteretic Redox Exceeding Conventional Transition Metal Capacity in Na-Ion Cathode Materials Daniil A. Kitchaev, Julija Vinckeviciute and Anton Van der Ven; University of California, Santa Barbara, United States

Harnessing electrochemical activity exceeding the limit of conventional transition metal redox, observed in Li-excess and Na-excess cathodes, is one of the most promising routes towards dramatically increasing the energy density of battery materials. However, the majority of materials exhibiting such anomalous capacity suffer from substantial voltage hysteresis and structural degradation. Two prominent exceptions are $Na_2Mn_3O_7$ and Li_2IrO_3, which are model systems for non-hysteretic redox beyond the transition metal limit. Nonetheless, the mechanism of their redox behavior and stability to structural transformation remains controversial, with significant inconsistencies between experimental observations and the "O-redox" theories proposed as explanations of their behavior. We derive the first redox mechanism to consistently explain all experimental observations in $Na_2Mn_3O_7$ and Li_2IrO_3, based on the oxidation of a delocalized, π-bonded network of metal-*d* and oxygen-*p* orbitals. This mechanism, which we term π-redox, leads to a unique behavior wherein the oxidation potential, capacity and structural evolution is dictated by the long-range structure of the π-network rather than local bonding environments. We show that π-redox competes with oxidation-driven transition metal migration, which is dominant in layered Li-excess materials based on Li_2MnO_3 but may be suppressed in layered Na-ion cathodes. The π-redox mechanism establishes the first rigorous framework for engineering non-hysteretic redox beyond the limit of transition metal capacity, which is particularly promising in layered Na-ion materials.

12:00 PM EN03.05.05
Controlling Covalency and Anion Redox Potentials Through Anion Substitution in Li-Rich Chalcogenides Joshua J. Zak[1], Andrew J. Martinolich[1], David N. Agyeman-Budu[2], Seong Shik Kim[1], Nicholas H. Bashian[3], Ahamed Irshad[3], Sri Narayan[3], Brent C. Melot[3], Johanna Nelson Weker[2] and Kimberly A. See[1]; [1]California Institute of Technology, United States; [2]SLAC National Accelerator Laboratory, United States; [3]University of Southern California, United States

Conventional positive electrode materials for Li-ion batteries utilize a Li^+ intercalation mechanism charge-balanced by redox on transition metals within an oxide host lattice. Moving forward, multielectron cathodes that exhibit contributions to the redox from structural anions are of interest for the potential to dramatically increase charge storage capacity. Oxidation of Li-rich oxides can achieve >1 electron oxidation per transition metal, but, due to the high-voltage redox, electrolyte degradation and other unwanted side reactions can convolute interpretation of the electrochemistry. Later group chalcogenides, however, operate within the potential window of the electrolyte preventing complications associated with electrolyte decomposition. Capacity beyond that

compensated by a one-electron oxidation on a transition metal is often attributed to anion oxidation enabled by covalent interactions with the metal. Here, we report anion redox in a solid solution, $Li_2FeS_{2-y}Se_y$, where the metal-anion covalency is tuned through systematic substitution of the anion to further understand the role of covalency on reversible anion redox. Multielectron redox is observed in all materials in the solid solution along with a systematic shift of the high-voltage plateau associated with anion oxidation. Spectroscopic studies indicate concomitant Fe and S/Se oxidation throughout charging contrary to the discrete Fe and S redox observed in Li_2FeS_2. Perselenide bonds are found to form in Li_2FeSe_2 accompanied by the irreversible formation of a new, high-impedance phase, which leads to poor cyclability. Therefore, while tuning metal-chalcogenide covalency provides a handle to control anion redox, the structural changes incurred through anion-anion bonding can be deleterious to material performance. As such, developing holistic understanding of the electronic and structural response to anion redox is necessary to design next-generation multielectron energy storage materials.

SESSION EN03.06: Advanced Performance and Phenomena in Batteries

Thursday Afternoon, April 22, 2021
EN03

1:00 PM *EN03.06.01
Charge Transfer in Intercalation Cathode Materials—Towards Extreme Fast Charging Christopher S. Johnson; Argonne National Laboratory, United States

Due to their exceptional high energy density, lithium-ion batteries are of central importance in many modern electrical devices. A serious limitation, however, is the slow charging rate used to obtain the full capacity. Thus far, there have been no ways to increase the charging rate without losses in energy density and electrochemical performance. Here we show that the charging rate of a cathode can be dramatically increased via interaction with white light. We find that a direct exposure of light to an operating $LiMn_2O_4$ 3-D intercalation cathode during charging leads to a remarkable lowering of the battery charging time by a factor of two or more. This enhancement is enabled by the induction of a microsecond long-lived charge separated state, consisting of Mn^{4+} (hole) plus electron. This results in more oxidized metal centers and ejected lithium ions are created under light and with voltage bias. We anticipate that this discovery could pave the way to the development of new fast recharging battery technologies.

1:25 PM *EN03.06.02
Insight on the Local Structure and Electronic Structure of Positive Electrode Materials for Na-Ion Batteries Using Solid State NMR Dany Carlier[1,2], Long Nguyen[1,2,3], Yohan Biecher[1], Paula Sanz Camacho[1,2], Jacob Olchowka[1,2], Marie Guignard[1], Christian Masquelier[3,2], Claude Delmas[1] and Laurence Croguennec[1,2]; [1]Institut de Chimie de la Matière Condensée de Bordeaux, France; [2]RS2E, France; [3]Laboratoire de réactivité et de chimie des solides, France

For energy storage, nowadays, Li-ion and Na-ion batteries are major technologies for mobility applications and also for large-scale storage of energy and their integration in the grid. In the scope of finding new positive electrode materials with improved performances, the deep understanding of the link between their structure, electronic structure and electrochemical behavior is crucial. To that extent, Magic Angle Spinning Nuclear Magnetic Resonance (MAS-NMR) appeared to be a key tool, as for paramagnetic materials, it allows to probe both, the local structure and the local electronic structure thanks to the hyperfine interaction.
Using MAS-NMR we showed that several phosphate materials as $Na_3V_2(PO_4)_2F_3$, which is a promising materials for positive electrode application Na-ion batteries exhibit some O-defects leading to the formation of V^{4+} ions locally. These V^{4+} ions are forming a vanadyl-type bond with the defect O, and affect the

electrochemical cycling performances. ^{23}Na, ^{31}P MAS (and ^{19}F) NMR was also used to probe the local structure and electronic structure of the solid solution series $Na_3V_2(PO_4)_2F_{3-y}O_y$ and other $Na_3(V,M)_2(PO_4)_2F_{3-y}O_y$ materials with M = Fe or Al. These studies combined with DFT calculations lead to a better understanding of the local arrangement and the local electronic structure.
Layered Na_xMO_2 oxides are also interesting for application in Na-ion batteries. Among them, P2-Na_xCoO_2 appears to be a model material with a very specific phase diagram and unusual physical properties. ^{23}Na MAS NMR was used to characterize the changes in the electronic structure during Na deintercalation. It was shown that the position of the signal is governed by an interplay between the Fermi contact interaction due to localized electrons and the Knight interaction due to the delocalized ones. Depending on the Na content, the evolution of the ^{23}Na shift provides then information about the local electronic structure in the material.

1:50 PM EN03.06.03
Na/K Ion Exchange Mechanism in Layered $Na_3Ni_2SbO_6$ Cathode—"Na Redistribution by K Insertion"
Haegyeom Kim[1], Deok-Hwang Kwon[2], Jaechul Kim[3], Bin Ouyang[2], Hyunchul Kim[1], Juila Yang[2] and Gerbrand Ceder[2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Stevens Institute of Technology, United States

Recently, an ion exchange reaction that can stabilize potassium intercalation oxides was proposed as a new approach to develop cathode materials for K-ion batteries (KIBs).[1-4] Such ion exchange method indeed has frequently used for the development of novel Li-layered oxides to attain structural features of Na layered oxides.[5-7] This ion exchange reaction has the potential to discover novel layered cathode materials by accessing the metastable states that cannot be achieved by conventional high-temperature calcination. However, the solid-state ion-exchange mechanism and the resulting phase evolution are not well understood.
In this work, we systematically investigate electrochemical Na^+/K^+ ion exchange in layered oxides using O3-type Na_3Ni_2SbO as a model system.[8] We found intriguing phase transitions according to the relative Na/K content upon K intercalation by *in-situ* XRD: (i) coexist of K-rich and Na-rich phases during charging and discharging and (ii) phase transformation of Na-rich phase upon K intercalation. Strong electrostatic repulsion between Na and K ions that have radically different bond lengths to coordinating oxygen ions can result in this complex phase evolution. We uncovered that upon Na^+/K^+ ion exchange Na ions remaining in the desodiated $Na_xNi_2SbO_6$ phase are pushed away from the intercalating K ions, thereby separating Na-rich and K-rich phases in a particle. Interestingly, this phenomenon creates complex, three-phase equilibrium during the desodiation and potassiation processes in $Na_xK_yNi_2SbO_6$: phase equilibrium between one K-rich and two Na-rich phases or two K-rich and one Na-rich phase is observed, as dictated by the Gibbs phase rule. Our computational study further demonstrated that this phase separation originates from the large lattice mismatch along the *c*-axis between the K-rich and Na-rich phases. Our observations and interpretations demonstrate that "ion-exchanged" systems may be more complex to interpret than the previously understood. Our analysis should be applicable to other ion-exchange systems where the exchanged ions are not well miscible in the host structure.

2:05 PM EN03.06.04
Re-Examining the Electronic Structure of Layered $NaMO_2$ Electrodes Christopher Savory and David O. Scanlon; University College London, United Kingdom

Ab initio modelling is a useful tool in the study of battery electrodes, able to support experimental findings and predict new phases and behaviours, providing a suitable and accurate method is used. Regular Density Functional Theory (DFT) functionals such as the commonly used PBE, however, are impacted by the 'self-interaction error' which severely impacts the accuracy of calculations involving the highly-correlated 3d valence electrons in transition metals (TMs).[1]
Historically, the study of battery cathodes using DFT has been improved through the addition of 'U' parameters, which correct for the self-interaction error,[2] however these parameters require tuning to experimental measurements on the specific system in question, while also need to be varied during intercalation (with changes in oxidation state) and can be highly sensitive to changes in transition metal composition. This makes them unideal for the description of complex cathode systems containing multiple transition metals and valencies, weakening them as a predictive tool for new systems.
Additionally, with the increased development behind the theory of anionic redox in cathodes, accurate assessment of the charge transfer transition, which standard DFT tends to underestimate, is crucial.[3] Minimally-parameterised hybrid DFT functionals such as HSE06 are routinely used to accurately predict the band gaps of semiconductors, however previous studies have highlighted disagreement between hybrid DFT and band gaps recorded from XPS-BIS for TM cathode materials, as well as overestimation of predicted intercalation voltages.[4,5]
In this study, we address this issue, using a combination of HSE06 and high-level quasiparticle self-consistent GW calculations (with the inclusion of additional terms to W from the Bethe-Salpeter equation) to explore the electronic structure of sodium intercalation cathodes such as $NaCoO_2$ and $NaFeO_2$, as well as comparisons to their lithium counterparts, at the highest feasible level of ab initio theoretical methods. We demonstrate how the inclusion of additional screening terms to the on-site Coulombic interaction leads to changes in the valence electronic structure of the cathodes not seen in cheaper methods. Secondly, we examine how the inclusion of corrections for the van der Waals forces, crucial to simulation of deintercalation behaviour, varies between hybrid and standard DFT. In doing so, we hope to set out a blueprint for guiding accurate future calculations of cathodes that rely less on parameterisation, and as such demonstrate reliable predictive power.

Exploration of A-Mn-O System with A=Li, Na, K for Cathode Material in Non Aqueous Batteries Valerie Pralong, Justine Jean, Erwan Chandler, Audric Neveu, Melanie Freire and Evan Adamczyk; CNRS CRISMAT, France

One of the major challenges of the 21st century is our ability to solve energy-related problems caused by ever-higher consumption, demography and standard of living. It is therefore imperative to anticipate this energy demand and this in a context of sustainable development. Storage technologies are highly dependent on the materials used and it is necessary to search for new materials with advanced properties that are also ecological and economical. Despite the high performance of lithium-based materials, its cost is driving scientists to develop alternative systems based on sodium and potassium, which are widely abundant in the earth's crust.

Manganese based oxide materials are promising cathodes for alkaline ion batteries due to their high energy density, low-cost and low-toxicity. Focusing on layered-type structures, one has to cite of course the A_xMnO_2 families showing interesting insertion properties in all the system based on lithium, sodium and even more recently potassium. Moreover, we notice that the system A-Mn-O are extremely rich in term of original structures. For example, we found a new lithium rich composition $Li_4Mn_2O_5$ with a disordered rock salt structure that was showing an exceptional capacity of about 300mAg/g. Interestingly, the material $Na_4Mn_2O_5$ has been reported with a layered type structure, different from the lithiated phase and we will discuss the

relationship between the structure and insertion properties. Also, we have reported the electrochemical properties of the phase $Na_2Mn_3O_7$ with a lamellar structure built of $[Mn_3O_7]^{2-}_{\infty}$ anionic layers hold by sodium ions; a reversible discharge capacity of 160 mAh/g at 2.1V vs Na^+/Na through a biphasic process is observed.

In recent years, we can see a growing interest of researchers for K-ion batteries (KIBs). Thus, many compounds have been studied belonging to families already studied for Li-ion and Na-ion batteries (LIBs and NIBs, respectively). So far, only lamellar phases K_xMnO_2 are reported. We will discuss on the possibility to explore and find other composition for this application.

In this presentation, we will discuss and compare the three system Li-Mn-O, Na-Mn-O and K-Mn-O in term of structure and properties towards the insertion of alkaline ions.

Direct Electrochemically Grown Layered Na Transition Metal Oxides as High-Capacity High-Rate Cathodes for Na-Ion Battery Arghya Patra, Beniamin Zahiri, Patrick Kwon and Paul Braun; University of Illinois at Urbana-Champaign, United States

State-of-the-art synthesis for layered oxide cathodes for Na ion batteries involves prolonged high temperature (>700ºC) processing for long reaction times (~24 hours) under high oxygen pressure, followed by slurry casting after mixing with binders and additives. Here, we introduce, an intermediate temperature (350ºC), dry molten sodium hydroxide mediated electrodeposition process to grow air and moisture sensitive layered sodium transition metal oxides, Na_xMO_2 (M=Co, Mn, Ni, Fe) as binder-and-additive-free cathode materials for Na ion battery. Despite being synthesized at the lowest reported synthesis temperature and reaction times, our electrodeposited oxide cathodes retain the key structural and electrochemical performance observed in the high temperature bulk synthesized analogues. We demonstrate that tens of microns thick, >80% dense Na_xCoO_2 and Na_xMnO_2 can be deposited at a growth rate of ~5-20 mg/cm^2/hr, with near theoretical gravimetric capacity, rate capability and chemical diffusion coefficient of Na^+ ions. The electrodeposited oxide cathodes can be accessed as both the thermodynamically stable O3 and metastable P2 polytypes. Growth texture, tortuosity and microstructure of the electroplated oxide cathodes are controlled by careful tuning of the deposition parameters and bath chemistry. Fast Na^+ ion conducting 110, 101 and 104 facets can be vertically oriented, enabling electrodeposited cathodes with ultrahigh loading (30-40 mg/cm^2), low tortuosity and reversible high areal capacity (3-4 mAh/cm^2) while operating at high current densities (~1 mA/cm^2).

SESSION EN03.07: Panel Discussion: Beyond Li Ion Battery
Session Chairs: Xin Li and Anton Van der Ven
Thursday Afternoon, April 22, 2021
EN03

8:15 PM *
Panel Discussion: Beyond Li Ion Battery M. Stanley Whittingham[1], Shinichi Komaba[2], Christopher S. Johnson[3] and Debra R. Rolison[4]; [1]State University of New York at Binghamton, United States; [2]Tokyo University of Science, Japan; [3]Argonne National Laboratory, United States; [4]U.S. Naval Research Laboratory, United States

Four distinguished panelists will share their vision with the audience on the topic of beyond Li-ion batteries through short presentations that are followed by a panel discussion. Next generation Li, Na, K and Zn ion batteries will be discussed in this 2 hour panel session with a particular focus on advanced cathode, anode and electrolyte concepts and designs. The audience will have the opportunity to directly interact with the panelists.

Schedule:
Introductory Remarks by Anton Van der Ven
Presentation by Stanley M. Whittingham—*Li Batteries for Energy Storage to Green the Environment - Is There Another Battery Alternative?*
Presentation by Shinichi Kimoba—*Sodium and Potassium Chemistry for Batteries*
Presentation by Christopher Johnson—*Calendar Life of Si Anodes in LIBs: Time is Ticking*
Presentation by Debra Rolison—*The Case for Zinc*
Panel Discussion
Closing Remarks by Anton Van der Ven

This session will be moderated by Anton Van der Ven and Xin Li

SESSION EN03.08: Poster Session
Session Chairs: Xin Li and Naoaki Yabuuchi

EN03.08.01
A Hierarchical Three-Dimensional Porous Graphene Film for Suppressing Polysulfide Shuttling in Lithium-Sulfur Batteries Eman Alhajji; King Abdullah University of Science and Technology, Saudi Arabia

The lithium-sulfur (Li-S) battery is a promising next-generation rechargeable battery with high energy density. Given the outstanding capacities of sulfur (1675 mAh g^{-1}) and lithium metal (3861 mAh g^{-1}), Li-S battery theoretically delivers an ultrahigh energy density of 2567 Wh kg^{-1}. However, this energy density cannot be realized due to several factors, particularly the shuttling of polysulfide intermediates between the cathode and anode, which causes serious degradation of capacity and cycling stability of a Li-S battery. In this work, a simple and scalable route was employed to construct freestanding laser-scribed graphene (LSG) interlayer with nano-sized carbon particles, which effectively suppresses the polysulfide shuttling in Li-S batteries. Thus, a high specific capacity (1160 mAh g^{-1}) with excellent cycling stability (80.4% capacity retention after 100 cycles) has been achieved due to the unique structure of hierarchical three-dimensional pores in the freestanding LSG.

EN03.08.02
The Effect of Microwave Heating Time on Electrochemical Energy Storage of Nickel Hydroxide Nanomaterials Nuha A. Alhebshi, Sumaih F. Alshareef and Faten E. Al-Hazmi; King Abdulaziz University, Saudi Arabia

The significant attention toward developing flexible electronic devices and smart textiles have been encouraging the utilization of various flexible current collectors as well as investigating their interface effects on the device performance. Using the traditional fabrication of supercapacitors and batteries onto textile fabrics and polymeric substrates requires additional processes of conductive-layer coatings and non-conductive binder additives. In this work, binder-free flexible electrodes of nickel hydroxide are directly deposited on conductive carbon cloth (CC) using a simple and short-time synthesis assisted by microwaves. The growth of nickel hydroxide nanoflakes is observed using x-ray diffraction and scanning electron microscopy after 10 min and 30 min of the microwave heating time at a fixed temperature. All our samples are tested as supercapacitor electrodes in potassium hydroxide aqueous electrolyte at room temperature. In specific, electrochemical impedance spectroscopy is used to study the electrode/electrolyte interface in terms of ions diffusion and charge transfer resistance. The redox Faradic mechanism of energy storage is confirmed by the cyclic voltammetry and

the galvanostatic charging-discharging techniques. Nickel hydroxide nanoflakes that are prepared in 30 min show a conformal coating on all substrate microfibers and a consequently larger electrochemical active area which results in higher capacitance than the electrodes prepared in 10 min. Such optimization in the design and fabrication of binder-free electrodes and current collectors could improve the flexibility of electronic devices and promote their implantation into functional textile applications.

EN03.08.03
Computational Modeling of Halogen Intercalation in Cathode Hosts for High Energy Density Dual Ion Batteries Naman Katyal and Graeme Henkelman; The University of Texas at Austin, United States

High voltage dual-ion batteries (DIBs) have been reported using a water-in-bisalt electrolyte, metal halides, and graphite electrodes but the full cell energy density is lower than commercialized batteries. Replacing graphite with heteroatom substituted graphite lamellar structures like BC_3, $B_3C_{10}N_3$ can improve the performance of the dual ion battery. Heteroatom substituted graphite materials have been studied for metal ion intercalation in anodes and show similar electronic conductivity as graphite but remain unexplored for the halogen intercalation process. Halogen intercalation process in cathode host is of significant importance because it is directly related to the capacity and cycling of the battery. Halogen intercalation in graphite has been explored using diffraction and isothermal based studies but a rigorous thermodynamic and kinetic investigation is still missing. From a thermodynamic standpoint, only one study has reported the existence of chlorine intercalated graphite structure but a range of bromine intercalated graphite structures have been reported although there is no consensus about the staging process or the composition of bromine in graphite layers at every stage. Hence, a computation model to understand the halogen intercalation processes in graphite structures is needed to resolve the inconsistencies that can be used to study heteroatom substituted graphite structures. Through this model, our aim is to predict materials that can replace graphite as host structures in dual ion batteries to achieve high energy densities and longer cyclability.

In this paper, we aim to find answers to fundamental questions about the thermodynamics and kinetics of bromine and chlorine intercalated graphite structures: a.) Develop a convex energy hull diagram for bromine-intercalated structures and study the staging at every composition from the most stable structure, b.) Find, if any, thermodynamic stable chlorine-intercalated graphite structures, c.) Develop a convex energy hull diagram for bromine and chlorine co-intercalated structures and study the staging at every composition from the most stable structure, d.) Kinetic investigation of halogen diffusion in graphite using adaptive kinetic Monte Carlo techniques. All the calculations in this work have been performed using Density Functional Theory (DFT) methods in Vienna ab-initio Simulation Package (VASP). For all the structures modeled in this work, we will model structural properties using Raman Spectrum, Extended X-Ray Fine Spectrum, X-Ray Diffraction, and Pair distribution functions that are directly accessible via experiments as well. This will help us guide experiments towards an informed choice of cathode hosts for dual ion batteries using water in the salt electrolytes from our computational results.

EN03.08.04
Machine and Deep-Learning for Intercalation Compounds—Elucidating Structure-Property Relationships Kaci L. Kuntz, Yuchen Yang, Elena K. Barker, Daniel Carlebach, Mahit Dagar, Madeleine K. Eatchel, Tyler L. Gerstein and Anna K. Jiricko; University of Utah, United States

With the extensive research of intercalation in layered materials beginning in 1841, these compounds have since found use in battery, optoelectronics, and biomedical wearable devices (*Inorg. Chem. Front.* 2016, 3, 452; *Adv. Mater.* 2019, 1808213). With essentially limitless possibilities of intercalation compounds due to combinations of different host lattices and guest species (e.g. donor, acceptor, and neutral compounds), intercalation chemistry creates the unique opportunity to engineer and design future compounds for specific applications such as electrodes. However, this is only feasible if structure-property relationships of intercalated materials are extracted. Due to the large quantity of data on intercalation compounds, machine learning (ML) is an ideal approach (*J. Phys. Mater.* 2019, 2 032001). Previous ML studies of graphite intercalated compounds have often

been limited in scope to alkali metal guests (*J. Mater. Chem. A* 2019, 7, 19070-19080; *ACS Appl. Mater. Interfaces* 2019, 11(20), 18494–18503). Here, we employ ML and deep-learning (DL) to elucidate structure-property relationships in bulk graphite intercalation compounds with donor, acceptor, and neutral guests. Furthermore, we explore the application of these structure-property relationships to single and few-layered intercalation compounds where surface adsorption and intercalation of these ultra-thin materials can play significant roles in resulting properties of the intercalation compound as the 2D limit is approached.

EN03.08.05
Spin Structure and Magnetic Ordering of $Li_2Ni_2TeO_6$ Kory Wells, Tekiyah Robinson, Jonathan Valenzuela, Sunil Karna and Doyle Temple; Norfolk State University, United States

We studied tellurium containing oxide $Li_2Ni_2TeO_6$ using x-ray diffraction, magnetic measurements, and neutron powder diffraction. $Li_2Ni_2TeO_6$ crystallizes in the orthorhombic crystal structure having *Fddd* space group. The magnetic susceptibility measurements performed at H*a* = 1 kOe exhibits an upturn below ~80 K and maintains its constant value up to lower temperatures. The magnetic hysteresis is seen at lower temperatures below 80 K indicating the development of a ferromagnetic component that get disappears above 80 K revealing a ferromagnetic transition at ~80 K. Both ferromagnetic and antiferromagnetic peaks are revealed in neutron powder diffraction patterns below 80 K.

EN03.08.06
Transition Metal Monochalcogenides as Anodes for Metal-Ion Batteries Shakir Bin Mujib, Marren Ellis, Porter Herold and Gurpreet Singh; Kansas State University, United States

As the most promising energy storage system (ESS), rechargeable alkali metal-ion batteries have been attracting great attention. The selection of suitable electrode material is a fundamental step in the development of metal-ion batteries to achieve enhanced performance. In the present study, we have explored the feasibility of monolayers of phosphorene analogs, namely, group IV monochalcogenides. The monochalcogenide layers form structures belonging to the same orthorhombic crystal system and possess similar hinge-like structures like phosphorene. Just this unique hinge-like structure and the isolation of 2D forms will introduce strong anisotropic properties endowing them with fascinating properties, such as tunable bandgaps, high carrier mobility, and predominantly anisotropic and optical properties. We present two-dimensional (2D) sheets of germanium and tin sulfides and tellurides as promising high-capacity and stable materials for energy storage. GeS, GeTe, SnS, and SnTe with layered structures are prepared via a simple liquid-phase exfoliation approach. As-synthesized 2D nanosheets can effectively increase the electrolyte-electrode interface area and facilitate metal ion transport. As a result, GeS, GeTe, SnS, and SnTe nanosheets deliver a high areal capacity of 1.76 mAh cm^{-2},1.05 mAh cm^{-2}, 2.66 mAh cm^{-2}, 1.22 mAh cm^{-2} respectively as anodes in lithium-ion batteries (LIBs). Further analysis of these monochalcogenides in sodium-ion batteries (SIBs) and potassium-ion batteries (KIBs) suggest that layered monochalcogenides can be potential anodes in other metal-ion batteries.

EN03.08.07
Late News: Detailed Redox Mechanism and Self-Discharge Diagnostic of 4.9 V LiMn1.5Ni0.5O4 Spinel Cathode Revealed by Raman Spectroscopy Ankush Bhatia, Jean Peirre Pereira-Ramos and Rita Baddour-Hadjean; Institut de Chimie et des Matériaux Paris-Est (ICMPE) UMR 7182 CNRS, France

Lithium-ion rechargeable batteries have been widely used as a power source for portable devices and are available for applications to electric vehicles, which demand high power, high energy, inexpensive and safe batteries[1]. Their continuous improvement is tightly bound to the understanding of lithium (de)intercalation phenomena in electrode materials. Here we address for the first time the use of Raman spectroscopy to understand the mechanisms involved in high voltage spinels $LiNi_xMn_{2-x}O_4$ (x = 0; x = 0.5).

Although the “classical” lithium-containing spinel $LiMn_2O_4$ (LMO) has been extensively studied, certain points remain unclear. For instance, very little is known on the nature of the intermediate composition $Li_{0.5}Mn_2O_4$

postulated halfway during charge/discharge for which attempts to model a lithium/vacancy ordering have been made. On the other hand, compositions within the solid solution $LiNi_xMn_{2-x}O_4$ ($0 < x \leq 0.5$) are of interest as they exhibit increasing voltage upon lithium extraction. The best compromise is found for $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO): with a high specific capacity of 140 mAh g^{-1} available along a wide potential plateau at ≈ 4.7 V vs Li^+/Li, LNMO is widely studied as a next-generation positive electrode material for Li-ion batteries. LNMO exists as two polymorphs, "disordered" (*Fd-3m*) where Mn/Ni occupy *16d* sites randomly and "ordered" (*$P4_332$*) where Ni and Mn sit on ordered *4a* and *12d* sites. So far, the disordered form has outperformed the ordered form from an electrochemical point of view [2]. The delithiation/lithiation mechanism of disordered LNMO has been previously investigated using mainly X-ray and neutron diffraction and *in situ* synchrotron. Although these methods provide a picture of the phase evolution during cycling, we still lack information about the atomic level variations as lithium ions deintercalate/intercalate in the crystal structure of LNMO. Raman spectroscopy on the other hand is a very appropriate tool to enrich the knowledge of the structure of Li intercalation compounds at the scale of the chemical bond. A wealth of structural information including symmetry changes, local disorder, changes in bond lengths, emergence of secondary phases, etc… can be extracted from the Raman study of various Li intercalated host lattices, providing therefore a better insight into the mechanisms governing the electrode performances [3].

In this work, Raman spectroscopy (RS) is used to explore the short-range environment in LMO and LNMO. We provide here for the first time a complete assignment of the LMO and LMNO Raman fingerprint as well as a detailed qualitative and quantitative picture of structural and vibrational changes during the charge-discharge of these cathode materials. A careful RS investigation led on the LMO cathode during the first charge process provides the first detailed experimental evidence of an ordering scheme at the scale of the chemical bond of the intermediate composition $Li_{0.5}Mn_2O_4$. A combined approach using XRD and RS allows picturing changes in LNMO crystal structure and in the oxidation states of the nickel during stages of the charge-discharge process. Raman spectra collected between 3.5 and 4.9 V display rich and varying features. Appropriate analysis based upon Raman spectra fittings allow access to a quantitative estimation of the different Ni^{2+}, Ni^{3+} and Ni^{4+} redox species in the LNMO spinel oxide at different oxidation-reduction states. This makes RS a powerful probe to evaluate the state of charge of the cathode material. Finally, we demonstrate the great efficiency of RS as an efficient and simple diagnostic tool of the self-discharge phenomenon occurring in the LNMO electrode.

Late News: High-Throughput Screen Printing of Supercapacitors Based on Vanadium Dioxide Amal Alamri[1], Mohammad Vaseem[2], Nuha A. Alhebshi[1,1], Bashaer Minyawi[1] and Atif Shamim[2]; [1]King Abdulaziz University, Saudi Arabia; [2]King Abdullah University of Science and Technology, Saudi Arabia

Vanadium dioxide-based materials have promising structural, electrical, and chemical properties that promote it as an essential component in electronics, energy conversion, and storage devices such as supercapacitors. One of the main challenges that may limit the implementation of vanadium dioxides in large-area applications is the vacuum-based synthesis processes such as chemical vapor deposition. In addition, the high-cost and complication of the conventional fabrication of supercapacitor electrodes are considered as other challenges. In this research, our high-quality vanadium dioxide-based ink is synthesized using a solution process [1]. Then, the ink is monolithically printed on flexible substrates. The printing technique is straightforward, scalable, and cost-effective. The electrochemical impedance spectroscopy was used to measure the resistance of the printed supercapacitors, while the cyclic voltammetry was conducted to confirm the energy storage mechanism of our materials. The areal electrode capacitances are calculated from the galvanostatic charging-discharging experiment to be in the range of 650-200 μF/cm^2 at areal currents of 10-80 μA/cm^2. Interestingly, the effects of the material properties on the device performance are investigated and deeply correlated to explain the results.

Such innovative printed supercapacitors would attract attention as energy storage components that can be fully integrated into systems of flexible electronic devices, the Internet of Things, and smart textiles.

Electrochemical Studies of TaS_2 as Electrode Material for Monovalent-Ion Batteries Davi Marcelo Soares and Gurpreet Singh; Kansas State University, United States

Electronic and automotive industries are strategic towards economic development owing to their substantial participation in the gross domestic product of several countries. Currently, these industries converge on the pursuit of higher energy density batteries for their products, for instance, wearable electronic devices and electric cars. Furthermore, beyond lithium-ion battery systems are also gaining traction given the uncertainty of lithium supply in the future. As a consequence, in order to develop high-performance monovalent-ion batteries further understanding of intercalation process of monovalent ions – such as Li^+, Na^+ and K^+ – in layered materials is desirable, because this process is the stepping-stone towards novel battery technologies. Belonging to transition metal dichalcogenides (TMD) family, tantalum disulfide (TaS_2) is a layered polymorph with superconducting behavior that, unlike several TMD, presents metallic conductivity in its 2H phase. In addition, the interlayer spacing of TaS_2 – approximately 6% larger than TiS_2 – makes it a promising host material for intercalation of alkali metal ions with radii larger than Li^+. Here we report 2H-TaS_2 as electrode material for lithium- (LIB), sodium- (SIB), and potassium-ion (PIB) batteries in a comprehensive electrochemical study to unveil aspects such as charge storage mechanism, ionic diffusion coefficient calculation, and impedance information obtained in the frequency domain analysis in half-cell configuration. Results indicate that first cycle charge specific capacity of LIB is 344 mAh g^{-1}. Moreover, long term cycling reveals reasonable stability with capacity decay of 0.23% per cycle within 40 cycles as PIB at 50 mA g^{-1}. To summarize, this work intends to shed light on the understanding of charge storage mechanism of 2H-TaS_2, and ultimately contribute towards the development of high-performance electrode materials for monovalent-ion batteries.

8:10 AM EN03.09.03
Effect of Sodium Dodecyl Benzene Sulfonate on Self-Discharge in Electric Double-Layer Capacitors Tareq Kareri[1,2] and Arash Takshi[1,1]; [1]University of South Florida, United States; [2]Najran University, Saudi Arabia

One of the most important obstacles that make supercapacitors an inappropriate option to replace batteries at this time is self-discharge. Energy loss in supercapacitors is significant, especially when the charging time is short. Reducing the charge redistribution, by enlarging electrodes porosity is a possible solution to minimize the self-discharge. More focus has been given in this work to study the effect of sodium dodecyl benzene sulfonate (SDBS) on the spontaneous voltage drop in electric double-layer capacitors (EDLCs). Different concentrations of SDBS were added to change the porosity of PEDOT:PSS-based electrodes. The lowest voltage drop (ΔV) (-11.3%) was achieved in the PEDOT:PSS-based electrode with 2.0 wt% of SDBS. Also, the experimental results showed that increasing the concentration of SDBS more than 2.0 wt% leads to a reduction in the slope of the self-discharge curve and voltage drop directly. The samples with a high percentage of SDBS showed a sharp initial voltage drop due to high leakage current and high internal resistance. At the high scan rate of 200 mV/s,

the highest measured specific capacitance of 11.4 F/g was reached in the electrode with 2.0 wt% of SDBS. Results indicated that the porosity structure of the electrode has an important role in decreasing the self-discharge in EDLCs by reducing the spontaneous voltage drop.

8:20 AM EN03.09.04
Elucidating the Na, and K Intercalation and Diffusion in Carbon Anodes – Insights from Computational Modelling at the Atomic Scale Emilia Olsson and Qiong Cai; University of Surrey, United Kingdom

DFT simulations of Na, and K on different carbon motifs (defective graphene basal planes, planar graphitic layers, cylindrical pores, and combinations of these) found in hard carbon anode materials were conducted to investigate their effect on the metal intercalation. We show that both oxygen-, and nitrogen-containing defects are energetically favorable to form on these carbon motifs (in agreement with experimental characterization),[3–5] both at the basal plane, in the graphitic stacks, and on strained edge sites. Assessing the effect of these defects on Na, and K interaction with the carbon structure, we found that these defects improve the initial sodiation and potassiation steps, but that the strong interaction between the metals and the defects can limit their diffusion, leading to irreversible capacity loss. To elucidate the effect of the same defects on divalent ion battery metals (Ca, Mg, and Zn) we expanded our study to also include these. Ca was shown to have the highest affinity towards these anode models, whereas neither Mg or Zn could not be shown to favorably adsorb. Intercalation in expanded graphitic pores showed that the narrow graphitic stacks with interlayer distance of < 3.4 Å for Na, and < 3.8 Å for K is inaccessible for intercalation. Graphitic stacks with interlayer distance < 6 Å were found to be important for metal storage, whereas wider planar pores and cylindrical pores are beneficial for Na and K diffusion. [2] These simulations further showed that both these pore shapes and sizes are instrumental in the electrochemical performance of these anodes and need to be considered in computational modelling.

Outlook on K-Ion Batteries Mauro Pasta and Shobhan Dhir; University of Oxford, United Kingdom

Due to the rapid battery market expansion, and the limited and geographically concentrated lithium and cobalt resources, there is significant concern regarding the short-term supply and long-term sustainability of lithium-ion batteries (LIBs). Potassium-ion batteries (KIBs) are emerging as a promising complementary technology to LIBs due to the relative abundance of potassium. KIBs can also use graphite anodes providing a critical advantage over sodium-ion batteries (NIBs).

In my talk, I will provide a brief overview of the most promising cathodes [1], anodes [2] and electrolytes to date and a concise techno-economic model of KIBs. I will then discuss the critical research challenges that need to be addressed for KIBs to become a viable technology [3].

Practical Li||NMC Batteries Enabled by Designs of Fluorinated Electrolyte Solvents Hansen Wang, Zhiao Yu, William Huang and Yi Cui; Stanford University, United States

Development of Li metal anodes is critical to the realization of next generation high specific energy batteries. Commercialization of Li metal anodes, however, is plagued by its poor cyclability. This is because Li metal inevitably reacts with electrolytes, forming mechanically vulnerable solid-electrolyte interphase (SEI). With the significant volume fluctuation during Li metal cycling, the SEI easily cracks, leading to dendritic growth and continuous capacity loss. Electrolyte engineering recently arises as one of the most promising approaches to address these issues. Novel electrolyte systems alter the Li-ion solvation structure, enabling much improved Li deposition homogeneity and Coulombic efficiency (CE). However, further studies are still in demand. First, recently developed electrolyte recipes are usually complicated or cost-inefficient (high concentration, multi-solvent, multi-salt, etc.). Second, understandings on the working mechanisms of these Li-compatible electrolytes are still controversial. **Here, we design and synthesize a family of fluorinated ether molecules that enables practical Li metal battery cycling performances with optimized electrolyte formulations and study their working mechanisms**.
Fluorinated 1,4-dimethoxylbutane (FDMB), 1,5-dimethoxylpentane (FDMP), 1,6-dimethoxylhexane (FDMH) and 1,8-dimethoxyloctane (FDMO) are designed and synthesized for the first time as solvents for Li metal battery electrolytes. When Li salts are dissolved, the O and F atoms on these molecules chelate onto Li-ions simultaneously, leading to a unique brownish electrolyte color and **high stability to metallic Li as well as high voltage cathodes**. With these molecules, we demonstrate two electrolyte formulations that enables practical Li metal battery cycling performances. In the first formulation, we combine FDMB with 1 M LiFSI salt. It achieves excellent CE (over 99.5%) with a single-salt-single-solvent electrolyte configuration. As a result, a Cu||NMC532 anode-free pouch cell (~250 mAh) runs for 100 cycles before 80% capacity retention under lean electrolyte condition. In the first formulation, we use FDMH as the main solvent. Due to its reduced Li salt solubility, small portion of dimethoxyethane (DME) is added to enable much reduced ionic and interfacial resistance, resulting in the 1 M LiFSI/6FDMH-DME electrolyte. It enables 250 cycles of 20 μm Li||NMC811 cells before 85% capacity retention. Cu||NMC811 anode-free pouch cells also last for 120 cycles before reaching 75% of initial capacity. We show that the molecular design of solvent molecules could serve as one of the most promising strategies enabling practical Li metal batteries. Additionally, with an **advanced pouch cell pressure sensing platform**, we show that the cycling performances of these electrolytes are weakly affect by the operational pressure.
With characterization tools, we further demonstrate the working mechanism of these electrolytes. XPS shows an FSI^- anion-derived SEI chemistry with LiF nanoparticles accumulating with cycling on the deposited Li metal surface. This inorganic, anion-derived SEI chemistry is further confirmed by Cryo-STEM and AFM characterizations. With electrochemical experiments, we verify that **the formation of an anion-derived, LiF rich rSEI (residual SEI, SEI remaining on the electrode after Li stripping) framework is likely the key to homogeneous Li deposition and prolonged cycle life in these electrolytes**, as well as other previously reported Li-compatible electrolyte systems with LiFSI. These findings will serve as critical guides to the electrolyte designs of Li metal battery in the future.

8:50 AM EN03.09.07
First-Principles Predictions of New Lithium Iron Oxysulfides for Battery Applications Bonan Zhu and David O. Scanlon; University College London, United Kingdom

Historically, the identification of new Li-ion cathode materials has led to significant advances in the field, and currently, they underpin the overall performance and production costs of batteries. Accurate first-principles calculations, coupled with the database-based big-data approach, has led advances and predictions into new materials in the past[1]. The scarcity of data among the underexplored chemical spaces, however, has limited the ability of such approaches for computationally predicting truly new materials. In this work, we apply *ab initio* random structure searching (AIRSS)[2,3], an unbiased massively parallel structure prediction method, to search for stable phases in the Li-Fe-O-S chemical space. Experimentally, an anti-perovskite phase Li_2FeSO[4] had been shown to be a promising low-cost earth-abundant cathode material with good rate capacity. Our search was able to re-discover this phase and its low-temperature distortions, along with a range of other previously unknown stable and metastable phases. Their potential for battery applications has been assessed. The use of crystal structure prediction helps us pursue fundamental structure-property relationships in cathodes, and thus will also help the field to explore and find new paradigms in the future.

Theoretical Exploration on the Defect Chemistry of Sodium Titanates for High Power Sodium-Ion Anodes
Yong-Seok Choi[1,2,1], Sara I. Costa[3,2], Nuria Tapia-Ruiz[3,2] and David O. Scanlon[1,2,1]; [1]University College London, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]Lancaster University, United Kingdom

The low cost and abundance of sodium have driven growing interest in Na-ion batteries (NIBs) as a possible alternative to Li-ion batteries. Nevertheless, fundamental differences between Na and Li, such as ionic radius and reduction potential, make it challenging to develop suitable electrode materials for embedding Na ions. Among the various electrodes explored to date, sodium titanates ($Na_2Ti_nO_{2n+1}$) anodes arise as one of the most promising candidates due to its large abundance and nontoxicity [1,2].
Early approaches on improving electrochemical performance of sodium titanates revealed that the adjustment of n value of $Na_2Ti_nO_{2n+1}$ can change the arrangements of constituent TiO_6 octahedra and thus, affect the capacity and cycle life of the anodes [3-5]. In general, sodium titanates with higher Na contents (e.g. $Na_2Ti_3O_7$) possess layered structures with high capacity, whereas those with lower Na contents (e.g. $Na_2Ti_6O_{13}$) have tunnel structures with long cycle life [6]. Despite these efforts, titanate anodes without any materials modifications commonly suffer from poor rate performance, which mainly results from the intrinsic insulating nature of titanate anodes associated with large band gap of 3.7-3.9 eV [3,7].
One of the most effective ways to improve the electrical conductivity is to narrow the band gap of materials. The defect chemistry of sodium titanates, however, has not been fully analyzed, and remains a bottleneck in the design of anodes for high power applications. In this study, using layered $Na_2Ti_3O_7$ and tunneled $Na_2Ti_6O_{13}$ as testbed materials, we analyze the intrinsic defects and their effects on electronic structures and fermi level position. Using hybrid Density Functional Theory calculations, we evaluate the dominant native defects, and provides guidelines for defect engineering for anodes with improved performance.

Transition-Metal Dichalcogenide Heterostructures for Use as Electrodes in Li-Ion Batteries Conor J. Price, Francis Davies, Edward A. Baker and Steven P. Hepplestone; University of Exeter, United Kingdom

In order to address the ever-increasing demand for better battery materials [1], we present a study exploring the potential of multi-layered heterostructures made from transition-metal dichalcogenides (TMDCs) in order to understand the benefits and drawbacks such layered materials could have as potential device electrodes.

Layered materials of atomically thin sheets have demonstrated promise as electrode materials due to their interlayer spacing allowing for easy lithium intercalation and diffusion. One family of such materials is the transition metal dichalcogenides (TMDCs) [2,3], which have already demonstrated promise in this application [4]. Further, recent advances in CVD [5] have allowed the development of novel materials formed from the heterostructuring of component TMDCs. These 'designed' materials allow for tailoring of material properties by utilising the new physics that arises from their combination. In particular, the opportunity to optimise transport, diffusion barriers and maintain the higher capacities that some structures offer, could provide a new generation of electrode materials.

We show how the properties of heterostructures and superlattice systems change compared to the constituents, highlighting the advantages and disadvantages of these materials, and estimate the maximum capacity of these structures. We do this using first principles density functional theory, explaining how the open-circuit voltage profiles and lithium diffusion barriers change for the composites, and the potential such structures have for future battery development.

Structure-Dependent Sodium–Ion Storage Mechanism of Cellulose Nanocrystal-Based Carbon Anodes for Highly Efficient and Stable Batteries Jung-Eun Lee, Su Jeong Yeom, Hyun-Wook Lee and Han Gi Chae; UNIST, Korea (the Republic of)

In the recent time, sodium-ion batteries (SIBs) has been attracted as a substitute of lithium-ion batteries (LIBs) due to the depletion of Li and the similar physicochemical properties of Na to Li. However, because of the larger ionic radius of Na^+ (102 pm) than Li^+ (78 pm), the hard carbon which shows wider interlayer spacing and porous structure compared to graphite has been actively investigated for use as anodes of SIBs. In the current study, spray-dried cellulose nanocrystals (CNCs) carbonized over a wide temperature range (i.e., 800–2500 °C) were prepared for carbon anodes of SIBs. The carbonized CNCs exhibited low surface area of 1.5 m^2/g which is required to ensure minimal loss of Na ions for SEI layer formation. The structural variations in the CNC-based carbon anodes are correlated with the sodiation mechanism by investigating the galvanostatic voltage profiles, and it is found that Na ion adsorption takes place in the less-ordered carbonaceous structures followed by intercalation into the more ordered internal carbon structure with an average interlayer spacing of >0.37 nm. Among the various anodes examined, the CNCs carbonized at 1500 °C (C1500) deliver the highest reversible

specific capacity of 311 mA h g^{-1} at a current density of 10 mA g^{-1}, and exhibit an outstanding rate capability (273 mA h g^{-1} at 400 mA g^{-1}). In addition, they also possess an excellent specific capacity retention of 92.3% even after 400 cycles at 100 mA g^{-1}, along with an initial coulombic efficiency of 85%. Density functional theory (DFT) calculation exhibits that the energy barrier for Na ion intercalation of C1500 (0.20 eV) is almost a half that of the CNCs carbonized at 2500 °C (0.39 eV). We therefore believe that our results establish a foundation for the materials and their corresponding electrochemical properties, in addition to providing a novel route for the development of highly effective SIB systems.

9:30 AM EN03.09.16
Anchored Mediator Enabling Shuttle–Free Redox Mediation in Lithium–Oxygen Batteries Youngmin Ko and Kisuk Kang; Seoul National University, Korea (the Republic of)

Redox mediators (RMs) are considered an effective countermeasure to reduce the large polarization in lithium-oxygen batteries. Nevertheless, achieving sufficient enhancement of the cyclability is limited by the trade-offs of freely mobile RMs, which are beneficial for charge transport but also trigger the detrimental shuttling phenomenon. Here, we successfully decoupled the charge-carrying redox property of RMs and shuttling phenomenon by anchoring the RMs in polymer form, where physical RM migration was replaced by electron self-exchangealong polymer chains. Using a model system of a polymer, PTMA (2,2,6,6-tetramethyl-1-piperidinyloxy-4-yl methacrylate), whose repeating unit containsthe well-known RM tetramethylpiperidinyloxyl (TEMPO), it is demonstrated that PTMA is capable of functioning as a stationary RM, preserving not only the redox activity of TEMPO, but also the charge-carry property enabled by electron exchange along polyemr chain. Anchoring the RM in air electrode as polymer foam successfully prevents the shuttle phenomena. Consquently, the efficiency of RM-mediated Li2O2 decomposition remains remarkably stable without the consumption of oxidized RMs or degradation of the lithium anode, resulting in marked improvement of the performance of the lithium-oxygen cell.

9:40 AM EN03.09.17
Performance of Selenium-Graphene Composite as Potassium Ion Battery Cathode Vidushi Sharma and Dibakar Datta; New Jersey Institute of Technology, United States

Current advancements in energy technologies rely on combining the high-performance active electrodes with two-dimensional materials such as graphene for enhanced conductivity, mechanical stability and flexibility. Understanding the physical and electrochemical attributes of the formed interfaces can assist in device designing and performance. We utilize Density functional theory (DFT) to present an insightful analysis of selenium(Se) and graphene(Gr) composite cathode for potassium ion batteries. Se is replacing S as a favored cathode choice for being less reactive, free from shuttle effects, and possessing superior electrical conductivity. However, it falls short on electronic conductivity and abundance as per the industrial scale. Thus, Se based electrodes are consistently used with a carbon-based conductive additive to target long product life and weighted efficiency. To this end, the electrochemical performance of the Se-K cathode is determined by open-circuit voltage (OCV) plot and is compared with its counter-part Gr interfaced Se-K cathode. Significant variation in voltage plot and inter-atomic distances is seen due to the presence of Gr additive. To further the interface analysis, the interface strength of the Se/Gr 3D/2D interface has been quantified and correlated to the crystal structure, size, surface chemistry, and surface potential of the interfacing materials. The present analysis covers the chemical, physical and electrochemical contributions of Gr additive to the Se-K cathode for potassium ion battery which can assist the experimentalist and industries in fine-tuning the design of Se/Gr composite cathodes.

9:50 AM EN03.09.18
Deep Learning Inverse Design of Vascular Porous Structures for High Rate Performance Batteries Po-Chun Hsu; Duke University, United States

Vascular channel structures are ubiquitous in nature. Examples such as roots, blood vessels, and lung alveoli

show how vasculatures represent the optimal structures with a perfect balance between surface area and mass transport. For lithium-ion batteries, creating vascular porous channels in the electrodes can potentially enhance the transport and kinetics by ensuring the fresh supply of electrolyte that mitigates the electrode polarization and thereby achieve high power or fast charging without damaging the electrode. However, it is challenging to optimize for the vascular structure from the immense parameter hyperspace. Variables such as radii, angles, and branch numbers constitute millions of possible combinations. In addition, even if the vascular structure could be optimally designed, it is nontrivial to fabricate them at the scale of battery cells. In this talk, I will show our recent research progress that uses deep learning and finite element modeling to quickly predict the battery performance and also to inverse-design the parameters of the most efficient vascular electrode structure. Depending on the model complexity, we can arbitrarily choose the performance criteria among charge capacity, cycle life, maximum local temperature, and maximum local stress. The performance of the predicted vascular electrode is then validated by microfabrication. By connecting artificial intelligence and micromanufacturing, we envision this research will significantly broaden our design parameter hyperspace of high-rate energy storage devices and provide an effective general approach for solving multiscale and multiphysics problems in reactive flow systems.

10:00 AM EN03.09.20
Unforeseen Electrical Breakdown Properties of Metal-Aluminum Oxide-Metal Structures Herbert Kliem and Kapil Faliya; Saarland University, Germany

The electrical breakdown properties of metal-aluminum oxide-metal structures are investigated. The structures are prepared on silicon wafers in vacuum. A bottom electrode consisting of Cu (thickness 600nm) and Al (60nm) is prepared by thermal evaporation first. Then the aluminum oxide film (200nm) is deposited by electron beam evaporation from ceramic powder with a low oxygen support. Au, Cu or Pd (85nm) are evaporated on top using a shadow mask. The diameter of the top electrodes varies between .1mm and 1.9mm. The whole structure is prepared without breaking the vacuum.
Capacitance vs. frequency measurements of the device reveal a relaxational dielectric permittivity caused by fluctuating protons in the amorphous oxide [1]. Then a ramp voltage positive at the top electrode with speed 1V/s is applied. Before the sample finally has an electrical breakdown in fields of up to 4.5MV/cm single partial breakdown spots are visible at the top electrode. They appear in fields above 1MV/cm. At comparable voltages the density of the spots is three to four times higher at the Pd electrode than at the Cu and Au electrodes. A similar observation was published by P. Ball [2]. Pd electrodes can exhibit an electrochemical mechanical damage because of a high H flux and hydrogen evolution.
On the top the breakdown spots have a diameter of about 20 micrometer. Using an AFM it is found that the spots form caves or craters which are as deep as 1.5 micrometer. They penetrate the bottom electrode and reach down into the silicon substrate [3]. Considering the crater's volume and the specific heats of the different materials the energy necessary to form the craters by thermal energy can be calculated. This energy is compared to the electrostatic energy stored in the capacitance at the voltage where the spot appears. For the smallest capacitance of about 3pF with a diameter of .1mm and a spot voltage of 36V the electrostatic energy available from the structure is 50 times smaller than the energy necessary to melt the materials. If the materials are evaporated, the electrostatic energy is even 350 times smaller than the required evaporation energy [3].
It seems that the electrical breadown with its hot plasma channel triggers another so far unknown process which delivers the energy necessary to form the craters. At the present moment one can only speculate about the physical nature of this effect. It remains an open question if this process is somehow related to the supposed cold fusion reported 31 years ago [4] and recently discussed again in [2].

Design Optimization of Low Cost, Highly Efficient Aqueous Zinc-Iodide Flow Battery Monalisa

Chakraborty[1], Sebastian Murcia[1], Joan Ramon Morante[1,2] and Teresa Andreu Arbella[1,2]; [1]Catalonia Institute for Energy Research, Spain; [2]University of Barcelona, Spain

Redox flow batteries offer a reliable solution for future grid-scale energy storage due to its flexible design in decoupling energy and power independently. In comparison with mostly investigated and commercialized all vanadium redox flow batteries, aqueous zinc-iodide flow battery (ZIFB) is a highly promising contender due to its cost-effectiveness, environment friendliness, safety, and high energy density. Currently it is possible to achieve a ZIFB with high energy density based on aqueous ZnI_2 as electrolytes. However, there are still obstacles to overcome before utilizing its full potential. Therefore, various research is under investigation to improve the battery design by optimizing its components towards the development of high-performance batteries. For example, achieving reversible Zn deposition/dissolution is highly challenging in Zn-based batteries. Inhomogeneous growth of metallic Zn on the surface of the anode during charging, can lead the cell to improper discharge. Herein, we have carried out the performance comparisons of different carbon based anodes on the basis of their physical structure, hydrophilic properties and electrical conductivities. We have found that planar, graphitized and highly conductive anode can lead to efficient Zn deposition/dissolution, resulting the cell to achieve high energy efficiencies. On the other hand, electrolyte has a major contribution in scaling up the battery performance. Due to an imbalance of concentration of solutes between the anode and cathode compartments during electrochemical cycling, the differential osmotic pressure results in water migration through the ion-permeable membrane from the compartment with lower ionic strength to the compartment with higher ionic strength, which is usually overlooked by using a static positive compartment, limiting its capacity. The addition of extra solute to the electrolyte solution is a way out to resolve this issue and reach an ionically balanced situation between two compartments. In this work, we have carried out the experimental analysis of a lab-scale Zn-I flow battery as per our theoretical ionic strength calculations to reach an overall balanced system. From the theoretical calculation, it has been proven that by adding extra potassium iodide (KI) to an electrolyte of 1:1 ZnI_2: KI, the ionic balance between the compartments could be achieved. We have performed electrochemical impedance spectroscopic (EIS) as a tool to study the solution resistance and ionic conductivity of the half-cell compartments. Further full cell cycling following post-mortem analysis of the half-cell electrolytes ensured no water migration between compartments during cycling, also excellent cycling efficiencies have been achieved. Overall, the mechanisms of optimizing anode material and electrolyte design, show an promising path to enhance the performance Zn-I flow batteries, which enlighten a step forward to the research in the next-generation aqueous flow batteries.

The work was funded by MINECO/ERDEF through WINCOST (ENE2016-80788-C5-5-R) and CCU+Ox (PID2019-108136RB-C33) projects.
M. Chakraborty received PhD grant from the EU Horizon 2020 research and innovation programme (DOC FAM COFUND 2016) under the Marie Sklodowska–Curie grant agreement No 754397.

10:20 AM EN03.09.24
Enabling Highly Efficient High-Voltage Potassium-Ion Batteries with Ionic-Liquid Electrolytes Samuel J. Wheeler[1], Michele Fiore[1,2], Kevin Hurlbutt[1], Isaac Capone[1], Jack Fawdon[1], Riccardo Ruffo[2] and Mauro Pasta[1]; [1]University of Oxford, United Kingdom; [2]University of Milano-Bicocca, Italy

Potassium-ion batteries are a promising alternative to conventional lithium-ion batteries. They have the potential to be low cost and sustainable as they can contain only cheap and abundant elements. In potassium-ion batteries lithium is replaced with potassium, the copper current collector is replaced with aluminium, and high-performance cathodes do not require cobalt. They have the crucial advantage over sodium-ion batteries that graphite, the commercial lithium-ion anode, can reversibly intercalate potassium but not sodium.

Potassium manganese hexacyanoferrate (KMnHCFe), a Prussian blue analogue, operates at a high voltage of around 4 V vs. K^+/K and has a high theoretical specific capacity of 155 mA h g^{-1}. During a recent analysis of non-aqueous potassium-ion batteries we identified KMnHCFe||graphite as one of the most promising potassium-ion battery chemistries [1]. However, numerous challenges remain such as preventing aluminium

current collector corrosion at high voltage and minimising parasitic reactions from water remaining in the KMnHCFe structure, both of which reduce the coulombic efficiency. Additionally, an electrolyte that performs well with both the KMnHCFe cathode and graphite anode must be developed.

In this work we make two key advancements to address the challenges presented by the KMnHCFe||graphite system [2]. Firstly, a systematic optimisation of the citrate-assisted synthesis of KMnHCFe was performed, using high-throughput synthesis and characterisation tools, to reduce the defect and water content whilst controlling for particle size. Secondly, an ionic-liquid based electrolyte, 1 M KFSI in $Pyr_{1,3}FSI$ (potassium bis(fluorosulfonyl)imide in N-butyl-N-methylpyrrolidinium bis(fluorosulfonyl)imide)), was employed that forms stable passivating layers on both the cathode and anode, leading to highly efficient half-cell cycling. The electrochemical performance of KMnHCFe was observed to be highly dependent on particle size, the larger particles showing lower specific capacity but better cyclability. An optimised KMnHCFe material displayed a specific capacity of 119 mA h g^{-1} and a stable coulombic efficiency of 99.3%, a significant improvement over the previous state of the art. In the same electrolyte graphite displays excellent electrochemical performance maintaining 99% of its specific capacity after 400 cycles and a stable coulombic efficiency of 99.94%.

Understanding the Nuclear Quantum Effects on Proton Transfer in $Ti_3C_2T_2$ MXene with Co-Cation (Li^+, Na^+, K^+) Intercalation Using ReaxFF Path-Integral Molecular Dynamics Karthik Ganeshan and Adri C. van Duin; The Pennsylvania State University, United States

Due to the fast intercalation kinetics and the potential for pseudocapacitance, layered materials are promising for supercapacitor energy storage and understanding the role of ion confinement and transport is critical in enhancing the required properties of high energy and power density. Two-dimensional metal carbides and nitrides of early transition metals (MXenes) are one such class of materials that enable fast surface redox reactions and combine properties of high conductivity with hydrophilicity [1]. High volumetric capacitance of 1500 F cm^{-3}, has been achieved with the most widely used Ti_3C_2 MXene with aqueous H_2SO_4 electrolyte [2], indicating a dominant role of proton transport and surface protonation reactions contributing to the enhanced energy storage.

Nuclear quantum effects (NQEs), e.g. tunneling, on the structural and dynamical properties might be of significance due to the delocalization of light nuclei such as hydrogen but are often ignored in computational simulations. Here, we explore the NQEs on proton under confinement and under the influence of co-cation intercalation of Li^+, Na^+, and K^+ using ReaxFF Path-Integral Molecular Dynamics (PIMD) simulations. Considering two cases of $Ti_3C_2O_2$ MXene with sparse intercalation of water and a single layer of water, we use grand-canonical monte carlo to reach equilibrium of intercalated protons for each system with/out co-cation intercalation, followed by thermosetted ring polymer MD method of PIMD to capture NQEs. The difference in the number of protons intercalated show a strong interplay between the protons, co-cation, water and the MXene surface. Benchmarking against equivalent classical MD simulations of bulk water, first we show that the NQEs enable a broadening of the O-H and O-O radial distribution functions (RDFs), indicative of bond stretching due to proton delocalization. Although capturing NQEs in simulations is vital in matching experimentally obtained properties of bulk water [3], we investigate its importance in proton transport mechanism in the MXene configurations considered using RDFs, hydrogen-bonding network and proton/water diffusion coefficients.

These insights into the NQEs may help understand the proton transfer mechanism more accurately and lead

towards a rigorous procedure for the associated simulations.

Paramagnetic Molecule Induced More Than Five Orders of Current Suppression on Magnetic Tunnel Junctions at Room Temperature Pawan Tyagi, Christopher Riso and Edward Friebe; University of the District of Columbia, United States

Magnetic tunnel junction (MTJ) can serve as an excellent testbed for connecting molecule between two ferromagnetic electrodes. A paramagnetic molecule covalently bonded to two ferromagnetic electrodes with two thiol functional groups can produce intriguing transport and magnetic properties. We have chemically bonded paramagnetic molecules between two ferromagnetic electrodes of a MTJ along the exposed side edges. In this paper we discussed the observation of molecule induced dramatic changes in the magnetic and transport properties of the conventional magnetic tunnel junctions. Paramagnetic molecules were chemically bonded to ferromagnetic electrodes to bridge them across the insulating spacer along the exposed edges. Paramagnetic molecular channels along the tunnel junction edges decreased the overall current, through tunnel barrier and molecular channels, > 5 orders of magnitude below the leakage current of the bare tunnel junction at room temperature. These molecules caused significant changes in the spin density of states due to potential spin filtering effect. Also, paramagnetic molecules produced antiferromagnetic coupling between the affected magnetic electrodes. In this state spin transport in the magnetic tunnel junction based molecular devices plummeted by several orders. It is also noteworthy that our experimental studies provide a platform to connect a vast variety of ferromagnetic leads to the even broader array of high potential molecules such as single molecular magnets, porphyrin, and single ion molecules. The strength of exchange coupling between ferromagnetic electrodes and molecules can be tailored by utilizing different tethers and terminal functional groups. The MTJMSD can provide an advanced form of logic and memory devices, including a testbed for the molecule-based quantum computation devices. Future studies about the interaction between molecular magnets and ferromagnets and the interaction of thiol ended alkanes with ferromagnets will be of very valuable. This study indicates the potential of magnetic molecules as a means of transforming conventional magnetic tunnel junctions and producing unprecedented magnetic and transport properties.

10:50 AM EN03.09.28

Late News: High-Voltage K-Ion Battery Cathode Using a Spinel LiNi0.5Mn1.5O4 Oxide Ankush Bhatia, Jean Peirre Pereira-Ramos and Rita Baddour-Hadjean; Institut de Chimie et des Matériaux Paris-Est (ICMPE) UMR 7182 CNRS, France

On the recent research front for the next generation secondary batteries beyond Li, potassium insertion into graphite in non-aqueous cells has brought new insights into the electrochemical K^+ intercalation behavior and introduced advantageous benefits from potassium. Since potassium resources are much abundant and the standard potential of K^+/K is 0.13 V below that of Li^+/Li, potassium-ion batteries can be regarded as an appealing alternative to LIBs to realize high voltage systems with low cost. The crucial issue is the development of cathode materials able to accommodate the large K-ion without displaying detrimental structural changes toward cycle life and rate capability performance. The 4.7 V $LiMn_{1.5}Ni_{0.5}O_4$ spinel is already a promising cathode for the next generation of high voltage LIBs, and its host structure, λ-$Mn_{0.75}Ni_{0.25}O_2$, could be of great interest for K-ion batteries. Here, we investigate for the first time the potassium insertion properties into electrochemically prepared λ-MnO_2 (λ-MO) and λ-$Mn_{0.75}Ni_{0.25}O_2$ (λ-MNO) spinels[1,2]. We show the λ-MNO material is capable of reacting with potassium ions along the first discharge in KPF_6/EC/PC electrolyte to convert to a layered phase, $K_{0.5}Mn_{0.75}Ni_{0.25}O_2$ (KMNO). Then, a highly reversible potassium extraction/insertion is observed, corresponding to the exchange of ≈ 0.3 K^+ (90 mAh g^{-1}) during the first cycle at a C/20 rate at an

average potential of 3.3 V vs K^+/K. Excellent cycling stability is observed from the 15th cycle with 70 mAh g $^{-1}$ still available after 60 cycles. Note also that 65% capacity is retained after 350 cycles at a C/5 rate. A comparative analysis between λ-MO and λ-MNO highlights the even greater performance of λ-MNO as high voltage cathode material for K^+-ion batteries. Moreover, the origin of the attractive electrochemical performances of λ-MNO is investigated by XRD, Raman, and EDS experiments after discharge and charge cycles.

11:00 AM EN03.09.29
Late News: Modified H2V3O8 as Cathode Material for Na-Ion Batteries Daniela Söllinger, Jürgen Schoiber and Simone Pokrant; Paris Lodron University of Salzburg, Austria

Today the implementation of renewable energy supply is an important task for society. In this context, efficient energy storage is a key element for the successful realization of the energy turnaround. One of the most promising electrochemical energy storage concepts relies on rechargeable batteries such as Li-ion batteries as a very prominent example. [1]

However, lithium is listed as critical raw material since the production of lithium is only controlled by a few countries (e.g. in South American countries). [2] Therefore, new alternatives for anode-materials have to be found, which offer a higher accessibility combined with a high standard electrode potential. One promising candidate is sodium since it is an abundant resource in the earth crust and offers easy access worldwide. [3][4]

In addition to identifying alternatives for lithium as anode material, suitable cathode materials, which are electrochemical active versus Na^+-intercalation, have to be found. In this context, layered vanadium oxides like hydrated vanadium oxide ($H_2V_3O_8$ or V_3O_7*H_2O) offer a flexible platform for cathode materials based on metal ion insertion. [5] $H_2V_3O_8$ possesses mixed valance states of V^{4+} and V^{5+} and due to its open framework it allows for reversible intercalation of various ions like Li^+, Na^+ or Zn^{2+}. By changing its morphology from particles to thin fibers, faster charging and higher charge densities are enabled.

In this contribution, we present structural and morphological properties of $H_2V_3O_8$ synthesized under hydrothermal conditions with additives (e.g. rGO) in addition to the electrochemical properties. We show that conductive additives lead to higher energy densities combined with higher cycling stabilities for Na-ion batteries. Further modifications such as presodiation of $H_2V_3O_8$ are explored to compensate the loss of Na^+-ions due to the formation of the solid electrolyte interface (SEI) in the first cycles.

Late News: Crystal Structures and Local Environments of NASICON-Type Na3FeV(PO4)3 and Na4FeV(PO4)3 Positive Electrode Materials for Na-Ion Batteries Sunkyu Park[1,2,3], Jean-Noël Chotard[1,4,5],

Dany Carlier[2,4,5], Iona Moog[3], Mathieu Duttine[2], Antonella Iadecola[4], François Fauth[6], Christian Masquelier[1,4,5] and Laurence Croguennec[2,4,5]; [1]Laboratoire de Reactivite et de Chimie des Solides, France; [2]Institut de Chimie de la Matière Condensée de Bordeaux, France; [3]TIAMAT Energy, France; [4]RS2E, Reeseau Francais sur le Stockage Electrochimique de l'Energie, France; [5]ALISTORE-ERI European Research Institute, France; [6]CELLS-ALBA Synchrotron, Spain

NASICON-type $Na_3V_2(PO_4)_3$ (NVP) is promising as positive electrode material for Na-ion batteries due to its robust crystal structure, providing long cycle life and great rate capability.[1,2] However, it is able to exchange only two Na^+ ions per two Vanadium transition metals leading to a moderate specific capacity of 118 mAh/g. Therefore, it has been an important challenge in the research field to improve the specific capacity while keeping the solid framework of NASICON structure. Recently, several new NASICON-type materials such as $Na_{3+x}Mg_xV_{2-x}(PO_4)_3$,[3] $Na_4MnV(PO_4)_3$,[4-6] and $Na_4MnCr(PO_4)_3$,[7] have been reported attempting to gain higher specific capacity and have better sustainability. Surprisingly, $Na_4FeV(PO_4)_3$ has not been reported yet in literature. We thus decided to study the Fe/V-mixed system demonstrating possible extraction of three Na^+ ions per two transition metals. Sol-gel and solid-state methods with various synthesis parameters were investigated to synthesize the target material, $Na_4FeV(PO_4)_3$. We obtained the NASICON-type phase with small amount of secondary phases ($NaFePO_4$ and Na_3PO_4). To obtain the pure phase, $Na_3FeV(PO_4)_3$ has been synthesized and electrochemically sodiated to form $Na_4FeV(PO_4)_3$. Herein, we present for the first time crystal structures of the NASICON materials, $Na_3FeV(PO_4)_3$ and $Na_4FeV(PO_4)_3$, using high resolution Synchrotron X-ray diffraction (SXRD) as well as the electrochemical performances. 2.64 Na^+ were extracted from the $Na_4FeV(PO_4)_3$ upon charge process, corresponding to a specific capacity of 146.3 mAh/g. We could clearly observe a superstructure in $Na_3FeV(PO_4)_3$ due to Na^+ ordering, which is different from the structure reported in the literature.[6] Thermal analyses of $Na_3FeV(PO_4)_3$ were performed combining *in situ* temperature XRD and differential scanning calorimetry (DSC). An ordered/disordered phase transition is observed at 123°C with an increase symmetry from monoclinic (Space Group: *C*2/*c*) to rhombohedral (Space group: *R*-3*c*). The superstructure reflections from the ordered phase completely disappear at high temperature, which reversibly appear again as temperature goes down. The fully electrochemically sodiated $Na_4FeV(PO_4)_3$ crystallizes in a rhombohedral unit cell (*R*-3*c*) with all the sodium sites almost fully occupied. Since Vanadium and Iron share the same crystallographic site synchrotron X-ray absorption spectroscopy (XAS) at V and Fe K-edges and Mossbauer spectroscopy were performed. These technics allow to differentiate the local V, and Fe environments, respectively, and their oxidation states in both $Na_3FeV(PO_4)_3$ and $Na_4FeV(PO_4)_3$. Extended X-Ray Absorption Fine Structure (EXAFS) analysis shows that average bond distance of Fe – O increases from 1.99 Å in $Na_3FeV(PO_4)_3$ to 2.06 Å in $Na_4FeV(PO_4)_3$ while that of V – O remains unchanged as 2.02 Å suggesting the reduction of Fe^{3+} to Fe^{2+} without noticeable distortion of the MO_6 octahedra. The details of the local environments and oxidation states evolution and the electrochemical performances will be discussed.

Late News: Restoring Relevance to Old Battery Chemistry via Direct Cathode Upcycling Anthony

Montoya and Jack Vaughey; Argonne National Laboratory, United States

In recent years, the increase in demand for lithium-ion batteries (LIBs) has brought attention to the supply of the raw materials used in production of the cathode. Using a direct recycling process to reclaim spent cathodes for second use not only recovers the component elements, but also aims to keep the existing structure in-tact and minimize steps and costs associated with reprocessing the material. Cobalt in particular is a high value material of concern and is a major component of the commonly used $Li(Ni_xMn_yCo_z)O_2$ (NMC) class of cathodes. While NMC materials have gained marketplace acceptance, their exact composition has evolved. For instance five years ago NMC111 was commonly used, versus NMC622 or NMC811 are more common now. This change in composition over time presents a challenge to directly recycling cathode materials since those coming out of service are no longer in line with current compositions. The goal of this work is to upcycle an NMC111 powder to the more relevant Ni-rich NMC622 target composition. Reactions with different Ni-rich coatings were explored as a method of incorporating nickel into the structure through solid state methods. The challenges of obtaining identifying reaction conditions which avoid the formation of undesired oxides and lead to a more homogeneous material will be discussed. Structural and compositional analysis will be detailed.

Late News: Electrolyte-Dependent Phase Heterogeneity and Its Atomic Origin within Primary Cathode Nanoparticles Wenxiang Chen[1], Xun Zhan[1], Renliang Yuan[1], Heonjae Jeong[2], Cheng Zhang[2], Kim Ta[2], Hyosung An[1], Paul Braun[1], Ryan Stephens[3], Andrew Gewirth[2], Hong Yang[2], Elif Ertekin[2], Jian-Min Zuo[1] and Qian Chen[1]; [1]University of Illinois at Urbana Champaign, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Shell International Exploration and Production Inc, United States

We study the electrochemical and structural responses of primary cathode nanoparticles for magnesium ion insertion. By systematically varying the electrolyte, we observe a successful Mg^{2+} insertion and the consistent solid-solution phase transition in the nanoparticles. Further examination by scanning electron nanodiffraction (SEND) in scanning transmission electron microscope (STEM) revealed two distinctive strain and phase distribution patterns in the cathode nanoparticles at nanometer resolution regulated by the electrolyte. One is consist of a uniform, major phase domain distribution due to an elastic strain relaxation mechanism at the atomic level, whereas the other one is consist of a non-uniform, scattered phase domain distribution or “core-shell” structure with a plastic strain relaxation mechanism. The varied chemo-mechanical behaviors are associated with the coherency strain and charge screening effect occurred in the Mg^{2+} insertion revealed at the atomic level by STEM imaging and DFT calculations. Our work shows that electrochemical parameters such as the electrolyte have a direct influence on the cathode structural heterogeneity during Mg ion insertion, which rationally guide the design of battery materials with high stability and capacity.

Late News: MD Simulation Study of Sodium-Ion Transport In Na-Ion Battery Cathode Materials Deepak Seth, M. A. Haider, Manish Agarwal, Uzma Anjum, Shaharyar Wani and Tuhin S. Khan; Indian Institute of Technology Delhi, India

Classical molecular dynamics (MD) simulations are applied to study the transport of Na-ions in cathode materials for Na-ion batteries (SIB). Two different materials (in $Na_xTi_2(PO_4)_3$) are studied to access and compare the level of Na-ion diffusion in electrode structure. Sodium constitute a potential alternative of Lithium in alkali metal batteries, since sources of Li are limited, and Na is readily available. titration, impedance measurements etc.) diffusivity estimates specifically from impedance curves are often measured away from the equilibrium and fitting parameters are prone to produce large errors. MD simulations using universal force field have provided a direct assessment of self-diffusion coefficient of Na-ions in the structure of $Na_xV_4O_{10}$ with varying concentrations of Na-ions ($0.33 < x < 1.33$), calculating a diffusion coefficient of 5.75×10^{-8} cm^2/s for $x=0.66$ at 300 K, which is in good agreement with experiments. Mean square displacement (MSD) and Na-ion density plots are further providing a mechanistic insight on the route of Na-ion transport.

As a next generation material, NASICON structured type ($NaTi_2(PO_4)$) SIB material, are investigated for Na-ion transport. Inter-atomic based partial charge potential model is applied, and concentration of Na-ion is varied (from $0.82 < x < 0.98$) in the supercell (total of 9000 atoms) of $Na_xTi_2(PO_4)_3$ at 323 K. Na^+ transport of different sets of runs are calculated and MD trajectory are visualized. MSD of Na^+ as a function of time. Self-diffusion coefficient of Na^+ is calculated from the slope of MSD vs time plot for the three-dimensional transport, following Einstein's relation. Calculated diffusivities are in the range of $\sim 10^{-8}$-10^{-9} cm^2/s and corresponding ionic conductivity is estimated to be ($\sim 10^{-4}$ S/cm). These values are in agreement with experimentally measured values of Na-ions in the same structure.

Challenges Facing Solid-State Batteries with Alkali Metal Anode—Voids and Dendrites Ziyang Ning[1], Dominic Spencer Jolly[1], Jitti Kasemchainan[1], Stefanie Zekoll[1], Gareth O. Hartley[1,2], T. J. Marrow[1] and Peter Bruce[1,2,3]; [1]University of Oxford, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]The Henry Royce Institute, United Kingdom

All-solid-state batteries could deliver a step change in energy density and improved safety through the use of an alkali metal anode and a ceramic electrolyte. However, dendrites form at the anode that penetrate the ceramic electrolyte is one of the greatest challenge facing solid-state batteries. While dendrite formation on charging

directly leads to short-circuit and cell failure, the formation of voids on discharging can also lead to interfacial contact loss and trigger dendrite initiation. To enable the use of an energy dense alkali metal anode, voids and dendrites both need to be fundamentally understood.

We have investigated the process of stripping as a function of current density and stack pressure in both Li/Li_6PS_5Cl/Li and Na/Na-β"-alumina/Na cells, revealing the dominant role of metal creep in preventing void accumulation and cell failure. By using a combination of 3-electrode cells, scanning electron microscopy and X-ray tomography, we show that there is a critical stripping current density, above which voids will not only form at the interface but increase in number and size on cycling, eventually leading to dendrite formation on charge. The combined effect of stack pressure and temperature have been studied to better understand and potentially eliminate void formation on stripping. We show that by applying high stack pressure, or moderate pressure at higher temperature, higher current densities can be achieved with stable cycling.

For a better mechanistic understanding of Li ingress into solid electrolytes, we've utilised *in-situ* phase-contrast tomography combined with spatially mapped X-ray diffraction to follow penetration of Li into ceramic electrolyte and the associated propagation of cracks. Based on our observation, the new understanding of how dendrites grow in solid-state batteries will be discussed.

8:25 AM *EN04.01.02
4 V All-Solid-State Battery Enabled by a Passivating Cathode/hydroborate Solid Electrolyte Interface
Ryo Asakura, David Reber, Léo Duchêne, Seyedhosein Payandeh, Arndt Remhof and Corsin Battaglia; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Designing solid electrolytes for all-solid-state-batteries that can withstand the extreme elec-trochemical conditions in contact with an alkali metal anode and a high-voltage cathode is challenging, especially when the battery is cycled beyond 4 V. Here we demonstrate that a hydroborate solid electrolyte $Na_4(CB_{11}H_{12})_2(B_{12}H_{12})$, built from two types of cage-like anions with different oxidative stability, can effectively passivate the interface to a 4 V-class cathode and prevent impedance growth during cycling. We show that $[B_{12}H_{12}]^{2-}$ anions decompose below 4.2 V vs Na^+/Na to form a passivating interphase layer, while $[CB_{11}H_{12}]^-$ anions remain intact, providing sufficient ionic conductivity across the layer. Our interface engineering strategy enables the first demonstration of a 4 V-class hydroborate-based all-solid-state battery combining a sodium metal anode and a cobalt-free $Na_3(VOPO_4)_2F$ cathode without any artificial protective coating. When cycled to 4.15 V vs Na^+/Na, the cells feature a discharge capacity of 104 mAh g^{-1} at C/10 and 99 mAh g^{-1} at C/5, and an excellent capacity and energy retention of 78% and 76%, respectively, after 800 cycles at C/5 at <0.2 MPa at room temperature. Increasing the pressure to 3.2 MPa enables a discharge capacity of 117 mAh g^{-1} at C/10 with a mass loading of 8.0 mg cm^{-2}, corresponding to an areal capacity close to 1.0 mAh cm^{-2}. The cell holds the highest average discharge cell voltage of 3.8 V and specific energy per cathode active material weight among all-solid-state sodium batteries reported so far. Combined with their low gravimetric density <1.2 g/cm^3, low toxicity, high thermal and chemical stability [2], stability vs lithium and sodium metal anodes [3], soft mechanical properties enabling cold pressing [4], compatibility with solution impregnation [5] and infiltration [6], and potential for low cost [7, 8], hydroborate electrolytes represent a promising option for a competitive future all-solid-state battery technology.

A Li Metal Ink Towards Ultrathin Li Foils and Interface Compatible Solid-State Li Metal Batteries
Wangyan Wu and Wei Luo; Institude of New Energy for Vehicles, China

Li metal anode, after being in the doghouse for several decades, revived in recent years due to the merits of lowest potential (-3.04 V vs. SHE), low density and high specific capacity (3860 mAh/g) under the circumstance that the intercalation chemistry is reaching the ceiling of energy density. Nonetheless, it is not until the chronic diseases related with Li metal and organic electrolyte, such as dendrite growth, excessive N/P ratio, being knocked off can its commercialization be realized. Plagued by the incompatibility with organic electrolytes, one of the research directions branches out towards the combination of Li and inorganic solid-state electrolytes, where the poor interface brings a new challenge. Focusing on resolving the issue, here, a Li metal ink was prepared by introducing biomass-derived carbon particles into molten Li.[1] Due to the significantly decreased surface tension, the ink is able to directly write on copper foils or other substrates that customized thickness and **ultrathin Li foils with a remarkably small thickness (<10 μm)** can be achieved. Moreover, when the ink directly writes on garnet-type LLZTO pellets, a desirable interface is obtained and therefore an extremely **low interfacial resistance of 6 Ω cm^2** is delivered, in sharp contrast to 939 Ω cm^2 of pure Li and the garnet. Thanks to the distinguished interfacial compatibility, **a critical current density of 2.5 mA/cm^2** and stable plating/stripping more than 800 h in symmetric cells are achieved. Full cells consisting of the ink, garnets and NCM523 also enable to deliver stable cycling performance. Due to the successful partnership with non-flammable solid-state electrolytes, the Li metal ink may have a chance to bring us very close to the use of solid-state lithium metal batteries with high safety and high energy density.

9:05 AM EN04.01.04
Revealing the Role of the Cathode-Electrolyte Interface on Solid-State Batteries Beniamin Zahiri[1], Arghya Patra[1], Chadd Kiggins[2], John B. Cook[2] and Paul Braun[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Xerion Advanced Battery Corporation, United States

Interfaces play crucial, but still poorly understood roles in the performance of secondary solid-state batteries (SSBs). Using crystallographically oriented and highly faceted thick cathodes, we directly assess the impact of cathode crystallography and morphology on long-term performance of SSBs. The controlled interface crystallography, area, and microstructure of these cathodes enables understanding interface instabilities unknown (hidden) in conventional thin film and composite solid-state electrodes. A generic and direct correlation between cell performance and interface stability is revealed for a variety of both lithium and sodium-based cathodes and solid electrolytes. Our findings highlight that minimizing interfacial area, rather than its expansion as is the case in conventional composite cathode, is key to both understanding the nature of interface instabilities and improving cell performance. Our findings also point to the use of dense and thick cathodes as a new path for increasing the energy density and stability of SSBs.

9:20 AM EN04.01.05
Computation-Guided Discovery of Materials for Stabilizing Interfaces in High-Energy Solid-State Lithium-Ion Batteries Adelaide M. Nolan, Yunsheng Liu and Yifei Mo; University of Maryland, United States

The continued improvement in operating time and lifetime of electric vehicles and portable electronic devices requires higher energy density lithium ion batteries. The energy density of lithium-ion batteries can be increased

by implementing high-voltage cathodes, but these cathodes are reactive and unstable during cycling with the electrolyte. To design coatings or solid electrolytes that can stabilize these cathodes, an understanding of how different chemistries interact with high-voltage cathodes is critically needed. We employ novel thermodynamic analyses based on a large-scale computation database to systematically evaluate the thermodynamic stability of a broad range of solid-state chemistries with common cathodes. By analyzing a large number of materials in high-throughput computation, we find a trade-off in that materials stable with lithiated cathodes are often unstable with delithiated cathodes, which limits the possible choice of materials stable throughout the cycling voltage. In addition to reaffirming previously demonstrated coating and solid electrolyte chemistries, our computation predicts several new chemistries, including lithium phosphates and lithium ternary fluorides, are promising solid-state chemistries stable with high-voltage cathodes. Additionally, we systematically study the chemical and electrochemical stability of coatings at the interface between promising solid electrolytes and high-capacity cathodes for all-solid-state lithium-ion batteries, which are a promising next-generation battery technology. Based on our new computation approach and our high-throughput materials analyses, we offer suggestions to improve the stability of the interface for application in all-solid-state batteries. Our computational study provides guiding principles for designing coating materials with long-term stability with high-voltage cathodes for lithium-ion batteries.

9:35 AM EN04.01.06
Characterization of Interface Evolution in Argyrodite Solid Electrolytes with Li Metal Anode for Practical, High Energy Density Solid-State Batteries Sudarshan Narayanan[1], Ulderico Ulissi[2] and Mauro Pasta[1]; [1]University of Oxford, United Kingdom; [2]Nissan Technical Centre Europe, United Kingdom

An all solid-state approach is fast becoming the most promising direction in realizing the goal of rechargeable Li-ion batteries with improved safety and performance for widespread use in portable electronics and electric vehicle applications. Such an approach employing solid electrolytes enables the use of Li metal as the anode, thereby extending access to much higher energy densities than previously envisioned in cells with liquid electrolytes. While a variety of material systems such as oxides, anti-perovskites, garnets, sulfides, and polymers, to name a few, have been extensively explored for their suitability as solid electrolytes (SE), most SEs are known to be unstable in contact with Li metal, leading to formation of decomposition products that can affect the performance of the electrochemical cell. Among these SE material systems, a class of sulfides called argyrodites (Li_6PS_5X, X = Cl, Br, I) have been identified as most promising candidates for practical solid-state Li-ion batteries owing not only to their relatively high ionic conductivities but also easy manufacturability and scalability[1].

Our study probes the chemistry at the interface of Li metal and argyrodite SE surface and the evolution of decomposition products thus formed through X-ray photoelectron spectroscopy (XPS) under ex-situ and in-situ conditions. Previous studies by Janek and coworkers, Schlenker et al. and Wood et al.[2-4] have reported interfacial characteristics in related cell materials, considering some of these aspects, but contrasting chemistries and a lack of consensus on electrode-electrolyte interphase products underscores the complexity of such a system. In my talk, I will discuss the effect of using different methods of depositing/plating Li metal on the SE surface while comparing and contrasting the interphasial products therein. I will also present a characterization of the evolution of the interface when subjected to electrochemical cycling under “in-operando” conditions, closely simulating a practical system. Additionally, investigations of the effect of surface roughness of the argyrodite SE as a means to understanding Li metal to SE contact will also be reported.

Understanding Interfacial Atomistic Mechanisms of Lithium Metal Stripping and Plating in Solid-State Batteries Yifei Mo; University of Maryland, College Park, United States

The all-solid-state battery based on the Li metal anode is a promising next-generation energy storage system, but is currently limited by the low current density and short cycle life of the anode. Further research to improve the Li metal anode is impeded by the lack of understanding in its failure mechanisms at the lithium-solid interfaces, in particular the fundamental atomistic processes responsible for interface failure. Here, we perform the large-scale atomistic modeling study of lithium stripping and plating on solid-electrolyte interfaces by explicitly considering key fundamental atomistic processes and interface atomistic structures. Our simulations found the interface failure mechanisms and the effects of interface structures, lithium diffusion, adhesion energy, and applied pressure on such failure. By systematically varying the independent parameters of our simulations, we provide a guiding map of selecting solid-state lithium cells, in which indicates the required high interfacial adhesion energy and high applied pressure for inhibiting interface failure during cycling. Optimal solid interfaces and new research strategies are also predicted for the research and development of solid-state Li-metal batteries.

12:10 PM *EN04.02.02
Multi-Modal *Operando* Analysis of Lithium-Solid Electrolyte Interfaces Neil P. Dasgupta; University of Michigan, United States

Solid-state batteries have seen a dramatic increase in research in recent years because of their ability to address safety challenges associated with flammable liquid electrolytes, and the potential to enable Li metal anodes. However, the formation of solid-solid interfaces poses unique challenges compared to solid-liquid interfaces. This requires new methods to study the fundamental behavior of solid-solid interfaces, and understand their dynamic evolution during cycling[1].

In this talk, I will present a suite of multi-modal *in situ/operando* characterization approaches that we have used to study Li metal-solid electrolyte interfaces during cycling. First, to gain an improved understanding of the electrochemical stability, I will discuss *operando* X-ray photoelectron spectroscopy (XPS) analysis of lithium metal-solid electrolyte interfaces[2]. This approach allows us to directly observe interphase formation and evolution as the electrochemical potential of the solid-electrolyte surface is biased to potentials below the thermodynamic potential for Li plating. A range of sulfide and oxide ceramic electrolytes were explored, since they exhibit a range of (in)stability levels during Li metal plating.

To compliment these spectroscopic measurements, a range of *in situ/operando* microscopy techniques will also be presented. First, *operando* optical microscopy results will be presented, which allow for direct observation of the nucleation and growth of Li filaments both into, and out of, solid electrolyte surfaces[2-3]. By time synchronizing the optical video analysis with the electrochemical signatures of plating and stripping, new

insights into the dynamic evolution of morphology and associated electrochemical analysis can be obtained. This micro-scale imaging will also be complimented by *in situ* analysis at the nanoscale. By integrating the observations across this multi-modal characterization approach, the implications for SSB performance and stability will be discussed, and critical needs for future research will be described.

Fast Charge Transfer Across the LLZO Solid Electrolyte/LCO Cathode Interface—A Thin-Film Model System Jordi Sastre-Pellicer, Xubin Chen, Abdessalem Aribia, Ayodhya Tiwari and Yaroslav Romanyuk; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Thin film batteries can be valuable model systems to investigate interface charge dynamics and to serve as playgrounds for interface engineering, without the complexity of bulk systems. Here we investigate the charge transfer properties between the lithium garnet $Li_7La_3Zr_2O_{12}$ (LLZO) solid electrolyte and the $LiCoO_2$ cathode using a thin-film model system, with the aim of reducing the interface resistance and allowing high charge-discharge rates.
We developed a method for fabricating crystalline LLZO thin films using magnetron co-sputtering followed by an annealing step at 700°C (significantly below the standard processing temperatures). The resulting 500 nm-thick Ga-doped LLZO thin films show densities and ionic conductivities (2×10^{-4} S/cm) comparable to the values observed in bulk ceramic pellets.[1]
Based on this thin film fabrication process, we fabricated an all-thin-film model system to investigate the LLZO / LCO cathode interface. This architecture provides an easy access to the interface for characterization, allowing one to identify the degradation processes taking place at the interface under high-temperature co-sintering. Introducing an in situ-lithiated Nb_2O_5 diffusion barrier at the interface, it was possible to lower the LLZO / LCO charge transfer resistance to about 50 Ω cm^2. The low interfacial resistance combined with the high conductance through the LLZO thin-film electrolyte allows charge transfer at high charge-discharge rates up to 40 C (0.9 mA/cm^2).[2]

Aluminum Oxide Interlayer Enabling Facile Li-Ion Transfer Between $LiCoO_2$ and Garnet Electrolyte Yaoyu Ren, Angelique Jarry, Gary Rubloff and Eric Wachsman; University of Maryland, United States

$Li_7La_3Zr_2O_{12}$ (LLZO) garnet-type lithium-ion conductors are being investigated as a promising solid electrolyte for solid-state lithium batteries. To enable a functional all-solid-state configuration intensive investigations have focused on reducing the cathode/electrolyte interfacial resistance which contributes the most to cell performance loss [1]. Among the commercial cathode materials investigated so far, $LiCoO_2$ (LCO) is one of the most stable with garnet electrolytes as only a superficial reaction has been detected between the two materials.

However, even this minor reaction would block the Li-ion transport through the interface, resulting in deteriorated cell performance.
In this work, we demonstrate that a thin aluminum oxide layer (5 nm) can be an effective interlayer to impede the formation of harmful interphase and enable facile Li-ion transfer between LCO and LLZO garnet. Room-temperature-sputtered LCO thin films were employed to form an interface with the garnet electrolyte and annealed at various temperatures to reveal the effect of the extent of the interfacial reaction on the Li-ion transfer across the interface. The aluminum oxide layer was then introduced between LCO and the garnet electrolyte by sputtering a metallic aluminum layer which is then annealed together with the upper LCO layer in oxygen. Compared to the cells without an aluminum oxide interlayer, those with the interlayer exhibited much-improved performance, i.e., a stable discharge capacity of up to 110 mAh/(g LCO) at a C/10 rate and a rate capability up to the 3C rate. Atomic layer deposition was also employed to fabricate the aluminum oxide interlayer and a similarly improved cell performance was observed. The specific conditions for implementing the two methods for depositing the aluminum oxide layer and their effectiveness are compared to distinguish their capabilities in practical cell application.

Towards Uniform Lithium Plating for Anode-Free Solid-State Batteries Using Amorphous Carbon Interlayers Moritz H. Futscher, Thomas Amelal, Jordi Sastre-Pellicer, Sebastian Siol and Yaroslav Romanyuk; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

To keep pace with the ever-increasing demands for high energy density, low cost, and long cycle life of rechargeable batteries, advanced battery designs are needed. The greatest improvement over conventional batteries is expected to come from the use of metallic lithium as an anode. However, non-uniform electroplating of lithium metal results in the formation of dendrites, which greatly shortens battery life.
Researchers from Samsung have recently shown that introducing an amorphous interlayer of Ag-C composite leads to a long term stability without dendrite formation.[1] However, the reason why the interlayer shows this advantageous behaviour is not understood. We deposit amorphous carbon interlayers with different properties between anode and solid-state electrolyte by direct current and high power impulse magnetron sputtering. We show the influence of the microstructure and conductivity of the carbon interlayer on lithium plating through lithium phosphorus oxynitride and garnet-type solid electrolytes. Our results shed light on the key factors that enable homogeneous lithium plating and thus the use of lithium metal in solid-state batteries.

Elucidating Interfacial Instability in All-Solid-State Lithium Batteries from First-Principles Simulations Liwen Wan, Aniruddha M. Dive, Marissa Wood, Kwangnam Kim, Tian Li and Brandon Wood; Lawrence Livermore National Laboratory, United States

All-solid-state batteries offer great promise for safer and higher-energy-density storage compared to conventional liquid-based Li-ion batteries. Yet they suffer greatly from high interfacial resistance caused by poor physical contact, structural and chemical heterogeneity and formation of undesired secondary phases that are detrimental to Li-ion transport. To overcome these challenges, atomic-scale visualization of the interfaces and a detailed understanding of how the structure and chemistry of the interface evolve during processing and operation, which ultimately dictates device performance is critical. In this talk, I will address how we combine high-temperature ab initio molecular dynamics simulations with machine-learning and global optimization algorithms to study the structural and chemical evolutions of solid-electrolyte/cathode interfaces in all solid-state lithium batteries. I will also demonstrate how we integrate first-principles based simulations with high-

resolution microscopy and spectroscopy to unravel the atomic details of these interfaces under different processing conditions and discuss the implications of structural and chemical inhomogeneity at the interfaces towards Li-ion transport. Examples will be discussed in this talk includes the garnet and perovskite solid-electrolytes interfacing with layered lithium cobalt oxide cathode.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Cryo-Electrical Microscopy Platform for Battery and Quantum Energy Applications Khim Karki, Daan Hein Alsem and Norman Salmon; Hummingbird Scientific, Afghanistan

The introduction of cryogenic cooling of specimens in the (scanning) transmission electron microscopy (S/TEM) has recently allowed in understanding various quantum interfaces and phase co-existence in strongly correlated systems [1]. Understanding those quantum properties at the fundamental level had been difficult due to limited characterization techniques with inadequate spatial and temporal resolution. Quantum materials must be studied at cryogenic temperatures because many of the relevant properties in these quantum materials only manifest themselves at these low temperatures. Cryogenic S/TEM has also led to the observation of critical structural information related to battery interfaces at atomic resolution, which are traditionally difficult to achieve because they are air-sensitive and are prone to electron beam damage in the S/TEM [2-5]. Thus, most materials require cryo-transfer and-cryo preservation of the sample using cryogenic coolant (liquid nitrogen), limiting the studying of the sample to post-mortem analysis. The cryo-electrical holder previously tested was limited in applying electrical stimulus to the sample at cryogenic temperature, and the primary focus was on imaging[5]. Here, we present the development cryo-electrical biasing S/TEM holder that simultaneously allows electrical stimulus and high-resolution imaging of a sample in-situ at various cryogenic temperatures.

The newly developed cryo-electrical holder will enable the understanding of critical interfaces in battery systems and surface-electronic behavior of quantum topological insulators such in two-dimensional (2D) materials, among others, for artifact-free evaluation of the studied devices in high-resolution imaging and spectroscopy modes. Here, we present an example of studying battery processes using a single nanowire system from room temperature down to liquid nitrogen temperature as close as around -170°C. Electrical biasing is performed in a nanowire sample that sits across the electrodes on the biasing chip. A constant current experiment at cold temperatures on the nanowire shows a voltage drop as the reaction proceeds with a growth of the dendrite layer plated on the nanowire's surface. The cryo-electrical TEM holder will be vital in enabling scientists to expand the knowledge of structure-property relationships in materials, specifically the relation between temperature and electronic properties, and will allow for the accelerated development of the next generation of electronic, quantum, and energy storage materials devices [6]

Identifying the Structural and Compositional Features that Create High Li-Ion Mobility in Solid-State Compounds Gerbrand Ceder; Lawrence Berkeley National Laboratory, United States

High Li mobility is required in cathode materials as well as in solid-state electrolytes. While computationally driven searches have had considerable success in identifying new solid-state electrolytes in sulfides, considerably less high mobility oxide conductors have been discovered. In this presentation, I will show the four mechanisms that we have identified to produce high Li mobility in solids. These insights apply universally to solid ion conductors as well as to high-rate cathode materials. For each of the four mechanisms we have performed a high-throughput computational search through the relevant part of known compound space in order to develop new solids with the potential to have very high mobility. Our results indicate that there many oxides that are likely to have considerably higher Li-ion conductivity than LLZO. Time permitting, I will also show how the same principles apply to creating high rate cathode materials.

2:40 PM *EN04.03.02
Ultrafast High Temperature Sintering (UHS) Toward Solid–State Battery Manufacturing Chengwei Wang[1] and Liangbing Hu[2]; [1]HighT-Tech LLC, United States; [2]University of Maryland, United States

Ceramic-based solid-state electrolytes (SSEs) are attractive materials for improving battery safety. To develop improved ceramic SSEs, computational predictions based on first principles methods can be a valuable tool in accelerating materials discovery. Experimental confirmation is essential after such predictions; however, materials screening rates are limited by the long processing time of conventional ceramic synthesis and sintering techniques, which are also prone to poor compositional control due to volatile element loss. These problems also cause great challenges for the manufacturing of solid state batteries.
To overcome these limitations in SSE synthesis and manufacturing, we develop an ultrafast high-temperature sintering (UHS) process for the fabrication of ceramic materials by radiative heating that features a record-high temperature of up to 3,000 ºC and an ultrafast heating rate of up to 100,000 ºC/minute (Science 368.6490 (2020): 521-526). The UHS method can directly sinter oxide precursors into solid, dense ceramics in seconds. Compared with previous furnace-based fabrication techniques, the UHS process is >100–1000-times faster (e.g., reducing the sintering time from hours to ~10 s). As a result, we are able to achieve excellent compositional control of ceramics containing volatile components (e.g., Li in solid-state electrolytes), as well as prevent uncontrolled grain growth for outstanding material performance. Additionally, the UHS process can also be applied to manufacture SSE membranes with high conductivities and provide excellent sintering at material interfaces with limited interdiffusion, which are essential for devices such as thin film batteries. Furthermore, this technique is compatible with 3D printing to produce novel ceramic structures and devices that are otherwise impossible to achieve by other rapid sintering methods. Finally, the UHS process is universal, allowing us to synthesize a wide range of new ceramic materials with novel composition and structure. This technique has the potential to transform and expand the discovery of ceramic compounds, with significant impacts for rapid materials screening and manufacturing of solid-state batteries.
We also extended the method for sintering printed thin film batteries (Science advances 6.47 (2020): eabc8641) and multielement metals (Advanced Science, Rapid Synthesis and Sintering of Metals from Powders, accepted), which will be discussed briefly as well.

3:20 PM EN04.03.04
Dopant type (Al, Ga, Ta) on the Mechanical, Electrical and Electrochemical Behavior of $Li_7La_3Zr_2O_{12}$ Jeffrey B. Wolfenstine[1], GiGap Han[2], Heeman Choe[2] and Jeff Sakamoto[3]; [1]Solid Ionic Conducting, United

States; [2]Kookmin University, Korea (the Republic of); [3]University of Michigan–Ann Arbor, United States

Owing to its potential to improve battery performance compared to state-of-the-art Li-ion, there has recently been a resurgence in the development of Li metal anode technology. However, to date, efforts to cycle Li metal using liquid electrolytes with sufficient coulombic efficiency and safety have been largely insufficient to demonstrate commercial viability for electric vehicles. However, Li-ion conducting solid electrolytes are attracting considerable attention to overcome the issues associated with liquid electrolytes. One such solid electrolyte that meets many of these requirements is cubic Li-garnet of the nominal composition $Li_7La_3Zr_2O_{12}$ (LLZO). One of the major issues with cubic LLZO is increasing its critical current (charging current at which dendrites form). It was been shown that the critical current of LLZO is a function of its electrical and mechanical properties. It is the purpose of this talk to discuss the effect of three different aliovalent dopants (Al,Ta,Ga) on the electrical (total, grain, grain boundary conductivity), mechanical (hardness, fracture strength, fracture toughness) and critical current of hot-pressed near theoretical dense cubic $Li_7La_3Zr_2O_{12}$. These results will be correlated with the resulting microstructure. This information is required if LLZO is to be used as an electrolyte in solid-state batteries. In addition, implications of these results on the performance of all-solid-state batteries with a Li metal anode will be discussed.

Exploration of Li-P-S-O System for Discovery of New Solid Electrolyte Audric Neveu[1], Vincent Pele[2], Christian Jordy[2] and Valerie Pralong[1]; [1]CNRS, France; [2]SAFT, France

With the aim of making lithium batteries safer, the scientific community is looking in recent years to replace the liquid solvents used as electrolyte with a solid ionic conductor compound. Several families of materials have been developed, leading to major improvements in this technology (NASICON, perovskites, Garnets [1]). In addition, the thio-phosphate family is widely explored and several compounds have been discovered in the pseudo-binary Li2S-P2S5 diagram such as Li3PS4, $Li_7P_3S_{11}$ or Li_7PS_6 [2]. In 2011, R. Kanno and al. [3] had discovered a new phase: $Li_{10}GeP_2S_{12}$ showing ionic conduction of 12 mS/cm. Unfortunately, this structure is unstable with respect to lithium metal [4] and germanium remains a very expensive element. In order to improve the stability of this structure, a partial substitution of sulfur by oxygen has been successfully proposed [5]. Very recently, the germanium-free phase $Li_{9.6}P_3S_{12}$ has been obtained and exhibits better stability towards lithium despite a lower conductivity [6]. Recently we published about the effect of adding oxygen in this compound [7]. Here, we present the effect of added oxygen on the structure, on the ionic conductivity and during cycling in all solid-state battery.

3:50 PM EN04.03.06
Tunable Lithium-Ion Transport in Mixed-Halide Argyrodites Sawankumar v. Patel[1], Swastika Banerjee[2],

Haoyu Liu[1], Pengbo Wang[1], Po-Hsiu Chien[3], Jue Liu[3], Xuyong Feng[1], Shyue Ping Ong[2] and Yan-Yan Hu[1]; [1]Florida State University, United States; [2]University of California, San Diego, United States; [3]Oak Ridge National Laboratory, United States

Argyrodites, with fast Li^+ ion conduction, are promising for applications in rechargeable solid-state batteries. Here, we investigate a new compositional space of argyrodite superionic conductors, $Li_{6-x}PS_{5-x}XY_x$ [, X and Y are halides], with a remarkably high ionic conductivity of 24 mS/cm at 25 ºC. In addition, the extremely low Li-migration barrier of 0.155 eV makes it distinct and promising for low-temperature operation of SSBs. Average structure analysis via neutron Bragg diffraction reveals the retention of parent argyrodite structure with cubic space group (F-43m) with significant anion site disorder among the Cl^-, Br^-, and S^{2-} anions at Wyckoff 4a and 4d sites. Neutron pair distribution functions reveal the short-range order of anions in a monoclinic space group. Further characterization of the local structures by solid-state NMR confirms anion reordering. High-resolution ^{6}Li NMR reveals lithium disorder induced by diversifying the anion sublattice. ^{7}Li NMR relaxometry shows gradual increase in Li ion dynamics, eventually yielding a "melted" Li^+ sublattice with a flattened energy landscape when increasing x. In addition, the diversity of anion species and Li-deficiency induce hyper coordination and coordination entropy for the Li-sublattice, resulting in higher jump rates of lithium ions. Electrochemical impedance spectroscopy unveils enhanced Li^+-ion transport with increasing x. This study demonstrates that mixed-anion frameworks can help stabilize highly conductive structures in a compositional space otherwise unstable with lower anion diversity.

4:05 PM EN04.03.07
Late News: Investigation of Ionic Liquid Crystal Materials as Non-Solvating Lithium-Ion Conductors
Jiacheng Liu, Lingyu Yang, Hannah Collins, Emma Kerr and Jennifer Schaefer; University of Notre Dame, United States

Liquid crystals (LC) are known for forming hexagonal, smectic, and gyroid phase structures. These traits are favorable for LC electrolytes as they may contain ordered ion transport pathways that allow for higher ionic conductivity than isotropic materials. Furthermore, LC system is helpful for studying ion-transport mechanism in ion-aggregates which is a novel concept introduced by Winy and Frischknecht. Current research on LC electrolytes is mostly focused on ion-transport properties of organic ion pairs or metal-ions with solvation sites. Despite the promising potential, thus far there have been limited research performed on non-solvating LC electrolytes that lack polar matrices for ion-solvation; limited works of non-solvating LC have been done and focused on sulfonate/metal ion pairs with addition of solvent to promote charge dissociation. The ion transport property with non-solvating and higher charge delocalization anions have rarely been reported. Previously, we reported on the synthesis and characterization of side-chain, non-solvating single-ion LC polymer electrolytes with various anions and found that delocalization effect of the anion has a strong influence on the Li+ conductivity. It was shown using broadband dielectric spectroscopy analysis that the ion transport is correlated with dielectric relaxation. In this contribution, we report on the ion transport properties of an ionic liquid crystalline electrolyte with –TFSI anions for lithium-based batteries. This class of materials exhibits a wide smectic phase temperature window and a conductivity above 10E-5 at 60 ºC. The influence of addition of high dielectric constant moiety on phase transition, ion conductivity, and transport mechanism will also be discussed.

Advanced NMR and MRI Studies of Ion Conduction and Dendrite Formation in Solid-State Batteries

Yan-Yan Hu[1,2]; [1]Florida State University, United States; [2]National High Magnetic Field Laboratory, United States

Solid-state rechargeable batteries, which afford new chemistry with enhanced energy density and safety, are promising energy storage media. Solid electrolytes with fast ion conduction, good compatibility with electrodes, and superior electrochemical stability are key to the success of solid-state batteries. The development of such solid electrolytes rely on our fundamental understanding of important processes, such ion conduction and dendrite formation, which requires advanced characterization tools that can non-invasively examine various aspects of these processes.

Nuclear magnetic resonance spectroscopy (NMR) and imaging (MRI) are known as powerful and versatile tools to study structure and ion dynamics, particularly suitable for investigating the aforementioned topics. In this discussion, we will present our work on: i) ion transport mechanisms and their dependence on structure and compositions in superionic conductors studied with NMR spectroscopy and relaxometry. The insights from this study have enabled the discoveries of new materials with unprecedented ionic conductivities with the lowest activation barriers for Li^+ion transport. ii) The origin of dendrite formation in solid-state batteries and its propagation process investigated with 3D *in situ*MRI combined with tracer-exchange. This unravels dendrite formation process in the solids, very different from liquid-electrolyte based systems.

5:40 PM *EN04.04.02
***In Operando* Study of All-Solid-State Lithium Batteries Coupling Thioantimonate Superionic Conductors with Metal Sulfide** Hongli Zhu; Northeastern University, United States

All-solid-state lithium batteries (ASLBs) employing solid-state electrolytes (SEs) are considered as promising next-generation energy storage systems with high safety due to the elimination of the flammable liquid electrolyte used in convention lithium ion batteries. Among various SE candidates, sulfide SEs are one of the most studied species because of their ultrahigh ionic conductivity. However, sulfide SEs suffer from poor compatibility with the conventional transition metal oxide cathode, which is a challenging issue for the further application in ASLBs. In this work, an ASLB pairing a novel thioantimonate conductor, $Li_{6.6}Ge_{0.6}Sb_{0.4}S_5I$, with high capacity sulfide cathode FeS_2 is characterized by operando techniques, and a superior performance is achieved. Generally, FeS_2 is highlighted with high specific capacity, earth abundance and environmentally benignity, but constrained by fast-decaying performance in batteries using liquid electrolyte. Herein, sulfide SEs can successfully address the severe mass loss caused by the aggregation of Fe^0 nanoparticles and shuttle effect of polysulfides during cycling. $Li_{6.6}Ge_{0.6}Sb_{0.4}S_5I$ exhibits high stability with FeS_2 in an optimized voltage range. The operando energy dispersive X-ray diffraction (EDXRD) was firstly used to in situ study the interface stability. As a result of excellent compatibility between FeS_2 and $Li_{6.6}Ge_{0.6}Sb_{0.4}S_5I$, outstanding capacity and cycling stability is achieved at the same time.

6:05 PM EN04.04.03
***Operando* Probing of Lithium Metal Interfaces in Solid-State Batteries Using Synchrotron X-Ray Tomography** John Lewis, Francisco Javier Quintero Cortes, Yuhgene Liu, Jared Tippens and Matthew T. McDowell; Georgia Institute of Technology, United States

Solid-state lithium metal batteries have garnered significant interest in recent years due to the potential for solid-state electrolytes (SSEs) to enable a lithium metal anode by suppressing dendrite growth and eliminating hazardous liquid electrolytes. However, the development of solid-state lithium metal batteries has been limited by numerous challenges that exist at the interface between lithium and SSEs, such as lithium metal penetration through the electrolyte, void formation at the interface, and electrochemical decomposition to form an interphase. Here, we characterize the interface between lithium metal and the sulfide SSE $Li_{10}SnP_2S_{12}$ using *operando* synchrotron X-ray tomography. Owing to the high ionic conductivity of $Li_{10}SnP_2S_{12}$ ($> 10^{-3}$ S cm^{-1}), we were able to electrochemically test symmetric Li/$Li_{10}SnP_2S_{12}$/Li cells at the relatively high current density of 1 mA cm^{-2} while simultaneously collecting 3D images of the cell. Interphase growth and the formation of

interfacial voids were observed throughout the electrochemical experiments. Segmentation and detailed image analysis enabled quantitative analysis of these phases, which were coupled to electrochemical measurements to establish links between interphase growth and void formation to cell failure. We ultimately found that the loss of interfacial contact area caused by void formation at the lithium interface is primarily responsible for failure, with current constriction effects exacerbating the voltage polarization in the cell due to the formation of smaller contact spots with highly localized current flow. Our results highlight the power of *operando* X-ray imaging to probe buried interfaces in solid-state batteries during relevant electrochemical processes.

Three-Dimensional ^{7}Li MRI Investigation of Li Microstructure Formation in Solid Electrolytes

Haoyu Liu[1], Po-Hsiu Chien[1], Ghoncheh Amouzandeh[2], Jens Rosenberg[2], Samuel C. Grant[2] and Yan-Yan Hu[1,2]; [1]Florida State University, United States; [2]National High Magnetic Field Laboratory, United States

Li-ion batteries (LIBs) using solid-state electrolytes (SSEs), known as all-solid-state batteries (ASSBs), have gained much attention due to their improved safety as well as energy density compared with the current generation of LIBs. However, Li microstructure/dendrite growth still persists as the major issue that largely compromises stability and causes short circuits of batteries especially at high cycling rates, which hinders the success of ASSBs for practical applications. While much effort has been invested to understand where, when, and how Li microstructures grow in SSEs, direct evidence has yet to emerge to illustrate where the growth of Li dendrite initiates in SSEs, either from SSEs−Li interfaces or the bulk of SSEs and how it propagates. Herein, for the first time, we report 3D images of Li microstructures to reflect the variations of lithium density distribution in $Li_7La_3Zr_2O_{12}$ (LLZO) upon electrochemical polarization of a Li/LLZO/Li cell via non-invasive ^{7}Li Magnetic Resonance Imaging (MRI). By combining *ex situ* high-resolution 3D MRI of cycled LLZO pellets and *in situ* 2D MRI of the Li/LLZO/Li cell upon electrochemical cycling, the process of Li microstructure formation is revealed, which proves to be significantly different from the liquid-electrolyte-based LIBs. The techniques developed and demonstrated in this work will also benefit studies of other material systems.

6:35 PM EN04.04.06

Isolating and Analyzing the Behavior of Single Grain Boundaries in $Li_7La_3Zr_2O_{12}$ Solid-State Electrolyte

Alexandra C. Moy[1], Grit Haeuschen[2], Martin Finsterbusch[2] and Jeff Sakamoto[1]; [1]University of Michigan, United States; [2]Forschungszentrum Jülich GmbH, Germany

The need for improved battery performance and safety has created the impetus to replace carbon-based anodes used in state-of-the-art batteries with lithium metal. However, it is generally known that lithium metal anodes cannot cycle with state-of-the-art liquid electrolytes due to dendrite formation. Owing to its stability and stiffness, the solid-state electrolyte, lithium lanthanum zirconium oxide (LLZO), is known to physically stabilize lithium during cycling. However, LLZO is typically polycrystalline and there is evidence that grain boundaries potentially serve to initiate lithium filament growth. Thus, there is a need to better understand the behavior and properties of the individual grain boundaries and how grain boundary networks may or may not affect lithium filament penetration in LLZO.

Single crystal and bi-crystal LLZO doped with aluminum were fabricated using rapid induction hot pressing. Grain size and crystallographic orientation were confirmed by x-ray diffraction and electron backscatter diffraction. The ability to grow grains larger than a millimeter enabled electrochemical characterization of single grains and grain boundaries based on orientation and position. Characterization techniques included electrochemical impedance spectroscopy and chronoamperometry. This work presents electrochemical characterization of single grain boundaries and single crystals, increasing the understanding of grain boundary and bulk effects on solid-state electrolyte performance. With this understanding, optimal design and fabrication of solid-state electrolytes can be determined to allow for the implementation of lithium metal anodes into advanced battery technology.

Low Tortuosity Ice Templated Composite Solid-State Cathodes Stephen K. Heywood[1], Eongyu Yi[2], Stephen Sofie[1], Marca Doeff[2] and Guoying Chen[2]; [1]Montana State University, United States; [2]Lawrence Berkeley National Laboratory, United States

The solid-state lithium garnet structured electrolyte $Li_{6.25}Al_{0.25}La_3Zr_2O_{12}$ (LLZO) has shown strong viability in the fabrication of solid-state lithium batteries given its stability with lithium metal anodes than can drive nearly double the specific energy density of conventional lithium ion batteries. However, the integration into low cost battery systems with high capacity for electric vehicles requires a means of minimizing lithium transport distance from the electrolyte into cathode of a bulk 3D electrolyte to overcome the increased ohmic resistance of solid-state lithium garnets. To reduce lithium transport length in bulk solid batteries, our approach is to utilize scalable and aqueous based freeze tape casting to create low tortuosity porous scaffolds of LLZO co-sintered with a dense LLZO film to form a bi-layer battery architecture that can be incorporated with high nickel NMC cathodes. LLZO bi-layer micro-structure development for Li ion transport and NMC incorporation as well as methods to ameliorate interfacial resistance in the solid-state composite cathode without added liquid/polymer electrolytes will be presented.

Polymer-Based Hybrid Solid Electrolytes for Highly Safe Rechargeable Lithium Batteries Dong-Won Kim; Hanyang University, Korea (the Republic of)

Rechargeable lithium-ion batteries (LIBs) have become the main power sources for portable electronic devices, and their applications have rapidly expanded to electric vehicles and large-scale energy storage systems due to their high energy density and excellent cycle life. Although current commercialized LIBs employing liquid electrolytes exhibit superior cycle performance compared to other rechargeable battery systems, there are still concerns related to the use of liquid electrolytes, such as solvent leakage, high volatility and flammability, which make full utilization for large capacity applications very challenging due to the safety issues. As a strategy for enhancing battery safety, all-solid-state lithium battery assembled with a solid-state electrolyte has gained great attention. Among the various types of solid electrolytes, solid polymer electrolytes have attractive properties such as absence of leakage problem, non-flammability, easy processing for producing a thin film, low cost, design flexibility, cuttable shapes and good interfacial contacts with electrodes. However, solid polymer electrolytes exhibited low ionic conductivities at ambient temperature, and their mechanical properties were often poor and thin free-standing films could not be obtained without a thermal curing process. In our work, different types of polymer-based hybrid solid electrolytes with high ionic conductivity and good mechanical property are prepared and applied to rechargeable lithium- batteries. First, the solid polymer electrolytes supported by porous polymer membrane are prepared and their electrochemical properties are characterized. Second, the solid-state hybrid electrolytes composed of ion-conductive polymer and oxide-based inorganic conductive materials are investigated. Third, the hybrid solid electrolytes based on highly conductive Li_6PS_5Cl

was prepared in the form of thin film and their electrochemical characteristics are investigated. All types of the polymer-based solid-state electrolytes are applied to Li/$LiNi_xCo_yMn_{1-x-y}O_2$ cells, and their electrochemical performance will be reported.

8:40 PM *EN04.05.02

Understanding Stability Issues Related to Sulfide Based Solid Electrolytes and Composite Cathodes for All-Solid-State Lithium-Ion Batteries Jae-Ho Park[1,2], Jiwon Jeong[1,2], Da-Seul Han[3], Eun-Seong Kim[1,4], Jun Tae Kim[1], Hun-Gi Jung[1,4], Kyung-Wan Nam[3], Woo Young Yoon[2] and Kyung Yoon Chung[1,4]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Dongguk University-Seoul, Korea (the Republic of); [4]KIST School, Korea University of Science and Technology, Korea (the Republic of)

All-solid-state lithium-ion batteries (ASLBs) have been proposed due to the expectation that they can overcome two major problems on the present lithium-ion batteries based on organic liquid electrolyte : (1) thermal instability of the liquid electrolyte with flammable organic solvent, (2) limitted energy density of battery. Sulfide based solid electrolytes are attracting attention, owing to their high formability and high ionic conductivity which enable favorable interfaces between solid electrolyte and active material particles. The well-connected interfaces can lead to increasing in lithium ion channels and energy density of active materials, however, it also causes a side reactions which form a resistive layer and decreases long cycling life of ASLBs. In this regard, many researchers focused on solving interface problems of ASLBs. To solve these problems, it is important to analyze the stability issues concerning sulfide solid electrolytes and their interfacial reactions accurately with various analysis techniques.
In this talk, we will present the results of comparative analysis on chemical and electrochemical stability with two sulfide-based solid electrolytes, $Li_7P_3S_{11}$ and Li_6P_5SCl which have been widely studied. We will also report the results of electrochemical characterization for composite cathodes by applying each of solid electrolytes. Furthermore, our recent research results of post-mortem analysis for composite cathodes using X-ray based analytical techniques will also be presented.

9:05 PM EN04.05.04

Late News: Rational Design of Solution-Processable Sulfide Solid Electrolytes for All-Solid-State Lithium-Ion Batteries Yong Bae Song[1], Hiram Kwak[1,2] and Yoon Seok Jung[1]; [1]Yonsei University, Korea (the Republic of); [2]HYU, Korea (the Republic of)

Application of lithium-ion batteries (LIBs) has been expanded to large-scale energy storages, such as electric vehicles and energy storage systems. However, safety issues of conventional LIBs have emerged as the most critical concern in recent years. In this respect, all-solid-state batteries (ASBs) have been regarded as one of the most promising alternatives. Especially, ASBs employing sulfide solid electrolytes have shown outstanding performances compared with those fabricated with others such as oxides and polymer electrolytes. Specifically, Li argyrodites are unique due to their solution processability that offers the practical fabrication process of ASB electrodes and intimate ionic contacts between active materials and SEs. However, solution-processable Li argyrodites have been studied only for a composition of Li_6PS_5X (X = Cl, Br, I) with insufficiently high Li^+ conductivities (~10^{-4} S cm^{-1}). Recently, notable progress on new-compositional Li argyrodites has been achieved.

In this presentation, compositional design of solution-processable Li argyrodites and microstructural analyses are presented. Also, promising electrochemical performances of ASBs prepared by an infiltration of solution-processable new Li argyrodites are shown.

9:20 PM BREAK

9:35 PM EN04.05.05
Late News: Slurry-Fabricable Li+-Conductive Dry Polymer Electrolyte Binders with Sulfide Solid Electrolytes for Practical All-Solid-State Batteries Kyu Tae Kim, Dae Yang Oh, Seunggoo Jun, Yong Bae Song and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

The solidification of electrolytes using inorganic materials has great potential of enhancing safety and energy density. While sulfide solid electrolytes (SEs) have been considered as a promising candidate due to their high conductivity and mechanical deformability, the chemical instability for organic polar solvents complicates the wet-slurry fabrication of sheet-type electrodes and SE films for all-solid-state Li batteries (ASLBs). Thus far, only a limited number of organic solvents has been investigated with lacking systematic approach. In addition, the disruption of interfacial Li^+ conduction by binders has been regarded as the origin of the poor electrochemical performances. This could be relieved by hybridizing with liquid electrolytes but at the expense of the ASLBs' thermal stability.
In this presentation, we will show our recent development of dry polymer electrolyte (DPE) binders via a tactical approach considering reactivities between organic solvents and SEs. New liquid-free DPE-based Li^+-conductive binders that could cope with practically adaptable processing solvents are thus tested. Significant improvements in utilizing electrode active materials and their outstanding thermal stability, enabled by slurry-fabricable DPE-based binders, are demonstrated.

9:50 PM EN04.05.06
Late News: Electron and Ion Transfer Across Interfaces of the NASICON-Type LATP Solid Electrolyte with Electrodes in All-Solid-State Batteries—A Density Functional Theory Study via an Explicit Interface Model Hong-Kang Tian[1], Randy Jalem[1,2], Bo Gao[1] and Yoshitaka Tateyama[1,2]; [1]National Institute for Materials Science (NIMS), Japan; [2]Kyoto University, Japan

NASICON-type oxide $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (LATP) is expected to be a promising solid electrolyte (SE) for all-solid-state batteries (ASSBs) owing to its high ion conductivity and chemical stability. However, its interface properties with electrodes on the atomic scale remain unclear, but it is crucial for rational control of the ASSBs performance. Herein, we focused on the LATP SE with $x = 0.17$ and investigated the electron and ion transfer behaviors at the interfaces with the Li metal negative electrode and the $LiCoO_2$ (LCO) positive electrode via explicit interface models and density functional theory calculations. Ti reduction was found at the LATP/Li interface. For the LATP/LCO interface, the results indicated the Li-ion transfer from LCO to LATP upon contact until a certain electric double layer is formed under equilibrium, in which LCO is partially reduced. The calculation results agree well with experimental observations. Co–Ti exchange was also found to be favorable where the Li ion moves with Co^{3+} to LATP. We also explored the possible interfacial processes during annealing by simulating the oxygen removal effect and found that oxygen vacancy can be more easily formed in the LCO at the interface. It implies that partial Li ions move back to LCO for the local charge neutrality. The calculation results are well in line with the experiments. We also demonstrated higher Li chemical potential around the LATP/LCO interfaces, leading to the dynamical Li-ion depletion upon charging. The calculation results and the deduced mechanisms well explain the experimental results so far [1-2] and provide insights into the interfacial electron and ion transfer upon contact, during annealing, and charging [3].

10:05 PM DISCUSSION TIME

10:20 PM EN04.05.08
Late News: Fe3+-Substituted Li2ZrCl6: New Halide Li+ Superionic Conductors for All-Solid-State Batteries Hiram Kwak[1,2], Da-Seul Han[3], Juhyoun Park[1,2], Yoonjae Han[1,2], Kyung-Wan Nam[3] and Yoon Seok Jung[1]; [1]Yonsei University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]Dongguk University, Korea (the Republic of)

For the development of all-solid-state Li batteries with improved safety and energy density, solid electrolytes (SEs) showing a high Li^+ conductivity ($\geq 10^{-3}$ S cm^{-1}) are the key. This is met by several types of inorganic compounds of sulfides, oxides, borohydrides, and halides. Among them, sulfide materials have been considered to be highly promising due to their mechanical deformability which enables scalable cold-pressing-based fabrication. However, uncoated conventional layered $LiMO_2$ (M = Ni, Co, Mn, Al) cathodes showed poor performances in combination with sulfide SEs, which is due to poor oxidation stability of sulfide SEs and (electro)chemical reactions between $LiMO_2$ and sulfide SEs. Since new halide SEs of Li_3YX_6 (X = Cl, Br) showing high Li^+ conductivities (0.51 and 1.7 mS cm^{-1} for Li_3YCl_6 and Li_3YBr_6, respectively) and excellent (electro)chemical oxidation stabilities as well as mechanical deformability were reported, much efforts have been focused on the developments of halide superionic conductors. Despite advances in developments of halide SEs, high Li^+ conductivities of ~10^{-3} S cm^{-1} have only been achieved using scarce and expensive elements such as Y, Er, Sc, and In.
In this presentation, our recent results on the development of new cost-effective Li^+ superionic conductor, Fe^{3+}-substituted Li_2ZrCl_6, and their application to all-solid-state batteries will be presented.

10:35 PM EN04.05.10
Late News: Crystal Structure of Li3-xYb1-xMxCl6 Modulated by Heat Treatment Temperature for All-Solid-State Batteries Juhyoun Park[1,2], Da-Seul Han[3], Hiram Kwak[1,2], Yongjung Choi[3], Kyung-Wan Nam[3] and Yoon Seok Jung[1]; [1]Yonsei University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]Dongguk University, Korea (the Republic of)

The application area of lithium ion batteries (LIB) has been expanded from mobile electronics to electric vehicles and energy storage systems. Safety issue of LIBs employing organic liquid electrolytes has mounted as a serious problem. In this regard, all-solid-state lithium batteries using inorganic solid electrolytes (SEs) are considered as one of the most promising candidates. While sulfide SEs have been extensively investigated for practical , ASLBs owing to their high ionic conductivities and mechanical sinterability, they suffer from poor electrochemical stability, especially when combined with conventional layered $LiMO_2$ cathodes. Recent reinvestigation of halide SEs derived via mechanochemical method (Li_3YCl_6) has demonstrated high ionic conductivities of $>10^{-3}$ S cm^{-1}, which was contrasted by low conductivities of 10^{-4}~10^{-6} S cm^{-1} for samples prepared by conventional heat-treatment in the past. Importantly, halide SEs showed excellent (electro)chemical oxidation stabilities, which enables stable cycling of conventional $LiMO_2$ cathodes. Thus far, it has been considered that multiple factors such as bulk/local structures and contents of Li and central metals could affect ionic conductivities of halide SEs.
In this presentation, effects of crystal structures of Li_3YbCl_6 substituted with tetravalent metals on Li^+ conductivities, which are modulated by heat-treatment temperature, are presented.

8:00 AM *EN04.06.01
SOLBAT—The Faraday Institution's Solid-State Li-Metal Anode Project Mauro Pasta; University of Oxford, United Kingdom

Li-ion batteries have revolutionized the portable electronics industry and empowered the electric vehicle (EV) revolution. Unfortunately, the traditional Li-ion chemistry is approaching its physicochemical limit. The demand for higher density (longer range), high power (fast charging) and safer EVs has recently revamped the interest in solid state batteries (SSB). Historically, research has focused on improving the ionic conductivity of solid electrolytes, yet ceramic solids now deliver sufficient ionic conductivity. The barriers lie within the interfaces between the electrolyte and the two electrodes, in the mechanical properties throughout the device, and in processing scalability.
In 2018 the Faraday Institution, the UK's independent institute for electrochemical energy storage research, launched the SOLBAT (solid-state lithium metal anode battery) project aimed at understanding the fundamental science underpinning the problems of SSBs, recognising that the paucity of such understanding is the major barrier to progress.
In my talk I will present an overview of the fundamental challenges that are impeding the development of SSBs, the advances in science and technology necessary to understand the underlying science, and the multidisciplinary approach that the SOLBAT researchers are taking to face these challenges.

Monolithic Solid-State Lithium-Ion Batteries with Sulfide Electrolytes Liangliang Li; Tsinghua University, China

Solid-state lithium (Li)-ion batteries are attracting a lot of interest due to good safety and high energy density. Sulfide solid electrolytes have many advantages such as high ionic conductivity and easy processability. Recently, monolithic solid-state Li-ion batteries that utilize sulfide electrolytes as both the active material and ionic conductor have been developed. With a monolithic structure, the active material loading and active sites for electrochemical reaction can be increased and the unwanted interfacial reaction between the cathode and the electrolyte is avoided. In this talk, we will discuss monolithic solid-state batteries with argyrodite Li_6PS_5Cl and Li_2S-P_2S_5 glass-ceramic solid electrolytes. First, the synthetic methods of these sulfide electrolytes are introduced and the property optimization of the electrolytes is given. Second, monolithic all-solid-state batteries based on Li_6PS_5Cl and Li_2S-P_2S_5 sulfide electrolytes are fabricated and tested. The monolithic batteries show long cycle life and high discharge capacity at room temperature. The electrochemical activity of these sulfides is systematically analyzed and the main factors that affect the long-term cycling performance of the monolithic batteries are discussed.

8:50 AM EN04.06.03
"Water-in-Salt" Polymer Electrolyte for Li-Ion Batteries Jiaxun Zhang, Chongyin Yang and Chunsheng Wang; University of Maryland, United States

Lithium ion batteries (LIBs) deliver a high energy density, a long cycle stability and a high energy efficiency. While the intrinsic safety problem of LIBs impedes the application of current LIBs in large scale energy storage. Aqeuous rechargeable lithium ion batteries resolve several challenges of conventional LIBs. However, the electrochemical stability window of aqueous electrolytes is less than 2.0 V, beyond which H_2 or O_2 gas generated owing to the electrolysis of H_2O. Recently, the ground-breaking of "water-in-salt" electrolyte (WiSE) successfully expanded the ESW of water to 3.0 V. To enhance energy density of WiSE batteries, the catholic limitation of 1.9 V needs to further reduced, and a high Coulombic efficiency (CE) of > 99.9% at a matched areal capacities of cathode/anode at a low charge/discharge rates is required for a long-term cycling. Here, by

incorporating WiSE with UV-curable methacrylic polymer, we designed a solid-state aqueous polymer electrolyte (SAPE), in which the abundant hydrophilic groups stabilized water molecules due to the sluggish water mobility in SAPE and formed a water-less thin passivation interphase between anode and electrolyte. Moreover, the anode was pre-coated with a strongly basic water-free solid polymer electrolyte to further promote the formation of passivation interphase. All of these contributed the formation of a more robust SEI to reduce the water reduction reactions on anode surface. An extended electrochemical stability window of 3.86 V is achieved at 12 mol kg^{-1} aqueous polymer electrolyte enabled 3 V full cells with an unprecedented high initial CE of 90.5% and average CE of 99.97%. The SAPE exhibits intrinsic safety and tolerance of drastic mechanical abuse, the flexible full cell with supper robustness can be widely used for low-cost and high-safety flexible electronic devices. The UV-cured polymerization process possesses the merit of facile and high efficiency, and the whole process have the potential to be practical used in a large scale. Also, the high-voltage bipolar cell is fabricated to demonstrate aqueous solid state battery. Overall, this newly developed reduced salt concentration WiSE not only reduces the cost of aqueous electrolyte, but also opens up another perspective on future directions and guidance for the design of aqueous electrolyte for high-energy-density Li-ion batteries in practical applications.

9:05 AM EN04.06.04

Transformations in Structured Alloy Anodes for Solid-State Batteries Sang Yun Han[1], Chanhee Lee[1,2], Yuhgene Liu[1], John Lewis[1] and Matthew T. McDowell[1,1]; [1]Georgia Institute of Technology, United States; [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Alloy anode materials are promising for Li-ion batteries, as they have greater specific capacity than conventional graphite electrodes. Metals that form alloys with Li can electrochemically react to form Li-rich alloys at room temperature, such as $Li_{22}Sn_5$, $Li_{13}In_3$, and $Li_{15}Si_4$, with specific capacities of 990 mAh g^{-1} for Sn and 1012 mAh g^{-1} for In, as compared to 372 mAh g^{-1} for graphite. However, the severe volume changes associated with charging and discharging alloy anodes remain a problem. In the case of all-solid-state batteries, these electrode volume changes can substantially exacerbate chemomechanical degradation because of the all-solid nature of the battery system and the propensity for fracture of the solid electrolyte. Here, we investigate electrochemical transformations in alloy materials in solid-state batteries and correlate these transformations to stress evolution within the solid-state stack. Metal foils with bicontinuous porosity are shown to exhibit improved capacity and cycling behavior in solid-state batteries made from sulfide-based electrolytes. In particular, porous indium showed much better specific capacity, capacity retention, and cycle life than dense indium foil with similar mass loading in solid-state batteries. The porous metal foils are synthesized by chemically dealloying Li-rich alloys in dry methanol and directly used them as the anode for the solid-state cells. This performance enhancement is likely due to the capability of the porous material to accommodate volume changes during charging/discharging while minimizing mechanical damage to the solid electrolyte. An integrated force sensor within the solid-state cells allows for real-time measurement of subtle changes of stack pressure within the cell, and the porous vs. dense films show different evolution of stack pressure. We have also investigated the impact of anode geometry (foil vs. particulate anode structure) on stress evolution and accumulated mechanical damage. Our results demonstrate the importance of controlling volume changes and stress evolution at the anode of solid-state batteries.

9:20 AM EN04.06.05

Enhancement of Ion Conduction via Anion Structural Disorder in $Li_{6-x}PS_{5-x}Br_{1+x}$ Pengbo Wang[1], Haoyu Liu[1], Sawankumar v. Patel[1], Xuyong Feng[1], Po-Hsiu Chien[1], Yan Wang[2] and Yan-Yan Hu[1,3]; [1]Florida State University, United States; [2]Sumsung Research America, United States; [3]National High Magnetic Field Laboratory, United States

All-solid-state batteries (ASSBs) using fast-ion conductors as electrolytes are promising energy storage technology for enhanced energy density and safety. Among them, Li-argyrodites have attracted increasing attention because of their high ionic conductivity above 10 mS/cm and structural flexibility that can tolerate a variety of modifications in the anion sublattices. Here, we synthesized $Li_{6-x}PS_{5-x}Br_{1+x}$ with different amount of

Br^- at Wyckoff 4d sites which are predominantly occupied by S^{2-} in the pristine structure. The highest ionic conductivity of 11 mS/cm at 25 °C is achieved with low activation energy of 0.18 eV for $Li_{5.3}PS_{4.3}Br_{1.7}$. The influence of Br^-/S^{2-} mixing on ion conduction is systematically investigated with multinuclear solid-state NMR coupled with X-ray diffraction and impedance spectroscopy. Distinctive atomic arrangements (4S, 3S1Br, 2S2Br, 1S3Br, and 4Br) at 4d sites in the sublattices and a statistically random distribution of $Br^-$and S^{2-} at 4d sites are observed with ^{31}P NMR. The resulting local structures regulate the jump rates of their neighboring Li ions and Li redistribution. As a result, the increased Li^+ occupancy at Wyckoff 24g sites promotes fast ion conduction. Meanwhile, $^6Li \rightarrow ^7Li$ tracer-exchange NMR unveils that Li (24g) is more frequently visited than Li (48h). Experimental evidence combined with density functional theory calculations has revealed that the particular arrangement of 1S3Br at 4d sites maximizes overall Li^+ conduction. This insight applies to other argyrodites and will be useful to the design of new fast-ion conductors.

10:30 AM *EN04.07.01
Tools for Automated Rapid Screening of Fast Ion Conducting Solids Stefan N. Adams; National University of Singapore, Singapore

Identifying new materials that combine high ionic conductivity with structural and electrochemical stability so far remains a slow trial and error search process. To rationally accelerate materials design and exploit the opportunities in the materials genome a dependable rapid screening of materials is required so that promising structures can be shortlisted for higher level computational as well as experimental characterization. Here we report on the progress of our softBV bond-valence site energy-based automated pathway analysis that provides rapid and simplified visualization of pathways, in order to bridge the gap between experimentalists and simulation specialists [1,2]. Thereby meaningful approximate predictions of ion transport pathways can be achieved from crystal structure models within seconds or minutes providing a speedup factor of 3 to 5 orders of magnitude compared to DFT-based NEB methods. Combined with a graphical user interface our software suite (that is available free for academic use from [2]) this aims to enable experimentalists to quickly identify candidate solid electrolyte materials. We also aim to integrate the pre-screening into an automated workflow for subsequent DFT characterization [3].Results are benchmarked against both experimental and DFT NEB migration barriers. Besides the migration barriers the approach now also comprises an AI-based dopant predictor focusing on bond-valence-based crystal chemical descriptors to assist experimentalists in exploring favorable substitutional doping strategies.
We will also compare the predictability of absolute room temperature conductivities from static energy landscape analysis, bond-valence based empirical MD simulations and ab initio molecular dynamics (AIMD) simulations. While for small fast-ion conductor structures at sufficiently high temperatures AIMD appears to be the gold standard, the less reliable but computationally empirical approaches have an advantage in modelling complex disordered interfaces at low temperatures over longer periods. This eliminates the hazards involved in extrapolations down to room temperature properties for the frequent cases of order-disorder phase transitions at intermediate temperatures. As an example we will discuss lithium and sodium compounds containing multiple (poly)anions, in particular the combination of thiophosphate and halide anions or various MS_4 polyanions. Based on computational screening using our bond valence site approach and DFT studies several thiophosphate halides along the A_3PS_4-LiX (Cl, Br, I; A = Li, Na) tie line [4] and the $A_x(MS_4)_y(M'S_4)_z$ phase space [5] have been explored and their properties discussed based on BVSE pathway models and molecular dynamics

simulations in combination with experimental (X-ray and neutron) diffraction, solid state NMR and electrochemical characterisation. The simplicity of the approach also facilitates the study of homogeneity ranges as exemplified for the solid solution systems $Li_{4-x}PS4I_x$ ($0<x<0.67$) and $Na_{9+x}(MS_4)_{3-x}(SnS_4)_x$ or compound series such as $LiTX_4$. Thereby we also explore under which circumstances the predictions based on static BV calculations have to be complemented by dynamic simulations to capture the role of polyanion librations in promoting ion transport.

Photonic Methods for Rapid Annealing of Cathode Films on Flexible and Temperature-Sensitive Substrates for Thin-Film Solid-State Batteries Jordi Sastre-Pellicer[1], Xubin Chen[1], Matthias Rumpel[2], Andreas Flegler[2], Patrik Hoffmann[1,3] and Yaroslav Romanyuk[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]Fraunhofer Institute for Silicate Research ISC, Germany; [3]École Polytechnique Fédérale de Lausanne, Switzerland

High temperature and prolonged thermal annealing for the crystallization of cathode films in thin-film solid-state batteries (TF-SSBs) restricts the choice of current collector and substrates and causes lithium loss in the cathode. This work explores photonic-based alternatives for cathode crystallization, specifically xenon flash-lamp annealing (FLA), ultra-violet excimer laser irradiation (UV-laser) and infrared laser (IR) annealing. The effect of these methods is systematically compared to that of thermal annealing in terms of processing time, crystal structure and electrochemical performance of two model thin-film cathodes $LiMn_2O_4$ (LMO) and $LiCoO_2$ (LCO).

FLA can crystallize LMO cathode films in less than 6 minutes compared to the reference thermal processing time of 60 minutes at 600 °C. The performance of the FLA-processed LMO cathodes (crystallinity, capacity, diffusion coefficient) is comparable to that of the thermal reference. LCO cathodes with thicknesses up to 5 μm could be crystalized by FLA.

To demonstrate the fast crystallization of thin-film cathodes on temperature-sensitive substrates, we applied FLA to LCO cathode films deposited on flexible aluminum foil. Flexible TF-SSBs composed of LCO as cathode, lithium phosphorus oxynitride (LiPON) as solid electrolyte and Li metal as anode were fabricated and exhibited an energy density and power density up to 800 $\mu Wh\ cm^{-2}$ and 7000 $\mu W\ cm^{-2}$, respectively. Such performance is comparable to state-of-the-art thermally-annealed TF-SSBs on rigid substrates.

11:10 AM EN04.07.03

Quantifying the Density and Mobility of Mobile Ions in Solid Electrolytes by Transient Current Measurements Moritz H. Futscher, Jordi Sastre-Pellicer and Yaroslav Romanyuk; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Solid electrolytes are a key component in enabling new technological advances for rechargeable batteries by mitigating many of the challenges associated with the use of liquid organic electrolytes. One of the key properties of solid electrolytes is their ability to transport ions between the anode and the cathode. This ion migration is usually characterized by measuring the ionic conductivity by means of impedance spectroscopic measurements. However, the ionic conductivity is proportional to both the density and the mobility of mobile ions. Only the mobility represents the actual velocity of the mobile ions.

Using lithium phosphorus oxynitride (LiPON), we show how measuring the temperature-dependent current transients can be used to independently quantify both the mobility and the density of mobile ions in solid electrolytes. By changing the mobile ion density in $Li_7La_3Zr_2O_{12}$ (LLZO) solid electrolyte by co-sputtering LLZO and Li_2O, we show how samples that seem to have the same ionic conductivity can still differ in ionic mobility. Finally, we employ this method to quantify the effects of Al and Ga doping on the ion migration in LLZO solid electrolytes. The proposed approach in quantification of mobile ions can be extended to other solid electrolytes for a better understanding of ion migration and the influence on battery performance.

11:25 AM EN04.07.05
Fast Li-Ion Solid Electrolytes for Solid-State Batteries Jan Allen; U.S. Army Research Laboratory, United States

Solid Li-ion conducting electrolytes are one pathway towards future, energy-dense, intrinsically-safe solid-state batteries. Thus, it is of interest to study novel fast Li-ion solid electrolyte materials. Here we report the synthesis and characterization of a new family of oxide solid electrolytes. We detail the compositions that were explored and give the results of the synthesis, densification and the structural, physical and electrochemical characterization and its interface with electrode materials. The properties of the new materials will be compared and contrasted to well-known solid Li electrolytes such as garnet and NASICON structured materials.

11:40 AM EN04.07.06
Conditioning Hybrid Organic-Inorganic Solid Electrolytes for Improved Cation Mobility Vazrik Keshishian and John Kieffer; University of Michigan–Ann Arbor, United States

Conventional lithium-ion batteries that use liquid electrolytes are not very desirable due to lack of chemical stability, safety issues and cost of production. Solid state electrolytes (SSEs) not only have the potential to correct these drawbacks, but improve performance characteristics such as energy density and power density can also be improved. To simultaneously achieve high ionic conductivity and mechanical stiffness, a composite materials design approach for creating the novel SEEs is indicated. Here we report on our development of hybrid organic-inorganic electrolytes, in which a silica backbone is formed by sol-gel synthesis routes to provide a mechanically rigid backbone. The fluid in this nano-porous structure is subsequently replaced with polymer solutions. The polymer is grafted onto the backbone through reactive groups, and thus anchored into structure to establish the ion conducting phase. This unique approach allows us to decouple the influence of mechanical properties on ionic transport properties of materials and achieve both high elastic stiffness and ionic conductivity. We discovered that the network structure of a gel-cast material can be further conditioned by influencing the structural evolution during drying. Changing sample aspect ratio various degrees of anisotropy and spatial gradients can be achieved in the network topology. This is revealed through nano-mechanical characterization of the materials, using Brillouin light scattering. Since there is a strong correlation between the adiabatic elastic modulus and the activation energy of ion hopping, this anisotropy also affects ionic conductivity. Here we elaborate on strategies to harness this structural conditioning to create better performing SSE (Acknowledgement: NSF-DMR 1610742.)

Late News: Controlling the Cation Ordering on a LiNi0.5Mn1.5O4 Thin-Film Model System by Modifying the Cooling Rate During Annealing Andrea I. Pitillas Martinez[1,2,3], Christophe Detavernier[3] and Philippe Vereecken[1,2]; [1]imec, Belgium; [2]KU Leuven, Belgium; [3]Ghent University, Belgium

The introduction of cathode materials that have both intrinsically higher capacities as well as higher operating potentials can help to further move towards the usage of electric vehicles and renewable energies. In this regard, high energy density cathodes which are cobalt free are of high interest in the field of batteries, mainly due to their lower cost, as well as for environmental reasons. The high cost of cobalt [1], as well as the environmental conditions under which it is extracted are the main determining facts which rise major concerns in the continuing use of cobalt containing cathodes.

In this regard, cobalt free cathodes such as $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) are of high interest due to its high operating potential (4.7 V vs Li^+/Li) as well as its high specific capacity (147mAh/g). However, regardless of the intensive research done over the years, this material has not yet really made it into the market. One of the reasons being the contradictory results reported in literature trying to correlate the composition, material properties and electrochemical performance with the crystal structure as well as differentiating its bulk and interface properties when in contact with electrolytes [2].
For this reason, in this work, we would like to present the potential of using a thin film $LiNi_{0.5}Mn_{1.5}O_4$ model system to address this issue. So, it is possible to relate more accurately the composition, crystallinity and cation ordering of this material with its electrochemical performance.
Thin film LNMO has been previously reported as model system for study of cation ordering in LNMO. Yet only the effect of the pressure during RF sputter deposition was investigated so far, which, however, can affect both the cation ordering and the composition of the thin film [3],[4]. As such the correlation between the electrochemical performance with the cation ordering was challenging, as it is also dependent on composition. Herein, we present an approach to control the cation ordering of a thin film LNMO while maintaining the composition constant based on controlling the cooling rate during the annealing step after sputtering at the same deposition pressure.

1:00 PM *EN04.08.01
Structure, Chemistry and Charge Transfer Resistance of the Interface Between Garnet Solid Electrolyte and Oxide Cathodes Bilge Yildiz; Massachusetts Institute of Technology, United States

All-solid-state batteries promise significant safety and energy density advantages over liquid-electrolyte batteries. The interface between the cathode and the solid electrolyte is an important contributor to charge transfer resistance. Strong bonding of solid oxide electrolytes and cathodes requires sintering at elevated temperatures. Knowledge of the temperature dependence of the composition and charge transfer properties of this interface is important for determining the ideal sintering conditions. To understand the interfacial decomposition processes and their onset temperatures, model cathode systems of $LiCoO_2$ (LCO) and $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ (NMC622) thin films deposited on cubic Al-doped $Li_7La_3Zr_2O_{12}$ (LLZO) pellets were studied as a function of temperature, gas composition and electrochemical conditions. The methods combine interface-sensitive techniques, including X-ray photoelectron spectroscopy (XPS), synchrotron X-ray absorption spectroscopy, hard X-ray photoemission (HAXPES), and synchrotron X-ray diffraction. In this talk, we will present the found precipitation products at the interface as a function of synthesis and electrochemical conditions, their role in altering the interface resistance to Li transfer, and compare the LCO and NMC related cathodes in terms of their instability onset conditions.

Lithium Insoluble Interlayer Aids Dendrite Suppression and Enhanced Current Densities in Lithium Solid-State Batteries Vikalp Raj, Varun Kankanallu, Bibhatsu Kuiri and Naga Phani Aetukuri; Indian Institute of Science, Bangalore, India

Lithium ion batteries (LIBs) have been in prevalence for over two decades. They find use in portable electronics, electric vehicles and also grid storage. The conventional Li-ion battery technology employs electrolytes that have flammable organic solvents as key constituents. In addition, these electrolytes are thermodynamically unstable at voltages beyond 4 V; stability at voltages beyond 4 V is essential for the development of high voltage and therefore, high energy density Li-ion batteries. Moreover, state-of-the-art lithium ion batteries use a graphitic anode, which has a low theoretical specific capacity of 372 mAh/g. Due to this low specific capacity, conventional LIBs are limited in scope with respect to their energy and power density. Lithium metal anodes with a theoretical specific capacity of 3860 mAh/g are ideal for the development of high energy density Li-ion batteries. However, Lithium metal when used with liquid electrolytes tends to form filament like structures called dendrites due to uneven deposition of Li metal leading to short battery lifetime and also possible battery fires.
Over the years, solutions to this challenge included the development of solid-state electrolytes that could mechanically suppress dendrite growth. Solid-state electrolytes are non-flammable, mechanically robust and (electro)chemically stable. Several solid (inorganic and organic materials) have been proposed as candidate materials. However, dendrite growth is experimentally observed in most of these solid electrolytes. For example, garnet based Li-ion conductor $Li_7La_3Zr_2O_{12}$ (LLZO) and its doped variants have been extensively studied as potential candidates for utility in solid-state batteries. Garnet solid-state electrolytes have several favourable properties that are desired for solid-state Li-ion battery applications. However, dendrite growth at current densities as low as 100 $\mu A/cm^2$ has been observed. Improvements to the interface between lithium anode and the solid electrolyte via the use of metal interlayers and surface modification techniques, have been shown to mitigate dendrite growth at current densities exceeding 100 $\mu A/cm^2$. When such interfacial improvements have been coupled with an external mechanical pressure of several hundred kilopascal, cells were shown to sustain higher current densities without any dendrite growth. Although such high stack pressures are impractical for batteries development.
In this work we have synthesized high ion conductivity pure cubic phase LLZTO and studied dendrite growth mechanism. We observe that voids at Li/LLZTO interface act as field concentrators and have prime role to play in nucleation of dendrites. We suggest that these voids might be inevitable owing to nature of this battery system and propose the use of electron conducting interlayers which have no solubility with lithium metal as way of suppressing voids and mitigating dendrite growth.

1:40 PM EN04.08.03
A Proposed General Solution for Li Dendrite Penetration into Solid Electrolytes Yue Qi[1], Chunmei Ban[2] and Stephen J. Harris[3]; [1]Brown University, United States; [2]University of Colorado Boulder, United States; [3]Lawrence Berkeley National Laboratory, United States

Solid electrolytes (SEs) face significant technical challenges, in large part because lithium/sodium dendrites readily penetrate through SEs, leading to short circuits, even though early-on the high mechanical strength of ceramic separators was expected to suppress lithium growth. The ability of such a soft material (Li or Na metal) to penetrate through a ceramic is surprising from the point of view of models widely used in the Li battery field. We introduce a concept, new to the battery field, for suppressing penetration of lithium dendrites through SEs by putting the SE surfaces into states of residual compressive stress. For a sufficiently high compressive stress, cracks have difficulty forming, and cracks that do form are forced to close, blocking dendrite penetration. This approach is widely used to solve commercially important stress corrosion cracking problems in metals and static fatigue problems in ceramics and glasses (e.g., Gorilla Glass). However, the technique will not be useful for SEs if the Li ion transport rate through a SE is substantially reduced when the SE is in compression.

Our molecular dynamics calculations for Li ion transport through a common SE demonstrate that the introduction of even very high residual compressive stresses (10 GPa) has only a modest effect on Li ion transport kinetics, suggesting that the approach is viable and capable of providing a new paradigm for developing highperformance and mechanically strong SEs.

1:55 PM EN04.08.04
Solid-State Li-Ion Battery Performance and Electrolyte Conductivity Modeling in Python Maya Horii[1], Rebecca Christianson[2], Heena Mutha[2] and Chris Bachman[1]; [1]California State University, Los Angeles, United States; [2]Draper Laboratory, United States

High Li-ion conductivity solid electrolytes can allow for higher energy density and safer solid-state Li-ion batteries. One promising solid electrolyte is $Li_7La_3Zr_2O_{12}$ (LLZO) as it has both a high conductivity and stability. However, processing of ceramic electrolytes that are thin, dense, and have limited grain boundaries is a challenge. Additionally, understanding the effect of these properties on battery performance is not well understood. To analyze the effect of LLZO grain structure, a resistor mesh model was created. By solving for voltage using successive over-relaxation of Kirchhoff's Law, we can calculate the conductivity and diffusion coefficient of a material with varying grain sizes, grain boundary thicknesses, and voids. This model was coupled with a continuum battery performance model, which uses the Nernst-Planck equation to track the concentration of Li throughout a battery with an LLZO electrolyte, a Li metal negative electrode, and a $LiCoO_2$ positive electrode. Then, using the concentration data, the overpotential from diffusion, charge transfer, and resistance were found using the Nernst equation, Butler-Volmer equation, and the integral of the electric field in the electrolyte, respectively. By adding the overpotentials to the equilibrium voltage based on state of charge, we obtained charge/discharge curves, energy, and power for the battery under varying conditions. Combining these models, we can determine the effect of grain structure on overall battery performance. This modeling method can be used to evaluate the suitability of solid-state electrolyte materials and manufacturing methods.

As expected, the model predicted increasing energy output as grain size increased and grain boundary thickness decreased, due to the low conductivity of LLZO grain boundary. Similarly, it was able to predict increasing energy at lower C-rates. It was found that below ratios of grain size to grain boundary thickness of 10000, the diffusion coefficient begins to appreciably decrease. The low electrolyte diffusion coefficient has the largest detrimental effect at high C-rates, where the electrolyte becomes the limiting factor and is unable to support the Li diffusion.

2:10 PM EN04.08.06
From Atomistic Understanding of Correlation and Transport to Solid Polymer Electrolyte Design Nicola Molinari[1], Jonathan Mailoa[2] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Bosch, United States

Electrolytes control battery recharge time and efficiency, anode/cathode stability, and ultimately safety, consequently electrolyte optimization is crucial for the design of modern energy storage devices. However, conductivity and general transport properties of the cation/anion pair(s) dissolved in the electrolyte often pose a technological limitation to the viability of the battery, and progress in fundamental insights into the origin of transport limitations are challenging yet extremely valuable. We adopt theoretical and molecular modeling techniques to shine light on transport properties and correlation effects in solid polymer electrolyte systems.

Poly(ethylene oxide) (PEO) -based solid polymer electrolytes have a long history of research due to the easy processability and good transport properties, yet new observations that challenge our conventional understanding are still reported, especially at high salt concentrations relevant for technological applications. Our study of such regimes for PEO-Li-bis(trifluoromethane)sulfonimide (TFSI) reveals the central role of the anion in coordinating and hindering Li ion movements. In particular, we observe significant competition between the anion and the polymer backbone to coordinate lithium atoms and surprising formation of asymmetric cation-anion clusters. The latter observation resonates well with recent experimental findings,

where negatively-charged Li-anion clusters were speculated to exist to justify the negative lithium transference number measured in this system. We then leverage the atomistic understanding developed for PEO to propose and study a new class of poly(anhydride)-based solid polymers electrolytes. Remarkably, we find that the electrolyte consisting of Li-TFSI dissolved in poly(cis-hept-4-enoicanhydride) has a 50% higher conductivity than PEO and a lithium transference number as high as 0.79. We then rationalize these results by investigating the complex anion-polymer chain competition in coordinating lithium.

2:25 PM EN04.08.07
Late News: LiBH4-Oxide Composite as Solid-State Electrolyte for Solid-State Lithium-Ion Battery
Valerio Gulino[1,2], Matteo Brighi[3], Peter Ngene[1], Radovan Černý[3], Marcello Baricco[2] and Petra de Jongh[1]; [1]Utrecht Universty, Netherlands; [2]University of Turin, Italy; [3]University of Geneva, Switzerland

Solid-state electrolytes (SSEs) are promising candidates for resolving the intrinsic limitations of the organic liquid electrolyte currently employed in Li-ion batteries. Nevertheless, an SSE must fulfil several requirements to be employed in an all-solid state battery (SSB), such a high ionic conductivity. Complex hydrides (*e.g.* $LiBH_4$) are suggested as solid-state electrolytes.[1] Among the different polymorphs of $LiBH_4$, only the hexagonal phase, which is stable at temperatures above 110°C, has a remarkable high ionic conductivity (~10^{-3} S cm^{-1} at 120 °C). To practically access a room temperature (R*T*) SSB, a promising approach to enhance the Li-ion conductivity of $LiBH_4$ at R*T* is the development of new high conductive interface by mixing it with oxide nanoparticles (such as SiO_2, Al_2O_3 and MgO).[2]
In this work the Li-ion conductivity of $LiBH_4$ has been enhanced by means of MgO-mixing, optimizing the composition of $LiBH_4$-based composites in order to obtain a RT operating SSE. The optimum composition of the mixture results 53 v/v % of MgO, showing a Li-ion conductivity of 2.86 10^{-4} S cm^{-1} at 20 °C, four order or magnitude higher than pure $LiBH_4$ and comparable to the Li-ion conductivity of a liquid electrolyte. The improved Li-ion conductivity relies on the formation of a conductive interface that can be described by a core-shell model where the fraction of $LiBH_4$ (the core) is in direct contact with the oxide (the shell).
The formation of the composite does not affect the electrochemical stability window, which is similar to that of pure $LiBH_4$ (about 2.2 V *vs.* Li^+/Li). The mixture has been incorporated as solid-electrolyte in a TiS_2/Li all-solid-state Lithium metal battery. A freshly prepared battery failed at RT only after 5 cycles. On the other hand, a stable solid electrolyte interphase can be obtained by a pre-conditioning cycling at 60 °C. Afterward, a capacity retention of about 80 % at the 30th cycle was obtained operating at RT. We illustrate that the addition of oxide nanoparticles to $LiBH_4$ offers a promising strategy to obtain novel SSE candidates for Li-based SSB.[3]

EN04

4:00 PM *EN04.09.01

High-Energy All-Solid-State Organic–Lithium Batteries Yan Yao; University of Houston, United States

The race to safer and higher-energy batteries is prompting a transition from the liquid electrolyte-based lithium-ion batteries to all-solid-state lithium batteries. Recent studies have identified unique properties of organic battery electrode materials such as moderate redox potentials and mechanical softness which are uniquely beneficial for all-solid-state batteries based on ceramic electrolytes. Here we further explore the promise of organic materials and demonstrate a sulfide electrolyte-based organic-lithium battery with a specific energy of 828 Wh kg^{-1}, rivaling the state-of-the-art of all-solid-state batteries. Two innovation steps are responsible for the accomplishment. First, the combination of lithium anode and the high-capacity cathode material pyrene-4,5,9,10-tetraone ensures a high theoretical specific energy. Second, the microstructure of the organic cathode is optimized with the introduction of cryomilling, a technique common to processing soft materials but not familiar to electrode fabrication. The cathode material utilization increases to 99.5% as a result, up from the 55-89% previously reported for ceramic electrolytes-based solid-state organic batteries. The improvement highlights the special requirements of solid-state organic electrodes for microstructural engineering while preserving the chemical integrity of components.

4:25 PM EN04.09.02
Late News: Design of High-Voltage Stable Hybrid Electrolyte with an Ultrahigh Li Transference Number Chen Liao[1,2] and Kewei Liu[1]; [1]Argonne National Laboratory, United States; [2]Joint Center of Energy Storage Research, United States

Considering the high energy consumption during processing, and the low compliance and adhesion of ceramic electrolytes, the integration of polymer into ceramic electrolytes provides a way to mitigate the interfacial9issues. However, the severe ion concentration gradient, low ionic conductivity,and instability toward Li metal and high-voltage cathodes become the major concerns in applying hybrid electrolytes. In this work, we report a single-ion-conducting hybrid electrolyte with a new electrolytechemical stable polymer and LLZO. The composite electrolyte exhibited a high Li transference15number of 0.94 and electrochemical stability up to 5.6 V vs Li/Li+. Promising averaged Coulombic efficiencies of 99.97% and 99.91% were achieved in cells with LiNi0.8Co0.15Al0.05O2 (NCA) and LiNi0.6Mn0.2Co0.2O2 (NMC622) cathodes for 400 and 200 cycles, respectively.

4:40 PM EN04.09.03
Late News: Structural Insights into Mechanisms of Fast Ion Conduction in Li-Argyrodite Po-Hsiu Chien and Jue Liu; Oak Ridge National Laboratory, United States

Promoting fast ion conduction in solid electrolytes is of technological importance to the development of all-solid-state rechargeable batteries. Among solid electrolytes, it has reported that Li-Argyrodite has the potential to achieve high Li-ion conductivity on par with conventional organic liquid electrolytes. The anion-site disorder has been proposed as the root cause of flattening the energy landscape for 3D Li^+ migration. However, the structural origin in terms of ion migration pathways responsible for the high Li^+ conductivity remains unclear. It, therefore, prompts us to investigate the Li-ion conduction in Li-Argyrodite (Li_6PS_5X, X = Cl, Br, and I) using variable-temperature neutron diffraction in combination with maximum entropy method (MEM) analysis, bond valence site energy (BVSE), and impedance spectroscopy. Several novel insights are obtained in this work: (1) Li^+ is found suitable to occupy an interstitial site 16*e*, which then facilitates the 3D ion conduction by 48*h*–16*e*–48*h* jump with lower activation energy. This finding indicates that the 48*h*–48*h* jump alone is insufficient to describe the commonly accepted picture of long-range cage-to-cage ion conduction, (2) we find that the Li^+ conductivity is, despite rare discussion, influenced by the Li^+ distribution that can be altered by effective anion charge locating in the center of Li-cage, and (3) a rational approach, i.e., equal negative charge (ENC), is employed to improve the Li^+ conductivity (from 6 mS/cm at r.t. in Li_6PS_5Cl) through manipulating the distribution of anion charge over 4*c* and 4*a* sites in $Li_{5.7}PS_{4.7}ClBr_{0.3}$ (9 mS/cm at r.t.).

4:55 PM EN04.09.04

Late News: Chiral Salts for Solid-State Lithium Metal Batteries Lixin Qiao[1,2], Heng Zhang[3] and Michel Armand[1]; [1]Centre for Cooperative Research on Alternative Energies (CIC energiGUNE), Basque Research and Technology Alliance (BRTA), Spain; [2]University of the Basque Country (UPV/EHU), Spain; [3]Key Laboratory of Material Chemistry for Energy Conversion and Storage (Ministry of Education), School of Chemistry and Chemical Engineering, Huazhong University of Science and Technology, China

Solid-state lithium metal (Li°) batteries (SSLMBs) are considered as the most promising alternatives to improve the energy density and safety of state-of-the-art liquid-based lithium-ion batteries.[1] Solid polymer electrolytes (SPEs) with excellent processability and flexibility have attracted great attention in the development of practical SSLMBs.

The chemistry of lithium salts plays a pivotal role in dictating the physicochemical and electrochemical performance of SPEs, thus influencing the cyclability of SSLMBs.[2] In addition to the most popular salt, lithium bis(trifluoromethanesulfonyl)imide anion (LiTFSI), several new salts have been proposed to improve further the ionic conductive of SPEs, such as lithium (difluoromethanesulfonyl)(trifluoromethanesulfonyl)imide (LiDFTFSI),[2] lithium (trifluoromethanesulfonyl)(*N*-bis(methoxyethyl)sulfonyl)imide (LiEFA).[3] The implementation of these salts in SPEs resulted in significant improvement of lithium-ion conductivities. However, to date, little attention has been paid to chiral salts and their possible impacts on the physicochemical and electrochemical properties of SPEs.

In this work, we report a new type of chiral salts built from commercially available camphorsulfonic acid and their use as electrolyte salts for poly(ethylene oxide) (PEO)-based SPEs. The fundamental properties of the neat salts and PEO-based electrolytes are comprehensively characterized, in terms of surface morphology, thermal stability, phase transition, ionic conductivity, and electrochemical stability... The role of chirality on the properties of the PEO-based electrolytes is intensively revealed via a combination of experimental and computational methods.[4]

5:10 PM EN04.09.05

Late News: Structure and Ionic Mobility of Anti-Perovskite Compounds as Solid-State Electrolytes

Annie-Kim Landry[1,2], Gillian Goward[3], Dany Carlier[2,4], Frédéric Le Cras[1] and Brigitte Pecquenard[2,5,6]; [1]Commissariat à l'Énergie Atomiques et aux Énergies Alternatives, France; [2]Institut de Chimie de la Matière Condensée de Bordeaux, France; [3]McMaster University, Canada; [4]Université de Bordeaux, France; [5]Centre National de la Recherche Scientifique, France; [6]Bordeaux INP, France

The interest for solid-state electrolyte has increased over the last decade with the emergence of high-performance materials which avoid safety issues associated to inflammable solvents. Anti-perovskite compounds, which present an inverse perovskite-type structure where the anionic and cationic sites have been exchanged, are promising materials as solid electrolyte for all-solid-state batteries as they show a high ionic conductivity [1]. The stability of the cubic structure depends on the size of the ions and can result in a distorted system with a lower symmetry such as an orthorhombic or tetragonal structure.

This work investigates the $Li_{3-x}H_xOCl$ compounds to understand the relationship between the structure and the

ionic mobility of the lithium ions in anti-perovskite compounds. For these compounds, the cubic structure leads to a greater ionic mobility due to the anisotropic migration pathway. Li_2OHCl shows a phase transition from orthorhombic to cubic structure around 37 °C which leads to an increase of conductivity of one order of magnitude. To stabilize the cubic phase at room temperature, the Li/H ratio has been modified and the $Li_{2.1}H_{0.9}OCl$ has been synthesized. Li_2OHCl and $Li_{2.1}H_{0.9}OCl$ are characterized by variable temperature ^7Li and ^1H static and Magic-Angle Spinning Nuclear Magnetic Resonance (MAS-NMR) and by Pulsed-Field Gradient NMR (PFG-NMR). The two compounds are also studied by variable temperature synchrotron X-Ray Diffraction (XRD), Electrochemical Impedance Spectroscopy (EIS) and other characterization techniques. Other similar materials with an anti-perovskite structure where the halide has been partially or totally substituted by a superhalogen (BH_4^-, BF_4^- and AlH_4^-) have been investigated by density functional theory calculations and tend to show a higher ionic conductivity [2] as shown experimentally by Sun et al [3]. First syntheses were achieved with BH_4^- and characterized by XRD, EIS and NMR.

The Effect of Li and Na Mechanical Behavior on the Electrochemical Performance of Solid-State Batteries Jeffrey B. Wolfenstine[1], Michael Wang[2] and Jeff Sakamoto[2]; [1]Solid Ionic Consulting, United States; [2]University of Michigan–Ann Arbor, United States

Recently, there was been renewed interest in the use of pure alkali metals (e.g., Li, Na) as anodes for rechargeable batteries. Using a pure alkali metal anode with a liquid electrolyte can lead to dendrite shorting and flammability issues. To overcome the issues associated with liquid electrolytes solid-state batteries consisting of Li-ion and Na-solid electrolytes combined with Li and Na anodes and solid cathodes are attracting considerable attention. In the case of a solid-state battery it is anticipated that the alkali metal anode will be under load to maintain contact between it and the solid-state electrolyte. For example, one of the major issues with these batteries is that at high discharging currents voids form near the electrolyte/metal interface which results in an increase in cell resistance which eventually leads to cell failure. One way to achieve high discharge currents is to increase stack (cell) pressure which increases the creep rate of the metal and consequently, prevents void formation and hence, avoiding cell death. Thus, it is important to important to determine the creep mechanism of metal anodes to be able to predict and understand the effect of stack pressure on creep rate and hence, cell life. In addition, to creep behavior of the anode other mechanical properties such as; yield stress and elastic constants must be determined in order to optimize the performance of solid-state batteries with Na or Li anodes. It is the purpose of this talk to present and compare the elastic properties, yield stress in tension/compression and the creep behavior in tension/compression for Na to Li and limited existing values in the literature and show how these properties effect the charging/discharging behavior and cycle life of solid-state batteries with Li and Na anodes. In addition, provide new insights in the design, modeling, and understanding of solid-state batteries utilizing alkali metal anodes

Development of Cation-Substituted Na_3SbS_4 Solid Electrolytes Akitoshi Hayashi; Osaka Prefecture University, Japan

Na-ion conducting solid electrolytes are a key to develop all-solid-state sodium rechargeable batteries. Sulfide materials are suitable electrolytes because of their high conductivity and good deformability. In 2012, we reported cubic-Na_3PS_4 metastable phase, which was precipitated by crystallization of the mother glass, exhibited the conductivity of 10^{-4} S cm^{-1} [1]. Na_3SbS_4 with a higher Na^+ conductivities of 10^{-3} S cm^{-1} is developed [2]. In this study, we have focused on cation-substituted Na_3SbS_4 electrolytes to increase their conductivity. The electrolytes were prepared via mechanochemistry, followed by heat-treatment to enhance their crystallinity. A part of Sb was replaced by W to form solid-solutions $Na_{3-x}Sb_{1-x}W_xS_4$ and increased their conductivity. The sulfide superionic conductor with the composition of $Na_{2.88}Sb_{0.88}W_{0.12}S_4$ exhibited a room temperature conductivity of 3.2×10^{-2} S cm^{-1} in a sintered body [3], which is higher than the best Li^+ conductivity of 2.5×10^{-2} S cm^{-1} in LGPS-type $Li_{9.54}Si_{1.74}P_{1.44}S_{11.7}Cl_{0.3}$ [4]. Partial substitution of Sb with W induced the Na vacancy doping and the tetragonal to cubic phase transition. A similar conductivity increase was also observed by a partial substitution of Mo. Conductivity enhancement in the W- and Mo-substituted Na_3SbS_4 was discussed by the first-principles calculations [5]. In addition, the $Na_{2.88}Sb_{0.88}W_{0.12}S_4$ electrolyte was successfully prepared from an aqueous solution [6] and its precursor solution is useful for close contact with active material particles. All-solid-state Na/S cells with the Na_3SbS_4 electrolyte showed an almost full reversible capacity of 1560 mAh per gram of S and good cyclability at 25ºC [7].

Production and Purification of Anhydrous Sodium Sulfide William Smith, Jerry Birnbaum and Colin A. Wolden; Colorado School of Mines, United States

Anhydrous sodium sulfide (Na_2S) is a key component in sodium-sulfur batteries as well as an important chemical reagent. However, anhydrous Na_2S is currently prohibitively expensive for applications outside of research labs (>\$10 g^{-1}) and purity is a concern. Herein, we compare the properties of three forms of anhydrous Na_2S: (i) commercially supplied, (ii) Na_2S produced through dehydration and purification of commercial hydrate flakes (Na_2S-xH_2O), and (iii) Na_2S formed by the reaction of hydrogen sulfide with dissolved sodium alkoxide and recovered through solvent evaporation. Crystallinity, purity, thermal stability, and morphology of the various forms of Na_2S were characterized by XRD, FTIR/Raman, TGA, and SEM respectively. Vacuum annealing of low-cost Na_2S hydrate at 150 °C produced anhydrous Na_2S. This dehydrated material retains impurity signatures attributed to polysulfide (Na_2S_x) and sulfite groups (S=O) that were also observed in commercially supplied Na_2S. These impurities could be removed by heating to 400 °C under flowing H_2, the kinetics of which are well-described by a shrinking core model. The solution-based approach resulted in the direct synthesis of crystalline Na_2S anhydride at low temperatures (100 °C) without need for further purification. Both approaches presented herein are inherently scalable with materials costs that are one to two orders of magnitude lower than the current price of anhydrous Na_2S.

Late News: Surface-Dependent Stability of the Interface Between Li7La3Zr2O12 Solid Electrolyte and the Li Metal from First-Principles Calculations Bo Gao[1], Randy Jalem[1,2,3] and Yoshitaka Tateyama[1,2]; [1]National Institute for Materials Science, Japan; [2]Kyoto University, Japan; [3]Japan Science and Technology Agency (JST), Japan

The garnet-type $Li_7La_3Zr_2O_{12}$ (LLZO) solid electrolyte is of particular interest because of its high Li-ion conductivity, wide electrochemical window, and good chemical stability under atmospheric conditions, suitable for practical all-solid-state batteries (ASSBs). However, some stability issues, including the reduction of Zr [1]and the contact loss [2], at the LLZO/Li interface has been observed in a number of studies, leading to poor cycle stability and high interfacial resistance. Herein, we have revealed the origin of these instabilities by performing a comprehensive first-principles investigation with a high-throughput interface structure search scheme, based on the density functional theory framework. [3,4]Based on the constructed phase diagrams of low-index surfaces, we found that the coordinatively unsaturated (i.e. coordination number < 6) Zr sites exist widely on the low-energy LLZO surfaces. These undercoordinated Zr sites are reduced once the LLZO surface is in contact with the Li metal, leading to the chemical instability of the LLZO/Li interface. The employments of the approaches such as controlling the synthesis atmosphere are needed for preventing the reduction of LLZO against the Li metal. Besides, the calculated formation and adhesion energies of interfaces suggest that the Li wettability on the LLZO surface is dependent on the termination structure, which may result in the inhomogeneous Li depletion and contact loss. The present analysis with comprehensive first-principles calculations provides a novel perspective for the rational optimization of the interface between LLZO electrolyte and Li metal anode in the ASSB. [5]

Late News: Operando Differential Electrochemical Pressiometry for Probing Electrochemo-Mechanical Evolution in Li[Ni,Co,Mn]O2/Graphite All-Solid-State Batteries Seunggoo Jun, Young Jin Nam, Hiram Kwak, Kyu Tae Kim, Dae Yang Oh and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

Due to their potential of improved safety, energy density, and operating temperature ranges, all-solid-state batteries (ASBs) have been emerging as a promising power source for electric vehicles. Sulfide solid electrolytes (SEs), such as $Li_{10}GeP_2S_{12}$ (12 mS cm^{-1}) and $Li_{5.5}PS_{4.5}Cl$ (12 mS cm^{-1}), are attractive candidates for practical ASBs because of their high ionic conductivities being comparable to those of conventional liquid electrolytes (~10 mS cm^{-1}) and mechanical sinterability. In ASBs that lacks soft components, electrochemo-mechanical evolutions originating from breathing volumetric strains of electrode active materials upon charge-discharge are imperative in the viewpoints of not only improving performances but also comprehensive understanding complex interfacial phenomena.
In this presentation, we report newly developed operando differential electrochemical pressiometry (DEP) for ASBs. The pressure change signals reflecting volume changes of electrode active materials feature phase transitions of electrode active materials in $LiMO_2$/Gr all-solid-state cells. Thus, it is demonstrated that DEP analysis enables offering nondestructive determination of state-of-charges of ASBs. Complementary analysis results via ex situ X-ray diffraction measurements is also presented.

Silver-Carbon Composite Anodes for All-Solid-State Lithium Metal Batteries Yong-Gun Lee and Dongmin Im; Samsung Advanced Institute of Technology (SAIT), Samsung Electronics, Korea (the Republic of)

An all-solid-state battery with a lithium metal anode is a strong candidate for surpassing conventional lithium-ion battery capabilities. However, undesirable Li dendrite growth and low Coulombic efficiency impede their practical application. We have found that a silver-carbon nanocomposite anode layer, when employed in combination with solid electrolyte, prohibits the dendrite formation and allows the homogeneous Li metal plating and stripping on the surface of current collector. The high Coulombic efficiency thus achieved also eliminates the need of excessive Li metal, further increasing the cell energy density and decreasing the production cost. The silver particles are dissolved in the Li metal during the charging process and appear to assist the homogeneous Li plating. On the other hand, the carbon layer keeps the solid electrolyte physically separated from Li metal, preventing the chemical degradation of solid electrolyte and the Li metal penetration through it. Consequently, the nanocomposite anode formed on a current collector can offer high energy density (>900 Wh/L) and long cycle life (>1,000 times) in the solid-state batteries (0.6 Ah prototype pouch cell).

Doped Pyrochlores as Versatile Reagents for Formation of Lithium Conducting Garnet Solid Electrolytes Jon M. Weller and Candace Chan; Arizona State University, United States

Lithium conducting garnets in the family of doped lithium lanthanum zirconates (nominally $Li_7La_3Zr_2O_{12}$, LLZO) are of great interest as oxide solid electrolytes for solid-state lithium-metal batteries. Despite the promising properties of LLZO in terms of electrochemical stability and ionic conductivity, processing of garnet solid electrolytes is still a challenge. Many synthetic approaches have been investigated to-date, including sol-gel, co-precipitation, spray pyrolysis, combustion, and molten salt synthesis, not to mention the standard solid-state reaction method. Most of the aforementioned methods can generate LLZO with the expected properties, but nearly all are either costly or not amenable to producing thin films of LLZO, which are necessary for practical solid-state batteries based on lithium conducting garnets. Interestingly, in nearly all of these approaches the lanthanum zirconate pyrochlore phase ($La_2Zr_2O_7$, LZO) is seen as an intermediate phase before conversion of precursors to LLZO, nearly irrespective of precursor type. In this work, nanocrystalline, off-stoichiometric, doped pyrochlores based on the LZO structure are synthesized as a quasi-single-source precursor for formation of LLZO, maintaining a 3:2 ratio of La:Zr instead of the conventional 1:1 ratio in stoichiometric pyrochlores, while also incorporating necessary dopants to stabilize the cubic phase of LLZO after densification. Using these novel, nanosized pyrochlore precursors, LLZO is formed by the simple addition of a Li_2O source. Conversion of doped LZO to LLZO in molten salts is demonstrated as a novel synthetic approach, requiring only low synthesis temperatures (as low as 400 °C). Additionally, doped pyrochlores may be directly converted to garnets in a single reactive sintering step, resulting in both high density (> 90% relative density) and ionic conductivity (> 0.5 mS cm^{-1}), presenting a streamlined approach to formation of garnet solid-electrolytes amenable to more facile processing methods than conventional ceramic sintering.

Challenges with High Temperature Thermophysical Property Measurements Shannon Yee; Georgia Institute of Technology, United States

Robust and accurate thermophysical properties, namely thermal diffusivity, thermal conductivity, and specific heat of high-temperature (>1000 K) containment materials (CMs) and heat transfer materials (HTMs) are lacking, (i) because few measurement techniques exists, and (ii) unbeknown measurement inaccuracies exist in many commercially available techniques that are not well document in literature. This has resulted in surprisingly large spread in reported thermophysical properties at high temperatures of both CMs and HTMs, begging the question what are the true thermophysical properties of many CMs and HTMs. This presents a unique challenge for designing high-temperature thermal systems when there is such large uncertainty in physical properties of materials. It has been challenging to calculate (or model) the thermophysical properties due to the composite (or multi-component alloy) nature of these materials often resulting in microstructural phase transitions and spatially heterogenous composites. At elevated temperatures chemical stability (both oxidation and corrosion) and radiation effects make accurate measurements exceedingly difficult. To address this challenge, numerous repeated measurements on multiple samples spanning both spatial (e.g., heterogeneity) and temporal (e.g., aging) variations and subsequent statistical analysis (e.g., 95% confidence-interval) are required to confirm or refute the often single-measurements reported on material specification sheets or literature. This invited talk will highlight some “problematic materials” whose properties have been mis-reported previously, commenting on “likely” sources of error. This talk will also highlight new measurement techniques that are trying to address some of these identified short comings. And finally, this talk will present “lessons learned” from a more robust statistical approach to reporting thermophysical properties.

Nickel-Aluminide Based Anticorrosion Coatings Prepared by Plasma Spray for Concentrating Solar Power Applications Sarah Yasir[1], Adrianus I. Aria[1], Elena Guillen[2] and Jose Endrino[3]; [1]Cranfield University, United Kingdom; [2]PROFACTOR GmbH, Austria; [3]Basque centre of materials, Spain

The use of solar energy for power generation provides an efficient sustainable energy solution. Among a

number of technologies developed for power generation using solar energy, concentrating solar power (CSP) is encouraging because of the capability of thermal energy storage that makes it possible for the generation beyond sunset and in times of cloud cover. Although the use of molten salts as heat transfer fluid and thermal storage in CSP has various advantages, they have a major disadvantage as they make the component systems highly susceptible to corrosion. Different approaches to prolong life by suppressing corrosion have been adapted including the use of high alloy steels and the use of high purity molten salts, coating is a promising option because coatings are believed to provide shield to suppress corrosion.
In this study, we investigate the use of protective coatings to enhance the corrosion resistance of the component systems against molten salts at an elevated temperature. Nickel aluminide coatings are deposited using plasma spray system, as they hold high-temperature mechanical strength and it has a remarkable oxidation resistance performance as substrate component. Moreover, nickel aluminide has low solubility in the molten nitrate salt. Ni3Al coatings are much preferred to be used as corrosion resistant coatings as they possess strength at high temperature, oxidation protection and creep properties.
Corrosion behaviour of stainless steel 347 (SS347) and Ni3Al coated SS347 was investigated in molten nitrate salt (60wt% $NaNO_3$ + 40wt% KNO_3) immersion at 565ºC for 500 hours intervals up to 3000 hours. A growth of stratified oxide layers was observed on SS347 sample surface comprising of $NaFeO_2$, Fe_2O_3 and Fe_3O_4. The Ni_3Al coated SS347 samples were observed to undergo rapid oxidation within first 500 hours. The results presented in this study suggest that Ni3Al coating supresses the formation of oxide layers on the surface of stainless steel substrates and can be used to suppress corrosion in presence of molten nitrate salts. The fact, that Ni3Al coated SS347 gives mass change of one order of magnitude lower than the bare SS347, it means that these coatings can be used to prolong the lifetime of bare SS347 in molten nitrate salt at 565oC, which is of relevance to thermal energy storage applications. In my presentation, I will show the corrosion test results and discuss the potential of nickel aluminide coatings to suppress hot corrosion by molten salts in an environment that simulates that of concentrating solar power plants.

8:40 AM EN05.01.03
Wear in Particle Based CSP Systems From Particle Abrasion and Attrition at High Temperature Nipun Goel[1], Tessa Mei-lin Fong[1], John Shingledecker[2], Andrew Russell[1], Michael W. Keller[3], Siamack A. Shirazi[3] and Todd Otanicar[1]; [1]Boise State University, United States; [2]Electric Power Research Institute, United States; [3]The University of Tulsa, United States

High temperature particle-based receivers offer distinct advantages over conventional molten salt receivers due to their ability to achieve temperatures above 700 C, direct absorption of solar energy as they fall through a beam of concentrated sunlight, and the relative ease of storage (and retrieval using a secondary working fluid) in insulated storage tanks. The use of particles, however, also raises concerns with material degradation from the flow of hot or cold particles through discharge hoppers or along the inner receiver surfaces and other system components (e.g. tubes, valves etc.), depending on operating mode of the receiver. The flow of particles over surfaces may result in loss of material from abrasive wear, impact erosion from impingement under gravitational fall and particle attrition as particles fall and move on top of each other.
In the present study, the performance of candidate materials and particles were evaluated through a series of abrasion erosion and particle attrition experiments at room temperature as well as at 800 C. Candidate materials were subject to abrasive wear from particles at low particle to material velocities inside a resistance heated kiln, and analyzed for changes in mass and surface morphology using cross-sectional scanning electron microscopy (SEM) and energy dispersive x-ray spectroscopy (EDS) tests. The wear rate for different specimens was noted to be largely driven by the strength of chromia scales built on the specimens from exposure to high temperature. Particle attrition measurements explored the susceptibility of particles to breakdown from particle to particle interaction and the generation of fines from this process. At the low velocities expected in particle based Concentrated Solar Power (CSP) plants, the particles tested exhibited near negligible breakdown. However, changes in the particle hardness at 800 C resulted in a significantly higher particle breakdown to sizes <40 microns raising potential environmental concerns. In addition to particle breakdown, it was also noted that the sample had oxides from the stainless steel test setup mixed in with the particles. Similar oxides can be expected to turn up in the utility scale particle based CSP plants as well. The presence of oxide was also noted to affect

the solar absorptivity of the mixture compared to a clean initial specimen, potentially resulting in a change in the overall efficiency of the CSP plant.

8:55 AM EN05.01.04
Frequency-Domain Hot-Wire Measurements of Molten Nitrate Salt Thermal Conductivity Andrew Z. Zhao[1], Matthew Wingert[1,2] and Javier Garay[1]; [1]University of California, San Diego, United States; [2]PsiQuantum, United States

The thermal conductivity of liquids has traditionally been determined by measuring either the steady-state temperature gradient or time-dependent temperature rise in a sample due to an applied heat flux. The transient hot-wire method has become the standard for measuring liquid thermal conductivity; in this method, direct current Joule heats a long, thin wire immersed in a liquid sample, and the measured temperature rise over a particular time interval is fit to a heat transfer model to extract the thermal conductivity of the liquid. However, in the high-temperature environments of molten salts, long metal wires are vulnerable to corrosion, and convection errors are magnified in larger volumes of molten salts. Here, we utilize a new frequency-domain, corrosion-resistant, short hot-wire technique (sensor and model) to measure the thermal conductivity of molten $NaNO_3$ (2.78% standard uncertainty), KNO_3 (2.38% standard uncertainty), and Solar Salt mixture (2.66% standard uncertainty). Operating in the frequency domain and utilizing a full 3D model allows the use of short sensor wires, reducing the total contact area to minimize corrosion, and the use of small sample volumes, mitigating convection errors. An alternating current at varying frequencies Joule heats a short platinum wire sensor (6.5 mm), which is protected by a 1.6 mm thick Al_2O_3 coating, submerged in molten salt. The frequency-dependent temperature response of the sensor surrounded by salt is measured and fit to a 3D thermal model to obtain the thermal conductivity of the molten salt. Together, the new sensor design and 3D model keep the probed molten salt volume below 1 μL. Our frequency-domain measurements show an ~11-15% higher thermal conductivity of molten nitrate salts than the current reference correlations made from steady-state and time-domain measurements.

9:10 AM *EN05.01.05
Robust High-Temperature Materials for Concentrated Solar Power Ken Sandhage[1], Yujie Wang[1], Priyatham Tumurugoti[1], Jorge Velasco-Ramirez[1], Alexander Strayer[1], Gregory Scofield[1], Adam Caldwell[1], Supattra Singnisai[1], Qingzi Zhu[2], Mehdi Pishahang[2], Michael Sangid[1], Asegun Henry[2], Kevin Trumble[1], Grigorios Itskos[1] and Mario Caccia[1]; [1]Purdue University, United States; [2]Massachusetts Institute of Technology, United States

The efficiency of concentrated solar power (CSP) plants for generating electricity may be appreciably increased by operating at higher temperatures. By increasing turbine inlet temperatures to ≥750ºC and by using high-pressure, supercritical carbon dioxide (sCO_2) power cycles, instead of conventional cycles at ≤550ºC, the relative heat-to-electricity conversion efficiency may be increased by >20% (a key step towards direct competition with fossil fuel power plants and a large decrease in greenhouse gas emissions). However, inlet sCO_2 temperatures for CSP turbines are severely limited by current printed-circuit-type heat exchangers (PCHEXs) that are used to transfer heat to the sCO_2; that is, conventional metal alloys used in such PCHEXs exhibit a significant decrease in mechanical performance at >600ºC.

Here we present a robust composite of zirconium carbide (ZrC) and tungsten (W) for use in PCHEXs at ≥750ºC. Co-continuous ZrC/W composites possess an attractive combination of properties for this application. ZrC and W are chemically compatible; that is, these solids exhibit limited mutual solid solubility, do not react to form other compounds, and exhibit a solidus temperature of 2800ºC. Measurements of the thermal diffusivity and heat capacity of co-continuous ZrC/W composites have yielded an average thermal conductivity value of 66 W/m-K at 800ºC, which is appreciably higher than values reported for advanced Ni-based alloys at this temperature (e.g., 22.1 W/m-K for IN740H). Polycrystalline ZrC and W exhibit similar modest values of thermal expansion from 25ºC to 750ºC, and have been found to be resistant to thermal cycling and extreme thermal shock (e.g., >1000ºC/sec). The interconnected carbide phase can provide ZrC/W composites with high-

temperature stiffness and creep resistance, whereas W exhibits high-temperature ductility for enhanced resistance to fracture relative to monolithic ZrC. Indeed, co-continuous ZrC/W composites have been found to possess average failure strengths at 800ºC of 600 MPa (well above the maximum allowed stresses of Ni-based superalloys at this temperature at elevated pressures). Although not inherently resistant to high-temperature oxidation, ZrC/W composites have been endowed with such resistance via modest CO additions to sCO_2 (to generate a supercritical reducing fluid) and by placing a layer of Cu (a relatively noble metal) on the ZrC/W surface. Such Cu-bearing ZrC/W composites have exhibited negligible oxidation after 1000 h at 750ºC in mixtures of sCO_2 with 50 ppm CO at 20 MPa.

The fabrication of PCHEXs comprised of dense co-continuous ZrC/W-based HEX plates with tailorable channel patterns will also be discussed. Porous WC preform plates with desired channel patterns may be generated by low-cost forming (e.g., casting, pressing) of WC/organic mixtures, followed by organic pyrolysis and light (initial stage) sintering. The resulting rigid, porous WC preform plates can then be converted into dense ZrC/W plates via reactive pressureless infiltration with a Zr-bearing liquid. The Zr in the liquid undergoes a displacement reaction with the WC in the preform to yield ZrC and W as solid reaction products. These products possess a combined volume that is larger than the volume of WC consumed, so that the prior pores in the preform become filled with these new solids with little change in external preform shape, surface features, and size (typically <1% dimension changes). Because the channels present in the easily-formed porous WC preforms are retained in the dense ZrC/W plates, prolonged chemical etching (required for current metal-based PCHEXs) is not needed to produce such channels, and unique channel morphologies (higher aspect ratios, non-circular cross-sections) can be generated for tailored fluid flow and heat transfer. Techno-economic analyses indicate that ZrC/W-based PCHEXs can strongly outperform Ni-superalloy PCHEXs at lower cost.

Magnetically-Accelerated Solar-Thermal Energy Storage within High-Temperature Molten Salt Phase Change Materials Peng Tao, Chao Chang and Tao Deng; Shanghai Jiao Tong University, China

Thermal energy storage within high-temperature molten salts is critical to overcome solar illumination intermittency and ensure stable operation of concentrated solar-thermal systems. Current molten salt phase change materials, however, generally suffer from a low thermal conductivity, which seriously limits both the charging and discharging processes. It is challenging to effectively increase the thermal conductivity of high-temperature molten salts without affecting their heat storage capacity and other inherent thermophysical properties. In this work, we reported that magnetically moving mesh-structured solar absorbers within solar salts along the solar illumination path could significantly accelerate the solar-thermal energy storage rates. The mesh absorber continuously advances the melting solid/liquid interface thus achieves fast latent heat storage of solar-thermal energy within solar salts. Compared to conventional static charging processes, such magnetically-accelerated movable charging strategy increases the latent heat solar-thermal energy harvesting rate by 107% and maintains 100% heat storage capacity of solar salts. We also demonstrated that the movable charging supports large-area charging of solar salts with small-sized solar-thermal converters and continuous batch-to-batch solar-thermal storage. The movable charging system can be readily integrated with heat exchanging systems to serve as energy sources for water and space heating by using abundant clean solar-thermal energy. Alternatively, the high-temperature heat stored within melted solar salts can be direct converted to electricity through thermoelectric conversion, and the converted electricity can simultaneously light up multiple LEDs.

9:45 AM EN05.01.07
Doped ALPO-5 Zeolites as Promising O2 Sorption Pump Materials—A Density Functional Theory Study Steven A. Wilson, Ellen Stechel, Ivan Ermanoski and Christopher Muhich; Arizona State University, United States

Many chemical processes depend on having an environment that is low in oxygen partial pressure (PO2 < 100

Pa); sorption pumps are a promising route to establishing that environment by either oxygen pumping or oxygen separation from an inert gas. Near ambient sorption-based processes rely on either pressure or thermal swings, requiring no moving parts, no electricity, and neither very high nor very low temperatures. In this work, we use ab initio calculations to explore zeolites as a class of materials for sorption based oxygen pumping/separation. Our calculations indicate that while the neat ALPO-5 zeolite does not adsorb O2, O2 does adsorb on zeolites selectively doped with transition metals and metalloids and hence, can enable separation and pumping. ALPO-5 doped with Si, Ge, Sn, Pd, Pt, Ti, V, Cr, Mn, Zr, Mo, Hf, W, Ce, and Pr provides ad-sorption energies ranging from -0.19 to -3.92 eV, (-) indicates exothermic process. Additionally, we provide a comprehensive understanding of what controls the adsorption energy: 1) the dopant must be able to adopt an oxidation state that is more positive than the cation it replaces, and 2) the size of the pore into which the O2 adsorbs to the wall. Lastly, we conduct a thermodynamic analysis of a thermal swing cycle to approximate the optimal O2 binding energy for low energy O2 pumping/separation. We find that the minimum energy cost likely occurs when the adsorption energy is in the range of 0.75 – 1.00 eV (72 – 97 kJ*mol-1), which corresponds to Ge, V, Pt, or Ce doped ALPO-5.

9:50 AM EN05.01.09

Best Practices for Synthesizing Single Phase Thermochemical Materials in Multinary Systems Robert T. Bell[1], Dan Plattenberger[1], Sarah Shulda[1], Nicholas Strange[1,2], Karen Heinselman[1], James E. Park[3], Andrea Ambrosini[3], Michael F. Toney[2,4], Philip Parilla[1], Anthony H. McDaniel[3], Eric Coker[3] and David Ginley[1]; [1]National Renewable Energy Laboratory, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Sandia National Laboratories, United States; [4]University of Colorado Boulder, United States

Materials for solar thermochemical production of hydrogen (STCH) and other fuels often relies on the use of highly thermally stable multinary oxides. Often these oxides possess three or more cations and represent an alloy or line compound within a complex multinary phase space. These complex phase spaces often possess one or more other refractory phases which, if formed during synthesis, remain as secondary phases through repeated sintering. These secondary phases are typically inactive thermochemically, create a convoluted signal in measurements which can complicate isolating the performance and behaviors of candidate materials. This work discusses a number of best practices and potential routes for synthesizing single phase multinary oxides for thermochemical applications. Common synthetic routes discussed include mixed carbonate and oxide sintering, unary oxide blends, and modified Pechini sol-gel processing. The formation of different secondary phases based on the synthesis route is demonstrated for example systems such as $BaCe_{0.25}Mn_{0.75}O_3$. Results of sintering model systems at different peak temperatures demonstrate the need for furnace temperature in excess of 1200°C in many systems. Additionally, the effect of isothermal reduction and re-oxidation cycling on removing secondary phases, especially containing softer cations such as Mn, is demonstrated. These reduction and oxidation cycling results partially explain the commonly observed drift in performance during the initial few cycles of STCH materials. This work provides an important roadmap to synthesizing single phase thermochemical materials.

SESSION EN05.02: Solar Thermochemical Water Splitting I & Solar Thermochemistry and Energy Storage
Session Chairs: Adrianus Aria and Ramon Escobar Galindo
Tuesday Morning, April 20, 2021

11:45 AM *EN05.02.01

Metal Oxide-Based Thermochemical Redox Processes for Producing Solar Fuels and Storing Ellen Stechel[1], Alberto de la Calle[1], Ivan Ermanoski[2] and James E. Miller[2]; [1]Arizona State University, School of Molecular Sciences, United States; [2]Arizona State University, School of Sustainability, United States

High temperature endothermic reduction of metal oxides, which can liberate oxygen gas at achievable conditions, converts thermal energy to stored chemical energy. A subsequent re-oxidation step either recovers the stored energy as heat or utilizes it to drive other chemical reactions. If the re-oxidation step restores the material to its original state so that the two-steps can repeat indefinitely, the sequence of reactions constitutes a thermochemical cycle. Two related processes (reversibly re-oxidizing with oxygen or affecting bond breaking by re-oxidizing with CO_2 and/or water) are somewhat analogous; the fuel production option is significantly more constrained by thermodynamics and hence subject to greater challenges to efficiency and cost. Nonetheless, both chemistries have been of increasing interest due to their potential for high efficiency utilization of the sun and economic competitiveness for clean energy and most recently as a role in achieving negative emissions and closing the carbon cycle.

This presentation will discuss thermodynamic requirements and opportunities presented by the redox-active metal oxide thermochemistry and show recent progress towards developing the materials and cycles for thermochemical energy storage and CO_2/H_2O splitting.

12:10 PM EN05.02.02
Gaining Mechanistic Insight into the Relationship Between Electronic Structure and Reduction of Thermochemical Materials through Combined Empirical and Modeling Experimentation Sarah Shulda[1], Robert T. Bell[1], Dan Plattenberger[1], James E. Park[2], Anuj Goyal[1], Nicholas Strange[1], Karen Heinselman[1], Eric Coker[2], Josh Sugar[2], Andrea Ambrosini[2], Stephan Lany[1], Sami Sainio[3], Michael F. Toney[4], Philip Parilla[1], Anthony H. McDaniel[2] and David Ginley[1]; [1]National Renewable Energy Laboratory, United States; [2]Sandia National Laboratories, United States; [3]SLAC National Accelerator Laboratory, United States; [4]University of Colorado Boulder, United States

The layered perovskite $BaCe_{0.25}Mn_{0.75}O_3$ (BCM) is a proven solar thermochemical (STCH) water splitting material demonstrating higher hydrogen generation and improved redox kinetics relative to current state of the art materials. Recent results have revealed that BCM belongs to a larger family of STCH materials, BXM (X = Ce, Nb, Pr). Despite the three materials having identical structures, and differing only in 1/8 of their cation species, their water splitting performances are markedly different. Improved understanding of the mechanisms and material properties that determine performance of STCH materials is necessary for designing materials that better synergize with the operating temperatures of concentrated solar power (CSP). In this work, we present a comparative study of the electronic response of BXM materials to varying degrees of reduction, and use modeling to reveal the mechanisms driving these changes. Probing the oxygen with X-ray absorption spectroscopy (XAS) reveals substantial differences in the electronic structure between the BXM materials in both oxidized and reduced states. These results demonstrate that the oxygen K-edge is sensitive to even small concentrations of oxygen vacancies in large part due to the finding that the effect of vacancies on the electronic structure of the material extends far beyond second nearest neighbors. Comparisons of the oxygen K-edge measured by XAS and the complementary technique electron energy loss spectroscopy (EELS) confirm the veracity of the observed changes in electronic structure. Local density of states (LDOS) calculations carried out on oxidized and defected structures enable specific peaks in the XAS spectra to be correlated to hybridized molecular orbitals, providing valuable insights into the underlying electronic changes resulting in shifts in energy and intensity. These LDOS calculations correctly predict changes in XAS due to reduction. These results are a key component of elucidating structure-property relationships for this class of STCH materials.

A Renewable, Carbon-Neutral Route to Ammonia via Concentrating Solar Thermochemistry Andrea Ambrosini[1], Kevin Albrecht[1], H. E. Bush[1], Alberto de la Calle[2], Ivan Ermanoski[2], Tyler Farr[3], Xiang Gao[2], Matthew W. Kury[1], Peter Loutzenhiser[3], Nhu ". Nguyen[3] and Ellen Stechel[2]; [1]Sandia National Laboratories, United States; [2]Arizona State University, United States; [3]Georgia Institute of Technology, United States

Ammonia (NH_3) is an energy-dense chemical and a vital component of fertilizer. In addition, it is a carbon-neutral liquid fuel and a potential candidate for thermochemical energy storage for high-temperature

concentrating solar power (CSP). NH_3 is currently synthesized via the Haber-Bosch process, which requires pressures of 15- 25 MPa and temperatures of 400-500 °C. Nitrogen (N_2) and hydrogen (H_2) are essential feedstocks for producing NH_3: H_2 is generally derived by steam reforming of methane, and N_2 is sourced from air, after O_2 removal, via combustion of methane. Burning hydrocarbons produces the heat and mechanical energy required to drive the NH_3 reaction. All three processes (sourcing the energy, producing H_2 and N_2) produce CO_2 emissions. The development of a renewable pathway to NH_3 synthesis that utilizes concentrated solar irradiation for the process heat instead of hydrocarbon combustion and operates under relatively low pressure, will result in both a decrease (or elimination) in greenhouse gas emissions and avoid the cost, complexity, and safety issues inherent in high-pressure processes.

The aim of the Solar-Thermal Ammonia Production (STAP) project is to develop a solar thermochemical looping technology to produce and shuttle N_2 from air for the subsequent production of NH_3 in an advanced two-stage process. The endothermic thermal reduction of redox-active metal oxide particles is driven by concentrated solar irradiation; subsequent exposure to air re-oxidizes the particles, removing O_2 and producing relatively pure N_2 gas. The N_2 serves as a feedstock for a renewable NH_3 production process in an advanced two-step, low pressure, looping process. In the first step, H_2 reacts with metal nitride particles to produce NH_3 , resulting in a reduced (nitrogen deficient) metal nitride. In the second step, the nitride is regenerated utilizing the nitrogen produced in the air separation step. The net result is NH_3 produced from sunlight, air, and (green) H_2, while the metal oxide and nitride particles are recycled.

The STAP project consists of four thrusts: (1) Systematic synthesis, characterization, and thermodynamic analysis of oxides for N_2 recovery from air; (2) materials investigation and development of nitrides for NH_3 production and re-nitridation; (3) process and reactor design, modeling, fabrication, and small-scale demonstration; and (4) full system and techno-economic analyses. The system concept will be summarized in this presentation, and the synthesis and characterization of the working materials will be discussed, including x-ray diffraction, thermogravimetric analysis, and reaction performance.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Thermochemical Energy Storage Using Phosphatic Pebbles Sesha Srinivasan, Mc Ben Joe Charles, Haley Royce, Scott Wallen and Richard Matyi; Florida Polytechnic University, United States

Phosphatic Pebble or Dolomite, calcium magnesium carbonate ($CaMg(CO_3)_2$), is considered an undesirable mined resource for phosphoric acid production in Florida; as such, large quantities of the mineral are available. This study is aimed to characterize the phosphatic high concentration dolomite pebbles received from the Florida Industrial and Phosphate Research Institute (FIPR) and investigated their feasibility for thermochemical energy storage (TCES). The chemical composition of these dolomite minerals was studied using different techniques such as X-ray Fluorescence (XRF), Fourier-transform infrared spectroscopy (FTIR), and Scanning electron microscopy with energy-dispersive X-ray spectroscopy (SEM, EDS), which confirmed the phosphatic pebbles received from FIPR contained high percentages of dolomite. Thermogravimetric analysis (TGA) was used to calculate the activation energy for calcination and carbonation of the dolomite pebbles in Nitrogen (N_2) ambient and CO_2 ambient conditions respectively, and with temperatures up to 800°C. Values important for thermochemical energy storage such as heat capacity and enthalpy of reaction were also calculated using this TGA data. Changes in crystal structure after calcination, carbonation, and wet ball milling of the dolomite minerals were observed using X-ray diffraction (XRD). The effects of wet ball milling to reduce particle size were observed on the cyclic stability and carbonation of the dolomite pebbles. Particle size and surface area were measured using XRD and N_2 adsorption with the BET method. The structural characteristics of dolomite as explored via metrological techniques (QEMSCAN) thus demonstrating the presence of magnesium and calcium in combinations of carbonates, Calcium Oxide, Magnesium Oxides, and residual Carbon dioxide.

12:55 PM EN05.02.05
Materials for Concentrated Solar Energy-Driven Sulphur-Based Thermochemical Cycles Christos Agrafiotis[1], Vamshi Krishna Tanda[1], Dennis Thomey[1], Lamark de Oliveira[1], Lutz Mevißen[2], Hiroki Noguchi[3], George Karagiannakis[4], Martin Roeb[1] and Christian Sattler[1,5]; [1]DLR - German Aerospace Center, Germany; [2]RWE Generation SE, Germany; [3]Japan Atomic Energy Agency, Japan; [4]CERTH - Centre for Research & Technology, Hellas, Greece; [5]TU Dresden, Germany

Thermochemical cycles of the sulphur family recycle sulphur as the central element that appears in different compounds at changing oxidation state. Such cycles like the Hybrid Sulphur (HyS) and the Sulphur-Iodine (SI) cycle were originally conceived to produce hydrogen via water-splitting, but can be modified to produce solid sulphur that can be combusted in air to produce high-temperature heat and hence can be used both as a renewable fuel as well as a seasonal solar energy storage means. The HyS, SI and solid sulphur-based thermochemical cycles share the common step of the decomposition reaction of sulphuric acid: first thermally to steam and SO_3 and subsequently the catalytic SO_3 dissociation (splitting) to SO_2 and oxygen. The latter is their highest-temperature (700-900ºC), endothermic reaction step that can be aided by heat supplied by concentrated solar irradiation, either directly on porous ceramic volumetric receivers/sulphuric acid decomposition reactors or indirectly via solar-receiver-heated gaseous or solid particle streams operating as heat transfer fluids and transferring their enthalpy to the sulphuric acid decomposer downstream of the solar receiver. A common issue in all cycles has to do with the particular characteristics of sulphuric acid chemistry: highly corrosive environment combined with high temperatures. These peculiarities impose further necessities and research needs with respect to the structural materials and components to be employed, in addition to research on catalyst compositions and reactor designs. The work will present recent progress in this field in the context of designing, building and operating a novel, sulphuric acid decomposer/sulphur trioxide splitting reactor indirectly heated via hot moving particle streams. Aspects to be covered include materials solutions for the manifolds for the injection of the sulphuric acid solution, evaporator tubes, sealants, special ceramic adhesives to join anti-corrosive metallic-to-ceramic tubing e.g. (stainless steel to SiC) and materials and reactor solutions to compensate for thermal expansion/contraction. These results will be complemented with analogous results from long-term testing (up to 1,000 operation hours) of sulphur trioxide catalyst compositions shaped in the form of either catalytic particles or structured porous ceramic assemblies - and relevant post-operation characterization studies. The final technical solutions are articulated into an integrated sulphuric acid decomposer/sulphur trioxide splitting reactor from qualified materials and concepts, capable of concentrated solar irradiation-driven, long-term operation under the required demanding conditions.

1:10 PM EN05.02.06
Pure and Mixed Metal Oxides for High-Temperature Thermochemical Energy Storage via Reversible Redox Reactions Marco Gigantino, Daniel Notter and Aldo Steinfeld; ETH Zürich, Switzerland

Concentrated solar energy provides a clean source of process heat in excess of 600 °C and thus enables the decarbonization of several key energy-intensive industrial processes, such as mineral and metallurgical extraction, lime and cement manufacturing, biomass pyrolysis and gasification, as well as thermal production of power and fuels. These processes can be performed round-the-clock with solar process heat by making use of the endothermic-exothermic effect associated with the reduction-oxidation (redox) of metal oxides to store and release the high-temperature heat. This category of thermochemical energy storage (TCS) materials typically features high values of energy storage density and the advantage of employing ambient air as gaseous reagent. Of particular interest are the redox pairs BaO_2/BaO, Co_3O_4/CoO, CuO/Cu_2O, Fe_2O_3/Fe_3O_4 and Mn_2O_3/Mn_3O_4, which have their equilibrium temperature above 600 °C in atmospheric air. A common problem for these metal oxides when approaching their melting point is thermal sintering, which progressively reduces the gas-solid contact area and, hence, their redox rate and redox cyclic performance. In this work, we described the manufacturing of mm-size granules with tailored morphological properties that exhibit stable reaction kinetics and cyclic performance over multiple redox cycles. The material synthesis process involved the mixing of the reactive metal oxide with pore formers and sintering inhibitors - e.g., Al_3O_4, CaO, CeO_2, Fe_2O_3, MgO, Mn_3O_4,

SrO, Yr_2O_3-stabilized ZrO_2 (YSZ) - which were added in different concentrations and combinations to form binary and ternary mixtures. The synthetized granules were tested by thermogravimetry over up to 100 consecutive redox cycles at conditions relevant for the intended TCS applications. Thermodynamic and kinetics analyses were carried out for each binary and ternary system. In terms of cyclic stability, the best performing materials were Fe_2O_3 in pure form, the binary mixture CuO-YSZ (65-35wt%), and the ternary mixtures Co_3O_4-YSZ-MgO (80-15-5wt%), CuO-Al_2O_3-YSZ (70-22.5-7.5wt%), and CuO-Al_2O_3-MgO (60-30-10wt%), yielding gravimetric heat storage capacities of 421, 559, 609, 565, 439 kJ for kg of oxidized mixture, respectively. In these materials, the additives served as inert supports. The binary mixtures Mn_2O_3-Al_2O_3, Mn_2O_3-Fe_2O_3, Mn_2O_3-MgO, where the additives participated in the redox reactions, exhibited stable cyclic performance as well.

Solar-Selective Coatings for High-Temperature Solar Applications Based on a Selective Transmitter on Top of a Black Body Absorber Matthias Krause[1], Frank Lungwitz[1], A. Mendez[1,2], M. Hoppe[1], J. Sonnenberg[1], A. Garcia-Valenzuela[1], F. Munnik[1], J. Grenzer[1], R. Hübner[1] and Ramon Escobar Galindo[3]; [1]Helmholtz-Zentrum Dresden, Germany; [2]Nano4Energy, Spain; [3]Universidad de Sevilla, Spain

An alternative concept to achieve solar selectivity for solar thermal materials and applications consists in the use of spectrally selective transmitter coatings.[1] These are characterized by a high transmittance in the solar range and a high reflectance in the thermal range of the electromagnetic spectrum. Suitable materials for selective transmitters are dielectric/metal/dielectric multilayers and transparent conductive oxides (TCOs).[2] The concept has a series of advantages compared to multilayer- or cermet-based solar-selective coatings (SSCs) like the easiness of manufacturing, the possibility to use standard materials as transmitter (e.g., indium tin oxide (ITO)) and absorber (e.g. Pyromark or black chrome), and the adaptability to specific requirements with respect to receiver temperature and solar concentration factor.

After a conceptual introduction, the analysis of solar plant parameters, i.e., operation temperature and solar concentration, for which this concept provides a better solar efficiency than state-of-the-art bare black body absorber, will be given.[3] We will then review the recent developments in the field, which include an excellent high-temperature in-air stability of such type of solar coatings.[4] In the second part of the talk, we will report own results toward a new TCO on black body absorber coating. Vacuum and in-air stability of the TCO SnO2:Ta at 800 °C and its structural properties before and after heat exposure are demonstrated. As potential absorber, the formation, structure, and optical properties of dense, PVD-grown CuCr2O4 thin films are studied. They are obtained in high purity from as- deposited samples by a simple in-air annealing step at 800 °C and absorb light in the whole solar range from 300 nm to 2500 nm.

2:40 PM EN05.03.02

Spectral Emissivity Measurements and Conversion Efficiency Estimation in Black Spinel and Nanoneedle-Based Coatings for Solar Tower Plants Telmo Echaniz[1], Iñigo González de Arrieta[1,2], Raquel Fuente[1], Lizzie Rubin[3,3], Renkun Chen[3,3], Josu Mirena Igartua[1], Manuel José Tello[1] and Gabriel Alejandro López[1]; [1]University of the Basque Country, Spain; [2]Université de Orléans, France; [3]University of California, San Diego, United States

Infrared emissivity measurements at working temperatures are of great importance for solar absorber coatings in central tower plants, as they allow proper estimations of the conversion efficiencies of these materials, as well as heat transfer management. This is especially important in situations where the concentration flux of the plant is reduced (e.g., the start-up phase). To that end, the high-temperature directional spectral emissivities of new copper-alloyed spinel coatings with different structures have been researched for concentrated solar power applications.
Four new coatings based on black spinel nanoparticles [1], as well as two nanoneedle-based ones [2], were measured up to their desired temperature operation range (800 °C and 600 °C, respectively). The nanoparticle-based coatings feature improved thermal stability that allows them to withstand higher temperatures than the industry standard Pyromark® 2500. The emissivities of these coatings are highly dependent on the morphology of the nanoparticle agglomerates, even more than on sample composition. In particular, a porous $Cu_{0.5}Cr_{1.1}Mn_{1.4}O_4$ coating showed a promising combination of an enhanced solar absorptance and emissivity in the normal direction, and a reduced total hemispherical emissivity at all temperatures. Both effects can be linked to the porosity of the sample, by means of enhanced light trapping in the normal direction and increased semitransparency at high polar angles of emission. Thus, this coating shows signs of directional selectivity. Besides, using a porous coating would be more cost-effective, since less mass of the material would be required for the coating. When combined with absorptance measurements, these emissivity measurements allow estimating the real efficiencies of the coatings, which can even reach values around 0.93 [3].
$CuCo_2O_4$ nanoneedle-based coatings, on the other hand, possess an extremely high 99% solar absorptance, which is also coupled with very high hemispherical emissivity values, with values between 0.82 and 0.92 at working temperatures. It was observed that coating these nanostructures with aluminum-doped zinc oxide (AZO) is highly effective in increasing their emissivities at all angles and temperatures. Thus, outside of concentrated solar power applications, these thermally stable thin coatings can also find use as highly efficient black absorbers in the visible and IR ranges.

2:55 PM EN05.03.03

Design, Spectral Properties and Thermal Stability of High-Temperature Solar-Selective Coatings Based on Cr(Al)N Multilayer Stacks Ramon Escobar Galindo[1], Teresa Cristina Rojas[2], Alvro Caro[2] and Juan Carlos Sanchez-Lopez[2]; [1]Escuela Politécnica Superior, Universidad de Sevilla, Spain; [2]Instituto de Ciencia de Materiales de Sevilla (CSIC-Univ. Sevilla), Spain

Two multilayer solar selective absorber coatings [$Al/CrN_{0.95}/Cr_{0.96}Al_{0.04}N_{1.08}/Cr_{0.53}Al_{0.47}N_{1.12}/Al_2O_3$ (stack #1) and $Cr_{0.96}Al_{0.04}N_{0.89}/Cr_{0.62}Al_{0.38}N_{1.00}/Cr_{0.53}Al_{0.47}N_{1.12}/Al_2O_3$ (stack #2)] were deposited on 316L steel by

combining direct current (DC) and high power impulse magnetron sputtering (HiPIMS) technologies with the aim of increasing the working limit temperature. The composition and thickness of the constituent layers were optimized using CODE software to achieve a high solar absorptance (α) and low values of thermal emittance (ε) in the infrared region. The deposited multilayered stacks were heated for 2 hours in air at 600, 700 and 800 ºC to study their thermal stability and optical performance. Compositional, structural and optical characterization of the stacks (as-prepared and after thermal treatment) was performed. Both stacks presented a good solar selectivity with $\alpha > 95\%$ and $\varepsilon_{25\,^{o}C} < 15\%$, were stable up to 600 ºC and fulfilled the performance criterion PC < 5% after 600 and 700 ºC treatments. Despite the stacks suffered chemical transformations above 600 ºC, partial oxidation (stack #1) and Cr_2N formation (stack #1 and #2), the optical properties were optimum up to 700 ºC for stack #1 ($\alpha = 94\%$, $\varepsilon_{25\,^{o}C} = 12\%$) and 600 ºC for stack #2 ($\alpha = 93\%$, $\varepsilon_{25\,^{o}C} = 13\%$).The solar-to-mechanical energy conversion efficiencies (η) of the as-deposited and annealed (600 and 700 ºC) samples were up to 20 percentage points higher than the absorber paint commercially used (Pyromark). At 800 ºC, they underwent a further structural transformation, provoked by the oxidation of the inner layers, and they consequently lost their solar selectivity.

3:10 PM EN05.03.04
Late News: Design of High-Temperature Solar Selective Coatings Based on Cr(Al)N: Microstructure and Optical Properties of CrN_y and $Cr_{1-x}Al_xN_y$ Films Teresa Cristina Rojas, Alvro Caro, G. Lozano and Juan Carlos Sanchez-Lopez; Instituto de Ciencia de Materiales de Sevilla, Spain

In this work we present the microstructural and optical characterization of CrN_y and $Cr_{1-x}Al_xN_y$ films to be used in multilayered solar selective coatings (SSC) for high temperature application. The films were prepared by direct current (DC) and high-power impulse magnetron sputtering (HiPIMS) technology. The deposition parameters: N_2 flux, HiPIMS frequency and the aluminum power target, were modified to get a wide variety of stoichiometries. The composition, morphology, phases and electronic structure of the films were characterized in depth. The optical behavior was determined by UV-Vis-NIR and FTIR spectroscopies, and the optical constants were obtained from the measured transmittance and reflectance spectra based on appropriate dielectric function models. Small changes in the layer composition influence the optical constants. Our results indicate that a metallic-like behavior was obtained for CrN_y layers with N vacancies (y=0.67 and y=0.95) while a semiconductor-like behavior was observed for y=1.08. The optical properties of $Cr_{1-x}Al_xN_y$ layers can also be tuned from metallic to semiconductor-like behavior depending on the chemical composition. In particular, we demonstrated that CrN_y films could be used as effective absorber layer in multilayer-based SSC, and namely, the $CrN_{0.67}$ film also as IR reflector/absorber layer. Indeed, the absorption coefficients of $Cr_{1-x}Al_xN_y$ films with optimized Al content and N-vacancies are comparable to those reported for state-of-the-art materials such as TiAlN or TiAlCrN. In addition, a $Cr_{0.96}Al_{0.04}N_{0.89}$ film was found to be a suitable IR reflector/absorber layer. The ensemble of results highlights the potential of these materials as efficient components in multilayer-based SSC for high temperature applications. Three different multilayered- SSC were designed by applying optical simulations, obtaining excellent optical selective properties ($a > 95\%$ and $e < 15\%$).

3:15 PM EN05.03.05
Late News: Opportunities of HiPIMS Technology for Designing Complex Multilayered Cr(Al)N Coatings for Solar Selective Applications Juan Carlos Sanchez-Lopez, Alvro Caro, Juan Martinez-Romero and Teresa Cristina Rojas; Instituto de Ciencia de Materiales de Sevilla, Spain

High power impulse magnetron sputtering (HiPIMS) technology has emerged as a recent promising physical vapor deposition technique for coating with improved properties. The application of short high power pulses to the magnetron sources enables higher plasma densities and ionization rates, leading to improved film density and functionality. In this paper we explore the possibilities of this technique to design multilayered systems based on Cr(Al)N with controlled chemical composition and microstructure for solar selective absorption. By changing the pulse length (20 to 100 ms) and frequencies (200 to 1000 Hz) differences in the film stoichiometry, crystallinity, lattice parameters and morphology can be obtained, influencing the properties of interest for the foreseen application. In particular, we will present how to tailor the optical properties and the

oxidation resistance thanks to the variation of pulse parameters in the single individual layers. The benefits obtained by combining the high power pulse delivered to the target with a negative voltage applied to the susbtrate (bias) will be shown. A full design based on a multilayered CrAlN systems capped with an antireflective Al_2O_3 layer is prepared on 316L steel with and without the application of bias. The results demonstrated that the bias helped to densify the structure, decreasing the intercolumnar spaces, although affected the targeted film stoichiometry. The thermal stability and oxidation resistance properties of both stacks will be compared and discussed to establish a correlationship between synthesis conditions and practical performance at different temperatures (room temperature, 600, 700 and 800°C).

Oxide Dispersion Particle Clustering Using Phase Field Modelling in Nickel-Based Superalloys Bryan T. Kinzer, Aditya Sundar and Rohini Bala Chandran; University of Michigan–Ann Arbor, United States

Nickel-based superalloys are promising materials for next generation heat-exchangers in concentrated solar power technologies, including the supercritical CO_2 Brayton cycle, due to their superior corrosion resistance at high-temperatures of 1000 °C. However, many of these alloys lack sufficient yield and creep rupture stress required in power plants as strengthening from gamma prime precipitates is no longer effective at these elevated temperatures. One of the most promising methods of increasing yield stress at high temperatures is through the introduction of oxide dispersion strengthening (ODS) particles. At these high temperatures grain boundary sliding is activated; the ODS particles pin the grain boundaries reducing sliding improving creep and yield stress. Using the existing Reppich particle pinning model, our results indicate that by simply mixing in 0.3 wt% of 40 nm diameter ODS (Y_2O_3) particles, the yield stress of a typical Ni alloy, Haynes 214, can more than double at 1000 °C showing the promise of the ODS approach. Increasing the amount of ODS particles can result in improved strengthening of the base alloy, but only up to a certain mass-fraction. As the weight percent of ODS powders is increased clusters of ODS particles form causing stress concentrations, which leads to alloy cracking and to changes in grain recrystallization. Traditionally, the maximum mass-fraction of ODS powders is determined through trial and error, based on observing its effects on cracking during solidification. This process is time consuming and offers limited insight about the fundamental mechanisms at play. In this work, we apply phase-field modelling to inform how the microstructural evolution is influenced by the mass-fraction and initial distribution of the ODS particles. The model will be applied to explore the effect of ODS particle clustering on grain growth, which can influence creep and strength. Processing parameters, such as cooling rate, will be linked to initial ODS particle distribution offering insight into the driving forces that lead to particle clustering. These findings will shed light onto the mechanisms that determine the effectiveness of oxide dispersion particle strengthening on improving mechanical properties for high temperature applications to help enable next generation concentrated solar power technologies.

5:55 PM EN05.04.02
Multiscale Porous High-Temperature Heat Exchanger Design Using Ceramic Co-Extrusion Xiangyu Li, Chad Wilson, Lenan Zhang, Bikram Bhatia, Lin Zhao and Evelyn Wang; Massachusetts Institute of Technology, United States

We propose a high performance, compact and durable ceramic heat exchanger design capable of operating over

1200 °C and 250 bar for aerospace and CSP applications. Our checkered pattern design leverages porosity at the centimeter-scale that serves as macrochannels for the flow of working fluids. Meanwhile, a micrometer-scale porous core is embedded into these channels to significantly improve heat transfer and structural strength. Compared to traditional porous media approach, this multiscale porous configuration with straight ducts enables high heat transfer and a low pressure drop penalty. Furthermore, these structures can be fabricated using a ceramic co-extrusion process capable of creating both the channels and porous internal structure in one step. Overall, the heat exchanger is able to operate with hot flows over 1200°C and supercritical CO2 at 300°C and 250 bar, providing high volumetric power density and less than 1% pressure drop.

Due to the large difference in the feature size of the heat exchanger, it is computationally prohibitive to include all the detailed feature in one simulation. Therefore, a hierarchical model is proposed to optimize the design and predict the mechanical strength, pressure drop and thermal performance. An analytical thermal resistance model is also developed to optimize the thermal performance of the heat exchanger. Thermal performance is evaluated and optimized as volume power density, weight power density and effectiveness.

The proposed high-performance counterflow heat exchanger can enable efficient heat exchange at extreme conditions in a wide range of power generation application, due to its high thermal performance, low volume, light weight and scalable fabrication process.

6:10 PM EN05.04.03
Oxidation and Carburization Behavior of Iron- and Nickel-based Alloys in Supercritical CO_2 Environments Aditya Sundar, Bryan T. Kinzer and Rohini Bala Chandran; University of Michigan–Ann Arbor, United States

Advanced Iron (Fe) and Nickel (Ni) based alloys are potential candidates to serve as reactor components in high temperature, super-critical carbon dioxide (s-CO_2) heat exchangers. These high temperature (up to 1100°C) and high pressure (up to 20 atm s-CO_2) conditions pose the critical challenge of carburization induced corrosion, in addition to enhanced surface oxidation. In this work, we evaluate the relative performance of 3 such alloys: Fe-based Inconel MA 956, Ni-based Haynes 214 and Ni-based Amdry 386. Thermodynamic calculations and kinetic simulations are implemented using a CALPHAD (CALculation of PHAse Diagrams) based approach to understand the propensity of oxide and carbide formation. Thermodynamic analysis supports reported experimental findings that that carbide precipitates ($M_{23}C_6$, M_7C_3 etc.) are stable at the interface between the surface oxide (Corundum, rutile, spinel etc.) and the underlying metallic alloy. We propose a diffusion-driven model that combines oxide growth rates and gas transport through the oxide, to estimate the carbon activity at this interface. The reduction of carbon dioxide (CO_2) to carbon monoxide (CO) results in the formation of elemental Carbon (C), enhancing the thermodynamic driving force for carburization. Under similar boundary conditions for the interfacial carbon activity, Ni-based alloys exhibit better carburization resistance as compared to Fe-based alloys. Further, we also implement isothermal and non-isothermal heat treatment simulations to study the microstructural changes resulting from exposure to high temperatures and pressures (upto 1100°C and 20 atm). Thermo-kinetic nucleation and growth models employed in this study will be used to inform experiments about the design of particular heat treatments that promote/arrest the growth of desired high strength precipitate phases. The results from our work will guide the selection and processing of structural materials used as high temperature components in the next generation of concentrated solar power technologies.

6:25 PM *EN05.04.04
Optically Transparent and Thermally Insulating Aerogel Solar Collectors Thomas Cooper, Bikram Bhatia, Lee A. Weinstein, Lin Zhao, Yi Huang, Elise Strobach, Kenneth McEnaney, Sungwoo Yang, Evelyn Wang and Gang Chen; Massachusetts Institute of Technology, United States

Aerogels can be made transparent in the solar spectrum but opaque in the infrared spectrum. Such optically transparent and thermally insulating aerogels can be used in solar collectors, replacing the need for selective surfaces and vacuum in solar thermal systems. This talk will summarize several aspects of aerogel solar

collectors. Theoretical modeling suggests that aerogel collectors can have attractive performance. Optimization of the synthesis process for silica aerogel has led to highly transparent aerogels across the entire solar spectrum. Several experimental implementations of the aerogel collectors will be discussed. One configuration is to combine solar thermal with solar PV in one optical path to increase dispatchability of PV, enabled by the transparent aerogel. In another configuration, transparent aerogel will be used in linear Fresnel concentrators to achieve high temperatures. Experimental results on the system performance will be discussed. The transparent aerogel also enables nonconcentrating system to achieve high temperatures for other thermal applications such as sterilization.

Pathways to Renewable Fuels Using Concentrated Sunlight Anthony H. McDaniel; Sandia National Laboratories, United States

Population growth and continued industrialization of developing countries may double global energy consumption by 2035. If such energy demands are largely met by fossil fuels, the deleterious effects of anthropogenic carbon loading of the earth's ecosystems will greatly intensify. As such, developing technologies to create renewable and sustainable fuels from sunlight is widely seen as a global imperative.

While technologies for converting solar irradiance into hydrogen or hydrocarbons predicated on low-temperature pathways such as electrolysis and natural or artificial photosynthesis offer potential solutions, there is significant recent interest in utilizing high-temperature pathways powered by concentrated solar energy. Here we offer a perspective on a process that utilizes highly concentrated thermal energy from the sun to drive chemical reactions that split water into hydrogen or carbon dioxide into carbon monoxide, thereby creating simple fuels or precursors to more complex energy carriers like fungible liquids. Our implementation for converting sunlight to fuel is based upon a deceptively simple two-step redox cycle. In step one, a concentrated solar resource heats and reduces a non-stoichiometric oxide, spontaneously creating oxygen defects and depositing the solar energy directly into the reduced oxide, much like charging a battery. Once "charged," the reduced oxide is exposed to water or carbon dioxide in a second step under conditions that result in spontaneous gas splitting, yielding molecular hydrogen or carbon monoxide (i.e., solar fuel or solar syngas).

Effective and efficient redox-active materials are key to the commercial success of solar thermochemical water splitting technologies, and material discovery efforts at laboratories around the globe are currently underway. This talk will discuss the use of complex, multi-cation oxides to accomplish the redox cycle chemistry and describe our efforts to explore the fundamental underpinnings of important relationships between oxide composition, electronic structure, and functionality. Furthermore, we will review progress made by the HydroGEN Advanced Water Splitting Materials Consortium (h2awsm.org), which is a research community brought together and funded by the US DOE as an Energy Materials Network initiative in late 2017 and tasked with using high throughput computational material science approaches to discovering thermochemically active oxides. We will also review challenges and opportunities for discovering new redox cycle chemistries within the context of achieving high solar-to-fuel conversion efficiency in engineerable and appropriately designed solar reactors.

Designer Perovskites with Dual Reduction on A and B Sites—Lowering the Peak Temperature of Thermochemical Hydrogen Production Cycles Robert T. Bell[1], Sarah Shulda[1], Dan Plattenberger[1], Eric Coker[2], Josh Sugar[2], Sami Sainio[3], Nicholas Strange[1,3], Karen Heinselman[1], Philip Parilla[1], Anthony H. McDaniel[2], Michael F. Toney[4,3], Sai Gautam Gopalakrishnan[5,6], Emily Carter[5,7], Ellen Stechel[8] and David Ginley[1]; [1]National Renewable Energy Laboratory, United States; [2]Sandia National Laboratories, United States; [3]SLAC National Accelerator Laboratory, United States; [4]University of Colorado Boulder, United States; [5]Princeton University, United States; [6]Indian Institute of Science, India; [7]University of California, Los Angeles, United States; [8]Arizona State University, United States

Lowering the peak temperature required by solar thermochemical hydrogen (STCH) production cycles might be key to overcoming a range of technology readiness challenges. For oxide perovskite based STCH, the peak cycling temperature occurs during the oxide reduction step where reactive oxygen vacancies are generated, typically at temperatures >1300°C. Generally, oxygen vacancies are charge compensated by reduction of a single cation species on either the A or B site. However, recent modeling suggests a strategy for reducing the temperature would be to tune the enthalpy through doping while maximizing the entropy of reduction with dual reduction on both A and B site cations. We will report on experimentally validating these models and demonstrating dual cation reduction of Ce^{4+} to Ce^{3+} and Mn^{3+} to Mn^{2+} in (Ca,Ce)(Mn,Ti)O_3 perovskite. We designed techniques to measure samples with varying degrees of reduction in ex situ experiments through complementary use of in situ measurements. In situ techniques including TGA and XRD were used to quantify the reduction of ex situ samples, where reduced states are quenched into samples cooled under reducing environments. The oxidation state of cations in samples, both oxidized and reduced, were then determined through a combination of ex situ X-ray absorption spectroscopy (XAS) and X-ray photoelectron spectroscopy (XPS) measurements. We report the performance of this material during temperature and pO_2 cycling. These experiments both validate predicted routes to design STCH materials and demonstrate techniques to quantifiably quench reduction into samples for ex situ measurements.

9:40 PM EN05.05.03

Late News: Solar Thermochemical Hydrogen Production on Layered Perovskite BaX0.25Mn0.75O3 (X = Ce, Nb, Pr) and BaTi0.5Mn0.5O3 James E. Park, Eric Coker, Mark Rodriguez, Andrea Ambrosini and Anthony H. McDaniel; Sandia National Laboratories, United States

Solar thermochemical hydrogen production (STCH) is a two-step process that utilizes concentrated solar heat and metal oxide materials to produce hydrogen gas by splitting water molecules through oxide redox chemistry. Among the many different materials investigated, perovskite (ABO_3) materials, including $Sr_xLa_{1-x}Mn_yAl_{1-y}O_3$ (x, y = 0.4, 0.6)[1] and $ATi_{0.5}Mn_{0.5}O_3$ (A = Ca and Sr),[2,3] have been reported that are competitive with CeO_2, the current benchmark material. Multiple combinations of perovskite-like materials are possible with diverse crystal structures due to partial cation substitution and vacancy formation on the metal and oxygen sites, which influence the electronic structure and consequent STCH performance. Recently, $BaCe_{0.25}Mn_{0.75}O_3$ (BCM), a layered perovskite, was shown to have faster water oxidation kinetics than $Sr_xLa_{1-x}Mn_yAl_{1-y}O_3$ (x, y = 0.4, 0.6) and better hydrogen production capability than ceria at a lower thermal reduction temperature (T_R=1350 °C).[4] In the course of determining the chemical underpinnings of BCM's performance, three new water-splitting and isostructural materials, $BaNb_{0.25}Mn_{0.75}O_3$ (BNM), $BaPr_{0.25}Mn_{0.75}O_3$ (BPM), and $BaTi_{0.5}Mn_{0.5}O_3$ (BTM), were synthesized and characterized. Comparing the performance and structural changes of these materials *in operando* aids in the understanding of the relationship between hydrogen production capability and the different local environments of the metal-oxygen bonds resulting from the chemical modification. From this, a better fundamental understanding can be developed to aid in identifying new materials for solar thermochemical fuel production.

9:55 PM EN05.05.04
***Ab Initio* Study of Atomic and Electronic Structure of Promising $BaX_{0.25}Mn_{0.75}O_3$ (X=Nb, Ce, Pr) Oxides for Solar Thermochemical Hydrogen Production** Anuj Goyal and Stephan Lany; National Renewable Energy Laboratory, United States

The two-step metal oxide water-splitting cycle is one of the most viable approach for Solar Thermochemical Hydrogen (STCH) production. Challenges exist in finding suitable oxides that can satisfy thermodynamics of the STCH redox cycle under viable range of temperatures and partial pressures. Recently, BXM family members, *i.e.*, $Ba_4NbMn_3O_{12}$(BNM), $Ba_4CeMn_3O_{12}$ (BCM), $Ba_4PrMn_3O_{12}$ (BPM) are discovered to exhibit promising STCH performance. However, the magnetic degrees of freedom of their experimental crystal structures is not characterized, and only hypothetical models exist for their electronic structure. We performed Monte-Carlo sampling for the magnetic spin arrangement of Mn atoms to provide explicit atomic structure models for their ground state 12R polytype and determined the most stable spin configuration for each member after structure relaxation using density functional theory (DFT) calculations. We also elucidate the most stable charge configuration (Mn^{3+}/Mn^{4+} arrangement) for BNM among the existing hypothesis in literature. We investigate these strongly correlated oxides using different levels of theory (DFT+*U*, Hybrid-DFT) to develop better understanding of their electronic structure. These calculations allowed us to develop a model based on molecular orbital interactions that help explain the observed changes in their experimental x-ray spectroscopy measurements**.** Thereby, help link differences in electronic structure of BXM family members to their varying water-splitting behavior. These structure models will further facilitate future in-depth defect studies to model STCH redox cycle of these oxides.

10:10 PM EN05.05.05
Testing and Characterization of Liquid Metal Alloys for Hybrid Thermo-Electro-Chemical Water Splitting Cycles Laura Achola, Anthony H. McDaniel, Witman Matthew, Margaret Gordon and Andrea Ambrosini; Sandia National Laboratories, United States

Renewable and sustainable sources of energy are playing a much larger role in powering modern society driven by the need to limit global CO2 emissions and mitigate the anthropogenic influences on climate change. Hydrogen, a clean energy source with a high gravimetric energy density (≈140 MJ kg-1) and zero carbon emission, is a possible clean route to lowering emissions from transportation and as an alternate source of energy storage. Currently, the majority of hydrogen is produced from reforming of fossil fuels which is carbon intensive and non-renewable. Renewable production of hydrogen, such as electrolysis and solar thermochemical, are less developed and more expensive than hydrocarbon reforming. The primary challenge of renewable hydrogen production is reducing the cost of production technologies to make the resulting hydrogen cost competitive with conventional transportation fuels. We propose a novel route to hydrogen production via a hybrid thermochemical-electrochemical process utilizing liquid metal solutions (LMS) to effect a water splitting reaction. The process can be driven by heat and electricity from renewable concentrating solar power (CSP). In the first step, steam is thermochemically reduced by the LMS producing hydrogen and a metal oxide by product, while in the second step, an endothermic process, the metal oxide is electrochemically reduced back to metal, and oxygen is evolved. The LMS process has the potential to produce hydrogen via water splitting at temperatures much lower than current CSP-driven thermochemical processes (>> 1000 °C) and at applied potentials lower than conventional high-temperature electrolysis. A number of possible binary LMS

compositions that reduce at reasonably low overpotentials have been identified using machine learning. Here we test several alloy candidates for their ability to produce hydrogen in a flow reactor set-up. The basic proof of concept will be elucidated. X-ray diffraction and scanning electron microscopy of the LMS before and after the reaction to analyze byproducts and changes in microstructure, grain sizes of tin oxide, coalescence will be presented.

10:25 PM EN05.05.06
Rutherford Backscattering Spectrometry (RBS) for Quantification of Oxygen and Vacancies in Solar Thermochemical Hydrogen Production Materials Karen Heinselman, Robert T. Bell, Dan Plattenberger, Sarah Shulda, Philip Parilla and David Ginley; National Renewable Energy Laboratory, United States

Many classes of materials for production of solar thermochemical hydrogen (STCH) and other fuels depend on reversible formation of oxygen vacancies which react with oxygen in steam or other gases. The change in oxygen vacancy stoichiometry during the gas reduction step ($\Delta\delta$) is directly proportional to the hydrogen produced each cycle. Despite being a key property of STCH materials, the oxygen stoichiometry is rarely quantitatively measured with sufficient accuracy to capture changes in vacancy concentration. In many cases, thermal gravimetric analysis (TGA) is used to observe mass loss during cycling, which is then attributed to oxygen loss. However, the dynamic nature of TGA measurements prevent its use to directly measure vacancy content of ex-situ and postmortem samples used in other measurements. In this work, we introduce the use of Rutherford Backscattering Spectrometry (RBS) to directly measure the oxygen and cation stoichiometry of multinary STCH oxide samples, both powders and thin films, at sufficient accuracies to determine the vacancy stoichiometry by comparing oxidized and reduced samples. The operating principles of RBS are described, and the capabilities of the technique are compared to complimentary elemental analysis techniques including X-ray fluorescence spectroscopy (XRF), energy-dispersive X-ray spectroscopy (EDX), X-ray photoelectron spectroscopy (XPS), and Inductively Coupled Plasma Mass Spectrometry (ICP-MS). The non-destructive depth profiling capabilities of RBS are demonstrated on representative STCH materials. Additionally, the sensitivity of RBS to light elements allows the determination of whether secondary phases are forming at surfaces, including the formation of carbonates which is a concern for STCH materials featuring alkaline rare earth elements. Together, this work demonstrates an underutilized technique for quantitative analysis of oxygen vacancy stoichiometry in STCH materials; a key material property to STCH performance which has been under-reported in the field.

10:40 PM EN05.05.07
First-Principles Screening of Ca-Ce-M-O (M = 3*d* transition metal) Oxide Perovskites for Solar Thermochemical Applications Sai Gautam Gopalakrishnan[1,2], Ellen Stechel[3] and Emily Carter[1,4]; [1]Princeton University, United States; [2]Indian Institute of Science, India; [3]Arizona State University, United States; [4]University of California, Los Angeles, United States

Solar thermochemical (STC) processes have to potential to be an efficient way to generate renewable fuels or fuel precursors using concentrated sunlight. Specifically, an STC process can use redox-active, transition-metal oxide substrates to split water and CO_2, generating syngas, H_2 and CO. Importantly, STC processes benefit from oxide substrates that can *i*) withstand large temperature swings, *ii*) sustain high degrees of oxygen off-stoichiometry and *iii*) be resistant to adverse phase transformations. Currently, the state-of-the-art material used in STC applications is pure CeO_2; identifying materials that can operate at lower temperatures and achieve higher efficiency is an active area of research. Here, we explore the chemical space of Ca-Ce-M-O (M=3*d* transition metal) oxide perovskites, with Ca and/or Ce occupying the A site and M occupying the B site within an ABO_3 framework, as potential STC candidates, using density functional theory (DFT) based calculations. To account properly for electron exchange and correlation, we use the strongly constrained and appropriately normed functional, with an appropriately determined Hubbard *U* correction to reduce the inherently large self-interaction error DFT engenders when describing 3*d* (M) and 4*f* (Ce) electrons. While we consider only Ca and/or Ce on the A-site because of their similar size and the potential redox-activity of Ce, we evaluate all 3*d* transition metals except Zn on the B-site (Zn^{+3} is uncommon in solids). We evaluate the oxygen vacancy

formation energy (~enthalpy of reduction in an STC process), electronic properties, and thermodynamic stability of ternary Ca-M-O, Ce-M-O, and quaternary Ca-Ce-M-O perovskites, identify promising candidates, and extract metrics that govern the enthalpy and entropy of reduction that are key to improving STC efficiencies.

Charge Carrier Dynamics and Non-Radiative Recombination in Chalcogenide and Halide Perovskite Photovoltaic Materials Thomas Unold; Helmholtz Zentrum Berlin für Materialien und Energie GmbH, Germany

Application of semiconductor thin film materials in photovoltaic devices requires optimized optoelectronic properties and thus understanding of the underlying physical mechanisms and limits governing carrier transport and recombination. Although material parameters such as doping density, recombination lifetimes and mobilities belong to the most basic properties eventually defining the solar cell operation, they can be quite elusive or ambiguous in their characterization. Here, chalcogenides (e.g. chalcopyrite and kesterite) and halide perovskites share some similarities, but also a number of differences. Considerable discussion prevails about the role of interface versus bulk recombination in devices, the values of carrier mobilities, doping levels and minority carrier lifetimes. Combining different characterization techniques such as time-resolved luminescence, photoluminescence quantum yield as well as pump-probe terahertz spectroscopy we attempt to draw a relatively consistent picture of material properties and device function, exposing current limits and paths to improvement.

8:25 AM *EN06.01/EN07.01.02

Towards Perovskite-CIGS Large Area Tandem Architectures Valerio Zardetto[1], Marcel Simor[1], Pieter Jan Bolt[1], Tom Aernouts[2], Gianluca Coletti[1], Mariadriana Creatore[3], René A. Janssen[3], Veronique Gevaerts[1], Sjoerd Veenstra[1], Hans Linden[1] and Ronn Andriessen[1]; [1]TNO partner in Solliance, Netherlands; [2]IMEC partner in Solliance, Thin Film PV, Belgium; [3]Eindhoven University of Technology, Netherlands

The fabrication of cost-effective multi-junction (MJ) device architectures is presently considered the strategy to increase the Power Conversion Efficiency (PCE) of the solar cells in order to lower the levelized cost of energy (LCOE), decreasing therefore the price of an installed photovoltaic (PV) system. The outstanding advancement of metal halide perovskite absorber (PSC) technologies in the last years motivates the PV community to investigate tandem hybrid architectures, consisting of a perovskite based top cell with a commercial bottom PV device such as crystalline silicon (c-Si) or copper indium gallium selenide (CIGS). The combination with the latter, in particular, offers unique advantages: i) compatibility with lightweight flexible plastic or metal foils as substrates, in view of a roll to roll (R2R) manufacturing line, further reducing the manufacturing and the installation costs, as well as the environmental footprint of the KWh generated; ii) large scale integration of PV devices in, amongst others, buildings (BIPV and vehicles (VIPV).
This contribution will provide an overview of the activities within the Solliance consortium on 4 terminal tandem and preliminary work on 2 terminal architectures, on rigid, as well as flexible substrates. In order to increase the overall PCE of the tandem hybrid configuration, the optimization of the sub-cells' performance with respect to their spectral responses is required. Several combinations of suitable complementary band gaps of the two absorbers are explored, as well as the optimization of the near infrared transparency of the top perovskite cell by tuning the free carrier absorption of the TCO adopted. Furthermore, in the case of the 2-terminal architecture, the development of an efficient interconnected layer among the two sub-cells is utmost crucial to provide the monolithic series interconnection and, at the same time, to minimize the parasitic absorption.
Optimized TCO, transport layers and anti-reflective properties lead to a near-infrared transmittance of about 90% (an average taken from the wavelength range of 700-800 nm to 1200 nm) on glass or plastic based top PSC optimizing therefore the response of the filtered CIGS. As a result, coupling a semitransparent glass-based PSC and a flexible CIGS we calculate a 4T tandem PCE of 25.2% on small area devices (<0.1cm^2). When using a flexible semi-transparent perovskite solar cell, a record-breaking power conversion efficiency of 23.0% is calculated. We also evaluated the PSC-CIGS combination on a larger area (> 80 cm^2), currently adopting a no-optimized (in the NIR region) large area perovskite module. We calculated already a 1.9% absolute increase in the efficiency with respect to the single CIGS device, with a further improvement that can be achieved by improving the light management and fine tuning the perovskite band gap. Whereas the 4T architecture offers already a significant increment in performance with respect to the single junction devices, the development of the 2T tandem PSC-CIGS exhibits more challenges. As observed by the first results, the efficiency of the flexible 2T tandem PSC-CIGS, still lags behind the power conversion efficiency of the single CIGS. New upscalable perovskite formulations as well as the optimization of the recombination layer will also be addressed as crucial topics to boost the overall performance.

8:50 AM BREAK

9:05 AM *EN06.01/EN07.01.03

Chalcogenide Perovskite Thin Films for Energy Conversion—Prospects, Challenges and Routes Forward Corrado Comparotto, Kostiantyn Sopiha and Jonathan Scragg; Uppsala University, Sweden

Great progress in perovskite photovoltaics has been enabled by the excellent intrinsic material properties of lead-halide perovskites. These relatively newly-available materials are already opening paths to higher performance in mass-market PV technologies, including tandem PV modules. Nonetheless, reaching competitive levelized energy costs will hinge on achieving comparable robustness to existing silicon-based technology. This is a high and rising benchmark, which has not yet been approached by halide perovskite technologies. This makes it less likely that investors will support the upscaling and deployment of perovskite-

based solar technology.

Chalcogenide perovskites, in which halide anions are replaced by chalcogenides (O, S, Se) could offer a new path forward. Examples include $BaZrS_3$ and $SrHfS_3$, among several others. The solar cell-relevant properties of these materials are projected to be comparable to halide perovskites. More critically though, their chemistry provides them with excellent stability under conditions for which halide perovskites would rapidly degrade, e.g. in water, humid air or at high temperatures.

The major challenge with chalcogenide perovskites has been to synthesise them in thin film form with good quality. Therefore, despite impressive measurements from bulk materials, it has not been possible to validate their application in thin film solar cells. There are several reasons for the synthetic difficulties, connecting to intrinsic material properties as well as to the use of inappropriate synthesis methods. To date, we still have incomplete understanding of the growth processes of these materials.

In this presentation, we briefly summarise the potential of the chalcogenide perovskites based on prior literature. Then, our own progress toward thin films suitable for solar-cell integration will be presented. A number of sputter-based growth routes to $BaZrS_3$ have been investigated and evaluated using combinatorial approaches. Materials have been characterised using XRD, STEM-EDS, SEM/TEM imaging, XAFS, Photoluminescence mapping and Ion-beam techniques including RBS and ERDA, to construct a picture of the growth sequence and final compositional, microstructural and optoelectronic characteristics of the films. This is a means to establish the first “cookbook” for chalcogenide perovskite films suitable for solar cells, i.e. the optimal growth conditions for high quality material. Film formation will be discussed in the context of thermodynamic and kinetic aspects, applicable to any type of growth method. The aim of this talk is to promote and support research into these highly interesting materials in other labs, and stimulate collaboration on this exciting topic.

9:30 AM EN06.01/EN07.01.04
Effect of the HTM/TCO Interface on the Electrical Properties of Semi-Transparent Perovskite Solar Cells for Tandem Applications Emilie Raoult[1,2,3], Marion Provost[2], Romain Bodeux[1,2], Sébastien Jutteau[1,2], Marie Legrand[1,2], Samuel Rives[1,2], Armelle Yaiche[1,2], Damien Coutancier[2,4], Jean Rousset[1,2] and Stéphane Collin[2,3]; [1]Electricité De France (EDF), France; [2]Institut Photovoltaïque d'Ile-de-France (IPVF), France; [3]Centre for Nanoscience and Nanotechnology (C2N), France; [4]CNRS, France

Spiro-OMeTAD, CuSCN and PTAA are attractive hole transport materials (HTM) in conventional n-i-p architectures for perovskite cells[1]. In this work, we combine these three HTMs on semi-transparent (ST) solar cells with different sputtered electrodes made of In_2O_3-SnO_2 (ITO) or In_2O_3-ZnO (IZO) to study their impact on the optical and electrical properties of the cells.

First, thanks to an optical model based on the Transfer Matrix Method and careful material characterizations[2,3], a good agreement has been obtained between the transmission, reflection and absorption spectra of the complete structure of the ST cell with Spiro and ITO. This model allows to simulate the efficiency of a tandem cell with a silicon bottom cell, to identify optical losses and to optimize the thickness and properties of the each layer. It is shown that the Spiro and ITO layers have a non-negligible parasitic infrared absorption in the IR, resulting in a lower efficiency for the filtered silicon cell. The gain in efficiency enabled by the use of PTAA, CuSCN and IZO, which are almost transparent in the IR region, is assessed.

Second, triple cation perovskite solar cells with these three HTMs are synthetized and characterized in detail using scanning electron microscopy, ellipsometry spectroscopy, glow discharge emission optical spectroscopy, X-ray diffraction and transmission spectroscopy. Regarding the electrical properties, the Spiro is a layer known for its sensitivity, and the poor reproducibility obtained on ST cells is often associated with degradation due to energetic sputtering[4]. Investigations using CuSCN as HTM showed a slightly better reproducibility than Spiro but strong light soaking effects also appeared, and the resulting efficiencies are low. The replacement of the

Spiro by PTAA has improved the reproducibility of cells, while maintaining good performances. A 17.4% efficiency perovskite semi-transparent cell with PTAA was obtained and which is significantly above our previous results with Spiro (16.4%)[5].

After electrode sputtering deposition, a characteristic S-shape appears in IV characteristics. By regularly following the cells over time while keeping them under vacuum atmosphere and in the dark, IV curves recovered until the S-shape disappeared completely. For example, a cell with Spiro and ITO have 8.7% efficiency and 43% Fill Factor (FF) the first day and reach 16.8% with FF=70% after 66 days. When the Spiro is replaced by PTAA, the S-shape is less pronounced and the recovery time markedly reduced to 15 days. These effects are not visible on cells with CuSCN.

Lee et al.[6] obtained a similar S-shaped curve on perovskite cell with a Spiro/silver electrode, with a short recovery time of about one day. A local reaction between the dopant Li-SIF and the silver could cause the deoxygenation of the Spiro at the surface, which would create a temporary electrical barrier. It is interesting to note that this dopant is common to PTAA and Spiro but not to CuSCN. Preliminary results obtained by time resolved photoluminescence (TRPL) shows a decrease of the PL signal over time. Experiments are underway to determine if the cause of this decrease is due to improved extraction at the HTM/TCO barrier as suggested by Lee et al.[6], or if it comes from a reduction in radiative recombination related to defect healing. We will discuss the reaction mechanisms for these three HTM.

9:45 AM EN06.01/EN07.01.05
Late News: A Transparent Polymer Impregnated with Conductive Particles for Tandem Photovoltaic Devices Joshua Crunk, Kai C. Outlaw-Spruell and Nicolas Gaillard; Hawaii Natural Energy Institute, United States

Tandem photovoltaic (PV) devices offer great advantages over individual photovoltaic cells including the potential to reach power conversion efficiencies (PCEs) greater than that of the composing individual cells. The current record PCE for a PV tandem cell is over 29%, set by a perovskite/Si tandem. Perovskite solar cells (PSCs) are ideal for tandem devices because they have proven to be highly efficient and the bandgap can be tuned. However, PSCs are extremely sensitive to air and light. Another great candidate for tandem devices are chalcopyrite thin-film solar cells. Chalcopyrite cells also have tunable bandgaps and high efficiencies. The manufacturing process for chalcopyrite cells includes parameters that would degrade the performance of the bottom cell in a monolithic tandem device and the architecture of the cell prohibits a sufficient amount of energy below the bandgap from reaching the bottom cell. Thus, we present a strategy for fabricating a semi-monolithic chalcopyrite/perovskite tandem device by employing a transparent polymer impregnated with conductive particles (TPCP).
The TPCP was designed for electrically coupling solar cells into tandem devices. The TPCP can be employed in three ways: (i) fully-bonded, (ii) semi-bonded , and (iii) freestanding. When fully-bonded, the TPCP permanently bonds two surface allowing for passage of light and electrical current. TPCPs have been used to fabricate a $CuGaSe_2$/Si tandem device with an open circuit voltage of 1.04 V and PCE of 2.45%. Fully-bonded TPCPs were used to exfoliate the $CuGaSe_2$ cell at the $MoSe_2$ layer with an FTO-coated glass handle. The exfoliated $CuGaSe_2$ cell was then fully bonded with the TPCP to a Si bottom cell. The semi-bonded TPCP passes light and electrical current while also providing the protective features of a polymer over a surface. The semi-bonded TPCP has successfully been employed as an encapsulation technique for preserving PSCs. The TPCP encapsulation did not affect the performance of the PSC. An encapsulated PSC exposed to air and light

for 14 days did not show any visible signs of degradation. The freestanding TPCP enables the coupling of PV cells without permanently bonding the cells. Ultraviolet-visible spectroscopy measured over 90% transmittance across the visible spectrum. The resistance of the TPCP measured by linear sweep voltammetry yielded a series resistance to the order of 10^{-1} Ω●cm^2.
Based on the successful fabrication of the $CuGaSe_2$/Si tandem device and encapsulation of the PSC, we will investigate the fabrication of a chalcopyrite/perovskite tandem device composing of a wide bandgap chalcopyrite top cell and a narrow bandgap PSC. Additionally, the application of the freestanding TPCP to fabricate a tunable tandem device with exchangeable cells will be attempted.

SESSION EN06.02: Ion Moves in Perovskite Semiconductors
Session Chairs: Ivan Mora-Sero and Elizabeth von Hauff
Sunday Morning, April 18, 2021
EN06

10:30 AM *EN06.02.01
Ion Transport and Redistribution in Bulk and at Interfaces of Halide Perovskites Joachim Maier; Max Planck Institute for Solid State Research, Germany

The first part of the presentation summarizes parts of our work on bulk ion conductivity in halide perovskites. It discusses contributions from halide ions and methylammonium cations, and their relevance for polarization phenomena and stability [1]. The finding that light enhances the ion conductivity in the iodides [2] but not in the bromides, offers a simple explanation for the light induced demixing [3]. How far this surprising light effect on ion conduction has the potential to lead to novel "opto-ionic" devices is discussed [4].
The second part of the presentation refers to interfaces. It is shown that mobility of ions and the significant fraction of ionic charge carriers also gives rise to ionic built-in potentials, a point that had not been addressed in the photovoltaic literature and might lead to a paradigm change in the understanding of photoactive interfaces [5].

***In Situ* Monitoring of Iodine Migration in Mixed Halide Perovskites** Preethi S. Mathew, Jeffrey DuBose and Prashant Kamat; University of Notre Dame, United States

Trapping of holes at iodide sites in mixed halide perovskite, MHP ($MAPbBr_{1.5}I_{1.5}$) films cause iodide ions to migrate toward grain boundaries, thus inducing the formation of iodide rich phases and bromide rich phases. When mixed halide perovskite films are in contact with solution, the migration of iodine extends beyond phase segregation as it gets expelled into solution. The selective removal of iodine from MHP upon continued irradiation transforms the perovskite film into a bromide-rich perovskite film. Substituting A-site cation of MHP with cesium (Cs) slows down iodide expulsion due to increased thermodynamic stabilization of MHP lattices. Similar lattice stabilization has also been observed in Cl-alloyed perovskites. Furthermore, photoinduced iodide expulsion process in MHPs can be modulated through externally applied electrochemical bias. At anodic potentials, electron extraction at TiO_2/MHP interfaces becomes more efficient, leading to hole build-up within MHP films. This improved charge separation, in turn, favors iodine migration as evident from

the increased apparent rate constant of iodine expulsion ($k_{expulsion}$ = 0.0030 s^{-1}). Conversely, at cathodic bias (-0.3 V vs. Ag/AgCl potential) electron-hole recombination is facilitated within MHP films, slowing down iodine expulsion by an order of magnitude ($k_{expulsion}$ = 0.00018 s^{-1}). The tuning of the E_{Fermi} level through external bias modulates electron extraction at the TiO_2/MHP interface indirectly controls the build-up of holes, which ultimately induces iodine migration/expulsion. Suppressing iodine migration in perovskite solar cells is important for attaining greater stability since they operate under internal electrical bias.

Modulation of Photo-Induced Iodide Expulsion in Mixed Halide Perovskites with Electrochemical Bias
Jeffrey DuBose[1,2], Preethi S. Mathew[1,2] and Prashant Kamat[1,2]; [1]Radiation Laboratory, United States; [2]University of Notre Dame, United States

Mixed halide perovskites (MHPs) under photoirradiation phase segregate into iodide- and bromide-rich domains. When in contact with a solvent, the perovskite film expels iodine into solution. The trapping of holes at iodide sites dictates the overall iodide migration process. We have now succeeded in modulating the iodide expulsion process in MHPs through externally applied electrochemical bias. At anodic potentials, electron extraction at the electrode interface becomes more efficient, leading to build-up of holes within the MHP film. This in turn favors phase segregation and increases the rate iodine expulsion ($k_{expulsion}$ = 0.0030 s^{-1} at 0.5 V vs. Ag/AgCl). Conversely, at cathodic bias we facilitate electron-hole recombination within the MHP film and slow down iodine expulsion ($k_{expulsion}$ = 0.00018 s^{-1} at -0.3 V vs. Ag/AgCl). The tuning of E_{Fermi} through external bias modulates charge extraction at the perovskite electrode interface and indirectly controls the build-up of holes, which in turn induces iodine expulsion. Suppressing iodine migration in perovskite solar cell is important for attaining greater stability of perovskite solar cells since they operate under internal bias.

Late News: Towards Understanding the Origin of the Light-Induced Phase Segregation in the Mixed-Halide Perovskites Lyubov Frolova[1], Sergey Luchkin[2], Ernst Kurmaev[3], Sergey Aldoshin[1] and Pavel Troshin[1]; [1]IPCP RAS, Russian Federation; [2]Skolkovo Institute of Science and Technology, Russian Federation; [3]Ural Federal University, Russian Federation

Tunability of optoelectronic properties of lead halide perovskites achieved through halide mixing can potentially enable their multiple applications e.g. in tandem solar cells and light-emitting diodes. However, mixed halide perovskites are unstable under illumination due to their segregation into Br-rich and I-rich phases, which negatively affects the performance characteristics and operational stability of devices. Research efforts over the past years provided a substantial understanding of the factors influencing light-induced halide phase segregation. While several mechanisms were proposed, none of them could account for all available experimental data; and hence the origin of the effect is still under active debate. Herein, we thoroughly investigated the photodegradation of $CsPbI_2Br$ and $Cs_{1.2}PbI_2Br_{1.2}$ using a set of complementary techniques. *In-situ* atomic force microscopy provided a spectacular visualization of the real-time halide phase segregation dynamics demonstrating that iodoplumbate is selectively expelled from the mixed halide perovskite grains and nucleates as a separate I-rich phase at the grain boundaries. We propose a mechanism based on the reversible Pb^{2+}/Pb^0 and I^-/I_3^- redox (photo)chemistry, which explains our experimental findings and other previously reported results. Furthermore, it sheds new insights on the underlying mechanisms of multiple phenomena related to light- or electric field-induced degradation of various lead halide perovskites.
More details can be found in our recently accepted paper: L. A. Frolova et al., Reversible Pb^{2+}/Pb^0 and I^-/I^{3-} redox chemistry drives the light-induced phase segregation in all-inorganic mixed halide perovskites. *Adv. Energy Mater. 2021, DOI:* 10.1002/aenm.202002934.

Late News: Quantized Halide Diffusion in 2D Perovskite Vertical Heterostructures Akriti Akriti[1], Enzheng

Shi[2,1], Stephen B. Shiring[1], Brett M. Savoie[1] and Letian Dou[1]; [1]Purdue University, United States; [2]Westlake University, China

Solid state devices based on halide perovskites are now competing with other well-established semiconductors like silicon and gallium arsenide. However, the intrinsic instability of three-dimensional (3D) perovskites poses a great challenge in their widespread commercialization. The soft crystal lattice of hybrid halide perovskites facilitates anionic diffusion which impacts material stability, optoelectronic properties, and solid state device performance. Two-dimensional (2D) halide perovskites with bulky organic barriers have been used for improving the extrinsic stability as well as suppressing intrinsic anionic diffusion. With this strategy, devices with enhanced stability and reduced hysteresis have been achieved. Nevertheless, a fundamental understanding of the role of compositional tuning, especially the impact of organic cations, in inhibiting anionic diffusion across the perovskite-ligand interface is missing. Through this study, we demonstrate a quantitative investigation of the anionic inter-diffusion in flat 2D vertical heterojunctions between two arbitrarily determined phase-pure halide perovskite single crystals. Contrary to their 3D counterparts, anion diffusion across 2D halide perovskite vertical heterostructures does not follow the classical Fickian diffusion featuring continuous concentration profile evolution. Instead, the assembled vertical heterostructures show a “quantized” layer-by-layer diffusion behavior governed by a local free energy minimum and ion-blocking effects of the organic cations. We found that for a given organic cation, 2D perovskites (n = 1) are better inhibitors of halide diffusion compared to quasi 2D (n > 1) and 3D perovskites. Surprisingly, halide inter-diffusion coefficients for 2D perovskites capped with short aliphatic organic cations (*e.g.* butylammonium) are only 1~2 order of magnitudes smaller than that of 3D perovskites, suggesting the ineffectiveness of these cations in blocking the anionic migration. Furthermore, we found that bulkier and more rigid π-conjugated organic cations inhibit halide inter-diffusion much more effectively ($D < 10^{-20}$ m^2/s) compared to aliphatic cations. These results offer significant insights into the mechanism of anionic diffusion in 2D perovskites and provide a new materials platform for heterostructure assembly and device integration.

Mercury Rising in Perovskites Tze Chien Sum; Nanyang Technological University, Singapore

Slow hot carrier cooling in halide perovskites holds the key to the development of perovskite hot carrier (HC) and multiple exciton generation (MEG) solar cells that could potentially overcome the Shockley-Queisser limit. In this talk, I will focus on the new photophysical insights from our recent works on the hot carrier phenomena in halide perovskites.

6:55 PM *EN06.03.02
Narrowband Near-infrared Perovskite/Polymer Hybrid Photodetectors Zhaojue Lan, Linfeng Cai and Furong Zhu; Hong Kong Baptist University, Hong Kong

Solution-processable halide perovskite semiconducting materials have unique optoelectronic properties for applications in perovskite solar cells and photodetectors (PDs). The discrete perovskite PDs have a broadband photoresponse, which is sensitive over the visible wavelength range, while the discrete polymer PDs exhibit a broadband photoresponsivity with extended absorption in the near-infrared (NIR) wavelength range, e.g., from visible light to the NIR wavelength of >1100 nm. The visible-blind NIR photodetection with these broadband PDs requires the use of the filters or the specially designed photonic structures for attaining the photodetection

over a well-defined wavelength range. However, the use of the external filters adds additional cost and reduces the overall photosensitivity of the PDs.

Different narrowband photodetection approaches have been attempted, e.g., incorporating a microcavity structure and using charge collection narrowing (CCN) effect in the PDs. In the CCN-type PDs, a relatively thick photoactive layer, e.g., > 2500 nm thick photoactive layer, is adopted to reduce the collection efficiency of the charge carriers generated by the visible light absorbed near the upper region of a thick photoactive layer. The use of a thick active photoactive layer in a CCN-type PD faces some technical challenges: (1) The responsivity of the CCN-type PDs is limited as a large amount of the incident light is attenuated by the thick photoactive layer. (2) Perovskite PDs with a thick photoactive layer often associates with a slower response speed due to the decrease in its carrier transit time limited cut-off frequency. (3) The photodetection spectrum in the CCN-type PDs is limited by the absorption edge of the photoactive layer. This talk discusses a novel hybrid PD with a heterostructure perovskite/polymer photoactive layer for alleviating the challenges: (1) to achieve high hole transport efficiency by incorporating a thinner perovskite, (2) to realize narrowband NIR detection through buildup of the space charges at the perovskite/polymer interface, and (3) to improve the device design freedom by incorporating different combinations of perovskite charge transporting layer and the NIR absorbing layer in the perovskite/polymer structure. The hybrid PDs with a thinner photoactive layer results in an obvious increase in the responsivity and response speed. The hybrid PDs thus demonstrated have a narrowband NIR detection and a -3 dB cut-off frequency of 300 kHz, offering an exciting option for a plethora of applications in bio-imaging, environmental detection, and security monitoring.

7:20 PM EN06.03.03
A Perovskite Retinomorphic Sensor John G. Labram and Cinthya K. Trujillo Herrera; Oregon State University, United States

Designed to outperform conventional computers when performing machine-learning tasks, neuromorphic computation is the principle whereby certain aspects of the human brain are replicated in hardware. While great progress has been made in this field in recent years, almost all input signals provided to neuromorphic processors are still designed for traditional (von Neumann) computer architectures. For example, in a CCD detector an array of pixels is sampled at fixed intervals in time.

In this work we have taken inspiration from the human retina and demonstrated an event-driven sensor which pre-processes optical signals by design. Using a metal halide perovskite thin film as one dielectric layer of a bilayer capacitor, we demonstrate a device which changes its capacitance under illumination. When in series with a resistor, and a constant bias is applied across this device, the voltage dropped across the resistor will spike temporarily as the capacitor (dis)changes, before returning to its equilibrium value. The result is a sensor which spikes in response to changes in illumination, but otherwise outputs zero voltage. A simple model was developed to parameterize and simulate these sensors.

It is hoped that this work represents the first step towards a paradigm shift for the design of sensing systems for neuromorphic computation, and artificial intelligence in general. When combined with similar spiking sensors that respond to other stimuli (e.g. sound, vibration, temperature, etc..), the academic and commercial communities should be able to realize complex sensing systems for a broad range of applications in artificial neural networks. Such a sensor is not only optimized for use with spiking neuromorphic processors but anticipated to have broad appeal from fields such as LIDAR (light detection and ranging), autonomous vehicles, facial recognition, navigation, and robotics.

Enhanced Memory Properties in Tailored 2D/3D Halide Perovskite Heterointerface Resistive Switching Memory SangMyeong Lee, Won Bin Kim, Gill Sang Han and Hyun Suk Jung; Sungkyunkwan University,

Korea (the Republic of)

Halide perovskites (HPs) has been conceived as resistive switching (RS) memory devices; this is due to their low operation voltage, high on/off ratio, and tunable band gap. However, the HP-based RS memory devices have several challenges owing to the short endurance of 350 cycles, data retention of 4×10^3 s and stability of perovskite film.[1,2] Herein, 2D/3D halide perovskite heterointerface was made by a low-temperature all-solution process. The 2D/3D halide perovskite RS memory devices exhibits excellent performance with an endurance of 2700 cycles, a high on/off ratio of 10^6, and data retention of 10^4 s. The 2D halide perovskite layer could disturb the Ag ion migration into the 3D halide perovskite layer by calculated thermally-assisted ion-hopping activation energy and the results of the time-of-flight secondary ion mass spectroscopy. Moreover, the 2D halide perovskite layer controls the rupture of the Ag conductive filament. Therefore, the 2D halide perovskite layer enhances the RS memory properties by controlling both Ag migration and filament rupture. This study provides another strategy for improving memory properties of HPs based resistive switching memory devices.

Lead Iodide Hybrids with Aromatic Diammonium Cations—From 2D Dion-Jacobson Perovskites to 3D Hybrid Structures. Xiaotong Li[1], Weijun Ke[1], Yihui He[1], Peijun Guo[2], Mikaël Kepenekian[3], Boubacar Traore[3], Jacky Even[3], Claudine Katan[3], Constantinos Stoumpos[1], Richard Schaller[2] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States; [3]University of Rennes, France

Aromatic diammonium cation, x-(aminomethyl)pyridinium (AMPY, x = 3 or 4) can form 2D Dion-Jacobson lead iodide perovskite, which adopt the general formula of $(xAMPY)(MA)_{n-1}Pb_nI_{3n+1}$ (MA = methylammonium, n = 1−4). By modifying the position of the $-CH_2NH_3^+$ group from 4AMPY to 3AMPY, the stacking of the inorganic layers changes from exactly eclipsed to slightly offset. The perovskite octahedra tilts are also different between the two series, with the 3AMPY series exhibiting smaller bandgaps than the 4AMPY series. Compared to the aliphatic cation of the same size (AMP = (aminomethyl)piperidinium), the aromatic spacers increase the rigidity of the cation, reduce the interlayer spacing and decrease the dielectric mismatch between inorganic layer and the organic spacer, showing the indirect but powerful influence of the organic cations on the structure and consequently on the optical properties of the perovskite materials. Preliminary solar cell devices based on the n = 4 perovskites as absorbers of both series exhibit promising performances. More interestingly, when using 1:4 ratio of AMPY:PbO as starting materials, totally different structures with 3D connection motif form instead. However, because of the steric requirement of the Goldschmidt tolerance factor rule, it is impossible for $(xAMPY)M_2I_6$ to form proper perovskite structures. Instead, a combination of corner-sharing and edge-sharing connectivity is adopted in these compounds leading to the new 3D structures. Devices of $(3AMPY)Pb_2I_6$ crystals exhibit clear photoresponse under ambient light without applied bias, reflecting a high carrier mobility (μ) and long carrier lifetime (τ) and great potential for photo and X-ray detection applications.

High Performance Perovskite Solar Cells via Two-Step Deposition Jingbi You; Chinese Academy of Sciences, China

The champion efficiency of perovskite solar cells is over than 25%, which is great potential for practical application. Most of the high performance perovskite solar cells are based on the one step deposition with solvent engineering. Two-step deposition is easily controlled, and could be good for deposition of uniform and large area devices, while the efficiency of the device using two-step method is lag behind the one step. Here, we rationally designed the two-step method, and pushed the perovskite solar cells performance close to 25%.

9:25 PM *EN06.04.02
Smart Interface Engineering to Achieve Perovskite Solar Cells with Low Energy Loss, High Operational Stability and the Capability to Capture Degraded Pb-Containing By-Products Alex Jen; City University of Hong Kong, Hong Kong

Minimizing energy loss is a key aspect to transcend the current limitations on the performance of perovskite photovoltaics (PVSC). Our recent study combined composition and interface engineering to dramatically improve the efficiency and long-term operational stability of the PVSC. Moreover, a very innovative approach has also been developed to combine both efficient charge extraction and the ability to trap decomposed Pb-containing perovskites into one material to address the most challenging environmental contamination issue for the commercialization of PVSCs.

This talk will be divided into two parts: (1) Progress of achieving the highest efficiency (23.4%) in inverted perovskite solar cells (PVSCs) through smart engineering of the interfaces; (2) Demonstration of the simultaneous achievement of high PCE (>22%), excellent operational stability (85°C at MPP for 1000h under 1 Sun illumination), and the ability to capture degraded Pb-containing by-products by employing 2D metal-organic frameworks (2D-MOF) as a charge extraction layer in PVSCs.

9:50 PM *EN06.04.03
Interfacial Engineering for High Voltage (>1.4V) Performance of Inorganic Perovskite Solar Cells Tsutomu Miyasaka[1,2]; [1]Toin University of Yokohama, Japan; [2]Waseda University, Japan

Molecular design for improving and modifying the quality of the interfacial structures involved in carrier transports is becoming the major challenge towards high performance and stable perovskite solar cells (PSCs). Various approaches of interfacial engineering have been attempted in the past decade by using modulator molecules and mixing 2D and 3D structures to perovskites, as overviewed by our group as a comprehensive review.[1] These efforts lead to enhance the stability of the organic—inorganic hybrid perovskite devices, which have currently achieved a record efficiency of 25.5%. However, organic cations in hybrid perovskites (methylammonium, etc.) and use of diffusible ionic dopants in hole transport materials (HTMs) are responsible for low stability of perovskites at high temperatures (>120ºC). In this respect, use of all-inorganic perovskite materials and dopant-free HTMs will be a main direction of perovskite photovoltaics.[2] $CsPbX_3$(X=Br, I) is the widely studied candidate of the all-inorganic materials although the stability of its photo-active black phase depends on the halide composition and $CsPbI_3$ lacks in high stability. We have conducted the device fabrication using $CsPbI_2Br$ as the perovskite absorber. The $CsPbI_2Br$ film was made into junction with a solution-processed film of dopant-free HTMs which are copolymer materials and thermally stable up to 300ºC. The quality of interfacial structure at the $CsPbI_2Br$ and HTM junction was improved by inserting an ultra-thin layer (<3 nm) of amorphous SnOx. The all-inorganic and dopant-free PSCs thus fabricated yielded a power conversion efficiency exceeding 15%. Further we could enhance the open-circuit voltage (Voc) of this PSC up to 1.42V as the highest Voc ever achieved with a single perevskite cell.[3] In preparation of all-inorganic perovskites, a big challenge should also be directed to development of lead-free perovskite materials for environmental safety in

practical applications.[2]
All-inorganic dopant-free PSCs are expected to have robust stability against high temperatures. Among extensive applications, use of thermally robust PSCs in space environments is promising because the device is exposed to temperatures in the range of —100 to +100ºC. Further, thin perovskite photovoltaic films demonstrate high stability and tolerance against exposure to high energy particle irradiations (proton and electron beams).[4,5] In the near future, perovskite photovoltaics will undergo more research for space applications.

10:15 PM EN06.04.04
Interface Passivation by Atomic Layer Deposition of Alumina in Inverted (p-i-n) Perovskite Solar Cells
Tamanna Mariam, Ramez Hosseinian Ahangharnejhad, Zhaoning Song, Abdul Quader, Zahrah Almutawah, Suman Rijal, Kamala Khanal Subedi, Adam Phillips, Yanfa Yan, Randy J. Ellingson and Michael Heben; University of Toledo, Wright Center for Photovoltaics Innovation and Commercialization, United States

Over the past decade heavy investment in understanding perovskite solar cells have led to high power conversion efficiency (PCE) regular (n-i-p) structure devices fabricated from low cost, scalable methods. In recent years, interest in the inverted structure (p-i-n) perovskite solar cells due to suppressed hysteresis effects, lower temperature processing, flexibility, and, most importantly, applications in tandem structures. However, the device performance of inverted structure devices lags behind, likely due to added recombination at one or both of the perovskite/charge transport layer (CTL) interfaces. Here, we investigate passivation of both of these interfaces to reduce the interfacial recombination in the inverted planar perovskite solar cell. For this study we use fully solution processed Poly[bis(4-phenyl) (2,5,6-trimethylphenyl) amine (PTAA) hole transport layer (HTL) and (6,6)-phenyl C61 butyric acid methyl ester (PCBM)/Bathocuproine (BCP) electron transport layer (ETL). For the absorber perovskite material, we use a triple cation and mixed halide material with composition $Cs_{0.05}(FA_{0.83}MA_{0.17})_{0.95}PbI_{0.83}Br_{0.17}$ and 1.62 eV bandgap. For the passivation layer we use alumina (Al_2O_3) deposited via atomic layer deposition. We fabricated devices with and without alumina at the HTL/perovskite, perovskite/ETL and both CTL/perovskite interfaces. The unpassivated devices show Voc of 1.08 V, fill factor (FF) of 72.1% and PCE of 15.4%. The Voc does not change when the alumina is included at the HTL/perovskite interface, but the FF improves to 74.8%, leading to a PCE of 15.7%. When less than 1nm of alumina is added at only the perovskite/ETL interface, the Voc does not change, but the FF and PCE increase to 75.8% and 16.2%, respectively; however, when the alumina thickness is 1-1.6 nm, the V_{OC}, FF and PCE increase to 1.10 V, 76.0% and 16.5%, respectively. When 1-1.6 nm of alumina is included at both CTL/perovskite interfaces, the performance increases further, with champion devices exhibiting PCEs of 18.3% with Voc of 1.11 V and FF of 76.8%. In addition, the passivated devices show less hysteresis than unpassivated devices. These results demonstrate that the interface between the CTL and perovskite affects the devices performance, and that thin layers of inorganic materials can be used to reduce the interfacial recombination. In addition, incorporation of an inorganic layer at both perovskite interfaces may lead to an encapsulation-like effect and reduce degradation of the devices through several mechanisms, including limiting water ingress. The device performance is being monitored to investigate if this is the case. The results show a promising next step toward developing high PCE and stable inverted perovskite solar cells via interface passivation.

10:30 PM EN06.04.05
Fracture Behavior of Organic-Inorganic Halide Perovskite Thin Films for Solar Cells Zhenghong Dai,

Srinivas Yadavalli and Nitin Padture; Brown University, United States

Organic-inorganic halide perovskites (OIHPs) has emerged as the most promising light-absorber materials in the photovoltaic community due to their near-ideal bandgaps. However, the low formation energies of OIHPs render them unstable. While significant progress has been made in improving the stability of OIHPs, perovskite solar cells (PSCs) will also need to be mechanically reliable if they are to service satisfactorily for years. In this context, we study the fracture behavior of PSCs by measuring their cohesion energies (Gc) using double cantilever beam method and report a novel approach to strategically enhance the interfacial adhesion and performance of PSCs by interface modification. The reliability was greatly improved after interfacial toughening. This work points to a new route for designing mechanically robust PSCs with long-term durability.

10:45 PM EN06.04.06

Late News: Conversion of P-Type to N-Type Surface of Tin-Lead Perovskite Leading to Efficiency More Than 22% Gaurav Kapil[1,2], Takeru Bessho[2], Qing Shen[1], Hiroshi Segawa[2] and Shuzi Hayase[1]; [1]The University of Electro-communications, Japan; [2]The University of Tokyo, Research Center for Advanced Science and Technology, Japan

Introduction

Tin-lead (Sn-Pb) perovskite solar cells (PSCs) are now getting great attention due to the rapid increase in photoconversion efficiency (PCE) more than 20%, which brings them near to their Pb counterparts [1]. They possess the bandgap of 1.2-1.3 eV, which is according to Shockley-Queisser (SQ) limit can give higher PCE than Pb-PSCs where bandgap lies in between 1.45-1.55 eV. Also, according to SQ limit the Voc of 0.9-1 eV is possible for the solar absorbing materials with a bandgap of 1.2-1.3 eV [2]. In our previous work, we have reported a PCE of 20.4% using $Cs_{0.025}FA_{0.475}MA_{0.5}Sn_{0.5}Pb_{0.5}I_3$ (1.27 eV) perovskite as the absorber layer in PSCs with a Voc of 0.81 V [3]. In the work, we revealed that lattice strain relaxation is one of the important properties to look for cation mixing at A position of ABX_3 (where, A is monovalent cation, B is bivalent cation and X is halide anion) perovskite. Therefore, following the same strategy, in the present research, we added a small fraction of Br anion with I anion at X position that led to further decrease in lattice strain and reduction of urbach energy that resulted into increase in Voc. In addition to this, we used Lewis base surface passivation that solved the two major problems of Sn-Pb perovskite, first is the reduction in formation of amount of Sn^{4+} and second is neutralization of positive surface of perovskite due to I anion vacancy. Further, it is shown that lewis base post treatment of tin-lead perovskite led to the evolution of n-type surface that resulted in increased electron diffusion length and charge collection in the device.

Results and discussion

The perovskite used in the study is $Cs_{0.025}FA_{0.475}MA_{0.5}Sn_{0.5}Pb_{0.5}I_{3-x}Br_x$ (where x=0, 0.025, 0.05, 0.1). Four devices with different concentration of Br anion are prepared such as Br 0%, Br 2.5%, Br 5% and Br 10%. Device with Br2.5% showed a best PCE of 21.10% with a FF of 0.81, Voc of 0.84V and Jsc of 31.22 mA/cm^2. The change PCEs with Br concentration is well supported by UV, PL, SEM, XRD, XPS analysis of perovskite films. Finally, PSC with 22.64% (highest so far in Sn-Pb) after optimization will be reported.

Tetrazine-Incorporating Layered Halide Perovskites Featuring Type II Electronic Interface—A Small Cation with Several Optical and Electronic Resonances Emmanuelle Deleporte[1], Ferdinand Lédée[1,1], Pierre Audebert[1], Gaëlle Trippé-Allard[1], Laurent Galmiche[1], Damien Garrot[1], Jérome Marrot[1], Jean-Sébastien Lauret[1], Claudine Katan[2], Jacky Even[2] and Claudio Quarti[2,3]; [1]Université Paris-Saclay, France; [2]Univ Rennes, France; [3]University of Mons, Belgium

2D-layered perovskites form assembled natural quantum well structures, where the perovskite layer is separated by large organic cations. They have been known for decades, but they are attracting growing interest, for their strong photoluminescence properties, their chemical versatility and their low sensitivity to external degradation mechanisms due to UV light and moisture. In particular, the chemical versatility of the organic part is a decisive advantage compared to their 3D counterparts.

Energy matching and band alignment engineering between the organic/inorganic parts can either be done by tuning the halide composition, by modifying the number of haloplumbate layers or by adjusting the HOMO/LUMO gap and/or levels of the organic spacer, that is to say by incorporating optically active molecules in the perovskite structure. In this case, instead of playing a simple passive barrier role, the organic part can be used to engineer the optoelectronic properties to these materials. Depending on the optical matching, defined for hybrid perovskites as the spectral overlap between the perovskite and organic absorbers optical transitions, along with the type I/II of interface, charge and/or energy transfers can be induced between the inorganic and organic moieties

We have synthesised two novel layered perovskites containing optically active s-tetrazine (R-C_2N_4-R) as sole included organic spacer. Thanks to the various energy resonances between the inorganic and the organic component, both at the level of the single particle electronic states and at the level of many-body exciton states, this system represents the ideal test case to discuss in the detail charge and energy transfer processes at the type II interface. Furthermore, the incorporation of this novel chromophore as spacer is based on a new design concept, which exploits heterocycles with large fraction of nitrogen, rather than extending the size of carbon-based pi-core. We further performed extensive optical characterization supported by computational studies, in order to gain a complete picture of all potential charge and energy transfer processes ongoing in this complex perovskite-luminophore system. More specifically, both excited states as well as band alignment were studied to rationalize the complete quenching of the perovskites light-emission. We conclude that several decay channels may coexist between the s-tetrazine and the perovskite frame, and highlight the necessity of depicting these materials at the level of both excitonic and monoelectronic states.

Superfluorescence in Assemblies of Cesium Lead Halide Quantum Dots Michael Becker[1], Gabriele Rainò[2,3], Franziska Krieg[2,3], Ihor Cherniukh[2,3], Yuliia Berezovska[2,3], Maryna Bodnarchuk[2,3], Rainer Mahrt[1], Maksym Kovalenko[2,3] and Thilo Stoeferle[1]; [1]IBM Research Europe - Zurich, Switzerland; [2]ETH Zürich, Switzerland; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Fully inorganic cesium lead halide nanocrystals exhibit giant oscillator strength and long dephasing times at cryogenic temperature, making them ideally suited to explore settings that make use of their exceptionally strong intrinsic light-matter coupling. Through drying-mediated self-assembly of the colloidal perovskite nanocrystals, we can realize various superlattice geometries.

In these assemblies, we observe coherent, cooperative emission so-called superfluorescence. There the quantum dots spontaneously synchronize, thereby forming effectively a giant dipole, and emit an intense burst of light. We will discuss the characteristic signatures of excitation-dependent decay acceleration, superlinear burst intensity and Burnham-Ciao ringing within the different assemblies. Furthermore, we will compare the behavior in these assemblies to giant nanocrystals.

Our experiments demonstrate that in contrast to many other quantum dot systems, cesium lead halide nanocrystals can be made with sufficiently small energy spread to efficiently couple many of them and explore collective optical properties. Superlattices of these nanocrystals are a versatile tool that opens a new door to

investigate these effects.

New 2D Iodide Perovskites for Stable Photovoltaics Mercouri G. Kanatzidis; Northwestern University, United States

The 2D halide perovskites layers can be formed by the introduction of bulky organic cations that tend to interdigitate between the perovskite sheets. It is a multi-member family of materials with variable thickness of the inorganic slabs presents natural quantum wells (QW) type structures with increased Coulombic shielding, lowering the exciton binding energy and increasing the effective charge carrier mobility. These materials are enabling higher solar cell stabilities and record-breaking efficiencies. It is important to understand the thermodynamic and chemical limitations of their structures and how they vary from one 2D member to the next. We employ a combination of synthetic chemistry, calorimetry and crystallography to obtain and identify the thickest known 2D halide perovskite compound characterized to date and we use thermodynamics analysis to assess the enthalpy of formation for these compounds. The current application of these low dimensional semiconductors in stable photovoltaics will be discussed.

Mixed-Metal Perovskites and Expanded Perovskite Analogs Kurt Lindquist[1], Daiki Umeyama[2,1], Michael Boles[1], Adam Slavney[1], Stephanie Mack[3,4], Linn Leppert[5], Jeffrey B. Neaton[4,3] and Hemamala Karunadasa[1,6]; [1]Stanford University, United States; [2]National Institute for Materials Science, Japan; [3]University of California, Berkeley, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]University of Twente, Netherlands; [6]SLAC National Accelerator Laboratory, United States

Halide perovskites provide a flexible platform for tuning optoelectronic properties through changes in composition, connectivity, and dimensionality. I will present our recent studies on further increasing the accessible electronic structures of this versatile family of materials by synthesizing mixed-metal perovskites and expanded analogs of halide perovskites. Through both stoichiometric and substoichiometric metal substitutions we can synthesize a variety of halide perovskites, including those with unprecedented lattices and unusual electronic structures. I will also discuss our recent efforts on expanding the cavities in typical 3D perovskites to incorporate more complex organic ions, including aromatic molecules with low-lying states that form the conduction band and organic radicals that add spins to the lattice.

Room Temperature Printing and *In Situ* Investigation of Perovskite Thin Films for Printable Solar Cells Gang Li; The Hong Kong Polytechnic University, Hong Kong

Hybrid organo-metal halide perovskite solar cells (PSCs) are promising candidates for next generation photovoltaic device primarily due to their high efficiency, printability and low cost. PSCs have exhibited externally verified power conversion efficiencies (PCE) exceeding 25% outclass from 3.8% in 2009, which have encouraged recent efforts on scalable coating technique in PSCs towards manufacturing. However, devices fabricated by scalable techniques are still lagged the state-of-the-art spin coated devices because the power conversion efficiency (PCE) is highly dependent on the morphology and crystallization kinetics under a controlled environment, and delicate solvent system engineering.

In this talk, we will present the recent works using in-situ technique to guide the development of high performance PSCs using blade coating technology.
(a). Via a laminar air-knife assisted room temperature meniscus coating approach to control the drying kinetics during the solidification process, we recently manufacturing friendly, antisolvent-free room-temperature coating of hysteresis-free PSCs with power conversion efficiency (PCE) of 20.26% for 0.06 cm2 and 18.76% for 1 cm2 devices. Moreover, this approach offers a solid model platform for in-situ UV-vis and microscope investigation of the perovskite film drying kinetics.
(b) One step further, based on the widest studied champion perovskite solution system DMF-DMSO, we report air-knife assisted fabrication of perovskite solar cell in AMBIENT condition at high relative humidity of 55±5%. In-depth in-situ time-resolved UV-vis spectrometry is carried out to investigate the impact of solvent removal and crystallization rate, which are proven to be a critical factor on influencing the crystallization kinetics and morphology due to moisture attack. The UV-vis spectrometry also enables accurate determination of wet precursor film thickness – a key parameter for fabrication. Anti-solvent free, high humidity ambient coating of hysteresis-free PSCs with PCE of 21.1% and 18.0% are demonstrated for 0.06 cm^2 and 1 cm^2 devices, respectively. These PSCs coated in high humidity ambient conditions also show comparable stability with those made in N2 glovebox.
(c) The room temperature meniscus coating of high-quality perovskite films incorporated with a multifunctional sulfobetaine based zwitterionic surfactant. Systematic in-situ studies uncover the perovskite crystallization pathway and emphasize the surfactant's synergistic role in film construction, crystallization kinetics modulation, defect passivation, and moisture barrier protection. This strategy is applicable across perovskite compositions and device architectures with the enhanced power conversion efficiencies up to 22%. In addition, this approach significantly improves the stability of perovskite films and devices under different aging conditions.

Halide Perovskite Perovskite Stabilization by the use of Embedded Nanostructures and Outdoor Characterization Ivan Mora-Sero; Universitat Jaume I, Spain

The interaction of halide perovskite and colloidal semiconductor nanostructures (quantum dots or nanoplatelets) can produce interesting synergistic interactions. We show that the interaction of PbS quantum dots and nanoplatelets can produce the stabilization of $FAPbI_3$ and $FACsPbI_3$ perovskite black phase and also the increase of the efficiency, stability and reproducibility of the photovoltaic devices prepared with these halide perovskites. Incorporation of PbS QDs allows the dramatic decrease of the annealing temperature for the formation of black $FAPbI_3$ phase perovskite thin film, from the 170C required without QDs to 85C when QDs are present. In addition, stability of these systems including embedded nanostructures is extended not just for samples prepared in the glove box but fabricated in ambient conditions. These result points the interest of Perovskite-Quantum Dot Nanocomposites, for further development of advanced optoelectronic devices.
In addition, a new methodology to analyze halide perovskite outdoor will be described. We will show that this methodology complement the analysis obtained with the figure of merit T_{80}, parameter that refers to the time at which the device reaches 80% of its initial rated power, providing further physical insight into the recombination mechanism dominating the performance, improving the understanding of the degradation processes and device characterization.

Dynamical 2D/3D Interfaces a Boost to Perovskite Solar Cell Stability—Processes and Energetics Behind
Giulia Grancini; Università degli Studi di Pavia, Italy

Engineering two-/three- dimensional (2D/3D) perovskite solar cells is nowadays a popular strategy for efficient and stable perovskite solar cells [1-3].
However, the exact function of the 2D/3D interface in controlling the long-term device behavior and the interface physics therein are still obscure.
Here I will discuss the 2D functions which can simultaneously act as surface passivant, electron blocking layer, a sheath to physically protect the 3D underneath, but also impact on the ion movement and charge accumulation. We found a peculiar dynamical structural mutation happening at the 2D/3D interface: the small cations in the 3D cage move towards the 2D layer, which acts as an ion scavenger. If structurally stable, the 2D physically blocks the ion movement at the interface boosting the device stability. Otherwise, the 2D embeds them, dynamically self-transforming into a quasi-2D structure. [2]
In concomitance, we discovered that the stable 2D perovskite can block ion movement, improving the interface stability on a slow time scale. [2,4]
The judicious choice of the 2D constituents is decisive to control the 2D/3D kinetics and improve the device lifetime, but also can impact on the interface energetics, which can vary and influence the interface processes and ultimately device open circuit voltage. This knowledge turns fundamental for device design, opening a new avenue for perovskite interface optimization.

Rapid Open-Air Fabrication of Perovskite Solar Modules Nicholas Rolston[1], William Scheideler[2], Austin Flick[1], Justin Chen[1], Hannah Elmaraghi[1], Andrew Sleugh[1], Oliver Zhao[1], Michael Woodhouse[3] and Reinhold Dauskardt[1]; [1]Stanford University, United States; [2]Dartmouth College, United States; [3]National Renewable Energy Laboratory, United States

We report on the scalable open-air fabrication of large-area perovskite solar modules comprising several key advances in the field including scalable large-area spray deposition, new scribing techniques for monolithic integration, advanced optoelectronic characterization using photoluminescence, and a demonstration of reproducibility and high-throughput manufacturability across multiple module batches and open-air process environments. The Rapid Spray Plasma Processing (RSPP) method enables crystallization of perovskite films in ambient with linear speeds of 12 m/min without a post-anneal. RSPP is a moisture-resistant process with better device performance, higher luminescent yield over the largest reported field of view in literature, and carrier lifetimes > 10X than spin coated perovskite to achieve the highest device performances for open-air perovskite deposition. Manufacturability and reproducibility of RSPP is shown using monolithic integration of series-connected modules with 17 subcells on active areas of 5.9 cm^2 with a rapid fiber laser scribing method. This low-cost, 1064 nm laser scribing process using a unique indirect ablation mechanism has not been demonstrated in literature and is fully compatible with all scribing processes for monolithic integration. A stable cell and module power output of 18.0% and 15.5%, respectively, was achieved with a subcell V_{oc} > 1.06 V that is reproducible and significantly outperforms spin-coated modules. A comprehensive and complete technoeconomic model for the full 9-step in-line perovskite manufacturing process starting with the glass substrate and ending with the junction box of the encapsulated module is used to calculate the module manufacturing cost, to estimate the balance of system costs and to determine a levelized cost of energy for a range of module efficiencies and lifetimes. The analysis provides novel insights and guidelines for necessary

tool speeds, efficiencies, and lifetimes to enable the viability of perovskite module manufacturing for utility-scale energy generation.

***In Situ* Grazing-Incidence Wide-Angle X-Ray Scattering Reveals Mechanisms for Phase Distribution and Disorientation in 2D Halide Perovskite Films** Justin M. Hoffman[1], Joseph Strzalka[2], Nathan C. Flanders[1], Ido Hadar[1], Shelby A. Cuthriell[1], Qingteng Zhang[2], Richard Schaller[2], William Dichtel[1], Lin X. Chen[2] and Mercouri G. Kanatzidis[1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Two-dimensional (2D) hybrid halide perovskites with the formula $(A')_2(A)_{n-1}Pb_nI_{3n+1}$ have remarkable stability and promising efficiency in photovoltaic and optoelectronic devices, yet fundamental understanding of film formation, key to optimizing these devices, is lacking. In particular, understanding the processes that lead to the perpendicular orientation of the layers in relation to the substrate, essential for charge carrier extract, and the phase distribution, which has been shown to have a beneficial carrier cascade effect, is needed. Here, in-situ grazing-incidence wide-angle X-ray scattering (GIWAXS) is used to monitor film formation during spin-coating.[1] This elucidates the general film formation mechanism of 2D halide perovskites during one-step spin-coating. There are three stages of film formation: sol-gel, oriented 3D, and 2D. Three precursor phases form during the sol-gel stage and transform to perovskite, first giving a highly oriented 3D-like phase at the air/liquid interface followed by subsequent nucleations forming slightly less oriented 2D perovskite. Furthermore, heating before crystallization leads to fewer nucleations and faster removal of the precursors, improving orientation. This outlines the primary causes of phase distribution and perpendicular orientation in 2D perovskite films and paves the way for rationally designed film fabrication techniques.

Using Electrohydrodynamic Deposition as a Potentially Useful Method for In-Space Manufacture of Perovskite Solar Cells Samuel Erickson[1], William G. Delmas[1], Albert Dibenedetto[1], Lyndsey McMillon-Brown[2], Timothy Peshek[2] and Sayantani Ghosh[1]; [1]University of California, Merced, United States; [2]NASA Glenn Research Center, United States

The difficulty in fabricating lightweight, stable, and efficient photovoltaic devices is compounded when in done *in situ* during space missions. Popular deposition techniques like spin coating and drop casting require gravity, making them useless in orbit. To overcome this problem, we have developed a thin film preparation technique utilizing electrohydrodynamic deposition (EHD). This technique entails drawing bi-solvent perovskite precursor solution from a source needle to substrate via an applied electric field. The difference in vapor pressure between the solvents drives surface coverage and film formation in a phenomenon known as Marangoni flow. Thus, EHD is not only a versatile and scalable method, but uniquely suited to our goal of developing stable and high-efficiency thin film devices without assistance from a gravitational field.

In addition to the deposition technique, other factors, including the chemical composition of the absorbing layer, selection of charge transport layers, and thickness of each layer, are among the dozens of choices that must be made when making a photovoltaic device. To best direct our research, metrics such as power conversion efficiency (PCE), annealing temperature, and long-term stability were extracted from literature published during between 2012 and the present. These variables were then analyzed to find useful correlations and compositions among high-performing cells.

A key trend among devices is the moderate correlation between number of cations in a cell and its efficiency.

While this may not be surprising, we found that the efficiency of methylammonium/formamidinium (MA/FA) lead perovskite cells was comparable to, or better than, cesium/MA/FA (Cs/MA/FA) cells. Since Cs greatly complicates fabrication and is generally added for increased stability (unnecessary for cells in space), we choose to focus on MA, followed by MA/FA films. Another influential finding was that cells with high PCE used tin oxide as their electron transport layer (ETL), which will also be incorporated in our devices. Other key findings include interesting trends regarding the relative roles of open circuit voltage versus short circuit current, and the halide composition of the perovskite.
This talk will focus on the EHD process, the data analytics, and our results in thin film fabrication.

Compositional and Defect Engineering in Halide Perovskite and Multinary Chalcogenide Solar Absorber Materials David B. Mitzi; Duke University, United States

Chalcogenide CdTe and $Cu(In,Ga)(S,Se)_2$ (CIGS) and halide-perovskite-related (e.g. $CH_3NH_3PbI_3$) semiconductors represent the fastest growing commercial and the most vigorously studied thin-film photovoltaic (PV) technologies, respectively. Alternatives to these semiconductors are also being sought to mitigate toxicity and elemental abundance concerns, for improved compatibility with pervasive scaling of the technologies. Inherent to these pursuits, is the need to understand materials and device limitations, especially as they relate to defects. In this talk, we will consider additive engineering and doping in $CH_3NH_3PbI_3$-related semiconductors [1,2], as well as proposed defect-resistant $Cu_2Ba(Sn,Ge)(S,Se)_4$ materials [3,4], and employ a range of characterization techniques, including carrier-resolved photoHall, conventional Hall effect, terahertz spectroscopy and other time-resolved spectroscopies, to understand associated properties and performance-limiting or -enhancing mechanisms.

Searching Stable Perovskite Solar Cell Materials Using Materials Genome Techniques and High-Throughput Calculations Su-Huai Wei; Beijing Computational Science Research Center, China

The solar cells based on the emerging organic-inorganic hybrid halide perovskite is progressing rapidly in the last decade, but the commercialization of the perovskite solar cells still faces significant challenges. The major issues are the poor long-term stability and toxicity. In light of this, materials design and screening of novel stable perovskites is becoming an important research direction. In contrast to conventional *trail-and-error* processes, materials genome techniques and high-throughput calculations have played important roles in this area and accelerated materials discovery. In this talk, I will present a review that summarizes our recent progress in this field, mainly focusing on four classes of perovskites including $AM^{2+}X_3$ halide single

perovskites, $AM^{4+}Y_3$ chalcogenide single perovskites, $A_2M^{+}M^{3+}X_6$ halide double perovskites, and $A_2M^{3+}M^{5+}Y_6$ chalcogenide double perovskites. The stability, electronic, optical, and defect properties of these materials in terms of their applications as solar cell absorbers are discussed.

8:35 PM *EN06.07/EN07.10.03
Carrier-Resolved Photo-Hall Effect in High Performance Perovskite Solar Absorbers Oki Gunawan[1], Seong Ryul Pae[2], Byungha Shin[2], Douglas M. Bishop[1] and David B. Mitzi[3]; [1]IBM T.J. Watson Research Center, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Democratic People's Republic of); [3]Duke University, United States

Majority and minority carrier properties such as type, density and mobility represent fundamental yet difficult to access parameters governing semiconductor device performance, most notably solar cells. Obtaining this information simultaneously under light illumination would unlock many critical parameters such as recombination lifetime, recombination coefficient, and diffusion length, however this goal has remained elusive. We demonstrate here a new carrier-resolved photo-Hall technique that rests on a new equation relating hole-electron mobility difference ($\triangle\mu$), Hall coefficient (H), and conductivity (σ), and a rotating parallel dipole line ac-field Hall system with Fourier/lock-in detection for clean Hall signal measurement (Nature 575, 151, 2019). We successfully apply this technique to a world-record-quality perovskite film and map the results against varying light intensities, demonstrating unprecedented simultaneous access to the above-mentioned parameters.

9:15 PM *EN06.07/EN07.10.04
Advances and Challenges for Commercialization of Perovskite Solar Cells Yulia Galagan; National Taiwan University, Taiwan

The interest in perovskite photovoltaics has significantly increased over the last few years. High power conversion efficiencies (PCE) and low-cost manufacturing make perovskite PVs a very promising candidate for future applications. Despite the very advantageous features of perovskite materials, several issues still need to be solved before the commercialization of perovskite solar cells (PSCs). The main challenges of bringing perovskite technologies to the market are (i) scaling-up of the cells and modules dimension, (i) usage of lead in the perovskite solar panels and (iii) stability of the PSC modules. These three challenging topics will be discussed in the presentation, and possible solutions to overcome these issues will be proposed. The implementation of the proposed measures will help to demonstrate the feasibility of high-volume production. It is an important milestone towards the industrial manufacturing of perovskite photovoltaics and their future commercialization.

9:40 PM EN06.07/EN07.10.05
Analysis for Efficiency Potential of II-VI Compound, Chalcopyrite and Kesterite Based Tandem Solar Cells Masafumi Yamaguchi[1], Hitoshi Tampo[2], Hajime Shibata[2], Nobuaki Kojima[1] and Yoshio Ohshita[1]; [1]Toyota Tech. Inst., Japan; [2]National Institute of Advanced Industrial Science and Technology, Japan

PV-powered vehicle application are very attractive for reducing CO_2 emission and creation of new market. Development of high-efficiency (> 30%) and low-cost solar cell modules is necessary [1]. The II-VI compound, chalcopyrite and kesterite based tandem solar cells are thought to be one of the most promising PV devices because of high-efficiency and low-cost potential. However, efficiencies of II-VI compound, chalcopyrite and kesterite based tandem solar cells (27.2% with III-V/CIGS 3-junction, 24.2% with perovskite/CIGS 2-junction, 16.8% with CdZnTe/Si 2-junction, 15.3% with CdTe/CISe 2-junction, 8.5% with CGSe/CIGSe 2-junction, 3.5% with CZTS/Si 2-junction tandem solar cells) are lower compared to 37.9% with III-V 3-junction and 35.9% with III-V/Si 3-junction tandem solar cells. Therefore, it is necessary to clarify and reduce several losses of tandem solar cells. This paper presents high efficiency potential of II-VI compound, chalcopyrite and kesterite based tandem solar cells analyzed by using our analytical procedure [2] and discusses about non-

radiative recombination losses in those tandem solar cells.
One of problems to attain the higher efficiency II-VI compound, chalcopyrite and kesterite based tandem solar cells is to reduce non-radiative recombination loss. The open-circuit voltage V_{oc} drop compared to bandgap energy (E_g/q - V_{oc}) is dependent upon non-radiative voltage loss ($V_{oc, nrad}$) that is expressed by external radiative efficiency (ERE). Open-circuit voltage is expressed by

where the second term shows non-radiative voltage loss, is radiative open-circuit voltage and 0.23V was used as $\triangle$ (= E_g/q -) in this study.
Correlation between V_{oc} values for II-VI compound, chalcopyrite and kesterite based tandem solar cells reported in the references and ERE values estimated by eq. (1) suggests that II-VI compound, chalcopyrite and kesterite based tandem solar cells have larger non-radiative loss and further improvements in efficiency are thought to be possible by improving external radiative efficiency (ERE). The ERE values estimated in this study are 0.00116% for 27.2% III-V/CIGS 3-junction, 0.024% for 24.2% perovskite/CIGS 2-junction, 0.00162% for 16.8% CdZnTe/Si 2-junction, $1.17x10^{-5}$% for 15.3% CdTe/CISe 2-junction, $5.87x10^{-8}$% for 8.5% CGSe/CIGSe 2-junction, and $8.05x10^{-10}$% for 3.5% CZTS/Si 2-junction tandem solar cells compared to 2.2% for 37.9% III-V 3-junction and 1.62% for 35.9% III-V/Si 3-junction tandem solar cells. According to our analysis [3], the 2-junction and 3-junction tandem solar cells have potential efficiencies of more than 36% and 42%, respectively. Several non-radiative recombination losses such as bulk recombination, interface recombination and so forth in tandem solar cells are discussed in this paper. In addition, resistance loss of tandem solar cells including inter-connection is discussed in this study.

Late News: Bandgap Tuning for Pt-Based Mixed Halide-Chalcogenide Perovskites Kristen Tagaytayan[1], Rubaiya Murshed[1], Ivano Castelli[2], Benedikt Ursprung[3,4], Edward S. Barnard[4] and Shubhra Bansal[1]; [1]University of Nevada, Las Vegas, United States; [2]Technical University of Denmark, Denmark; [3]Columbia University, United States; [4]Lawrence Berkeley National Laboratory, United States

Organic-inorganic hybrid halide perovskite solar cells (HPSCs) have attracted immense attention because of excellent optoelectronic properties and a record power conversion efficiency (PCE) that has surpassed 25.5% within a few years. HPSCs are competitive with conventional thin-film and c-Si photovoltaic technologies because of their high efficiency, tunable bandgap, high absorption coefficient, and easy and low-cost fabrication. However, despite the very high efficiency already attained by $(FA,MA,Cs)Pb(I,Br)_3$ single-junction solar cells, the toxicity of Pb and stability of these materials are challenges to commercialization of this technology. Many Pb-free technologies have been developed such as GeI_2 doped Sn based perovskites with promising PCE > 13%. However, a major challenge for Pb-free perovskites is poor power conversion efficiencies as divalent Sn^{2+} and Ge^{2+} tend to oxidize into 4+ oxidation state, generating excessive defects (Sn and Ge vacancies), and result in short carrier diffusion lengths.

Cs_2PtI_6 is a high absorption coefficient and optimal bandgap (E_g = 1.4 eV) material, which has shown promising power conversion efficiency of > 12%[1]. The material has shown high absorption coefficient, carrier lifetime > 2 μs and stability to heat and light soaking stress. ITO/SnO_2/Cs_2PtI_6/PCBM/Carbon devices have also shown to be stable in air without encapsulation for 60 days[2]. Hamdan and Chandiran have demonstrated Cs_2PtI_6 photoanode to be stable under AM1.5G illumination and extreme pH for over 12 hours, making the material promising for photoelectrochemical devices[3]. Although Pt offers an ideal model system, the search for a low-cost, stable, and high performance Pb-free halide perovskite continues. Replacement of Pt with Ni for A_2BX_6 is expected to reduce the bandgap with the reduction in cation size[4]. Here, we explore the effect of Pt precursor, solvents, and Pt-Ni solid solution on optical bandgap, absorption coefficient, structure, and morphology of

Cs_2PtI_6 films.

Cs_2PtI_6 films processed with PtI_4 precursor in a solvent mixture of DMF:DMSO[5] results in crystalline films with an optical bandgap of ~ 1.4 eV. PtI_2 precursor processed with a solvent mixture of DMF:GBL also results in structure and optical bandgap albeit with higher film porosity and preferred crystallographic orientation. Both these processes result in low oxygen content in the films as confirmed by EDS and XPS. On the other hand, films processed with PtI_2 precursor in DMF:DMSO solvent mixture results in oxygen containing films with a bandgap measured as 2.2 eV using UV-Vis-NIR and photoluminescence spectroscopy. Intermixing of B cation with a 50 at% of Pt and 50 at% of Ni results in an optical bandgap of 1.48 eV with the crystal structure of Cs_2PtI_6. Detailed composition analysis shows oxygen is incorporated at anion site resulting in a mixed halide-chalcogenide phase with a tunable bandgap with oxygen concentration. $Cs_2(Pt_xNi_{1-x})(I_yO_z)_6$ offers an interesting material with tunable bandgap for optoelectronic and sensor applications.

Superlattice Formation in the Perovskite Solar Cell and Enhancement of the Photovoltaic Performance
Satoshi Uchida[1], Naoyuki Shibayama[2], Ryota Jono[3] and Hiroshi Segawa[1]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan; [3]Research Organization for Information Science and Technology, Japan

Recently organic–inorganic halide perovskite solar cell have great attention for its high performance together with easy production and wide variety of the process & flexibility of substrate materials. The power conversion efficiency has already reached over 25% in 2020 much beyond another solar cells such as CIGS or amorphous Si. The further performance still looks promising toward the Shockley–Queisser limit at around 30%. For that purpose, physical chemistry understanding based on the crystallography must be essential to design the good light harvesting, good charge separation and good charge transfer.

Recently we reported the scientific revelation that the crystal phase of thin film CH3NH3PbI3 consists of the mixture of tetragonal phase and cubic phase. Moreover bold zebra patten with d-spacing with 14.2Å (2θ=6.22° for CuKα) was clearly observed by high resolution TEM with FIB processing that consists with tetragonal and cubic phase superlattice. To make more high performance, here the crystal phase control with liquid nitrogen quenching just after the hot plate heating was newly examined. The resulting cell performance was impressive, about 2% more than that without Liq. N2 treatment. For such treatment the detail about the TEM observation will also be discussed.

8:15 AM *EN06.08.02
Guiding Automated Synthesis of Metal Halide Perovskites Towards Enhanced Stability Kate Higgins[1],

Maxim Ziatdinov[2], Sergei Kalinin[2] and Mahshid Ahmadi[1]; [1]University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Metal halide perovskites (MHPs) have significant potential to revolutionize optoelectronics yielding the next generation of highly efficient, low cost devices including solar cells, light-emitting diodes, and photodetectors. However, a new materials engineering approach is required to realize the full potential of these compounds, since MHPs have a broad range of compositions and crystal structures that yield a multitude of diverse and yet unexplored property combinations. Currently, the primary concern at the forefront of scientific and application-driven research is the stability of these materials in the pure or device-integrated form.
An automated experimental workflow based on guided combinatorial synthesis and rapid throughput characterization has been developed to explore properties and stability of metal halide perovskite systems in ambient conditions [1]. We also develop a machine learning-based workflow to quantify the evolution of each system as a function of composition based on overall changes in photoluminescence spectra, as well as specific peak positions and intensities. We will discuss the stability dependence on composition and extremely non-uniform behavior within the composition space. The interpolative regression analysis of photoluminescent properties helps to distinguish mixtures that form *solid solutions* from those that *segregate* into multiple materials in ambient conditions. In addition, the analysis of bandgap energy provides key information about the optimal compositions for certain applications. This workflow is a necessary step to guide the material synthesis and to gain an insight into the intrinsic materials stability by studying the complex phase diagram of mixed perovskites. The workflow allows not only to explore large composition spaces, but also identify stability behavior. Furthermore, it is universal, simple and can be applied to other perovskite systems and solution-processable materials and can be implemented at low cost as compared to systems reported previously, a necessary condition of rapid adoption of these approaches. To further explore the materials level stability, we have studied several compositions of MHPs using time of flight secondary ion mass spectroscopy (ToF-SIMS) under operation condition in a laterally designed electrode configuration [2,3]. To interpret the multidimensional data obtained from such experiments, we develop a machine learning workflow combining the Hough transform and non-negative matrix factorization and non-negative tensor decomposition, to avoid this limitation and extract salient features of associated chemical changes and to separate the light- and voltage-dependent dynamics. Combining these *in-situ* characterizations and this machine learning workflow provides comprehensive information on the chemical nature of moving species, ion accumulation, and interfacial electrochemical reactions in metal halide perovskites devices, feeding back into automated discovery process.

8:40 AM *EN06.08.03
Watching and Understanding the Formation of Hybrid Metal Halide Perovskites Carolin M. Sutter-Fella; Lawrence Berkeley National Laboratory, United States

Material synthesis is a very important aspect in human kinds endeavor to discover and create new materials for energy applications. In order to make materials with desired functions we need to know how these functions relate to structure, synthetic variables, arrangement of atoms and molecules and how functions evolve during synthesis.

In this regard, the field of halide perovskites moved towards more and more complex compositions enabling improved device performance and stability. Most of the improvements however, are chemical intuition driven or achieved through empirical optimization of processing conditions. Establishing the relationships between synthesis condition and film properties will enable active control of synthesis parameters and increase

reproducibility. The formation of halide perovskites from colloidal precursors including the initial stages of formation and the physicochemical evolution of properties via polydisperse nanocrystal nucleation and solvent-complexation will be discussed. We identified for example how the precursor and antisolvent influence the crystallization pathway, how morphology can be templated, and how additives can aid room temperature processing. By correlating diffraction and photoluminescence (PL) measurements, it will be demonstrated how *in situ* PL can reveal subtle changes throughout all synthesis steps including the onset of film decomposition.

9:05 AM *EN06.08.04
How *In Situ* Experiments Can Help Us to Understand Multication Perovskite Formation, Stability and Composition Ana F. Nogueira; University of Campinas, Brazil

Multicomponent perovskite solar cells have reached the recent efficiency breakthrough of 25.5%, higher than silicon polycrystalline photovoltaics. Such fantastic result was only possible due to a precise control and engineering of the morphology, interfaces and the use of multiple cations in perovskite A-site, as Rb, Cs, MA (methylamonnium) and FA (formamidinium). For tandem perovskite solar cells, a mixture of different anions, as Br and I is also desired to adjust the band gap. Such cocktail of different cations and anions influences the formation of intermediates, new phases, favours halide homogenization, etc; so that at the end, the efficiency of the device is closely related to not only the optical quality of the film (e.g. crystallinity), but morphology and composition.
In this presentation, we will summarize important results using *in situ* experiments to probe perovskite formation (2D and 3D), stability and composition. We employed time-resolved grazing incidence wide angle x-ray scattering (GIWAXS), small angle x-ray scattering (SAXS) and high-resolution XRD taken at the Brazilian Synchrotron National Laboratory and SSRL-Stanford.
In situ GIWAXS experiments allowed us to understand the influence of the solvents, time to initiate the crystallization, humidity in the preparation of perovskite films and to get important information about final composition and morphology [1]. It is well known that a 2D layer on the top of a 3D bulk perovskite improves stability and performance. *In situ* GIWAXS revealed us that during thermal annealing the 2D layer transforms itself into a disorder layer, improving hole transfer and stability [2]. This technique was also employed to identify the first intermediates formed during the degradation of different Cs and Br perovskite compositions under ambient conditions [3].
In situ SAXS is another powerful technique to follow the first stages of the 2D perosvkite's formation. Our results suggest that the formation of the individual slabs in $BA_2[FAPbI_3]PbI_4$ is quite fast (within the first 10 s) and, then, these slabs self-assemble into bulk crystallites during the next 40 minutes [4].
Another topic of interest is the photoinduced phase segregation in FACs-based perovskite films. We investigated this phenomenon by photoluminescence (PL) studies and *in situ* high-resolution XRD (dark and under illumination). We found out that cubic-tetragonal transition is able to stabilize the samples with higher Br and Cs content, however this is not true for the films with 17% Br. Thus, other mechanisms must be operating and ruling phase segregation [5].

A Machine Learning Approach to Deconvolute the Role of Stressors in Perovskites' Stability Marina S.

Leite; University of California, Davis, United States

A complete understanding of the influence of the individual and combined effects of extrinsic (humidity and oxygen) and intrinsic (light, bias, and temperature) stressors on halide perovskite materials is key for the ultimate development of stable optoelectronic devices. Here, we present a suite of optical and electrical complementary tools that provide a detailed description of the dynamic responses within these materials. We unfold the impact of distinct humidity levels on charge carrier radiative recombination in CsxFA1−xPb(IyBr1−y)3 perovskites through *in situ* PL, where we temporally and spectrally measure light emission within loops of critical relative humidity (rH) levels. Our results demonstrate that the Cs/Br ratio strongly affects the spectral stability of light emission hysteresis, as well as its extent. The photo-emission dynamics in metal halide perovskites with both I and Br is also interrogated by environmental PL, where we find that the presence of Br suppresses hysteresis. We realize a machine learning (ML) approach based on supervised learning combined with environmental PL measurements and determine the (ir)reversible changes that takes place in $MAPbBr_3$ and $MAPbI_3$ model systems, and in state-of-the-art multication compositions such as $Cs_{0.05}FA_{0.79}MA_{0.16}Pb(I_{0.83}Br_{0.17})_3$ and $(Cs_{0.07}Rb_{0.03}FA_{0.76}MA_{0.14}Pb(I_{0.85}Br_{0.15})_3$. We further resolve transient processes such as ion motion by spatially resolving the local photovoltage and photocurrent at the nanoscale. Here, we quantify how the addition of Rb reduces the inactivity of the perovskites' grains. Combined, the macro- and nanoscale environmental measurements performed provide a comprehensive platform for tracking, in real-time, the relevant changes that can lead to degradation. Moreover, they represent a reliable diagnosis tool that can be expanded to any perovskite chemical composition.

High Efficiency Perovskite/Silicon Solar Cells and Solar Hydrogen Systems Kylie Catchpole; Australian National University, Australia

Combining perovskites with well-established photovoltaic materials such as silicon is an attractive option for producing cheap, high efficiency and high voltage solar cells. Perovskite/silicon tandems have the potential for further progress in increasing the efficiency to 30% and beyond, and we discuss some of the key ways forward to achieving this goal. We demonstrate a 4-terminal tandem perovskite/silicon configuration in which the efficiency is as high as 27.7% through a passivation approach using 2D perovskites. We also demonstrate efficiency above 21% and fill factor of 83% for a $1cm^2$ single junction perovskite cell using a nanotextured electrode transport layer. Perovskite/silicon tandems integrated with an appropriate catalyst are also a promising way to achieve high efficiency solar hydrogen generation. Using this approach we demonstrate a water-splitting system with a solar to hydrogen efficiency over 17%.

9:25 PM *EN06.09.02
Space within Perovskite/Silicon Tandem Solar Cells—Plenty of Opportunities for Perovskite Solar Cells Xiaodan Zhang; Nankai University, China

Perovskite/Silicon tandem solar cells (PSTSCs) have potentially remarkable energy conversion efficiency at a reasonable cost, which can significantly boost the future PV landscape. Recently, a newly certification efficiency of 29.15% had been reported, which further demonstrated the potential commercialization of this

devices. Despite these advances, stability and large area are the barriers which hinder the industrialization of the tandem devices. And, these issues are closely related to perovskite top cells. Therefore, eliminating the instability problem of perovskite materials and further increasing the efficiency of large scale perovskite devices which will promote the application of perovskite/Silicon tandem cells in the real world condition. In a word, there are many opportunities for perovskite devices to accelerate the development of PSTSCs.

9:50 PM *EN06.09.03
Perovskite Tandems Edward Sargent and Bin Chen; University of Toronto, Canada

I will discuss advances in perovskite tandems, both silicon:perovskite and perovskite:perovskite. I will discuss challenges in achieving the union of operating stability and high performance (especially high Voc) in both the small-bandgap and the large-bandgap cells making up the tandem stack.

10:15 PM EN06.09.04
Optical Design Guidelines for Perovskite/Perovskite Tandem Solar Cells in a Material Independent Approach Mehmet Koç, Zeynepnur Sahinel and Selcuk Yerci; Middle East Technical University, Turkey

Solar cells have presented significant improvements since their first introduction, and every day new developments are still being reported for different solar cell technologies.[1] Conversion efficiency improvements slow down as they become closer to their practical limits and it becomes a more challenging task for researchers to further boost the conversion efficiency. Researchers are continuously searching for alternative routes to surpass fundamental limits. One of the most promising routes is using tandem solar cell structures, which has a long proven success.[2]
Tandem solar cells enable better utilization of available illumination spectrum which leads to a higher conversion efficiency mainly by better spectral matching. However, some major design challenges are waiting to be addressed such as obtaining maximum absorption in absorbers of both subcells while having electrically advantageous design thicknesses in a material-independent way. Perovskite solar cells have attracted a lot of researchers since their introduction due to their excellent optoelectronic properties. The vast number of researches yields a very broad range of functional materials such as electron/hole transport layers, and transparent conductive electrodes (TCE); as well as various perovskites with different optical properties and bandgaps. Hence, optical design guidelines of perovskite solar cells should be carried out in a way to account for the optical properties of different materials. Therefore, previously we have documented optical design guidelines in a material independent approach for the perovskite solar cells in their standalone configurations.[3]
In this work, first, bandgaps of perovskite absorbers in both subcells are varied to find optimum pairs that yield the highest power output for both connection configurations, four- and two terminal. Subsequently, optimum optical design parameters for each layer in the tandem structure for a broad range of refractive index of conceptualized functional layers are computed. This expands the applicability of this approach to provide design guidelines for the already documented and future materials. Optimizations are carried out with the integration of machine learning algorithms due to the vastness of the parameter sets. Finally, optical loss mechanisms are quantized and alternative ways of addressing them are discussed.

Real-Time Optical Monitoring for Rapid Diagnosis of the Thermal Stability of Device Architectures for Perovskite Solar Modules Thomas W. Colburn, Oliver Zhao, Justin Chen and Reinhold Dauskardt; Stanford

University, United States

When exposed to elevated temperatures, metal halide perovskites suffer from decomposition to PbI_2, volatilization of the organic component from the crystal structure, and even metal diffusion of the top contact through the top carrier selective contact to the perovskite. Current methods to evaluate perovskite solar cell thermal stability involve fabrication of full cells and repeated testing over 1000+ hours, requiring considerable manual labor, equipment, and resources.

In our work, we employ a custom-built photo enclosure for high-resolution and real-time optical monitoring of large-area module test architectures during thermal aging for over 1000+ hours. The photo enclosure consists of an optical camera, adjustable light source, heated stage, and standardized color panel that act to normalize the RGB values of the illuminated samples between batches.[1] We analyze the color of the perovskite layer and establish threshold color intensity values corresponding to critical color changes in the film signaling an appreciable quantity of PbI_2 formation. These color changes indicate the presence of thermal degradation without the need for confirmation through extensive characterization methods. We map the entire module surface for color changes to determine both local and regional degradation modes to identify trends in spatial non-uniformities of modules. From the optical degradation profile of the module, we subsequently apply localized characterization techniques to highlight different features or high-interest areas without analyzing the full sample area. Furthermore, we employ our optical monitoring system to a wide range of strategies designed to mitigate thermal degradation, including incorporation of perovskite additives, perovskite surface functionalization, and hybrid organic-inorganic transport layers. The ability to rapidly evaluate thermal stability without the need for complex characterization equipment and time and resources for fabrication and testing of full devices streamlines the design iteration process towards achieving fully stable perovskite solar modules.

10:45 PM EN06.09.06
Late News: Avoiding Upscaling Losses for Perovskite Photovoltaics—Advantages of Fully-Evaporated Layer Fabrication and All-Laser-Scribed Interconnections David B. Ritzer[1], Tobias Abzieher[2], Thomas Feeney[2], Felix Laufer[2], Agit Basibüyük[1], Stefan Bergfeld[3], Bryce S. Richards[1,2] and Ulrich W. Paetzold[1,2]; [1]Institute of Microstructure Technology, Germany; [2]Light Technology Institute, Germany; [3]Bergfeld Lasertech, Germany

Perovskite-based semiconductors have considerable potential to become an important technology for the fabrication of efficient thin-film photovoltaics (PV). Owing to the ease of fabrication by various wet-chemical deposition techniques, outstanding optoelectronic properties as well as simple bandgap tunability, the international research community puts great effort into the technology's development, resulting in small-area perovskite solar cells exceeding 25% power conversion efficiency (PCE) within only a decade of research. However, perovskite-based PV still faces several challenges, such as low operational stability and the need for upscaling of the fabrication processes to application relevant device areas. In this context, literature reports a clear trend of significant PCE losses during upscaling of device area, as many established deposition processes become increasingly complex to control over larger areas.
In this work, we present for the first time the combination of an all-evaporated layer stack sequence with all-laser-scribed module interconnections as a promising method to close the gap between small-area record solar cells and large-area solar modules. By bringing together the ease of upscaling deposition area by vacuum-based techniques and the high-quality, high-throughput laser scribing method for fabrication of interconnections, a synergy employable as future industrial approach for high-quality module fabrication with excellent reproducibility and production yield is formed. First, an optimization of the laser scribing lines required for efficient serial interconnections is performed, eliminating reported problems such as incomplete ablation, redeposition of ablation debris and flake formation. Based on this, all-evaporated small area solar cells with an aperture area of 0.1 cm^2 are scaled up by a factor of up to 500 to a total aperture area of 51 cm^2, with geometric

fill factors of up to 96% and most importantly without significant upscaling losses. An in-depth analysis of the fabricated devices utilizing current-density-voltage-characteristics, laser-beam-induced current mapping and photoluminescence measurements reveals excellent layer homogeneity and interconnection quality. The fabricated solar modules reach PCEs of up to 16.5% for aperture areas above 51 cm^2 (active area PCE of 17.5% with small-area solar cells achieving a PCE of 18.0%), being a world record for fully-evaporated perovskite solar modules. The difference between small- and large-area devices corresponds to an exceptionally low upscaling loss close to $0.5\%_{abs}$ per magnitude of upscaled area, which significantly surpasses not only the upscaling efficiency of other solution-based upscaling methods of perovskite PV but also that of other thin-film technologies such as CIGS. Finally, the investigations are used to comprehensively assess the employed upscaling strategy, identifying further potential for improvement with the ultimate objective of approaching the industrial application of the perovskite PV technology.

SESSION EN06.10: On-demand

8:00 AM EN06.10.01
Late News: Pressure-Assisted Fabrication of High-Quality Perovskite Crystals for Efficient and Stable Perovskite Solar Cells Junsheng Luo; University of Electronic Science and Technology of China, China

The grain boundaries of organic-inorganic halide perovskite films not only function as defect centers, but also behave as intrinsic ion migrating channels and extrinsic moisture-induced degradation initiators, which are detrimental to the efficiency and stability of perovskite solar cells (PSCs). Here, an effective methodology for fabrication of high-quality perovskite layers with reduced non-radiative recombination, suppressed ion migration and increased moisture stability is reported for the first time, referred as the pressure-assisted solution processing (PASP). Through PASP strategy, the nucleation and growth of perovskite crystals can be controlled, leading to the micron-sized grains and microsecond-range carrier lifetimes. The resultant PSC shows champion power conversion efficiency (PCE) as high as 20.74% and a stabilized efficiency exceeding 20%, with superior long-term stability, maintaining above 90% of initial PCE even aging 60 days or continuous 1-sun illumination for 200 h in ambient environment without encapsulation. We unambiguously believe that the control of perovskite crystal nucleation and growth with high quality will be an important direction to improve the efficiency of PSCs to the theoretical limit, as well as to stabilize perovskite-based materials and devices.

8:10 AM EN06.10.02
Late News: Enhanced Optoelectronic Performance of Perovskite Solar Cells Integrated with Front Metal-Oxide Nanoholes Mohammad I. Hossain[1,2], Md Shahiduzzaman[3], Safayet Ahmed[2], Rashedul Huqe[1], Md Wayesh Qarony[2,4], Ahmed Mortuza Saleque[2], Md Akhtaruzzaman[5], Dietmar Knipp[6], Yuen H. Tsang[2] and Juan Antonio Zapien[1]; [1]City University of Hong Kong, Hong Kong; [2]The Hong Kong Polytechnic University, Hong Kong; [3]Kanazawa University, Japan; [4]University of California, Davis, United States; [5]National University of Malaysia, Malaysia; [6]Stanford University, United States

Improvement of optoelectronic properties of perovskite solar cells (PSCs) can be realized by employing efficient front contact. This study aims to enhance the optical and electrical performances of PSCs by utilizing metal-oxide nanoholes at the front. Such front nanostructures significantly contribute to the broadband light-incoupling and light trapping in a solar cell, resulting in an improvement of quantum efficiency (QE) and short-circuit current density (J_{SC}), leading to further enhancement of energy conversion efficiency (ECE). Furthermore, the metal-oxide contact exhibits high lateral conductivity, high optical transparency, and a suitable work function, facilitating PSC's optoelectronic performance. As most high-performance PSCs explore only the device's electrical properties, the current study reveals a detailed understanding of PSC optics, electrical

characteristics, and their practical fabrication process for achieving high ECEs. The optics, optimization, and electrical effects of PSCs are investigated by advanced three-dimensional electromagnetic simulations with the combination of finite-difference time-domain (FDTD) and finite element method (FEM) techniques. The investigation implies that the nanophotonic-structured front contact allows enhancing the J_{SC} by 11~27% while improving the light incoupling by 10~12%, compared to that of planar configuration. Herein, the validation of numerical modeling was performed by fabricating PSC in a superstrate configuration that was optimized to reach an ECE of 17.5%, V_{OC} of 1.02 V, J_{SC} of 22.1 mA/cm^2, and FF of 80%. Detailed descriptions of the nanophotonic contact, device, and fabrication process are provided.

8:20 AM EN06.10.03

Impact of Annealing Temperature on Mixed A-Site Halide Perovskite Device Stability Laura E. Mundt[1], Fei Zhang[2], Axel Palmstrom[2], Kai Zhu[2], Joseph J. Berry[2] and Laura T. Schelhas[2]; [1]SLAC National Accelerator Laboratory, United States; [2]National Renewable Energy Laboratory, United States

The term 'perovskite' denotes the crystal structures made of corner-sharing octahedra with ions placed in the octahedral interstitials with the ABX_3 formula. Particular attention has been targeted at compositions with the X-site occupied by a halide and the B-site by a metal, due to interesting functional properties, particularly those associate with photovoltaics (PV). A vast variety of elements and molecules have been incorporated into metal halide perovskite structures, the most prominent are methyl ammonium (MA^+), and/or formamidinium (FA^+) as A-site cations, Pb^{2+} and/or Sn^{2+} as the B-site metal, as well as I^- and Br^- on the X-site. The ability to maintain the perovskite structure, from a geometric point of view, is given by the Goldschmidt tolerance factor t_G. It takes into account the geometric constrains in the crystal lattice and is defined as the ratio of the octahedral interstitial and the A-site cation size. Compositions with non-ideal geometric conditions, such as $FAPbI_3$ and $CsPbI_3$, are prone to transition into unfavorable δ -phases. By utilizing a mixture of ions, the geometric conditions in the crystal structure can be finely tuned and thereby improve the inherent structural stability. As a consequence, the mixed perovskite composition of $FA_{1-x}Cs_xPbI_3$ with optimized tolerance factors features superior structural stability compared to the pure FA- or Cs-compositions.[1] However, previous studies showed that PV devices, featuring mixed perovskite compositions with similar tolerance factors as absorber layers, do not necessarily exhibit similar stability in structure or device performance. This strongly suggests there are further mechanisms that play a significant role in the structural and device stability in perovskite solar cells (PSCs). In this study, we explore the structure-function relationship in state-of-the-art mixed A-site halide PSCs and reveal the impact of annealing conditions of the device stability.

Time-of-flight secondary ion mass spectroscopy (ToF-SIMS) measurements on neat $FA_{0.83}Cs_{0.17}PbI_3$ perovskite films that had been annealed at different temperatures revealed local variations in the perovskite composition for low annealing temperatures.[2] Based on these findings we hypothesize that insufficient annealing leads to incomplete mixing. Local deviations from the mixed phase, either Cs-rich or FA-rich, can nucleate further phase segregation into the parent δ –phases. In sum, reaching thermal equilibrium during the film annealing is crucial for device stability.

We present a study that unambiguously correlates device performance with structural properties, revealing degradation mechanisms in $FA_{0.83}Cs_{0.17}PbI_3$ PSCs: Operando X-ray diffraction (XRD) allows us to probe the structure function relationship. By utilizing high-energy synchrotron X-rays, we are able to penetrate the perovskite absorber layer through the metal contact in a complete device held at max power. In order to accelerate degradation and to mimic realistic operational temperature conditions, the experiment is performed at elevated temperatures (50°C - 80°C). Using this technique, we compared devices annealed at 100°C and at 180°C. We clearly find superior performance and stability for the samples annealed at higher temperatures. Furthermore, we can identify δ –phases forming for insufficiently annealed samples, corroborating our hypothesis.

In conclusion, we present a study of state-of-the-art mixed A-site halide PSCs, directly correlate processing conditions to device stability and elucidate the underlying degradation mechanisms. Our findings help inform optimized processing protocols to lay the ground for efficient and long-term stable perovskite PV.

Efficient Interlayer Exciton Transport in Two-Dimensional Metal-Halide Perovskites Alvaro Magdaleno, Michael Seitz, Michel Frising, Ana Herranz de la Cruz, Antonio I. Fernández-Domínguez and Ferry Prins; Universidad Autónoma de Madrid, Spain

Two-dimensional (2D) metal-halide perovskites have emerged as a more robust alternative to their three-dimensional counterparts. Due to quantum and dielectric confinement effects, excitons dominate the energy transport characteristics in thinnest members of the 2D perovskites family. Recently we have reported on the in-plane exciton diffusion using transient photoluminescence microscopy, where high diffusivities were found (0.2 cm^2/s for PEA_2PbI_4). Using the same technique, here, we will show that this material exhibits remarkably efficient out-of-plane exciton transport (0.06 cm^2/s) as well. This out-of-plane diffusivity translates to a diffusion length of exceeds 100 nm, making it relevant to device design. Moreover, our result show that the individual energy transfer steps that underly the out-of-plane transport occur on a sub-ps timescale. Such ultrafast timescales are over two orders of magnitude faster than predictions using Förster theory. We will discuss the shortcomings of Förster theory for the case of excitons in the layered perovskites. Most importantly, our results show that the excitonic energy transport is considerably less anisotropic than charge-carrier transport for 2D perovskites.

Changes in Dielectric Constant of Metal Halide Perovskites Studied via Frequency-Dependent Time-Resolved Microwave Conductivity Min Ji Hong and John G. Labram; Oregon State University, United States

Metal Halide Perovskites (MHPs) have drawn significant attention due to their outstanding optoelectronic properties, such as high absorption coefficient and long carrier lifetime. While MHPs offer industry and the academic community many exciting opportunities, consistent mechanistic understanding and consensus still lag behind more established systems. One notable property of this class of materials is their large dielectric constant, which has been observed to change significantly under illumination. [1] While the polarizability of this sytem has been invoked to explain many of its unusual properties, the behavior of the dielectric constant under illumination is still poorly understood.

In this study, we have used frequency dependent Time Resolved Microwave Conductivity (TRMC) to investigate how the dielectric constant changes under illumination as a function of time, in a range of MHPs. Both changes in photoconductance and change in dielectric constant are analyzed as a function of time, with nanosecond precision. We observe that photo-induced change in dielectric constant are roughly proportional to photo-induced carrier density but decay over different timescales, indicating that the presence of charge carriers alone is not the only factor in changes in polarizability.

3D-to-2D Transition of Anion Mobility in $CsPbBr_3$ Under Pressure Thijs Smolders, Matthew Wolf and Alison Walker; University of Bath, United Kingdom

Unlike typical inorganic semiconductors, lead–halide perovskites exhibit significant ionic conductivity, which is believed to affect their performance and stability. Here, we present a detailed theoretical study of the atomic scale effects of pressure on anion migration in the low temperature orthorhombic *Pnma* phase of $CsPbBr_3$, using nudged elastic band calculations based on density functional theory. We compute all symmetrically inequivalent activation barriers for anion migration to their closest neighbours, as a function of hydrostatic pressure in the range 0.0–2.0 GPa, which we then use as parameters in a kinetic model which allows us to connect the atomic scale calculations to the macroscopic anion mobility tensor as a function of applied pressure.

We find that the mobility is enhanced by pressure in the plane spanned by the [100] and [001] lattice directions, while along the [010] direction it is severly diminished, leading to an effective 3D-to-2D transition of the mobility at elevated pressures. This can be explained by the fact that a network of only a few symmetrically inequivalent paths dominates the mobility at elevated pressures. Our results demonstrate the significant influence of pressure on both the rate and direction of anion migration in $CsPbBr_3$, which we consider likely to hold for other lead–halide perovskites.

Nanotemplating Effects on the Thermodynamic Stability of Perovskite-Phase $CsPbI_3$ Arkita Chakrabarti and Aaron Fafarman; Drexel University, United States

Perovskite phase cesium lead iodide $CsPbI_3$ has emerged as a promising all-inorganic photovoltaic (PV) absorber material for its remarkable optoelectronic properties such as a suitable band gap, high absorptivity, high charge carrier lifetime and solution processability, all desired qualities for PV cells. However, under ambient conditions, $CsPbI_3$ transforms into a high density, non-functional, non-perovskite yellow phase. However, perovskite-phase $CsPbI_3$ can be stabilized in the form of quantum dots and thin films. Proceeding with the hypothesis that this is an effect of reduced dimensionality, we have sought a robust approach for enforcing controlled nanostructure. To do so, we synthesized $CsPbI_3$ in the pores of various inorganic scaffolds: prefabricated anodized aluminum oxide (AAO) membranes and TiO_2 nanoparticle scaffolds. Nano-structuring provides a truncated crystal lattice, which we hypothesize weakens the impact of the long-range, compressive electrostatic forces that act upon the $CsPbI_3$ unit cell. Under such reduced compression, we hypothesize that the lower density, black perovskite phase, is favored. Herein is described a study of phase transition thermodynamics of $CsPbI_3$ for perovskite synthesized in scaffolds with pore sizes ranging from few nanometers to mesoscopic dimensions. X-ray diffraction is employed to quantify the resulting expansion of the lattice. We found a 250 C drop in the phase transition temperature and enhanced thermal and moisture stability as a consequence of nano-templating in AAO with pore sizes lower than 80nm; crystals synthesized in larger pores and mesoscopic TiO_2 showed standard phase transition temperature of 330 C, consistent with bulk $CsPbI_3$. This approach could potentially stabilize the functional perovskite phase of $CsPbI_3$ at near ambient conditions.

Bridging the Defect Chemistry and Device Physics of Hybrid Perovskite Devices Davide Moia, Gee Yeong Kim, Ya-Ru Wang, Mina Jung, Alessandro Senocrate, Jaehyun Lee and Joachim Maier; Max Planck Institute for Solid State Research, Germany

Hybrid perovskites are the first photovoltaic material class presenting competitive solar cell performance and, at the same time, significant mixed ionic electronic conduction at room temperature. Several studies have pointed out that the long time scale electrical response of hybrid perovskite solar cells can be related to the migration of ionic defects in the material, specifically to electrode polarization, [1] stoichiometric polarization [2] and ionic-to-electronic current amplification. [3] Yet, quantitative information on the contribution of each of these processes as a function of device properties and working conditions is still missing to date. Given that long time scale behavior has direct consequences on the photo-conversion mechanism and long time scale degradation in these materials, it is desirable to develop comprehensive device models that successfully describe both electronic and ionic phenomena. Progress in the understanding of these aspects will enable improved device design and is a most urgent challenge in the field.

In this contribution, we address such question using a combined experimental and numerical approach. First, we evaluate the contribution of different ion-related processes on the electrical response of hybrid perovskite devices. We carry out electrochemical conductivity measurements while varying the iodine partial pressure during the measurement, the device contact materials and the electrode geometry. Our results show that the behavior of bulk and interfaces are different under dark equilibrium vs out of equilibrium conditions, with consequences on the interpretation of the long time scale response. The data also highlight the need to combine multiple techniques when quantifying charge carrier conductivities in hybrid perovskite devices under light or voltage bias.

Next, we develop and validate a model that encapsulates the ionic and electronic properties of perovskite based devices. Our approach combines knowledge on the analytical description of mixed conductors and of the electronic processes determining much of the electrical behavior in solar cells under operation. First, we map the functional dependence of the recombination currents in perovskite semiconductors as a function of recombination mechanism and working conditions. By coupling electronic generation and recombination to the drift diffusion equations of electronic and ionic charge carriers, we develop a model bearing analytical consistency with the expected semiconductor and mixed conductor physics of hybrid perovskites' bulk. We then consider different descriptions for the device interfaces, and highlight the importance of majority carriers' behavior at establishing charge carrier equilibrium and quasi-equilibrium at these boundaries. [4] Based on these considerations, we develop equivalent circuit models that simulate impedance spectra of hybrid perovskite devices. Our numerical results give supporting evidence for our interpretation of the experimental measurements on horizontal devices under dark or under illumination.

Finally, we critically assess the potential of our model and its applicability to the experimental characterization of solar cell devices. We demonstrate the generality of the model and present a number of approximated versions, which are relevant to hybrid perovskite, but also to other traditional photovoltaic materials. The proposed approach will aid the interpretation of electrical measurements on perovskite solar cells, with also implications on other mixed conducting devices.

Thermodynamics and Kinetics of Photo-Demixing and Dark-Remixing in Two-Dimensional Mixed Lead Halide Perovskites
Ya-Ru Wang[1], Alessandro Senocrate[1], Gee Yeong Kim[1], Algirdas Dučinskas[2], Jovana V. Milić[2], Davide Moia[1], Michael Grätzel[2] and Joachim Maier[1]; [1]Max Planck Institute for Solid State Research, Germany; [2]EPFL, Switzerland

Mixed halide perovskites are promising materials for solar cells, light-emitting diodes and other optoelectronic devices due to their tunable bandgaps. However, under light, these systems show segregation into two phases with different halide compositions (photo-demixing). Interestingly, these two phases tend to remix back in the dark (dark-remixing)[1]. This phase instability is undesirable when aiming for solar cells with stable output, while it opens opportunities towards new device architectures.[2] The observed light-induced evolution of different phases involves significant ion transport. Therefore, an improved understanding of the underlying defect chemical mechanisms involved in photo-demixing (and dark remixing) can help both preventing and controlling this effect.

While several studies have characterized photo-demixing in 3D mixed halide perovskites, the role of decreasing dimensionality on this process has not yet been fully clarified. In the case of two-dimensional (2D) lead halide perovskites, increased resilience against intrinsic and extrinsic degradation routes has been attributed to the

suppression of ion migration in these materials with respect to the 3D counterparts.[3-4] It is therefore interesting to probe how the photo-demixing relates to the structure and composition of these mixed halide perovskite systems.

Here, we demonstrate that also 2D mixed halide perovskites show reversible demixing under light. The kinetics of the process is slower for the 2D systems compared with their 3D counterpart. We investigate the evolution of optical and structural properties of 2D perovskite thin films under different light bias conditions, providing information on the thermodynamics and the kinetics of the photo-demixing and dark-remixing processes. These techniques, combined with in-situ conductivity measurements, also allow us to assess the influence of light intensity, thin-film composition, substrate, and encapsulation. Lastly, we propose a model that describes photo-demixing and dark-remixing in 2D mixed lead halide perovskites based on our previous analysis of the 3D systems.[5] Our study contributes to defining the thermodynamic picture of 2D mixed halide perovskites, which will aid the compositional engineering of optoelectronic devices where photo-demixing is controlled.

9:30 AM EN06.10.11
Physical Passivation of Grain-Boundaries and Defects in Perovskite Solar Cells by PMMA Efrain Ochoa[1], Mario Ochoa[2], Roberto D. Ortuso[1], Parnian Ferdowsi[1], Romain Carron[2], Ayodhya Tiwari[2], Alke Petri-Fink[1], Ullrich Steiner[1] and Michael Saliba[3,4]; [1]Adolphe Merkle Institute, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]Institute for Photovoltaics (ipv), Germany; [4]Forschungszentrum Jülich, Germany

The present study analyses the use of poly(methyl methacrylate) (PMMA) interlayers as passivation agents between the photoactive perovskite films and the carrier transport layers in Perovskite Solar Cells (PSCs). Our study finds that the deposited PMMA acts exclusively as a very good electrical isolator. By accumulation at perovskite grain boundaries and defects, it physically prevents charge carriers from reaching these locations, rather than chemically passivating electronic trap states that may arise from surface defects. Spin-coating a very low concentration PMMA solution onto perovskite layers increases the shunt resistance and the fill factor, without increasing the series resistance, giving rise to an improvement in cell efficiency.

The characterization of the degree of passivation provided has been assessed through spatially and time-resolved photoluminescence, while a detailed atomic force microscopy analysis, complemented with ellipsometric and electrical measurements, allows distinguishing the PMMA morphology once deposited onto the perovskite film and its effect on finished devices.

This mechanism should apply to any perovskite composition or device architecture. Since the perovskite remains in immediate contact with the surrounding carrier transport layers, this method can be used in combination with other surface passivation methods, which could be applied before or after the PMMA treatment.

9:40 AM EN06.10.12
Can Structuring Make Hybrid Perovskite's $A_xA'_{1-X}PbX_yX'_{1-y}$ Result in a More Effective Stand-Alone

Hybrid Solar PV Material? Edmund Chan, Ned Taylor and Steven P. Hepplestone; University of Exeter, United Kingdom

Hybrid perovskite solar cells (with chemical formula ABX_3) are of great interest due to the recently measured power conversion efficiency of greater than 25% (but theoretically, 33.7%). Perovskite structures are easily customisable, with a range of options for A, B and X. This enables us to both tune the electronic band gap and the stability by varying the composition. Two promising perovskites are the $CH_3NH_3PbI_3$ (MAPI) and $CH(NH_2)_2PbBr_3$ (FAPB) structures. By varying the ratio of FA and MA and doping with Br, we can potentially tune the band gap and effective masses (and hence electronic transport).

We present a theoretical investigation of the structural and electronic properties of $MA_xFA_{1-x}PI_yBr_{1-y}$, performed using first-principles density functional theory. Our results show that in a solid-state solution setting, decreasing fractions of y dominates the fall of cell volume which increases the band gap. We discuss why the formation energies at the most favourable ground-state hexagonal phase and the experimentally observed cubic phase vary in these compositions, including the effects of the rotation of the organic groups, affect the effective masses and, ultimately, the transport. We also explore the effects of clustering and intermixing on these structures and their stability.

In order to compromise for a more desirable bandgap for stand-alone PV and better structural stability, the hybrid perovskite constituents are then strategically layered, with n:1 ratio, into superlattice form. We explore the bulk properties and interfacial engineering to improve the material's electronic transport.

9:50 AM EN06.10.13
Voltage Bias Stress Effects in Metal Halide Perovskites Laura Flannery[1], Jonathan Ogle[1], Daniel Powell[1], Christopher Tassone[2] and Luisa Whittaker-Brooks[1]; [1]The University of Utah, United States; [2]Stanford Synchrotron Radiation Lightsource, United States

The solar-to-power power conversion efficiencies (PCEs) of metal halide perovskites (MHP) have been improved over the last decade using a wide variety of methods, such as composition manipulation, dopant introduction, and interfacial buffers. These methods, however, have taken little regard for the electronic and interfacial effects such alterations may cause within devices under voltage bias stress -a condition required for most device operation. Here, we investigate the effect of halide and cation substitution in MHP structures [mainly, $CH_3NH_3PbI_{2.87}Cl_{0.13}$ and $Cs_{0.1}(MA_{0.17}FA_{0.83})_{0.9}Pb(I_{0.83}Br_{0.17})_3$] to understand current behavior while under a range of voltage bias stress in both light and dark conditions. With the use of a second device structure, without transport layers, the same voltage bias stress effects unique to the different MHP structures are observed thus confirming that the difference in the current trends are due to intrinsic behavior of the perovskite structure, rather than interfacial recombination and interactions with the transport layers. We also determine how changes in morphology and crystallite orientation in $CH_3NH_3PbI_{2.87}Cl_{0.13}$ and $Cs_{0.1}(MA_{0.17}FA_{0.83})_{0.9}Pb(I_{0.83}Br_{0.17})_3$ thin film absorbers can influence ion migration and therefore alter charge transport and current stability in MHP photovoltaic devices.

10:00 AM EN06.10.14
Lead-Free $Cs_4CuSb_2Cl_{12}$ Layered Double Perovskite Nanocrystals Tong Cai, Wenwu Shi and Ou Chen; Brown University, United States

Concerns about the toxicity of lead-based perovskites have aroused great interest for the development of alternative lead-free perovskite-type materials. Recently, theoretical calculations predict that Pb^{2+} cations can be substituted by a combination of Cu^{2+} and Sb^{3+} cations to form a vacancy-ordered layered double perovskite structure with superior optoelectronic properties. However, accessibilities to this class of perovskite-type materials remain inadequate, hindering their practical implementations in various applications. Here, we report the first colloidal synthesis of $Cs_4CuSb_2Cl_{12}$ perovskite-type nanocrystals (NCs). The resulting NCs exhibit a layered double perovskite structure with ordered vacancies and a direct band gap of 1.79 eV. A

composition−structure−property relationship has been established by investigating a series of $Cs_4Cu_xAg_{2-2x}Sb_2Cl_{12}$ perovskite-type NCs ($0 \leq x \leq 1$). The composition induced crystal structure transformation, and thus, the electronic band gap evolution has been explored by experimental observations and further confirmed by theoretical calculations. Taking advantage of both the unique electronic structure and solution processability, we demonstrate that the $Cs_4CuSb_2Cl_{12}$ NCs can be solution-processed as high-speed photodetectors with ultrafast photoresponse and narrow bandwidth. We anticipate that our study will prompt future research to design and fabricate novel and high-performance lead-free perovskite-type NCs for a range of applications.

10:10 AM EN06.10.15
Optical, Morphological and Electrical Characterization of Methyl Ammonium Lead Iodide Perovskite Films for Solar Cells Shambhavi R. Sakri, Liang-Chieh Ma, Bushra Alharbi and Anupama Kaul; University of North Texas, United States

There are varied approaches toward the synthesis of three-dimensional (3D) perovskites based on methyl-ammonium-lead-iodide ($CH_3NH_3PbI_3$) absorbers for solar cells which have now yielded power conversion efficiencies (PCEs) approaching ~ 26%. In this work, we explored multiple synthesis routes to systematically optimize the films through a careful analysis of their optical, morphological and electrical characteristics. In the first technique, a stable Lewis base adduct solution of CH_3NH_3I-PbI_2-DMSO in dimethylformamide (DMF) is formulated, where an antisolvent of diethyl ether is gently cast on the adduct film during spin coating to reduce the rapid evaporation of DMF from the film surface. Through this careful control of the antisolvent, the growth kinetics lead to the evolution of the $CH_3NH_3PbI_3$ morphology from needle or rod-like toward the preferred platelet-like topology. Other commonly used anti-solvents such as toluene are limited in usage because they tend to wash off the dimethyl sulfoxide (DMSO) which contributes towards stability and reduction of pin-holes. In the second technique, CH_3NH_3I and PbI_2 in a ratio of 1:3 by weight was stirred overnight at 60°C in gamma-butyrolactone. In this technique, grain growth of 3D perovskite crystal is primarily dependent on stirring time of the precursor solution and annealing temperature. The third technique involves a two-step approach where the PbI_2 (in DMF) and CH_3NH_3I (in 2-propanol) precursors are deposited in succession on the substrate and annealed. Loading time, i.e. exposure of CH_3NH_3I to PbI_2 before spinning is initiated, influences growth of the 3D perovskite on the mesoporous titanium dioxide, where the latter serves as the electron transport layer in the solar cell stack. The loading time was optimized to obtain a cuboid morphology with large size. We can confirm that our absorber is optically active with all the three techniques used, where a sharp photoluminescence peak of high intensity is obtained at the ideal location of ~ 774 nm. The onset of absorption in the UV-VIS spectra occurs at 826 nm and increases gradually up to 490 nm. The bandgap of our film calculated using the Tauc method was found to be consistent with our PL inferred bandgap at ~ 1.6 eV. From scanning electron microscopy (SEM) imaging, a uniform sized continuous granular platelet morphology of the absorber was evident for the optimized film, with a tightly controlled roughness as well. We calculate the average grain size, and a grain size of at least 1 μm in the homogeneous and smooth films is optimal for incorporation into the solar cell stack. The X-ray diffraction (XRD) analysis shows characteristic peaks for the tetragonal perovskite structure at room temperature. Current-voltage characteristics revealed that the absorber was electrically conductive in the dark and under illumination for our photo-responsive measurements, prior to its integration into the solar cell stack for the PCE characterization studies.

10:20 AM EN06.10.18
Interfacial Trap-Assisted Triplet Generation in Lead Halide Perovskite Sensitized Solid-State Upconversion Lili Wang; Massachusetts Institute of Technology, United States

Photon upconversion via triplet-triplet annihilation (TTA) has promise for overcoming the Shockley–Queisser efficiency limit for single-junction solar cells by allowing the utilization of sub-bandgap photons. Recently, bulk perovskites have been employed as sensitizers in solid-state upconversion devices to circumvent poor exciton diffusion observed in previous nanocrystal-sensitized devices. However, an in-depth understanding of the underlying photophysics of perovskite-sensitized triplet generation is still lacking due to the difficulty of

precisely controlling interfacial properties in fully solution-processed devices. In this study, interfacial properties of upconversion devices are adjusted by a mild surface solvent treatment, which specifically alters perovskite surface properties without perturbing the bulk, and thermal evaporation of the annihilator precludes further solvent contamination. Sequential charge transfer and interfacial trap-assisted triplet sensitization are demonstrated by comparing the upconversion performance, transient dynamics, and magnetic field dependence of the upconversion devices. Incomplete triplet conversion from transferred charges and consequent triplet-charge annihilation (TCA) are also confirmed as two limiting factors for upconversion performance. Our observations highlight the importance of controlling interfacial properties and provide guidance for further device design and optimization of upconversion devices using perovskites or other semiconductors as sensitizers.

10:30 AM EN06.10.19
Improved Crystallization of Triple Cation Perovskites Assisted by Mixed Antisolvents for High Performing Solar Cells Banashree Gogoi, Aditya S. Yerramilli, Terry Alford and William Petuskey; Arizona State University, United States

In the case of Perovskite solar cells, the active perovskite layer acts as a crucial component in influencing the solar cell's efficiency. Crack free perovskite films with enlarged grain size are essential for a highly efficient solar cell. Triple cation perovskite mainly relies on solvent-antisolvent engineering for achieving good crystal growth and enlarged grains. In recent years many kinds of research have been done involving antisolvents in Triple cation perovskites. The Antisolvent assisted crystallization (ASAC) method is considered one such way to obtain better film quality. However, the perovskite films prepared by this ASAC method still suffers from low coverage and rapid degradation. Thus, the choice of antisolvent or mixture of antisolvents can be crucial in effectively precipitating the perovskite and demonstrating high efficiency. To achieve an ideal choice of antisolvents, we have examined a mixture consisting of Ethyl acetate (EA) with Chlorobenzene (CB) and EA with Isopropyl alcohol (IPA) in different ratios for the fabrication of the perovskite layer. In this case, EA acts as a solvent that will assist in dissolving the excess perovskite precursor due it its polar nature; and, IPA and CB will enhance crystallization by reducing the solubility of the perovskite. The devices fabricated using these mixtures of antisolvents improved efficiency by more than 13% when compared to only 8% for those prepared using only EA, CB, and IPA individually. High quality, crack free perovskite layers with enhanced grain sizes were attained from using mixtures of CB and EA, which lead to improved photovoltaic properties.

10:40 AM EN06.10.20
Strain in Ruddlesden-Popper Films with Target-*n* Emission Rhys M. Kennard[1], Clayton J. Dahlman[1], Juil (Jay) Chung[1], Benjamin L. Cotts[2], Naveen R. Venkatesan[1], Ryan DeCrescent[1], Lingling Mao[1], Alberto Salleo[2], Jon A. Schuller[1], Ram Seshadri[1,1] and Michael Chabinyc[1]; [1]University of California, Santa Barbara, United States; [2]Stanford University, United States

Keywords: Strain engineering, structural formulation, light-matter interaction, 2D films, phase purity, photoluminescence emission.

Two-dimensional Ruddlesden-Popper (RP) hybrid perovskites have been instrumental to the unprecedented development in the areas of energy harvesting and light emission technologies, as well as to studying cutting-edge fundamental science. RP formulations exhibit the $(A')_2(A)_{n-1}B_nX_{3n+1}$ structure, where A' is the spacer cation between A-Pb-X sheets, the A cation residues between Pb-X octahedra and X is a halide. A major challenge surrounding RP hybrid perovskites with $n > 1$ has been poor phase control when casting the materials as films. Competing reaction pathways and stacking faults cause phase heterogeneity at the nanoscale, inducing charge carrier funneling to the lowest-bandgap phase, and poor optoelectronic control. This prohibits both fundamental film characterizations and use of RP formulations in photodetector and light-emitting devices.

Here, we experimentally identified A' and A-site cations for which large-*n* RP films retain the photoluminescence emission of the single crystal formulations. Notably, the emission did not contain undesired

n RP emission, nor the large 3D-like emission typical of other spin-cast RP films. We correlated changes in the proportions of different emissive features with strain and morphology, and further controlled emission using small amounts of additives. These results will help push RP-based perovskite fundamental characterization and energy-based technologies to the next level.

10:50 AM EN06.10.22
Effect of the Chemical Composition on Structural, Thermodynamical and Mechanical Properties of $CsBX_3$ (B = Pb, Sn; X = Cl, Br) All-Inorganic Perovskites Pablo Sánchez-Palencia Vallejo[1,2], Gregorio García Moreno[1,2], Perla Wahnón Benarroch[1,2] and Pablo Palacios Clemente[3,2]; [1]Universidad Politécnica de Madrid, E.T.S.I. Telecomunicación, Spain; [2]Universidad Politécnica de Madrid, Instituto de Energía Solar, Spain; [3]Universidad Politécnica de Madrid, E.T.S.I. Aeronáutica y del Espacio, Spain

Despite their vertiginous growth in power conversion efficiency (PCE) terms and their ultra-competitive cost, perovskite solar cells (PSC) carry stability as their main warhorse towards commercialization. Pursuing solutions to a key problem of instability in most commonly used $MAPbI_3$ caused by the rotation of the complex organic molecules located in the A position (chemical formulae ABX_3), all-inorganic perovskites like $CsPbI_3$ and relatives are attracting considerable attention, although in comparison they present only promising results yet, being necessary a profound study of their properties to overcome new problems. Set the focus on stability, a review of the main structural, thermodynamical and mechanical properties of all-inorganic halide perovskites with general formula $CsPb_{1-b}Sn_b(I_{1-x}Br_x)_3$ is flagged as crucial, with the goal of elucidate the connection of those properties with the stability and its dependence upon the composition of the compounds.

In this work, a DFT-based study has been performed, allowing to cover a wide range of chemical compositions and knowing in detail how the composition changes affect those different properties and consequently the stability. Firstly, stability has been assessed through a series of structural tolerance parameters, like the Goldschmidt factor, the Sun's parameter and the intrinsic hardness. Also, thermodynamical stability in terms of formation enthalpies considering different competitor phases and compounds have been evaluated according to standard procedures. Furthermore, several mechanical properties defining response to different kind of stresses, as an important characteristic for their integration in complex multilayer devices or flexible and wearable applications, having also a big impact on their absorptivity which relies on their crystallinity and stress state, have been obtained from the elastic constants following the stress-strain methodology. All those properties will define a complete set that properly describes the different facets of the intrinsic stability of these halide perovskites and their correlation, providing a guide of how to improve that weak point through composition engineering.

11:00 AM EN06.10.23
Exciton Fine Structure of Individual $CsPbBr_3$ Nanoplatelets in a Vector Magnetic Field Alexander Schmitz[1,1], Federico Montanarella[2], Maksym Kovalenko[2] and Gerd Bacher[1,1]; [1]Universität Duisburg-Essen, Germany; [2]ETH Zürich, Switzerland

Nanoplatelets (NPL) of all-inorganic perovskites are promising candidates for application in light-emitting devices due to their high exciton binding energy, their exceptionally high quantum efficiency, and their improved stability.[1] While quantum dots of this material class have been studied excessively in the weak or intermediate quantum confinement regime providing interesting information on their exciton fine structure[2,3], such signatures are expected to be strongly modified when introducing strong confinement conditions in a selected direction, as in nanoplatelets.
In this work, we examine the exciton fine structure of individual $CsPbBr_3$ nanoplatelets with a thickness of five monolayers at cryogenic temperatures by means of polarization-resolved micro-photoluminescence spectroscopy. We find photoluminescence signatures comprised of either two or three clearly resolvable emission lines with linewidths down to 300 μeV and a fine structure splitting of ~ 1 meV. Such splitting has already been observed in quantum dots of the same material and was attributed to intrinsic Rashba effects in the orthorhombic structure.[3] The two lowest energy emissions exhibit strong linear polarization of up to > 90 %

with orthogonal polarization directions, corresponding to the dominant lateral crystal axis. This correlation enables us to derive the relative orientation of the NPL under investigation relative to the observation direction and substrate orientation.
To further elucidate the exciton fine structure, we apply a rotating vector magnet field of up to 5 T to the individual NPLs. The observed emission lines split up into doublets with rising magnetic field, with an average splitting of ~ 300 μeV at 5 T. This behavior clearly indicates that all three emission lines are spin-degenerate at zero field and it yields a small effective g-factor of < 1.1 for the strongly confined perovskites. A systematic study of a variety of individual NPLs in the vector magnetic field further yields insights into the anisotropy of the exciton fine structure.

Enhanced Optical Absorption via Mixed-Valent Doping of Vacancy-Ordered $A_3B_2X_9$ Triple Perovskites

Seán R. Kavanagh[1,2,2], Aron Walsh[2], David O. Scanlon[1] and Robert Palgrave[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Vacancy-ordered triple perovskites have recently come under the scientific spotlight as promising materials for high-performance next-generation optoelectronic technologies.[1–3] Their $A_3B_2X_9$ stoichiometry facilitates the replacement of the toxic Pb^{2+} cation with a benign isoelectronic B^{3+} cation (e.g. Bi^{3+} or Sb^{3+}) while preserving the perovskite crystal structure. Unfortunately, however, these materials tend to exhibit large bandgaps (> 2 eV), impeding their application in many photo-catalytic/voltaic devices.[3,4]
In this work, we demonstrate a drastic shift of over 1 eV in the optical absorption onset of $Cs_3Bi_2Br_9$ (from 2.58 eV to 1.39 eV), upon doping with tin. The origin of this broadband absorption is identified through a combination of detailed theoretical and experimental characterization of this novel material. Sn atoms are found to disproportionate in the doped material, inducing a strong intervalence charge transfer (IVCT) transition, whilst preserving the structural integrity of the perovskite framework. Moreover, using hybrid Density Functional Theory, including spin-orbit coupling effects, alongside the Marcus-Hush theory of IVCT behavior, we comprehensively elucidate the origin of unusual concentration dependence of absorption in the doped perovskite.
Our work provides valuable insight regarding the effects of mixed-valency and structure-property relationships in perovskite-inspired materials, guiding design strategies and expanding the compositional space of candidate materials. Furthermore, we anticipate that this massive reduction in absorption onset could aid charge transport and/or photo-catalytic performance, opening the door to unexplored applications of this material class.

Temperature-Dependent Ferroelectric Measurement of Methylammonium Lead Iodide

Allen Zhao[1,2], Zhaoning Song[1], Rasha Awni[1], Manoj Jamarkattel[1], Michael Heben[1] and Yanfa Yan[1]; [1]The University of Toledo, United States; [2]University of Michigan–Ann Arbor, United States

Organic-inorganic metal halide perovskites are a family of semiconductor materials with a number of unique and multifaceted optoelectronic properties, making it suitable for a wide range of applications. Despite the rapid progress of halide perovskite research in recent years, many challenges remain in understanding the fundamental properties of these materials. Among them, probing the ferroelectric response of halide perovskite-based devices has been shown to be challenging due to the soft lattice of halide perovskite and the large electronic and ionic contributions to conductivity. To date, there is limited research on ferroelectricity in metal halide perovskite thin films, and as a result, the existence and impact of these ferroelectric characteristics remain under debate. Here, we use a facile Sawyer-Tower measurement circuit with tunable stimulated frequencies to measure the ferroelectric hysteresis loop of perovskite capacitors and photodiodes at temperatures varying from 90 to 300 K. Utilizing this setup, we investigated variations in the polarization-electric field (P-E) hysteresis of different perovskite-based devices as a result of increasing and decreasing temperatures. We observed different temperature-dependent hysteresis behaviors in capacitors and photodiodes based on a prototype perovskite, methylammonium lead iodide ($CH_3NH_3PbI_3$). It was noted that the critical points of change in the P-E curves of these devices were observed at ~150K, which is attributed to the phase transition from the tetragonal to the orthorhombic crystal structure resulting from the temperature change. The Sawyer-Tower measurements, combined with thermal admittance spectroscopy measurements provide insights to understanding the material and device properties of halide perovskites.

Impact of Processing and Solution Engineering on the Film Formation of Lead-Free Halide Double Perovskite $Cs_2AgBiBr_6$

Maged A. Abdelsamie[1], Finn Babbe[1], Kevin Cruse[2], Gerbrand Ceder[2] and Carolin M. Sutter-Fella[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Lead-Free halide double perovskites with enhanced stability have gained attention as a promising environmentally friendly alternative to lead halide perovskites. Amongst different halide double perovskites, $Cs_2AgBiBr_6$ has shown attractive optoelectronic properties and stability, making it a promising candidate for stable high-efficiency optoelectronic devices. Motivated by a text-mining effort that not only illustrates the prevalence of powder over thin-film synthesis but also the discrepancy between the number of compositions experimentally realized and studied as compared to the many predicted compositions we present here on the intricacies of thin-film synthesis of $Cs_2AgBiBr_6$. Understanding the role of processing strategies on film formation pathways is of crucial importance as crystallization strongly affects the film microstructure, stability, and functionality in optoelectronic devices. Herein, using time-resolved spectroscopy, we investigate the film formation of $Cs_2AgBiBr_6$ *in situ* during blade-coating, spin coating, and the subsequent post-deposition thermal annealing under different processing conditions including antisolvent- and additive (HBr)-assisted synthesis. We show how different processing routes affect the film formation and microstructure of $Cs_2AgBiBr_6$. For films prepared by spin-coating and thermal annealing, we show that dropping anti-solvents during spin coating induces immediate supersaturation and crystallization of the wet film, whereas the time point of dropping the antisolvent has implications on the film formation dynamics and the final microstructure. Furthermore, due to the limited solubility of precursor salts, the thickness of the films is constrained by the low concentration of the precursor solution. HBr additive increases the solubility of precursor salts allowing to obtain thicker and pinhole-free films. We also show how the addition of HBr induces colloid formation in solution and thus influences the crystallization pathway during thin-film processing. For films prepared by blade-coating, our findings reveal that using blade-coating not only affects the crystallization pathway but also promotes the formation of highly crystalline films with preferential orientation as compared to films prepared by spin-coating followed by thermal annealing. Our work highlights the importance of real-time investigations to provide a mechanistic understanding of film formation and therefore can inform synthetic parameter choice.

Late News: An Efficient and Hydrophobic Molecular Doping for High-Efficiency and Stable Perovskite Solar Cells Junsheng Luo; University of Electronic Science and Technology of China, China

Longevity has been a long-standing challenge for perovskite photovoltaics. In general, Li-TFSI/*t*-BP are the state-of-the-art bi-dopants for the hole-transporting layer (HTL) in perovskite solar cells (PSCs), although such dopants significantly diminish the stability of devices. Here, we reported a novel dopant of fluorinated iron(III) porphine (Fe(III)-PP) as a potential alternative to the Li-TFSI/*t*-BP. The optimized PSCs exhibit a champion power conversion efficiency (PCE) of 21.734%, which is the highest efficiency among the ever reported PSCs based on novel dopant in HTL and also outperforms the standard bi-dopants Li-TFSI/*t*-BP (21.065%). The high migration barrier together with the hydrophobic nature of the Fe(III)-PP, which in turn suppress intrinsic ion migration and alleviate extrinsic moisture-induced degradation, resulting in prominent improvement of long-term stability of PSCs up to 1200 h under air exposure without encapsulation.

Late News: Applying Small Perturbation Techniques on Perovskite Solar Cells—Combining Experiments with Drift Diffusion Modelling Antonio J. Riquelme[1], Lawrence Bennett[2], Francisco Gálvez[1], Nicola Courtier[2], Lidia Contreras-Bernal[1,3], Matthew Wolf[4], Hernan Miguez[3], Alison Walker[4], Giles Richardson[2] and Juan Anta[1]; [1]Universidad Pablo de Olavide, Spain; [2]University of Southampton, United Kingdom; [3]Centro de Investigación Superiores Científicas, Spain; [4]University of Bath, United Kingdom

Metal Halide Perovskites (MHPs) are mixed electronic–ionic semiconductors with an extraordinary complex optoelectronic behaviour and a record efficiency surpassing 25%. Interpreting small perturbation response of perovskite solar cells (PSCs) is significantly more challenging than for most other photovoltaics. This is for a variety of reasons, of which the most significant are the mixed ionic-electronic conduction properties of metal halide perovskites and the difficulty in fabricating stable, and reproducible, devices. Experimental studies, conducted on a variety of PSCs, produce a variety of spectra shapes, with different physical interpretations. The impedance response has commonly been analyzed in terms of sophisticated equivalent circuits that can be hard to relate to the underlying physics and which complicates the extraction of efficiency-determining parameters. By a combination of experiment and drift-diffusion (DD) modelling of the ion and charge carrier transport and recombination within the cell, the main features of common impedance spectra are well reproduced by the DD simulation. Based on this comparison, we show that the high frequency response contains all the key information relating to the steady-state performance of a PSC, focusing on the charge collection efficiency of the device. We also analyze Intensity Modulated Photocurrent Spectroscopy (IMPS) data in MHPs based on the analysis of the internal quantum efficiency, connecting them to the charge collection obtained from Impedance, and the time signals featuring in the frequency spectra. We look at the change of each signal when optical excitation wavelength, photon flux, and temperature are varied for an archetypical methyl ammonium lead iodide solar cell. We compare the Perovskite IMPS results with relatively simpler dye-sensitized solar cells (DSC) with viscous and non-viscous electrolytes to help us to understand the origin of the three signals appearing in MHP cells and the measurement of the internal quantum efficiency.

12:00 PM EN06.10.30
Late News: On the Origin of Current Losses in Lead-Tin Perovskite Solar Cells and Beyond Jarla Thiesbrummel[1], Vincent M. Corre[2], Carlos Peña-Camargo[2], Fengjiu Yang[3], Steve Albrecht[3], Dieter Neher[2], Henry J. Snaith[1] and Martin Stolterfoht[2]; [1]University of Oxford, United Kingdom; [2]University of Potsdam, Germany; [3]Helmholtz-Zentrum Berlin, Germany

The power conversion efficiency of mixed metal lead-tin perovskite solar cells still lags behind those of their full-lead equivalents. One reason for this is that Sn^{2+} is easily oxidised to Sn^{4+}, which leads to the formation of charge carrier trap states and to p-doping. Though several strategies have been developed to prevent or limit this oxidation, the degradation of the perovskite layers upon exposure to oxygen remains problematic. Moreover, the

exact influence of self-doping on the performance of lead-tin perovskites is poorly understood. On top of that, other factors that could strongly affect device performance, such as the influence of mobile ions, have barely been explored for this system. Here, we take a closer look at the origin of current losses in lead-tin perovskite solar cells and find that, beside optical losses, the cells also suffer from significant charge collection losses. Voltage dependent photoluminescence (PL) measurements at open-circuit (V_{OC}) demonstrate a signigificant reduction in PL upon a switch from open- to short-circuit, indicative of efficient charge extraction. However, then the PL rises again over the course of several seconds, before stabilising at about 6% of the PL value obtained at V_{OC}. The current decays on the same timescales as the extraction becomes less efficient due to band flattening, amounting to a loss of 1.4 mA cm^{-2} under 1 sun illumination. In the following, we show that the reduction in the charge extraction efficiency and band flattening is linked to the movement of mobile ions in the perovskite rather than electronic charge (doping) and we show that this effect is well reproduced by numerical simulations. Importantly, as far as we could assess in this research, doping in mixed lead-tin perovskites is not directly causing current losses as the doping density is insufficient to screen the built-in field. Finally, we generalise our findings to lead-based perovskites, where we also find that the timescales of the band flattening and current loss correspond to the timescales of mobiles ions. Hence, the mechanisms appear to be generic for Pb and Pb/Sn based perovskites, which paves the way towards understanding a key loss mechanism in perovskite cells.

Late News: Nonlinear Band Gap Dependence of Mixed B-Site 2D Ruddlesden-Popper Perovskites
Cameron Underwood, David Carey and S. Ravi P. Silva; Advanced Technology Institute, University of Surrey, United Kingdom

Ruddlesden-Popper phase (RPP) perovskites have the general form $A1_{n-1}A2_2B_nX_{3n+1}$. The reduced dimensionality and structural characteristics of RPPs reportedly improve the stability of these crystals in comparison to their 3D perovskite counterparts[1]. Two dimensional (2D) Ruddlesden-Popper perovskites (RPPs) of the form ABX_4 can be used as the tunable active layer in photovoltaics, as the passivating layer for 3D perovskite photovoltaics or as light emitting diodes.

Here we show a nonlinear band gap behaviour with Sn content in mixed phase 2D RPPs of the form $AB1_{1-x}B2_xI_4$. GGA level density functional theory calculations (with and without spin-orbit coupling) are employed to study the effects of the short range ordering of B1 and B2 in $AB1_{1-x}B2_xI_4$ compositions with x = 0, 0.25, 0.5, 0.75 and 1. The origins of the nonlinearity are shown to be due to the chemical behaviour of the relative energies of the B s states in the VBM composition, much like in 3D perovskites[2]. This is also influenced by the relative X-B-X angles, where increased angles result in a higher overlap between X and B orbitals, resulting in a higher dispersion and a decreased band gap. The short range ordering of B site atoms is discussed, especially in the case of x = 0.5, where the short range ordering is most significant, the band gap energy is shown to be dependant on this. We have also highlighted the role of using SOC in calculations of 2D RPPs, discussing that SOC does not significantly affect the nonlinearity of the band gap, but strongly affects the linear term, and is also crucial for understanding other electronic properties of 2D RPPs, such as accurate effective masses. This research underlines the importance of supercell permutations as well as providing a good platform to study other 2D perovskites, such as other A sites, other mixed B sites, or mixed halide RPPs.

Late News: DFT Calculations of Neutral and Charged Tin-Halide Perovskites Cameron Underwood[1], Zhou Wang[2], Guosheng Shao[2], David Carey[1] and S. Ravi P. Silva[1]; [1]Advanced Technology Institute, University of Surrey, United Kingdom; [2]Zhengzhou University, China

3D bulk perovskites have shown amazing promise as photovoltaic devices, but are still curbed by various instabilities. Sn based perovskites in particular are extremely susceptible to oxidation in both air and moisture. We report on the evolution of the electronic structure with partial oxidation state of tin and iodine from $ASnI_3$ to a charged system of $[ASnI_3]^{2+}$, where A = CH_3NH_3 (MA), $CH(NH_2)_2$ (FA) or Cs. When a simulated charge cell is tested, most of the charge is reduced in the SnI_3 unit due to the valence band edge being dominated by Sn 5s and I 5p antibonding staters, this charge reduction is accompanied by a reduction in unit cell volume in $[ASnI_3]^{2+}$ compared to $ASnI_3$. Generalized gradient approximation (GGA) level density functional theory (DFT) band structure calculations with spin orbit coupling show semiconducting behaviour in $ASnI_3$, with metallic behaviour in $[ASnI_3]^{2+}$. We also show a similar behaviour for $APbI_3$ and $[APbI_3]^{2+}$, where the Pb atoms lose less partial charge than Sn due to the higher relative energy of the Pb 6s states compared to Sn 5s states. Phonon band structure calculations show an increase in imaginary modes in the charged system, for both Sn and Pb based systems.

12:30 PM EN06.10.33
Late News: Multi-Functional Conjugated Ligand Engineering for Stable and Efficient Perovskite Solar Cells Ke Ma and Letian Dou; Purdue University, United States

With the advancement in understanding the device physics of perovskite solar cells, tremendous attention has been paid on the interface between perovskite layer and the charge transporting layer, where the significant efficiency loss and degradation occur. Surface passivation is an effective way to improve the efficiency and stability of perovskite solar cells. However, a key challenge faced by most of the passivation strategies is reducing the interface charge recombination while avoiding imposing energy barriers to charge extraction. This is usually achieved through fine control of the passivation process. In this talk, I will present a novel multi-functional semiconducting organic ammonium cationic interface modifier for post-treatment of the perovskite surface, to overcome this dilemma through molecular engineering. The conjugated organic ammonium halide salt can simultaneously facilitate charge extraction, improve energy level alignment, reduce interface recombination, and stabilize the perovskite lattice. The conjugated ligand treatment also exhibits a high degree of tolerance to the capping condition and capping layer thickness, owing to its semiconducting properties. Based on this strategy, a triple-cation mixed-halide medium-bandgap perovskite solar cell is delivered with an excellent power conversion efficiency of 22.06% (improved from 19.94%). More interesting, the ion migration and halide phase segregation in perovskite films are significantly suppressed due to the lattice anchoring effect of conjugated ligand, which lead to a long-term stability of over 1000 hours under continuous illumination. Our molecular engineering strategy provides a new practical method of interface engineering in perovskite solar cells towards improved efficiency and stability.

12:40 PM EN06.10.34
Late News: A Strategy for Constructing Dispiro-Based Dopant-Free Hole-Transporting Material—Spatial Configuration of Spiro-bifluorene Changes from Perpendicular to Parallel Arrangement Zhongquan Wan; University of Electronic Science and Technology of China, China

Due to the low intrinsic hole mobility caused by orthogonal conformation of two fluorene units in Spiro-

OMeTAD which is a classic hole-transporting material (HTM) in perovskite solar cells (PSCs), Spiro-OMeTAD based PSCs generally can only obtain high performances through a sophisticated doping process with dopants/additives which adds to the cost and complicacy of device fabrication, but also adversely affects the stability of PSC device. Herein, a novel dispiro-based HTM, WH-1, is designed by cleverly replacing the central carbon atom of Spiro-OMeTAD with cyclohexane, and the spatial configuration of HTM is changed from vertical orthogonality of the two fluorene units to parallel arrangement, which is beneficial to the formation of homogeneous and compact HTM film on the surface of perovskite film, improvement of intermolecular electronic coupling and intrinsic hole mobility. WH-1 is obtained in a two-step facile synthesis with a high yield from commercially available materials. WH-1 is used in PSCs as dopant-free HTM, which is the first time that the dispiro-based molecule is applied as dopant-free HTM, and power conversion efficiency (PCE) of 19.57% is obtained, rivaling Li-TFSI/t-BP doped Spiro-OMeTAD in PCE (20.29%), and showing obvious superior long-term stability.

12:50 PM EN06.10.35
Late News: A Periodic Half-Cylinder Photonic Plate to Polarize and Recycle Light Using Perovskite Solar Cells Applicable to Liquid Crystal Displays Guillermo Martínez-Denegri[1], Catarina G. Ferreira[1], Johann Toudert[1], Mariia Kramarenko[1], Paul Fassl[2,3], Marco A. Ruiz-Preciado[2,3], Saba Gharibzadeh[2,3], Ulrich W. Paetzold[2,3] and Jordi Martorell[1,4]; [1]ICFO - Institute of Photonic Sciences, Spain; [2]Light Technology Institute - Karlsruhe Institute of Technology, Germany; [3]Institute of Microstructure Technology - Karlsruhe Intitute of Technology, Germany; [4]Universitat Politècnica de Catalunya, Spain

Liquid crystal displays (LCDs) are widely used to obtain high resolution full color images in many electronic devices. Unfortunately, such devices are far from being energetically efficient. In fact, in current portable electronics or large TV monitor screens based on LCDs, a considerable amount of light emitted by the light-emitting diodes does not reach the eye of the user but instead it is lost as heat somewhere in the device. Here, we propose a novel light guiding system which we name half-Cylinder Photonic Plate (h-CPP). The h-CPP is based on a periodic array of intercalated half-cylinders where light propagates chaotically and transversally to the cylinders, exiting the array from the top surface with a diffused light intensity pattern. By applying inverse electromagnetic design to modify the optical properties of such periodic array surface, we are able to induce a lossless polarization selectivity which can be made suitable for LCD applications. Furthermore, the design of the h-CPP allows to collect the non-transmitted light, unusable for the display and otherwise wasted, by two perovskite solar cells. Thereby, this light can be recycled back to electricity, considerably increasing the overall device efficiency. Based on such h-CPP, we will present a combination of numerical and experimental results demonstrating the polarization as well as light recycling capacities of our novel design.

1:00 PM EN06.10.36
Investigation of Heterogeneous Charge Trapping Dynamics at Nanoscale Defects in Triple Cation Mixed Halide Perovskite Thin Films Sofiia Kosar[1], Andrew Winchester[1], Stuart Macpherson[2], Christopher E. Petoukhoff[1], Julien Madéo[1], Michael K. Man[1], Samuel Stranks[2] and Keshav M. Dani[1]; [1]Okinawa Institute of Science and Technology, Japan; [2]University of Cambridge, United Kingdom

Hybrid organic-inorganic perovskites (HOIPs) have been introduced as promising semiconductor materials for fabrication of photovoltaic (PV) devices about a decade ago [1]. Since then the photoconversion efficiencies of record HOIP PV devices have exceeded 25 % [2], which approaches efficiencies of traditional single crystal Si solar cells. Nevertheless, theoretical calculations predict that there is potential to boost the efficiency of HOIP PV devices even further, to more than 30 % [3]. However, to do so we need to first overcome limitations that prevent these materials from reaching their theoretical efficiencies.

One of the main performance-limiting factors for HOIP PVs has been attributed to the presence of non-radiative losses [4]. These non-radiative losses have been shown to be inhomogeneously distributed at the nanoscale, implying local carrier trapping. Therefore, understanding the nature of these non-radiative losses and their detrimental impact on PV device performance, requires use of techniques having high degrees of spatial and

temporal resolution. Recently, using a custom-designed time-resolved photoemission electron microscope (TR-PEEM), we have directly imaged nanoscale distribution of defects that induce non-radiative losses in HOIP thin films, identified their formation sites with respect to surface microstructure, and revealed their hole-trapping nature [5].

Here, we further elucidate the nature of nanoscale defects in triple cation mixed halide perovskite thin films that have been fabricated by solution-processing methods. We employ the TR-PEEM technique to explore the nanoscale electronic properties of these defects, including their spatial distribution, energy-level position within the band gap, and their charge trapping dynamics. We correlate these defects to non-radiative recombination sites, and to the surface morphology. We find the presence of multiple types of defects, the formation of which is related to the growth stoichiometry. We reveal that these nanoscale defects have inhomogeneities in their charge trapping dynamics. Our study provides insight into the relationship between composition of HOIP thin films and formation of nanoscale performance-limiting defects.

Photo-Effect on Ion Transport in Mixed Cation and Halide Perovskites and Implications for Photo De-Mixing Ya-Ru Wang, Gee Yeong Kim, Alessandro Senocrate, Davide Moia and Joachim Maier; Max Planck Institute for Solid State Research, Germany

Since the discovery of anomalous polarization phenomena in solar cells based on organic-inorganic hybrid perovskites, much attention has been devoted to the mixed ionic-electronic conducting properties of these materials.[1, 2] Strikingly, investigation of mixed conduction in methylammonium lead iodide ($MAPbI_3$) under light showed – along with the expected increase in electronic conductivity – huge enhancement of ionic conductivity (photo-ionic effect).[3] The photo-induced ion conductivity is assumed to be the consequence of hole localization that neutralizes iodide locally; the so-formed neutral iodine atoms can occupy interstitial sites where they are further stabilized by the polarizable environment in $MAPbI_3$.

As mixed-cation/anion perovskites show the greatest potential for achieving high-efficiency solar cells, understanding the role of cations and anions on this“photo-ionic effect” is of utmost importance. Here, we quantitatively deconvolute ionic and electronic transport properties in which the A-site cation or the anion is partially or fully substituted. Specifically, the electronic and ionic conductivities of $MAPbBr_3$, $CsPbI_3$, $CsPbBr_3$, as well as $FAPbI_3$ -$MAPbI_3$ and $MAPbBr_3$- $MAPbI_3$ mixtures are investigated.[4] As far as the photo-ionic effect is concerned, we find that A-site substitution was of only small influence compared with anion substitution. By substituting I by Br, a significant lowering of the photo-ionic effect was observed. This corroborates our hole trapping mechanism for the photo-induced ion transport owing to the fact that Br is less polarizable than the counterpart of I. Our electrical characterization performed on mixed halide perovskite $MAPb(I_{1-x}Br_x)_3$ thin films as a function of x confirms the previously reported phase instability under light of these materials in the intermediate composition range. On the basis of these observations, we draw a possible interpretation explaining the photo-demixing in mixed halide perovskites where the formation of neutral iodine interstitial defects stabilizes the coexistence of I-rich and Br-rich domains. This factor may represent an important contribution to the driving force for phase segregation and emphasizes the importance of the coupling between electronic and ionic defects in the phase behavior of halide perovskites.

Untangling the Ionic Conductivity Tuning by Changing A-Site Cation and X-Site Anion in Hybrid Perovskites by Photoelectrochemical Impedance Spectroscopy Priya Srivastava, Ramesh Kumar and Monojit Bag; Indian Institute of Technology Roorkee, India

Mixed electronic-ionic conductors such as hybrid perovskite materials exhibit the complexity in conduction. A deeper understanding of both ionic conductivity and electronic conductivity is important. Herein, the role of A-site cation and X-site halide ion was investigated by employing Photoelectrochemical Impedance Spectroscopy technique on perovskite-electrolyte interface-based devices in controlling the charge and ionic conductivity of the perovskite material. It was observed that ionic conductivity of the perovskite material can be easily tuned either by changing the A-site cation (MA+/FA+) or by changing the X-site halide ion (I-/Br-). Significantly different (opposite) photo-induced ionic conductivity in different cation or different halide-based perovskites was noted. Therefore mixed-cation or mixed-halide perovskite can be utilized to reduce photo-induced ion conductivity of the material. Furthermore, very fine-tuning is also possible by modulating the externally applied voltage. The effect of ion accumulation and migration on the charge storage and transport property of the device is analyzed using vacancy hopping and jump relaxation model. Ionic conductivity spectra revealed Jonscher's law dependence at mid- and low- frequency regime with a constant plateau at high-frequencies. It was concluded that the interplay of ion migration and accumulation dictates the resulting conduction and storage property of the complete device structure. These perovskite/electrolyte-based devices, therefore, can be promising candidates for electrolyte gated perovskite field-effect transistors where switchable ion conductivity can be achieved either by external applied electric field or photo-excitation.

Late News: Spatial Chemical Heterogeneity Circumvents Power Losses from Local Electronic Disorder in High-Performance Halide Perovskite Solar Cells Kyle Frohna[1], Miguel Anaya[1,1], Stuart Macpherson[1], Jooyoung Sung[1], Tiarnan A. Doherty[1], Yu-Hsien Chiang[1], Andrew Winchester[2], Keshav M. Dani[2], Akshay Rao[1] and Samuel Stranks[1,1]; [1]University of Cambridge, United Kingdom; [2]Okinawa Institute of Science and Technology, Japan

Halide perovskites perform remarkably in optoelectronic devices[1,2]. This class of materials exhibits a considerable defect tolerance, with long charge carrier lifetimes in spite of large concentrations of defects, which has been related to exotic phenomena such as polarons, Rashba effect and photon recycling[3,4]. However, their performance is still not properly understood given they exhibit compositional and structural heterogeneity in addition to large concentrations of deep charge carrier traps in well localized spatial clusters[5,6]. In this talk, we resolve this paradox revealing that compositional disorder of the perovskite can induce carrier funneling away from deep trap states, improving performance[7].

We use a series of multimodal microscopy techniques based on synchrotron nanoprobe and optical spectroscopic techniques, including hyperspectral and transient absorption microscopy. We map the local chemical and structural heterogeneity of device relevant FA0.79MA0.16Cs0.05Pb(I0.83Br0.17)3 (FA=formamidinium, MA=methylammonium) perovskite samples on the nanoscale using nano X-ray fluorescence and diffraction. We spatially correlate these measurements with local values of quasi-Fermi level

splitting and Urbach energy, which are important device metrics, as well as ultrafast carrier dynamics from transient absorption microscopy. We show that local quasi-Fermi level hotspots are caused by carriers funneling onto local regions with low electronic disorder. Importantly, this funneling mechanism collects charges over micrometers and thus sequesters carriers away from trap clusters associated with higher electronic disorder. The visualization of this nanoscale landscape provides an explanation for the purported defect tolerance in these materials and may open an avenue for a new class of intrinsically disordered but high performing materials.

1:40 PM EN06.10.40
Late News: Perovskite Solar Cells for Space Application Lennart Reb[1], Michael Böhmer[1], Benjamin Predeschly[1], Sebastian Grott[1], Goran I. Ivandekic[1], Renjun Guo[1], Christoph Dreißigacker[2], Roman Gernhäuser[1], Andreas Meyer[2] and Peter Muller-Buschbaum[1,3]; [1]Technische Universität München, Germany; [2]Deutsches Zentrum für Luft- und Raumfahrt, Germany; [3]Heinz Meier-Leibniz Zentrum, Germany

Perovskite solar cells possess a revolutionary potential for space applications. The thin-film solar cells can be processed onto thin polymer foils that enable an exceptional specific power, i.e. obtainable electric power per mass, being superior to their inorganic counterparts. However, research towards space applications was mainly restricted to terrestrial conditions so far. We report the first demonstration of operation of perovskite solar cells in space conditions [1]. A stabilized payload orientation allowed us to obtain current-voltage characteristics under stable irradiance conditions in low Earth orbit altitudes. By tracking the evolution of short-circuit currents we can identify phases of direct solar irradiation and weak diffuse-light irradiation arising from the Earth's surface. During phases of strong solar irradiance, both perovskite solar cell types (planar and mesoscopic nip-type) exceeded power densities (power per area) of 14 mW cm^{-2}. Thus, the different solar cells reached their performance expectations exposed to space conditions. Also during a phase of being turned away from the sun, the solar cells still generated power, just collecting faint scattered light from the Earth. Interestingly, the power densities reached levels as anticipated for deep-space irradiance conditions. These results highlight both the suitability for near-Earth applications as well as the potential for deep space missions for perovskite cells.

Investigating the Role of Band Alignment of the Transparent Conductor and Electron Transport Layer Interface in Wide-Bandgap Perovskite Solar Cells Jared Friedl, Ramez Hosseinian Ahangharnejhad, Adam Phillips and Michael Heben; The University of Toledo, United States

Wide-bandgap mixed-halide perovskites such as $CH_3NH_3Pb(I_xBr_{1-x})$ are of great interest because of their favorable bandgaps for use as top subcells in multijunction photovoltaic devices. Recently, we have shown

through numerical simulation that the performance of single junction wide-bandgap perovskite devices strongly depends on the energetic alignment between the absorber and the charge transporting layers. Those results showed interesting behavior in the power conversion efficiency at high conduction band offset between the electron transport layer (ETL) and wide-bandgap absorber; namely, the open circuit voltage rapidly increased, but the fill factor decreased just as drastically. These results suggest the formation of a large potential barrier that impedes electron flow out of the absorber. Such a barrier was not evident at the ETL/absorber interface but may be the result of poor band alignment at the transparent conducting oxide (TCO)/ETL interface. Here, we investigate the impact of TCO band alignment with the ETL in wide-bandgap perovskite solar cells. We show that varying the conduction band position of the TCO can lead to reductions in both the recombination and fill factor loss. The reduction in recombination allows the device to maintain a high fill factor, near 90%, not previously observed for a wide range of conduction band offsets (CBOs) between the ETL and wide-bandgap absorber. Simultaneously, varying the conduction band position of the TCO preserves a high V_{OC} and results in a 1-2% increase in efficiency compared to our previous modeling with a standard TCO and optimized ETL/absorber CBO. These results indicate that as the bandgap of the perovskite absorber layer is increased, the choice of ETL and TCO will have a significant joint effect on performance.

Triple Halide Perovskite Composition Exploration Assisted by DFT and Data Science Methods Qingmu Deng[1], Zachary del Rosario[1] and Rebecca Belisle[2]; [1]Olin College of Engineering, United States; [2]Wellesley College, United States

Lead halide perovskites are promising materials for tandem solar cell applications due to their easily tunable bandgap through cation and halide compositions. However, photo-induced halide segregation in iodide-bromide perovskite chemistries often results in iodine-rich and bromine rich domains and limits the efficiency of tandem solar cells. One approach to mitigate such segregations reported in the literature is the addition of chlorine to the cesium-formamidinium iodide-bromide perovskite compositions. However, the literature on the effects of varying degrees of chlorine incorporation in thin-film perovskite is limited. In this study, we present an experimental study of the iodine-bromine-chlorine composition space aided by density functional theory (DFT) calculations and data science methods. By loosening cesium-to-formamidinium ratio at the same time, we allow for more possible selections of triple halide compositions that could fall in the optimal range of Goldschmidt's tolerance factor and result in stable perovskite. Among these selections, we look for compositions whose band gaps are optimized for tandem applications and whose halide segregation effects are minimized. Since all possible hybrid-cation mixed halides samples at one percent increments are too numerous to fabricate, we perform a screening informed by DFT and data science methods to intelligently search the compositional space. Through iterative experimental and computational exploration, we identify triple halide perovskite compositions with optimized opto-electronic properties well suited for tandem applications. Our data science and DFT approach demonstrates an expedition to experimental work in material discovery and characterization, which could be adapted to optimizing perovskite chemistries for alternative optoelectronic applications.

$MAPbBr_3$ Single Crystal Stability with Co-Exposure of Oxygen and Light Ke Wang[1], Benjamin Ecker[1], Jinsong Huang[2] and Yongli Gao[1]; [1]University of Rochester, United States; [2]University of North Carolina at Chapel Hill, United States

The stability of methylammonium lead bromide ($MAPbBr_3$) single crystal was investigated when subjected to simultaneous oxygen exposure and light illumination of one solar intensity. The exposure process was monitored with X-ray photoelectron spectroscopy (XPS) with detailed control of the exposure time and pressure. It was found that the with light the oxygen degradation process of the $MAPbBr_3$ was substantially accelerated. Quantitative analysis showed that Carbon, Bromine and Nitrogen lost 52%, 56% and 90% of their initial concentration respectively at 10^{12} Langmuir of oxygen exposure. It further showed that ~11% of the perovskite's Pb degraded to metallic Pb at 10^9 Langmuir, and then was oxidized with the increase of the oxygen pressure.

2:06 PM EN06.10.45

Unraveling the Role of Alkali Cations on Perovskite Phase Segregation of Multi-Cation and Mixed-Halide Perovskites Ming-Chun Tang[1,2], Siyuan Zhang[1,3], Nhan V. Nguyen[1] and Christina A. Hacker[1]; [1]National Institute of Standards and Technology (NIST), United States; [2]University of Maryland, United States; [3]Theiss Research, United States

Control and prevention of perovskite phase segregation are crucial to realizing stable and tunable multi-cation and mixed-halide perovskite optoelectronic devices. Herein we report the comprehensive analysis of band structure, compositional heterogeneity, and phase segregation in the novel alkali cesium (Cs^+) and potassium (K^+)-doped 3D perovskites using a suite of powerful and highly complementary techniques [such as X-ray photoemission spectroscopy (XPS), depth profiling, ultraviolet photoelectron spectroscopy (UPS) and grazing incidence wide-angle X-ray scattering (GIWAXS)]. Perovskite phase segregation information has been extracted from the optical or electrical properties using techniques such as absorption and photoluminescence spectroscopy, external quantum efficiency (EQE), transient difference absorption spectroscopy, and photovoltaic performance. However, all of these techniques provide indirect compositional information and cannot reveal the spatial distribution. We found that the incorporation of metal cations raises the conduction band minimum (CBM), facilitating electron transfer to the electron transport layer. Notably, the depth profile by XPS and GIWAXS analysis show that the formation of iodide- and bromide-rich regions are strongly correlated to the alkali metal cation concentrations: low metallic concentration (5%) can prevent phase segregation where the halides and cations are distributed evenly across the films, while high metallic cation ratio (20%) leads to halide segregation where the concentration of iodide decreases accompanied with the increase of bromide and metal cation concentration as the sampling depth increases. These differences in electronic properties, element distribution, and film morphology were reflected in solar cell performance: >20 % of power conversion efficiency (PCE) was demonstrated with low Cs^+ incorporated perovskite, while ≈16.7 % of PCE with high Cs^+ concentration perovskite. Similar trends were also observed in the K^+-doped perovskite system. We believe this work will advance the perovskite community by providing a direct and straightforward route to characterize the impacts of perovskite phase segregation.

2:09 PM EN06.10.46

Extraction of Perovskite Solar Cell Parameters Based on a Consistent Device Model Andreas Schiller[1,2], Martin T. Neukom[1,2], Simon Züfle[1], Evelyne Knapp[2], Christoph Kirsch[2], Balthasar Blülle[1], Sandra Jenatsch[1] and Beat Ruhstaller[1,2]; [1]Fluxim AG, Switzerland; [2]Zurich University of Applied Sciences, Switzerland

Parameter extraction based on numerical simulation is error-prone because model parameters are often correlated [1]. The accuracy of the extracted parameters can be improved by combining multiple steady-state and transient measurement techniques to reduce these correlations. This method has been successfully applied to organic solar cells [2].

Modelling perovskite solar cells, however, involves additional complexity. Characteristic features, such as IV curve hysteresis [3,4] and slow transient current rise [5,6] indicate the presence of mobile ionic charges in the perovskite layer. Simulation models including ionic charges could qualitatively reproduce these individual features [3-5]. However, the reliable determination of these ionic parameters additionally requires suitable characterization techniques.

To increase the trustability of the model, we systematically study the influence of individual model parameters on different experimental techniques. We therefore model multi-layer methylammonium lead iodide (MAPI) perovskite solar cells in a coupled opto-electrical simulation including mobile ionic charge carriers, charge trapping, Shockley-Read-Hall (SRH) recombination and doped transport layers. We find a single set of parameters to explain the combined results from various measurement techniques in DC, AC, and transient regime [6]. The applied techniques include IV curves with different scan rates, light intensity dependent open circuit voltage, impedance spectra, intensity-modulated photocurrent spectra (IMPS), transient photocurrents and transient voltage step responses. As expected, the various measurement techniques show different sensitivities to material and device parameters, which a model fit can benefit from.

Yet correlated parameters remain an issue. Namely it is difficult to distinguish between concentration and mobility of ionic charge carriers [6]. M.H. Futscher et al. [7] recently applied a measurement technique called transient ion drift to perovskite solar cells. This technique was originally developed for inorganic p-n junctions and allows to individually and quantitatively measure both concentration and mobility of slowly moving mobile charges [8]. It is unfortunately restricted to materials with low concentrations of mobile charges and comparably high doping [7-8]. Using our model we evaluate this characterization technique for devices beyond these restrictions. Specifically we investigate materials with high concentrations of mobile ions or absence of doping, as many perovskite materials meet one or both of these specifications. We further investigate the correlation between other parameters and the extracted ones.
Our consistent device simulation model allows for a better understanding of the governing physical effects and provides a powerful tool to study the influence of device parameters on the solar cell performance and efficiency. The variety of applied measurement techniques allows one to reduce the correlation between parameters. Furthermore, an in depth parameter study suggests possible paths towards an optimized device [6].

Probing the Mechanism of Anion Exchange and Dopant Migration in Cesium Lead Halide Perovskites

Kyle Kluherz[1,2], James J. De Yoreo[2,1] and Daniel Gamelin[1]; [1]University of Washington, United States; [2]Pacific Northwest National Laboratory, United States

Colloidal $CsPbX_3$ (X = Cl, Br, I) perovskite nanocrystals have attracted a great deal of interest due to their bright, narrow emission, high photoluminescence quantum yields, tunable band gap, and defect tolerance. Various dopants have been successfully incorporated in their structure, including notably Mn^{2+} and Yb^{3+}, allowing for novel emissions properties such as broadband emission and quantum cutting. However, the structure and chemistry of dopants within the perovskite lattice are not well understood. A characteristic property of $CsPbX_3$ nanocrystals is their facile anion-exchange chemistry in the liquid or gas phase, which allows ready conversion between different halide structures, formation of mixed halide compositions, and access to materials that are difficult or impossible to synthesize directly. The mechanism(s) by which this anion exchange occurs are still poorly understood, as are its effects on dopant sites. Our work focuses on probing these reactions at the atomistic level to gain mechanistic insight into this important chemical transformation. We have employed X-ray total scattering measurements of the ensemble anion exchange reaction to observe structural changes during this process. These indicate a continuum shift in the structure during anion exchange, with expected expansions in the long-range order. A substantial change in the majority of atom pair positions and intensities was also observed in the Mn-doped system, while the Yb-doped system is nearly identical to the undoped structure, except for a small shift in the Pb-Cl peak. Furthermore, we are pursuing a combination of environmental TEM and HR-STEM with EDX mapping at multiple points ex-situ and in-situ in the gas phase in order to understand the mechanism of anion exchange in doped and undoped halide perovskite nanomaterials.

Does Mechanical Strain Drive Ion Migration in Mixed Halide Perovskites? Jacob Bolduc and Aaron Fafarman; Drexel University, United States

Metal halide perovskites possess fascinating material properties and significant technological promise. The

materials consist of a nominal formula of APbX3, where A is a large cation (e.g. Cs, MA or FA), and X is a halide, however much attention has been devoted to the alloys composed from mixtures thereof, e.g. (MA/Cs/FA)Pb(Br/I)$_3$. Alloying at the X-site provides bandgap tunability while alloying at both sites can significantly enhance stability towards both phase change and moisture-catalyzed degredation. Recent studies have identified the phenomenon of light induced halide demixing, whereupon illumination drives the formation of pure-phase halide clusters. This entirely reversible process has been hypothesized to be due to strain induced by photoexcited polarons. The facile and reversible nature of ion mobility in this system makes it an ideal setting for studying the coupling between external perturbations and the spatial distribution of ions in mixed alloys. These experiments test whether mechanically induced strain is another such external perturbation capable of driving ion migration. To determine the extent of ion migration in mixed halide perovskites to mechanically-induced strain, polycrystalline thin films of MAPbBrI$_2$ were placed under deliberate tensile strain and measured via steady-state photoluminescence for changes in the spatial distribution of halides at the point of strain as a function of time.

Late News: Organic and Inorganic A-Site Cation Induced Trends in the Electronic Structure of Lead Bromide Perovskites Gabriel J. Man; Uppsala University, Sweden

The presence of an organic or inorganic A-site cation has been associated with subtle differences in the electronic structures of lead bromide perovskite compounds. Through a bromine- and lead-selective core level spectroscopic study of three archetypal hybrid-organic and all-inorganic APbBr$_3$ compounds, including the first high-resolution hard X-ray absorption spectroscopy measurements on lead halide perovskite single crystals, we find the A-site cation has a substantial effect on the unoccupied states and a relatively smaller effect on the occupied states. We examine the conduction band states with Br K-edge X-ray absorption spectroscopy, finding Pb-Br states near the conduction band edge and higher-lying (A cation)-Br states. We find a linear correlation between relative Goldschmidt tolerance factors and relative conduction band widths. Through a combination of non-resonant X-ray emission spectroscopy and hard X-ray photoelectron spectroscopy, we find that the occupied states of the three compounds differ primarily at the valence band edge. We directly access lead-bromide bonding ionicity via X-ray emission spectroscopy and account for relative shifts in the energy levels with the chemical shift. Our findings have implications for interfacial energy level alignment in perovskite devices, the defect tolerance hypothesis, slow hot carrier cooling and other intriguing effects in this class of materials.

10:30 AM *EN07.02.01
Thin Film Solar Cells Using n-CdTe Absorber Layers Ken Durose[1], Luke Thomas[1], K Cheetham[1,2], M Isaccs[3], Theo Hobson[1], N Tarbuck[1], L Phillips[1] and Jon Major[1]; [1]University of Liverpool, United Kingdom; [2]STFC Daresbury Laboratory, United Kingdom; [3]Research Complex at Harwell, United Kingdom

There are good reasons to abandon the usual p-type absorbers in CdTe-based solar cells in favour of n-type ones. Despite recent advances in CdTe PV (e.g. eliminating CdS, the use of CdSeTe and intentional p-type doping using CdTe:As), the basic design of 'superstrate' CdTe-based devices remains unchanged since the 1960s: light enters through the glass/transparent conducting electrode/window layer and generation takes place in a shallow homojunction in the CdTe-based absorber layer - which is otherwise p-type. These cells have limited V_{oc}. The use of n-type CdTe absorbers sidesteps two fundamental physical limitations of p-CdTe and replaces them with technological challenges: For p-type CdTe it is well known that formation of Ohmic contacts requires that a barrier be overcome (this being the value of the electron affinity plus a large fraction of the bandgap). Also, wide- and medium-gap semiconductors cannot stably be doped p-type at a high density due to self-compensation limitations imposed by native defects. Such factors limit the V_{oc} achievable from CdTe-based devices. For n-type CdTe, doping with indium can achieve close to 100% activation and allows higher stable doping densities to be achieved than with CdTe:As for example. Ohmic contacts to it may be formed without issue. Both the n-doping and Ohmic contacts are well-known for single crystal n-CdTe.

Hence the challenge for n-type devices, lies elsewhere, notably in the choice of partner layers and their electrodes, the selection of a device architecture and the control of n-doping in the context of thin film growth and processing. There are essentially four choices of device architecture: A) 'substrate' devices in which the light enters through the glass/TCO combination and then first encounters either a) n-CdTe or b) a p-type partner layer or B) 'superstrate' devices in which the light enters through a transparent electrode and then first encounters either a) n-CdTe or b) its p-type partner layer. To sum them up in other words: there is either an n- or a p-type window layer. We ruled out using p-type TCOs immediately - since they have low conductivity - and instead we considered other options. In a preliminary simulation study (using SCAPS) we identified a range of materials choices and architectures for n-CdTe devices that gave $V_{oc} \geq 1$V. This indicated that experimentation would be worthwhile.

For the CdTe:In doping we have been trialling post-growth introduction of indium into CSS-grown CdTe using

elemental indium (with and without pre- or post-treatment using $MgCl_2$), both aqueous and methanolic $InCl_3$ and also treatments with and without nitric/phosphoric etching. We will report conductivity measurements, transfer length measurements (contacts), SIMS and XPS results. There is some indication that diffusion can be blocked by surface oxides. As an alternative we are trialling intentionally pre-doped CdTe:In source material for use in close space sublimation film growth directly. At the time of writing device work is in progress using a variety of wafer (test structure) and thin film partner layers including organics. This part of the work is at an early stage and we will report on progress at the conference.

10:55 AM EN07.02.02
Reconciliation of Theory with Experiment for Defects in CdTe—The Case of the Cadmium Vacancy Seán R. Kavanagh[1,2,2], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

The ability to accurately model, understand and predict the behaviour of crystalline defects would constitute a significant step towards improving photovoltaic device efficiencies and semiconductor doping control, accelerating materials discovery and design. In this work, we apply state-of-the-art *ab initio* techniques - hybrid Density Functional Theory (DFT) including spin-orbit coupling - to accurately model the atomistic behaviour of the cadmium vacancy (V_{Cd}) in cadmium telluride (CdTe). In doing so, we resolve several longstanding discrepancies in the extensive literature on this subject.

CdTe is a champion thin-film absorber for which defects, through facilitation of non-radiative recombination, significantly impact photovoltaic (PV) performance, contributing to a reduction in efficiency from an ideal (Shockley-Queisser) value of 32% to a current record of 22.1%. Despite over 70 years of experimental and theoretical research, many of the relevant defects in CdTe are still not well understood, with the definitive identification of the atomistic origins of experimentally-observed defect levels remaining elusive.[1–3]

In this work, through identification of a tellurium dimer ground-state structure for the neutral Cd vacancy, we obtain a single negative-U defect level for V_{Cd} at 0.35 eV above the VBM, finally reconciling theoretical predictions with experimental observations. Moreover, we reproduce the polaronic, optical and magnetic behaviour of V_{Cd}^{-1} in excellent agreement with previous Electron Paramagnetic Resonance (EPR) characterisation.[4]

The origins of previous discrepancies between theory and experiment, namely incomplete mapping of the defect potential energy surface (PES) and inherent qualitative errors in lower levels of electronic structure theory, are analysed in detail. Accordingly, this work helps to establish robust procedures for accurate and reliable modelling of defect processes in emerging materials, informing future investigations and enabling the acceleration of materials discovery and design procedures.

***In Situ* Doping for CSS Growth of n-CdTe Hetero-Structures** Theo Hobson, Luke Thomas, Laurie Philips, Jon Major and Ken Durose; University of Liverpool, United Kingdom

In this work we investigate the use of pre-doped n-type CdTe source material to fabricate PV devices via close-space sublimation (CSS). The more readily dopable n-type CdTe offers the potential advantages of easier Ohmic contacting and higher V_{oc} than are achieved with conventional p-type CdTe material.
Metallic indium was incorporated into bulk CdTe source material (Sigma Aldrich 6N) in quartz capsules sealed

under vacuum and heated above the melting point of 1091°C for 3 days. In order to achieve doping in the range 10^{18} – 10^{16} cm^{-3} successive dilution steps were required. The resulting material was qualified by chemical analysis using EDX (to determine homogeneity for the highly doped compositions) and by ICP-OES to determine the absolute indium concentrations in the bulk material more generally. XRD was used to confirm the phase purity.
Thin films of CdTe:In deposited using CSS onto NSG TEC-AB substrates (highly resistive SnO_2 on glass) were examined. Incorporation of the indium during the CSS deposition was investigated by quantitative SIMS of the films, and by scraping off the material for ICP-OES analysis. Growth on the resistive TEC-AB substrates also allowed for in-plane conductivity and contact resistance measurements using the transmission line method (TLM). C-V measurements were carried out on glass/Mo/CdTe:In/In structures and were used to give estimates of the carrier concentration. The carrier type was confirmed using the hot probe method.
In addition to the characterisation of the films, we also investigated the use of n-CdTe in test-structures and devices based on p-type semiconductor wafers. Simple evaluations of the band line-ups between n-CdTe and p-type wafers of Si, GaAs, and InP, using the Anderson model, indicated favourable junction properties. We therefore grew these structures by CSS transport of CdTe:In onto (001) oriented wafers. Initial deposition tests indicated that the films adhered well to their substrates and were crystalline in appearance. The junction properties and PV performances of these structures will be reported.

11:25 AM EN07.02.05
Post-Growth Doping of N-Type CdTe for Thin-Film Devices Luke Thomas[1], M Isaccs[2], K Cheetham[3], Theo Hobson[1], Jon Major[1] and Ken Durose[1]; [1]Stephenson Institute for Renewable Energy, United Kingdom; [2]HarwellXPS, United Kingdom; [3]STFC, Daresbury Laboratory, United Kingdom

The motivation of this work is to deploy intentionally doped n-type CdTe in place of the more conventional p-type: this offers the possibility of high, stable doping in the absorber layer which has the potential to give high V_{oc} in photovoltaic devices. In this work we explore the use of post-growth doping of CSS-grown CdTe films, both to investigate the feasibility of doping and in preliminary devices.

Several approaches to post-growth doping with indium were trialled, including in-diffusion of evaporated indium metal, and the annealing of films that had been sprayed with $InCl_3$ in either aqueous or methanolic solutions. Annealing was conducted either in air or under flowing nitrogen.

The surface chemistry of the treated samples was investigated using XPS. The instrument used was a Kratos Axis Ultra-DLD photoelectron spectrometer with a monochromatic AlKα x-ray source. The elements/peaks screened for were Cd3d, Te3d, In3d, Cl2p and O1s. The In MNN Auger line was also measured since it exhibits larger chemical shifts than the In3d XPS line. A pass energy of 20 eV was used for the XPS lines and 80 eV for the Auger.

Chemical incorporation of the indium in the CdTe films was evaluated by quantitative SIMS. Implantation standards were created using single crystal THM-grown B surfaces of CdTe (Japan Energy) with xxx-In and yyy-Cl. SIMS measurements were done by Loughborough Surface Analysis using a Cameca IMS 7F-auto SIMS instrument using O^{2+} and Cs^+ as the primary ion species at an energy of 10 keV. Profiles were obtained for Cd, Te, In, Cl, O and Sn. It was found that indium could be incorporated throughout an approx. 5 µm thick film at a density of 6 x 10^{18} cm^{-3}. The conductivity of the films and contact resistances were measured using the transmission line method (TLM) and the hot probe method was used to verify the carrier type.

A variety of ‘superstrate’ device structures were considered, for example glass/FTO/n-CdTe/ZnTe/P3HT/Au and SCAPS simulations indicated that many were capable of achieving V_{oc}s of > 1 V in principle. Preliminary devices were fabricated on NSG TEC15 FTO/glass. ZnTe was evaporated from a powder source while the CSS-grown CdTe films were post-growth doped using the indium metal route. Device and diode characterisation

results will be presented.

Combinatorial Development of MZO Emitters for Emerging CdTe Based Solar Cells Gavin Yeung[1], Carey Reich[2], Adam Danielson[2], Walajbad Sampath[2] and Colin A. Wolden[1]; [1]Colorado School of Mines, United States; [2]Colorado State University, United States

Due to the low material and manufacturing costs of polycrystalline CdTe-based solar cells, it is the leading thin-film photovoltaic technology. Magnesium zinc oxide ($Mg_xZn_{1-x}O$) has proven to be a highly effective emitter layer due to its transparency and ability to tune the conduction band alignment with CdTe. State-of-the-art devices employ graded $CdSe_yTe_{1-y}$ (CST) layer at the interface, and emerging absorbers employ group V doping with significantly higher carrier concentrations. The goal of this work is to engineer MZO to adapt to the evolving nature of the absorber. Combinatorial libraries of MZO were fabricated by reactive sputtering and characterized by ellipsometry, XRD, UV-visible spectroscopy, 4-point probe, and Hall effect. After screening to identify promising compositions, uniform MZO films are used to optimize device performance. For standard CdTe the optimum Mg content was found to be x~0.15, producing >16% devices. With CST based devices the optimum Mg content increased to x~0.25, producing >19% devices. The as-deposited MZO is highly insulating, so Ga was added to increase carrier concentration. GMZO libraries are fabricated with band gaps spanning 700 mV and whose electrical resistivity may be systematically varied >6 orders of magnitude by controlling the rate of Ga deposition. We plan to report on the efficacy of these promising GMZO libraries to optimize band gap and carrier concentration for both CST and CST:GrV based devices.

12:05 PM *EN07.02.09
What Limits the Voltage of CdSeTe Solar Cells—Material Quality, Surface Passivation or Contact Selectivity? Arthur Onno[1], Adam Danielson[2], Carey Reich[2], Siming Li[3], William Weigand[1], Darius Kuciauskas[3], Walajbad Sampath[2] and Zachary Holman[1]; [1]Arizona State University, United States; [2]Colorado State University, United States; [3]National Renewable Energy Laboratory, United States

Polycrystalline cadmium telluride (CdTe) and cadmium selenide telluride (CdSeTe) photovoltaic devices suffer from a sizable voltage deficit when compared with competing technologies (*e.g.*, crystalline silicon, perovskite, III-V). Record-efficiency devices have not yet broken the 900-mV open-circuit voltage limit, even though, given the wide direct bandgap of CdSeTe absorbers (1.4–1.5 eV depending on the selenium content), a voltage above 1100 mV could be theoretically expected. Yet, a precise understanding of the origin of this voltage deficit and, more importantly, a clear pathway to overcome it are currently lacking.
The historically poor material quality of polycrystalline CdTe absorbers with, until recently, minority carrier lifetimes τ in the nanoseconds at best, has long been held responsible for these poor V_{oc} performances. To remedy this, extensive work has focused on increasing both the lifetime and the acceptor (*i.e.* activated dopant) concentration N_A, as the quasi-Fermi-level separation is a direct function of the $N_A \times \tau$ product. Double heterostructure CdSeTe samples, with both surface passivated with either magnesium zinc oxide (MZO) or Al_2O_3, have reached lifetimes in the hundreds of nanoseconds, indicating that excellent material quality was achievable with CdSeTe absorbers and suggesting that poor *surface passivation—i.e.*, passivation of the absorber front and back interfaces, as opposed to passivation of defects at the grain boundaries—was an important contributor to the limited voltages measured on finished devices. Similarly, arsenic doping of the absorber has led to acceptor concentrations in excess of 10^{16} cm^{-3}.
Yet, these improvements in both lifetime and acceptor concentration have not translated into meaningful increases in V_{oc}. Two questions thus arise:
1) What limits the voltage of Cd(Se)Te devices?

2) How can we easily and systematically decouple the sources of voltage loss in finished devices?
In this work, we answer these two questions by comparing the thermodynamic voltage limit $V_{oc,ideal}$ of finished solar cells with their quasi-Fermi-level splitting (QFLS)—also referred to as the *internal* or *implied* open-circuit voltage iV_{oc} (QFLS=$q\times iV_{oc}$ with q the elementary charge)—and their *external* or *terminal* voltage V_{oc}. We calculate $V_{oc,ideal}$ from the external quantum efficiency (EQE) of the device and access iV_{oc} through measurement of the device external radiative efficiency (ERE) using a calibrated photoluminescence tool, while V_{oc} is measured through standard J–V curve tracing.
We show that As-doped cells with Al_2O_3-passivated contacts can exhibit EREs in excess of 1%—surpassing the best crystalline silicon devices and on par with the best perovskite devices—but, concurrently, band tails limit their thermodynamic voltage limit. Nevertheless, our best device achieves an *internal* voltage iV_{oc}>980 mV. This is close to 100 mV higher than the *external* open-circuit voltage (V_{oc}) of the record-efficiency polycrystalline CdSeTe solar cell. Thus, in these highly luminescent devices, the voltage is limited by the contact selectivity rather than by the material quality of the absorber. We then propose a novel passivated and selective back contact structure—based on an Al_2O_3 passivating layer followed by a p-type boron-doped hydrogenated amorphous silicon (a-Si:H) hole selective layer—with the goal of translating these high iV_{oc} values into high V_{oc} values and achieving V_{oc}>1 .

SESSION EN07.03: Advances in CdTe-Based Solar Cells II

On the Fundamental Aspects of Performance and Stability of CdTe Solar Cells Dmitry Krasikov; First Solar, United States

First Solar is the largest solar manufacturer in Western Hemisphere. While possessing CdTe cell and module efficiency records of 22.1% and 18.2%, respectively, we continue research to further push the boundaries of CdTe cell technology. In particular, we conduct fundamental studies of losses and instabilities within active layers of CdTe cells.

The current Cu-doped CdTe technology suffers from insufficient absorber doping caused by atomic interactions between Cu and Cl. Besides limiting the maximum doping achievable in practical fabrication process, defect reactions between Cu and Cl cause further reduction in absorber doping during field operation, which contributes to slow degradation of Cu-doped devices.

High and stable absorber doping of 1e16 cm^{-2} and above could be achieved in chlorinated CdTe films by replacing Cu with arsenic acceptors. However, taking the full advantage of heavily-doped CdTe absorbers requires high quality front interface with small conduction band offset. Our atomic simulations predict strong conduction band offset at CdTe/SnO_2 interface, which prevents achieving high Voc values. Additional performance improvement of arsenic-doped cells could be achieved by further increase in doping activation, which is currently limited by formation of kinetically-stabilized deep donors that not only reduce the built-in potential, but may also limit the bulk lifetime.

Another important aspect of CdTe cell performance is reversible short-range metastabilities present both in Cu- and As-doped devices. Our kinetic device modeling suggests that observed metastable phenomena are caused by the defect reactions at the front interface.

1:25 PM EN07.03.02

Investigating Carrier Dynamics in CdTe Full Device Studied with Time-Resolved Terahertz and Photoluminescence Spectroscopies Mohammad Mehdi Taheri[1], Triet M. Truong[1], Shannon L. Fields[2], William N. Shafarman[2], Brian McCandless[2] and Jason Baxter[1]; [1]Drexel University, United States; [2]University of Delaware, United States

Understanding the nature of recombination and its dependence on defects and interfaces is essential for engineering materials and contacts for higher V_{oc} and power conversion efficiency in photovoltaic (PV) devices. Time-resolved photoluminescence (TRPL) has conventionally been used to evaluate recombination, but not all materials are strongly emissive or otherwise suitable. Pump – probe spectroscopy presents valuable complementary information, wherein an optical pump pulse photoexcites carriers within the absorber and the transient photoconductivity is probed with a terahertz (THz) pulse. Until now, experimental constraints have limited the use of THz probes to interrogate full device stacks, and measurements were instead made on exfoliated films or films grown on unconventional substrates. However, interfaces are critical to the behavior of photoexcited carriers in solar cells, and the substrates themselves often influence the film growth and bulk properties. Therefore, it is important to probe the behavior of PV absorbers as close as possible to their normal operating conditions.

Here we report on cross-cutting metrology tools based on time-resolved THz spectroscopy (TRTS) and TRPL that enable *in operando* characterization of carrier dynamics and recombination mechanisms in working PV devices. Through a combination of experiments and modeling, we can obtain key parameters including Shockley-Read-Hall (SRH) lifetime, minority carrier mobility and diffusion length, and interface recombination velocity using non-contact probes. By varying pulsed photoexcitation conditions, the contributions of interface and bulk recombination can be determined as a function of applied bias.

TRTS has been applied to thin film absorbers but has not been used for full devices because the conductive contacts absorb or reflect the THz radiation. Here we create wire-grid patterns using conventional laser scribing to increase the signal-to-noise ratio by at least 5-fold compared to unscribed samples. The TRTS signal corresponds to transient photoconductivity, while TRPL arises from radiative recombination. We can simulate both of these by numerical solution of the continuity equations and Poisson's equation. Best-fit values of the SRH lifetime and surface and interface recombination velocities are then determined by global fitting of multiple TRTS and TRPL data sets having different photoexcitation conditions.

We have developed and validated this approach using CdTe thin film PVs. For instance, we found a bulk lifetime of 1.6 ns, CdTe/CdS interface recombination velocity of less than 100 cm/s, and back surface recombination velocity of ~$2x10^3$ cm/s for a CdTe device treated with $CdCl_2$. In contrast, as-deposited films without $CdCl_2$ treatment had bulk lifetime of only ~50 ps and higher interface and back-surface recombination velocities of ~$2x10^4$ cm/s. We are now applying this approach to understand how dynamics change depending on processing conditions designed to enable high doping densities and on choice of buffer material.

By determining the locus and mechanisms of performance-limiting recombination, we can accelerate the development of thin film PVs with high higher Voc and efficiency. While the method has been demonstrated here using CdTe, it is also applicable to perovskites, CIGS, CZTSSe, and other emerging technologies.

1:40 PM EN07.03.03

Towards Large-Grain Epitaxial CdTe Solar Cells Made by Close-Spaced Sublimation (CSS) or Vapor Transport Deposition (VTD) Mahisha Amarasinghe[1,2], David S. Albin[2], Matthew Reese[2], John Moseley[2], Helio R. Moutinho[2] and Wyatt Metzger[2]; [1]University of Illinois at Chicago, United States; [2]National Renewable Energy Laboratory, United States

Polycrystalline CdTe thin films for solar energy applications are deposited by fast high throughput deposition techniques on glass coated with nanocrystalline transparent conducting oxides. While this approach makes polycrystalline CdTe solar panels a cost leader, the deposition has resulted in small grain sizes on the order of microns for decades.

Grain boundaries (GBs) are active recombination centers that reduce overall carrier lifetime and hence the device performance of CdTe solar cells [1,2]. Therefore, increasing grain size and reducing GB density, especially at the critical junction region, can improve carrier lifetime and solar cell performance [3-5].

The CdTe community relies on $CdCl_2$ treatments to facilitate grain growth and passivate GBs, increasing the aggregate lifetime from ps to tens of ns. This passivation combined with CdSeTe bandgap engineering has improved CdTe record efficiency to 22.1%. Material challenges are that CdTe grain growth during $CdCl_2$ anneals is driven by Ostwald ripening, which has historically been limited to the order of the film thickness (i.e. a few microns). Furthermore, $CdCl_2$ treatments do not completely passivate GBs [4]. For example, correlated GB recombination velocities have been measured to be as high as 10^5–10^6 cm/s [6]. Finally, Cl compensation may reduce activation ratios in Group-V doped CdTe devices resulting in microscopic potential fluctuations and lower V_{OC} [7].

Colossal grain growth (CGG) was recently reported in micron-thick Cd(Se,Te) thin films deposited on glass [8]. The resulting CdTe structures had extremely large ~ 1-mm lateral size grains that were much larger than anything previously reported and a layer structure relevant for CdTe solar cells.

In this work, we will illustrate that the resulting, near single-crystal thin films can be used as a growth template for epitaxy of subsequent CdTe layers by techniques appropriate for making devices. Starting device structures have been made using Corning 7059/75-nm Cd_2SnO_4/60-nm MgZnO substrates upon which a $CdSe_{0.10}Te_{0.9}$ layer was evaporated for CGG. Because of its lower bulk resistivity, Cd_2SnO_4 films could be made thin enough for devices and smooth for CGG of the Cd(Se,Te) layer. After the Cd(Se,Te) was deposited, $CdCl_2$ treatments with temperatures ranging from 420 °C to 500 °C (with and without oxygen) were carried out before and after the CGG anneal, and subsequent CdTe was deposited epitaxially by using either close-spaced sublimation or vapor transport deposition. Lifetime, device performance, and cathodoluminescence results will be presented for both glass/Cd_2SnO_4/MgZnO/CGG-Cd(Se,Te)/CdTe and glass/Cd_2SnO_4/MgZnO/CGG-Cd(Se,Te) structures at the conference.

Direct Microscopy Imaging of Nonuniform Carrier Transport in Polycrystalline Cadmium Telluride

Chuanxiao Xiao; National Renewable Energy Laboratory, United States

Inhomogeneous microscopic carrier transport is difficult to study but important in many condensed-matter applications. For example, the role of grain boundaries (GBs) in polycrystalline semiconductors has been controversial for 20 years. In cadmium telluride (CdTe) solar cells, electron-beam-induced current (EBIC) measurements consistently demonstrate enhanced current collection along GBs, which is argued as evidence for interpenetrating CdTe *p-n* current-collection networks critical to high efficiency. Conversely, cathodoluminescence (CL) measurements consistently indicate that GBs are deleterious low-lifetime regions. Here, we apply transport imaging (TI) in conjunction with spatially correlated EBIC, CL, and scanning Kelvin probe force microscopy measurements to understand carrier drift, diffusion, and recombination in polycrystalline CdTe. We simultaneously observe GB potential wells, reduced carrier lifetime at GBs, and seemingly contradictory enhanced GB current collection, then describe their coexistence with microscopic TI and physical arguments. The results provide visualization of inhomogeneous transport that is critical to understanding and engineering polycrystalline solar technology.

2:10 PM *EN07.03.05

N-Type CdTe Thin Films and Solar Cells Chris Ferekides, Vasilios Palekis, Wei Wang, Sheikh Tawsif Elahi and Md Zahangir Alom; University of South Florida, United States

Recent developments in cadmium telluride (CdTe)-based thin film technology has demonstrated record efficiencies for both CdTe cells (22.1 %) and modules (18.6 %). Even with this progress, record-efficiency CdTe solar cells have open-circuit voltage VOC ~ 880 mV, which is considerably lower than the theoretical limit of VOC ~ 1.15V. Much of the focus on CdTe has been associated with increasing its net p-type doping concentration in order to increase the device VOC. High p-type doping in CdTe has been challenging, while various studies have shown 1016 - 1019 cm-3 n-type doping in crystalline CdTe using In grown by the Bridgman or molecular beam epitaxy (MBE) methods. Recent studies of In doped crystalline CdTe have shown lifetimes exceeding 2 μs and solar cells fabricated with this material demonstrated VOC greater than 1 V.
In this paper the effect of indium (In) doping on CdTe thin film solar cells will be discussed. CdTe thin films were deposited using the elemental vapor transport (EVT) technique under various Cd/Te gas phase ratios and In vapor concentrations. Solar cells of the superstrate configuration (glass/TCO/CdS/n-CdTe/p-ZnTe/BC) have been fabricated and characterized. There was a correlation between the concetration of In in the vapor phase and net n-type doping for CdTe devices fabricated near Cd/Te stoichiometric ratio. Increasing the amount of In vapors resulted in higher n-type doping in CdTe. From C-V measurements doping levels >1016cm-3 were achieved. Devices were also fabricated at various Cd/Te vapor ratios at a constant In vapor concentration. Films deposited under Cd-rich conditions exhibited higher lifetimes than those deposited under Te-rich conditions. On the other hand, films deposited at under Te-rich conditions exhibited higher n-type doping. To-date n-type CdTe solar cells yielded devices with VOC= 730 mV, JSC= 20 mA/cm2, FF= 62 % and efficiency near 9 %. SCAPS and AMPS solar cell simulation tools were used to better understand and aid the development of n-type CdTe solar cells. Doping, carrier lifetimes, and interface states of the CdTe-absorber and ZnTe window layer are being investigated.

2:35 PM *EN07.03.06
Progress and Challenges in Doping Polycrystalline CdTe-Based Alloys with Arsenic Amit H. Munshi, Akash Shah, Ramesh Pandey, Pascal Jundt, Carey Reich, Adam Danielson and Walajbad Sampath; Colorado State University, United States

Improvement in polycrystalline CdTe photovoltaics efficiency is primarily limited by the deficit in open-circuit voltage. The deficit can be overcome by reducing the carrier recombination while improving carrier concentration in the film. Traditionally, CdTe-based devices have been doped with copper. However, increasing carrier concentration using copper while reducing recombination is fundamentally limited by various complexes copper may form. To overcome this issue, doping with group V elements has been of interest to the research community for decades and more recently it has been one of the primary focuses of the CdTe research community.
Using sublimation as the deposition method, our research has shown that arsenic can be effectively used to improve carrier concentration while simultaneously reducing recombination. Doping with arsenic is certainly not devoid of challenges as various defects such as the presence of dimers, tetramers, AX-centers, and arsenic clusters in the device pose challenges. However, using an advanced fabrication approach guided by state-of-the-art predictive computational simulation models, we have been able to overcome several of these limitations. Using the method that will be discussed, we have been able to demonstrate carrier lifetimes greater than 2 μs, carrier concentration over $5x10^{15}$ cm^{-3}, and surface recombination velocity less than 100 cm/s. Following fabrication of films with characteristics suitable for high performing devices, several other factors in the film fabrication process and device structure had to be refined to employ the advantages of doping CdTe-based devices with arsenic as shown by various numerical simulations.
In addition to improvement in device performance, using arsenic as the doping element for CdTe-based photovoltaics may have advantages in terms of longevity of the modules in the field as well. With optimized doping in CdTe with copper, large volumes of modules have been commercially manufactured and installed. However, arsenic doping in polycrystalline films is found to have superior metastability. This is one of the critical factors to be taken into consideration as the elimination of copper may improve projected life of CdTe-based photovoltaic panels from 25 years currently to over 50 years.

4:00 PM EN07.04.01
Optoelectronic and Material Properties of Solution-Processed Earth-Abundant $Cu_2BaSn(S, Se)_4$ Films for Solar Cell Applications Betul Teymur[1], Sergiu Levcenko[2], Hannes Hempel[2], Eric Bergmann[3], Jose Marquez Prieto[2], Thomas Unold[2], Ian Hill[3] and David B. Mitzi[1,1]; [1]Duke University, United States; [2]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; [3]Dalhousie University, Canada

$Cu_2BaSn(S,Se)_4$ (CBTSSe) has been gaining attention as a prospective solar absorber, since it employs low-toxicity and abundant metals, while offering low-cost manufacturing options, controllable stoichiometry, high absorption coefficient ($>10^4$ cm^{-1}) and bandgap (E_g) tunability (1.5-2.0 eV). Besides these suitable optoelectronic properties, CBTSSe does not suffer from anti-site disorder in contrast with $Cu_2ZnSn(S,Se)_4$, as confirmed by Shin et al. with *vacuum-deposited* films [1]. The current study focuses on *solution-deposited* nominally stoichiometric CBTSSe films [2] with a bandgap of 1.59 eV and explores the fundamental film properties using several spectroscopic techniques. Temperature- and excitation-dependent photoluminescence studies reveal a dominant defect emission at ~1.5 eV and a second deep defect feature at 1.15 eV. Time-resolved terahertz spectroscopy measurements show few tens of picoseconds (~50 ps) surface and few nanoseconds (~3 ns) bulk lifetimes, as well as ~140 cm^2/Vs mobility, the latter of which is in the range of reported values for CZTSSe. The solution-processed CBTSSe films suffer from exacerbated surface recombination at the junction of CdS and CBTSSe, due to cliff-like band alignment with 0.63 eV conduction band offset (as measured by ultraviolet photoemission spectroscopy). Employing these films in an Al-Ni/ITO/ZnO/CdS/CBTSSe/Mo photovoltaic device structure, we report open-circuit voltage (V_{OC}), short-circuit current density, fill factor, and efficiency of 470 mV, 14.3 mA/cm^2, 43.6%, and 2.93%, a record performance level among solution-processed CBTSSe devices. Device performance in this study may be mainly limited by interfacial properties and inadequately selected device structure (e.g., poorly matched buffer layer), which both enhance recombination-associated losses in V_{OC}. The physical measurements provided for the nominally stoichiometric solution-processed CBTSSe absorber point to critical areas for future improvement of CBTSSe and related photovoltaic cells in the quest for higher efficiency devices based on earth-abundant metals.

Silver Doping of Enargite (Cu_3AsS_4) Absorbers Using Amine-Thiol Chemistry for the Fabrication of Solar Cells Apurva A. Pradhan, Scott A. McClary, Joe Andler and Rakesh Agrawal; Purdue University, United States

Enargite (Cu_3AsS_4) is an emerging candidate for photovoltaic applications with a direct band gap of 1.41 eV, consisting of earth abundant elements with differing ionic radii and consequently lower likelihood of cation disorder, ideal predicted and experimentally verified optoelectronic properties, and demonstrated use in working thin-film solar cells. Previous experimental work on this material from our group has demonstrated that enargite films have a Shockley-Read-Hall, or defect assisted, recombination lifetime on the timescale of nanoseconds, relatively shallow defect energies, and carrier concentrations on the order of 10^{15} cm^{-3}. However, carbonaceous

fine grain layers, secondary phases, pinholes in the film, and poor band alignment with n-type CdS may be part of the reason that power conversion efficiencies for enargite-based solar cells remained below 0.5%. While investigating suitable n-type junction partners is a subject of a parallel research effort, in this work, we present a novel solution-processed route to create enargite films using an amine-thiol based molecular precursor approach that eliminates carbonaceous fine grain layers, creates phase-pure films, and improves film morphology.

A mixture of amine and thiol has shown to be a very versatile solvent system for dissolving a variety of metal chalcogenides for the fabrication of thin films and nanoparticles. Arsenic sulfides and copper sulfides can undergo reactive dissolution in amine-thiol solvents to form complexes that can decompose at relatively low temperatures. These molecular precursor solutions can be combined into an ink that can be directly coated onto conductive substrates to create tennantite ($Cu_{12}As_4S_{13}$) films that transform and coarsen into micron-sized enargite grains with low surface roughness and no detectable secondary phases after heating in an arsenic-sulfide atmosphere at 425°C. Unfortunately, shunt resistances on devices made using this approach remained low and SEM has confirmed the presence of pin-holes in the film. To improve film morphology and increase shunt resistances, inspiration was taken from silver alloyed $Cu(In,Ga)Se_2$ thin films.

Silver alloying in $Cu(In,Ga)Se_2$ (CIGSe) solar cells has been an area of active research over the past decade. In CIGSe, Ag alloying has been shown to lower the valence band edge, increase the bandgap, increase grain size, and reduce structural defects, partially due to the lower melting temperature of these alloyed films. The amine-thiol solvent system allowed for facile incorporation of varying concentrations of silver sulfide into coating inks for the creation of silver doped enargite films. With silver incorporation, we observed significant improvements in film morphology that fused adjacent enargite grains in the film together and eliminated pinholes. Preliminary optoelectronic characterization on these films have revealed a shift to higher energy bandgaps with increasing silver content. Devices created with silver-doped enargite show increased shunt resistance and produced champion device efficiencies exceeding 0.6%. This is higher than past demonstrated efficiencies for this material and shows that silver alloying has the potential to improve film properties and device efficiencies. Further optimization of film growth conditions and silver content is expected to allow for further increases in device efficiencies.

4:30 PM EN07.04.03
Embedded Au and Ag Nanoparticles in Pulsed Laser Deposited Photovoltaic Thin Films Mehmet A. Sahiner, Jasmyne Emerson, Faith Akinlade, Matthew Herington and Venise Castillon; Seton Hall University, United States

We have used pulsed laser deposition to deposit nanoparticles (Ag, Au) to investigate the effects of these impurities on the photovoltaic properties of the CdS/CdTe based thin films. The main objective was to investigate how the inclusion of nanoparticles will affect light scattering in the at the interfaces and whether the different size and shape of nanoparticles will have a positive effect on the overall electrical performance of these thin film solar cells. In our previous studies, we have investigated the effects of the embedded Ag nanoparticles on the photoelectric conversion efficiency on CdS/CdTe based thin film solar cells as synthesized by Pulsed Laser Deposition (PLD). Silver was shown to enhance the photovoltaic performance by almost doubling the photovoltaic conversion efficiency of the conventional CdS/CdTe films [1]. A careful comparison of photovoltaic performance of Au/Si versus Ag embedded thin films of CdS/CdTe on indium tin oxide coated glass substrates have been performed. Our results on the Ag case revealed electrical performance of these cells have correlates with the particles density and the particle size on the CdS/CdTe interface. This study concentrates on the Au and Ag nanoparticle deposition on the CdS/CdTe interface with varying particle size and distributions. Structural and compositional characterization were performed using XRD, AFM, and SEM/EDX. Photovoltaic properties were measured using a LabView assisted Keithley Sourcemeter set-up. The comparison of Ag vs Au nanoparticles on the structure and photovoltaic conversion efficiency will be presented. Ag and Au nanoparticles have contrasting effects on the photovoltaic conversion efficiency in terms of their relative coverage at the interface, This will be discussed in the light of plasmonic resonances and effective light scattering for Ag and Au particles.

Synthesis and Characterization of Selenium-Alloyed Bournonite—A Prospective Semiconductor for Optoelectronic Applications Eric T. Chang, Gabrielle Koknat, Volker Blum and David B. Mitzi; Duke University, United States

In the search for solar absorber materials for thin-film photovoltaics (PV), the materials class of complex chalcogenides has maintained consistent interest. In the past two decades, the kesterite $Cu_2ZnSn(S,Se)_4$ (CZTSSe) has proven promising as an earth-abundant, nontoxic solar absorber. However, with an efficiency plateauing at 12.6%, a necessary search for novel earth-abundant and nontoxic chalcogenide PV candidates continues. Recently, bournonite ($CuPbSbS_3$) has been identified as a potential ferroelectric photovoltaic material with a bandgap (1.2-1.3 eV) appropriate for single junction photovoltaic devices (1-1.6 eV). Bournonite is an appealing candidate for a number of reasons, including its structural and electronic three dimensionality, absorption coefficients comparable to that of $MAPbI_3$ and GaAs, an optical dielectric constant similar to that of hybrid perovskites, high predicted defect tolerance, and the potential for Rashba/Dresselhaus splitting, a phenomenon that has been linked to slow electron hole recombination in lead-halide perovskites.[1] Additionally, as a naturally occurring mineral, bournonite is predicted to be stable, avoiding the instability challenges that face the highly popular perovskites. In the past year, progress in bournonite’s application for PV has accelerated with two studies reporting thin-film processing of bournonite.[2,3] One such study also reported the first PV device to employ bournonite as the absorber layer (PCE of 2.23%).[3] In an effort to explore band gap engineering of bournonite, we report the solid state bulk synthesis of selenium-alloyed bournonite ($CuPbSb(S_{1-x}Se_x)_3$) across the full range of selenium concentrations (x = 0.0 - 1.0). We characterize the crystal structure and band gap of the samples using x-ray diffraction and diffuse reflectance spectroscopy, reporting a band gap that approaches 1.1 eV near x = 0.5. We compare these results with computational band structure predictions.

4:40 PM EN07.04.05
Fabrication of pn Homojunction of SnS and Its Photovoltaic Properties Issei Suzuki[1], Sakiko Kawanishi[1], Sage Bauers[2], Andriy Zakutayev[2], Hiroyuki Shibata[1], Hiroshi Yanagi[3] and Takahisa Omata[1]; [1]Tohoku University, Japan; [2]National Renewable Energy Laboratory, United States; [3]University of Yamanashi, Japan

Tin sulfide (SnS) is a promising ligth-absorbing material for next-generation solar cells due to its safe and abundant constituent elements and suitable optical properties. SnS homojunction structure is expected to overcome the limitation of conversion efficiency (η) of the conventional SnS solar cells based on the heterojunction between p-type SnS and n-type CdS or Zn(O,S) with η of 4-5% at maximum[1]. However, SnS homojunction has not been reported due to difficulties in realizing n-type SnS. In recent years, we have demonstrated the n-type conductive SnS single crystals with halogen (Cl or Br) doping[2], and growth of large single crystal in centimeter-scale[3]. In this study, a p-type SnS thin film was deposited on the large size n-type

crystal to form a pn homojunction, and its photovoltaic properties were evaluated.
Cl-doped large n-type SnS single crystals were prepared by the flux method using Sn as the main solvent. A p-type SnS thin film with a diameter of 1 mm and a thickness of 270 nm was deposited at 340° C on the (100) cleavage plane of the n-type single crystal by RF sputtering. The device structure was GaIn/n-type SnS single crystal/p-type SnS thin film/ZnO/ITO. Structural and electrical properties of the film and homojunction were evaluated. Photovoltaic properties were studied by I-V and C-V measurements.
The p-type SnS thin film deposited on the single crystal was <100>-oriented in the growth direction and was also gently oriented in the growth plane. In addition, there was no void at the n-type single crystal/p-type thin film interface, and the change in Cl concentration was very abrupt. The open circuit voltage (V_{OC}) was 360 mV, which is comparable to the highest value of the previously reported SnS homojunction cells (372 mV[1]). Since the built-in potential of the homojunction was 920 mV and much larger than the previous heterojunction (~700 mV), it should be possible to improve the V_{OC} further. The conversion efficiency was 1.4%, which is lower than the record η of heterojunction (4-5%), mainly due to its low closed circuit current density (J_{SC}) of 7.5 mA/cm^2. Once the device structure of the homojunction cell is optimized to efficiently collect the photogenerated carriers and achieve a comparable J_{SC} as the conventional heterojunction cells (~25 mAcm^{-2}), conversion efficiency exceeding 4-5% would be realized with homojunction with improving the V_{OC}.

Synthesis of Cu_2ZnSnS_4 Using Low-Temperature, Water-Based Binary Sulfide Nanoparticle Inks for Sustainable, Low Cost Photovoltaics Han Wang, Nathaniel J. Quitoriano and George P. Demopoulos; McGill University, Canada

Kesterite Cu_2ZnSnS_4 (CZTS) is a promising semiconductor material for next-generation thin film photovoltaics since it has earth-abundant and nontoxic elements, a stable structure, and strong light absorption properties. Nanoparticle, solution-based methods have been demonstrated as a potential route for the deposition of CZTS thin films, but many of these methods incorporate organic solvents or additives which can leave a carbon residue that affects device performance. In addition, these organic solvents can create problems with scalability and sustainability. The presented work demonstrates the capability of an environmentally friendly, aqueous-based nanoparticle ink to create the CZTS absorber thin film. Metal chalcogenide complexes formed with ammonium sulfide and tin sulfide are used to stabilize a mixture of component binary sulfides in water without other additives, which are deposited as a compact absorber film with spin coating. It is shown that the concentration of the ammonium sulfide content greatly affects the ink stability, the thin film morphology, and optoelectronic properties of the absorber layer. Furthermore, the incorporation of the tin sulfide complex enables a low temperature transition from binary sulfide nanoparticles to the CZTS phase.

5:05 PM EN07.04.08
Tio2-Cuo Heterostructure for Cost-Effective and Better Optoelectronic Properties of Solar Cell Sajal Islam[1], Ariful Haque[2,2], M.F.N. Taufique[3] and Kartik Ghosh[1]; [1]Missouri State University, United States; [2]North Carolina State University, United States; [3]Pacific Northwest National Laboratory, United States

Oxide heterostructures have drawn great attention recently, because of its environment-friendly properties and potential applications in optoelectronic devices like LEDs and Solar Cells. In this work, we have performed a simulation study of the heterojunction solar cell with SCAPS (a Solar Cell Capacitance Simulator) using Ti02 as an n-type layer and CuO as a p-type layer. The thickness and the dopant dependent simulation studies have shown that the solar cell operates at a maximum efficiency of 19.15% when the thickness of the TiO2/CuO layers are chosen 1.4µm/1.2µm. We carried out an indium doped tin oxide (ITO) vs Fluorine doped tin oxide

(FTO) comparison study as well where FTO worked better as the anode in this structure. We chose gold as the cathode from the simulation study of a range of elements and observed that efficiency increases with better metal work function. Based on these simulation results we have fabricated the oxide-based heterojunction solar cell on FTO substrates using pulsed laser deposition (PLD) for the TiO2 layer and spin coating for the CuO layer. We have conducted structural-property correlations of individual layers using x-ray diffraction (XRD), Raman analysis, photoluminescence spectroscopy (PL), scanning electron microscopy (SEM), energy-dispersive x-ray spectroscopy (EDX), and different electrical measurements e.g. hall measurements, and sheet resistance measurements. Using specific PLD parameters, we have successfully grown both the rutile phase and anatase phase of TiO2 separately on several FTO substrates. The results and analysis from the characterizations confirm the successful growth of high-quality oxide thin film layers of TiO2 on FTO and CuO on TiO2. Finally, to make the cathode layer of gold, the sputtering technique is used. The solar cell characterization is performed by the I-V measurement using a standard solar simulator and UV-VIS. We have used Origin, Vesta, and MATLAB software for data analysis. The analysis of the solar cell characterization results will be presented at the conference. This facile and cost-effective process of fabrication of all oxide-based heterojunction solar cells will reduce the overall cost of solar cells and increase efficiency with a better optoelectronic performance.

5:10 PM EN07.04.09
Solar Cell Effect on Ferromagnetic Metal-Based Molecular Spintronics Devices Pawan Tyagi and Christopher Riso; University of the District of Columbia, United States

Can spin property of electron lead to a novel form of solar? This question is critical because almost all the solar cells created so far are based on electronic charge. This paper reports the solar cell phenomenon based on the spin property of electrons. The spin-based solar cell effect was observed on magnetic tunnel junction based molecular spintronics devices (MTJMSD). MTJMSDs were produced by covalently bonding organometallic molecular clusters (OMCs) between the top and bottom ferromagnetic electrodes along the exposed side edges of magnetic tunnel junctions with Co/NiFe/AlOx/NiFe thin film configurations. The MTJMSD configuration showing the photovoltaic effect also exhibited OMC induced strong antiferromagnetic coupling[1] and room temperature current suppression by >five orders of magnitude[2]. Our MTJMSD was fabricated below 100-degree C temperature and employed earth-abundant transition metals like nickel and iron. This paper shows that MTJMSD's photovoltaic effect was susceptible to the magnetic field, temperature, and light intensity. MTJMSDs exhibited three different current states termed as high (μA), medium (nA), and low (pA). In each state, light radiation produced the photovoltaic effect. OMC molecule appears to create robust exchange coupling between the two ferromagnetic electrodes of the magnetic tunnel junctions leading to significant changes in the electrical, magnetic, and optical properties of the ferromagnetic electrodes. OMC induced changes in the ferromagnetic electrodes also propagated outside the MTJ's perimeter. Magnetic studies, KPAFM, and Raman studies suggested that OMC transformed a ferromagnetic film into photoresponsive material and produced a built-in potential in the MTJMSD. MTJMSD's ability to absorb white light radiation and the ability to separate opposite spins in the three different current states lead to the net photovoltaic effect. MTJMSD's photovoltaic response responded to the magnetic field. This paper mainly reports the experimental observations. Further investigation about the deeper understanding of the spin-photovoltaic effect is needed. We were also not able to provide an exact estimate of the energy conversion efficiency. It was experimentally challenging to determine the exact area responding to light radiation. Future work may focus on simultaneous KPAFM, MFM, and I-V measurements under dark and light for further understanding and new insights.

5:15 PM EN07.04.10
Late News: Stability, Electronic and Optical Properties in Ternary Nitride Phases of MgSnN2—A First Principles Study Bishal B. Dumre[1], Daniel Gall[2] and Sanjay Khare[1]; [1]The University of Toledo, United States; [2]Rensselaer Polytechnic Institute, United States

We studied the disordered-rocksalt, orthorhombic and disordered-wurtzite phases of the ternary nitride semiconductor $MgSnN_2$ from first principles methods using density functional theory (DFT). We find that $MgSnN_2$ is mechanically and dynamically stable in all three phases. However, COHP analysis suggests that the

disordered rocksalt structure has anti-bonding states below the Fermi level between -5 eV to -2 eV as compared to the bonding states in other two phases, indicative thermodynamic metastability. Computed lattice constant and electronic band gap values of 4.56 Å and 2.69 eV of $MgSnN_2$ in disordered rocksalt structure compare well with experimentally reported values of 4.48 Å and 2.3 eV respectively. Furthermore, band gaps were computed in $MgSnN_{2-x}O_x$, with x = 0.5, 1.0, 1.5, 2.0, to elucidate the role of possible oxygen impurity. Of the three phases, disordered-rocksalt structure shows the lowest charge carrier effective masses. Moreover, this phase has promising absorption coefficient and reflectivity to be used as the absorber layer of tandem solar cells in the higher energy region of the visible portion of the solar spectrum. The other two phases can be utilized as a window layer of solar cells owing to their larger band gap values of 4.36 eV and 4.86 eV respectively.

5:20 PM EN07.04.11

Late News: Photocurrent Transient Characteristics of Chemically Synthesized Lateral and Vertical PbS Photovoltaics for Application as High Performance Infrared Photodetectors Emmanuel K. Ampadu[1], Eunsoon Oh[1], Jungdong Kim[1], DeaKwan Noe[1], KeunSoo Kim[2] and DongYun Lee[2]; [1]Chungnam Naitonal University, Korea (the Republic of); [2]Department of Physics and Graphene Research Institute-Texas Photonics Center International Research Center (GRI-TPC IRC), Korea (the Republic of)

Infrared (IR) photodetectors play a major role in numerous applications, including communications, environmental monitoring and security [1]. Various materials have been used for the purposes of infrared photo detection. Notable among them include Ge, InGaAs and InAs [2]. Research on lead based chalcogenide (PbTe, PbS, and PbSe) for infrared applications have been extensively explored by the scientific community due of the possibility to tune the bandgap in the infrared wavelength range even up to the Terahertz (THz) region [3]. Various photodetectors have been commercialized; photoconduction type which employ the use of an external bias and photovoltaic type detectors which operate with no external bias.
Owing to high transmission in the infrared region, high electrical conductivity, excellent atomic lattice structure and the broad applications for industrial purposes, great attention from the scientific community has been focused on graphene. Graphene is also a very good material for the purposes of transparent contacts in optoelectronic devices operating in the mid - to - far - infrared range, where other transparent oxides such as ITO are no longer desirable due to their free carrier absorption [4]. The increasing interest in the need for bendable, flexible and high performance optoelectronic devices makes graphene a good candidate and has therefore led to various functional materials/graphene hybridized materials [5-6]. Great efforts on the achievement of high-performance graphene-based photodetectors have been concentrated on the development of graphene (G) hybrid structure such as G-semiconductors, G-quantum dots (QD) and G-polymer. Studies have also been conducted to form epitaxial junctions by directly depositing various functional materials on large area CVD-graphene [7].
We fabricated vertical photovoltaic type G/PbS/Ti device by taking advantage of Ti/PbS Schottky junction and discussed the photocurrent transient characteristics. Lead sulfide (PbS), which has a bandgap of 0.42 eV at room temperature, was deposited directly on post-annealed large-area CVD (Chemical vapor deposition) graphene by CBD (Chemical bath deposition). Using a metal mask and an e-beam evaporator, we deposited Ti on glass/G/PbS. Temperature dependent photocurrent spectra of our G/PbS/Ti photovoltaic devices were measured by a Fourier transformed infrared (FTIR) set-up. Post-annealing was found to be an important activity for the adhesion of PbS films on G/glass. As the bandgap energy of PbS decreases with decreasing temperature, the cut-off wavelength increases to longer wavelength, as temperature decreases.
We also fabricated a lateral type device which was comprised of two (2) Ti electrodes separated by a gap of 7 mm and a PbS layer and discussed the laser power dependent photocurrent transient. Because we could obtain fast photo-response from the lateral type device, photocurrent spectrum at room temperature using a FTIR equipment was measured. The cut off wavelength of the detector was found to be ~3.2 μm at room temperature (300 K) which is typical for PbS devices. Our photovoltaic PbS devices can detect not only short - to – mid - infrared but also terahertz radiation at room temperature, which is highly applicable in many fields.

5:25 PM EN07.04.12

N-Type SnS Thin Films Applicable for Homojunction Solar Cells Issei Suzuki[1], Sakiko Kawanishi[1], Sage

Bauers[2], Andriy Zakutayev[2], Hiroyuki Shibata[1], Minesok Kim[3], Hiroshi Yanagi[3] and Takahisa Omata[1]; [1]Tohoku University, Japan; [2]National Renewable Energy Laboratory, United States; [3]University of Yamanashi, Japan

Since tin (II) sulfide (SnS) is a semiconductor composed of abundant and safe elements and possesses a bandgap (1.1-1.3 eV) suitable for solar cells, it is expected as a light absorber for the next-generation thin film solar cells. The acceptor-type defects, such as Sn antisite (Sn_S) and Sn vacancy (V_{Sn}), are easy to be formed in SnS due to their low formation enthalpy, SnS typically exhibits p-type conduction and it is difficult to convert it into n-type [1]. SnS solar cells, therefore, have adopted a heterojunction structure with p-type SnS and n-type semiconductors such as CdS, however, the conversion efficiency is still 4-5% at maximum [2]. Such low efficiencies are attributed to an unfavorable band offset and interface defects at the hetero interfaces. Homojunction structure is expected to exhibit higher conversion efficiency and therefore many efforts have been made to realizing n-type SnS. In recent years, it has been reported that n-type SnS sintered compact and single crystals are obtained by halogen (Cl or Br) doping, which paved the way for SnS homojunction [4]. However, the n-type SnS thin films have not been reported so far and it remains as a barrier towards realizing homojunction devices. In this study, we succeeded in obtaining n-type Cl-doped SnS thin films by RF sputtering deposition under a use of RF atomic sulfur supplier (sulfur cracker).
Cl-doped SnS thin films were deposited by RF puttering on a SiO_2 glass substrate heated at 220-340 °C. Atomic sulfur was supplied to the deposition field of the thin film at the same time from the sulfur cracker installed next to the sputtering cathode. The electrical conductivity, Hall coefficient, chemical compositions, and optical absorption spectra of the obtained thin films were studied.
All of the obtained SnS thin films were p-type conductive without using sulfur cracker and n-type conductive with sulfur cracker, which indicates that supply of the atomic sulfur to the deposition suppresses the formation of acceptor-type defects. Whereas the n-type films exhibited sharp absorption due to the direct band gap around 1.3 eV, p-type films additionally exhibited a broad absorption in the range of 0.9 to 1.2 eV. This broad absorption indicates that there are defect levels with a large density of states within the band gap, which supports the above speculation that the acceptor-type defects were suppressed by performing the deposition with the sulfur cracker.

First Principles Prediction of Incoherent Interfaces for CdTe/SnO_2 Abhishek Sharan and Stephan Lany; National Renewable Energy Laboratory, United States

The electronic structure properties of interfaces are of central importance to photovoltaics. Computational approaches can provide information complementary to experimental characterization. In particular, first principles methods can establish an unambiguous link between atomic structures features and their electronic consequences. This strength is also a challenge, because realistic atomic structure models must be available for such calculations. Only for highly idealized situations, such as the epitaxial interface between two reasonably lattice matched materials with the same crystal structure (coherent interface), can the atomic interface structure be trivially constructed. The situation becomes much more complicated when the interface must accommodate

incommensurate surface unit cells for the two materials. In this case, the interface becomes incoherent, i.e., exhibiting a reduced periodicity requiring a larger surface unit cell or even forming an essentially (2-dimensionally) amorphous non-periodic structure.
In this work, we adopted the kinetically limited minimization (KLM) approach, previously utilized for unconstrained crystal structure prediction, to sample atomic structures for SnO_2/CdTe interfaces without and with the presence of $CdCl_2$. The simulations treat SnO_2 as a substrate, and CdTe as a thin film, with a variable number of atomic layers. No initial assumptions are made about the CdTe atomic structure. Both the correct zinc-blende bulk structure and the known surface structures of the (110) and (001) back-surfaces are reproduced over the course of the sampling. The inclusion of $CdCl_2$ results in improved bonding and periodicity, and considerably lowers the total interface energy. While the full sampling of the compositional and configurational space remains challenging, this work provides a proof of concept for first principles atomic structure prediction for incoherent interfaces.

6:45 PM EN07.05.02
High Throughput, Single-Source Scribing Mechanism for Optimal Interconnections in Thin–Film Photovoltaic Modules Austin Flick and Reinhold Dauskardt; Stanford University, United States

The advancement of thin film photovoltaic devices requires the successful implementation of a series of high-performing, low-cost scribes for efficient module interconnections. These scribes, which serve to electrically isolate the front electrode (P1) and rear electrode (P3), and provide the electrical interconnection (P2) between adjacent cells, have been explored using a wide variety of scribing options, primarily laser-based mechanisms. Laser scribing offers the benefits of high tunability and alignment accuracy, allowing for the selective removal of specific layers while mitigating dead area losses. Different laser wavelengths and process parameters are often employed to achieve this selectivity; however, the demand for multiple unique laser systems for complete module fabrication results in high equipment costs and increased process complexity.

Our work demonstrates the successful implementation of a single-source scribing mechanism capable of performing the P1, P2, and P3 scribes, enabling further simplification and cost reduction over other laser scribing methods. This mechanism utilizes one of the most commercially available laser wavelengths (1064nm) without the need for expensive yet commonly employed ultrashort laser pulsed systems, relying exclusively on interactions between the laser and front electrode material and thus demonstrating broad applicability across a variety of materials and architectures. This unique scribing mechanism is compatible with extremely high throughputs on the order of several meters per second, an order of magnitude increase over the speeds of other laser scribing mechanisms. An improvement at this scale further enables reductions in cost of over 90% for the laser scribing steps in a MW-scale photovoltaic system.

6:50 PM *EN07.05.03
New Analysis Methods for Dopant Fluctuations in Thin-Film Solar Cells John Moseley; National Renewable Energy Laboratory, United States

Quantifying the performance impacts of band tails on CdTe, CIGSe, and CZTS thin-film solar cells remains a significant challenge to further development of these technologies. Band tails are prevalent in CdTe, CIGSe, and CZTS absorption, quantum efficiency, and luminescence data and are believed to reduce the open-circuit voltage (V_{OC}). However, quantifying band-tail related performance impacts is not straightforward. Tailing present in macroscopic optoelectronic data may arise from inhomogeneous impurity/matrix-element distributions, from structural defects such as dislocations and grain boundaries, or from intentional compositional grading [e.g., $Cu(In_xGa_{1-x})Se_2$]. Furthermore, inhomogeneities may span from nm to mm in scale. Thus, quantifying performance impacts includes the challenges of separating tailing due to inhomogeneities and structural defects from tailing due to compositional grading; determining the characteristic length scale of inhomogeneity; and reconciling macroscopic and microscopic data and models.

The thin-film solar cell community knows well that fluctuations in dopant densities produce electrostatic

potential fluctuations. However, the community still relies heavily on early theoretical work (from Shklovskii and Efros and others) to estimate potential fluctuation magnitudes. Commonly used expressions were only meant to provide first-order estimates and are potentially inadequate for describing fluctuations occurring in thin-film solar cell materials. In this talk, I will summarize our recent efforts to develop realistic estimates of fluctuation impacts on performance, using Cd(Se)Te solar cells as an example.

Optoelectronic data on Cd(Se)Te cells doped with arsenic show an increasing tail below the bandgap that is correlated with increasing arsenic incorporation level. These cells have As-dopant activation levels of only 1-5%, and an inverse relationship exists between dopant activation and incorporation, consistent with self-compensation mechanisms. Macroscopic photoluminescence and microscopic cathodoluminescence measurements were conducted at room and low temperature. The data indicate that, to a large extent, the tailing observed in macroscopic measurements, and the inhomogeneity that causes it, is present within individual μm-size grains.

Consistent with this picture, we consider that tails are created by randomly distributed As donor and acceptor (shallow) defects. The densities of donor and acceptor defects are based on incorporation (secondary-ion mass spectrometry) and carrier-density (capacitance-voltage) data. Donor and acceptor defects are randomly distributed in a cube and each is assigned a screened coulomb potential. Fluctuations in the potential can be clearly seen and we confirm that this numerical approach reproduces results from early semiclassical band-tail theory. Furthermore, we apply semiclassical theory to estimate V_{OC} losses in Cd(Se)Te solar cells.

Addressing the weaknesses of semiclassical theory, we develop self-consistent numerical methods to analyze random dopant fluctuations. We distribute donor and acceptor defects randomly within a 2D domain and solve Poisson's equation with density-gradient corrections to the electron and hole densities. The results show how compensation can enhance potential fluctuation amplitudes and induce large carrier-density fluctuations. Interestingly, we find that the effective band gap energy is not constant but has a distribution with a low energy tail. Finally, we use simple formulas to show how the effective bandgap tail can produce tails in absorption and luminescence spectra. These methods can potentially be used to form realistic models of fluctuation impacts on thin-film solar cell performance and facilitate progress.

Impact of Se Alloying on Metastable Defect Properties in Cd-Rich Group-V Doped CdTe Single Crystal

Akira Nagaoka[1], Kensuke Nishioka[1], Kenji Yoshino[1], Koji Kimura[2], Kouichi Hayashi[2], Darius Kuciauskas[3] and Mike Scarpulla[4]; [1]University of Miyazaki, Japan; [2]Nagoya Institute of Technology, Japan; [3]National Renewable Energy Laboratory (NREL), United States; [4]University of Utah, United States

Cadmium telluride (CdTe) photovoltaic (PV) modules are relatively easy to produce at a low cost, making them one of the most competitive commercially available PV technologies. Recently, the world-record PV cell has a power conversion efficiency of 22.1%, which is well below the theoretical limits. The improvement of efficiency without increasing the production costs will make PV generation more competitive with fossil fuels. The practical strategy for higher efficiency is improvements of open-circuit voltage (V_{OC}) and short-circuit current (J_{SC}).

Recently, it was discovered that group-V element doping (P, As, Sb, or Bi) and Cd-rich composition are key technologies for increasing V_{OC}, and these results were attributed to high p-type doping and long minority carrier lifetime. PV devices fabricated with P-doped CdTe single crystals as absorbing layer and with Cd-rich composition could result in hole concentration of ~10^{17} cm^{-3}, minority carrier lifetime of several hundreds of nano second, and V_{OC} exceeding 1 V. However, it is difficult to obtain group-V doping higher than 10^{17} cm^{-3} because doping efficiency typically becomes lower with higher dopant incorporation (above ~10^{16} cm^{-3}). The origin of this doping limit has not been established, but theoretical studies suggest that it may be caused by the formation of self-compensating AX center or defect complex. The AX center is formed due to a large lattice

relaxation of the substitutional dopant which results in conversion to a donor state. Recently, with in situ As-doping in polycrystalline thin film CdTe-based PV devices larger than 20% power conversion efficiency was be achieved, but dopant activation remained low (2-4%).
On the other hand, CdTe alloying with Se (CdTeSe) has attracted strong interest for improving J_{SC} because lower bandgap leads to increased absorption in the long wavelength part of the spectrum. Bandgap tuning through alloying is widely used in PV. For example, high-efficiency $Cu(In_xGa_{1-x})Se_2$ (CIGS) absorbers employ bandgap grading by controlled variation of In/Ga composition.
We combine both approaches to develop more efficient CdTe solar cells: group V doping and alloying with Se. We have grown high-quality As-doped Cd-rich CdTeSe single crystals from metal Cd solvent near thermodynamic equilibrium using the traveling heater method (THM). In this presentation, we will report growth and characterization of group-V doped Cd-rich CdTeSe single crystals from THM. It is not clear how the formation of CdTeSe alloy affects the activation of group-V doping, defect compensation mechanism and PV performance, and we propose some possible answers to these questions.

Semi-Transparent and Ultra-Thin Silicon Solar Cells Fabricated by the Surface-Bulk Micromachining
Erfan Pourshaban, Aishwaryadev Banerjee, Chayanjit Ghosh, Adwait Deshpande, Hanseup Kim and Carlos Mastrangelo; The University of Utah, United States

Widespread research in the field of wearable electronics, has ignited interest in stand-alone and efficient power generators. Photovoltaic devices are promising candidates for such applications. Due to their high stability and biocompatibility, Si solar cells are an attractive choice. However, the absorption coefficient of Si is highest in the visible and NIR region of the EM spectrum. Thus, efficient Si cells are opaque, which makes them undesirable for a wide range of applications that require the on-board electronics to be transparent. Additionally, the thickness of the conventional Si solar cells is ~200-300 μm which makes them rigid and unsuitable for applications that require the system components to be thin and flexible. Here, we present the design, fabrication, and performance evaluation of semi-transparent (T ~ 30% and 60%) and ultra-thin (15 μm) Si solar cells fabricated by surface-bulk micromachining (SBM) process.
A <111> boron-doped Si wafer with an average bulk resistivity of 5-10 Ω.cm was used as the substrate and base region. 400 nm of SiO_2 was thermally grown which acts as the diffusion barrier for subsequent doping steps. Phosphorous doping was performed at 1000 °C for 60 minutes to define the emitter region (sheet resistance = 8 $\Omega.sq^{-1}$). Micro holes (with a diameter of 170 μm) were then lithographically patterned in a hexagonal arrangement to achieve different levels of transparency in the fabricated Si solar cell. Next, deep reactive ion etching (DRIE) was performed on these patterns to realize trenches of 15 μm depth. This defines the final thickness of the solar cell. After this, 300 nm of LPCVD low-stress Si nitride was deposited on the sidewalls of the trenches as an etch resistant layer. This was followed by patterning and a second DRIE (DRIE 2) to dig deeper trenches than those achieved previously. The final transparency and effective surface area of the Si solar cell is determined during this step. The diameter of DRIE 2 micro holes was designed to be ~150 μm with a filling ratio of 25% and 50% that corresponds to an inter-hole distance (s) of 138 μm and 54 μm, respectively. This inter-hole spacing determines the required minimum depth of DRIE 2 trenches (h), which is crucial to release the ultra-thin device from the underlying substrate. Since (111) family planes have a negligible etch rate in KOH/TMAH, they act as an effective etch-stop layer. Therefore, to ensure that the etchant completely undercuts the device before reaching the etch-stop layer, the DRIE-2 depth (h) must be higher than $s \,.\, tan\,(19.47°)$. The DRIE-2 trench depth for 25% and 50% filling ratio devices were designed to be 394 μm and 154 μm, respectively. Finally, the samples were dipped into a 10 wt% tetramethylammonium hydroxide (TMAH) solution at 100 °C for completely releasing the structures. The time taken to release devices with 25% filling ratio and 50% filling ratio was 10 hours and 4 hours, respectively. After fishing out the released devices from the TMAH solution and removing the remaining Si nitride by CF_4/O_2 RIE dry-etching, 20 nm of SiO_2 was deposited as a passivation layer on the bottom of the solar cell and the sidewalls of DRIE trenches.
15 μm thick Si solar cells with a transparency of ~ 30% and ~ 60% were fabricated using the proposed method. Photocurrent-voltage measurements were conducted under indoor white light condition with an input power density of 13 $mW.cm^{-2}$. I-V results demonstrate the open-circuit voltage of 300, 120 mV and the short circuit

current density of 34, 1.4 μA.cm^{-2} for the 30% and 60% transparent silicon solar cells, respectively.

Controlling the Defects of Kesterite Solar Cells Xiaojing Hao; University of New South Wales, Australia

The Kesterite $Cu_2ZnSn(S,Se)_4$ (CZTSSe) semiconductor is a compelling emerging light-harvesting material for low-cost, environment-benign, and high-efficiency thin-film photovoltaics. The highest power conversion efficiency so far for kesterites are 11% and 12.6 % for pure sulfide kesterite and Se-containing kesterites, respectively. The current state-of-the-art kesterite devices suffer from the challenge of controlling defects (e.g. cation—disordering defects, defect clusters), which generally results in severe potential fluctuation, low minority carrier lifetime, and thereby unsatisfactory device performance. Identifying effective ways of controlling these defects is of vital importance for further efficiency breakthroughs. In our recent work, we demonstrated that some of these defects can be suppressed by either controlling the local chemical environment during the chalcogenisation synthesis of kesterite, or lithium post-deposition-treatment. By controlling the local chemical environment in time when the kesteirte phase starts to form, we demonstrated an independently confirmed 12.5% efficiency for CZTSe solar cells with high V_{OC} of 491 mV, showing the promise of these defect control strategies.

Ag-Alloying in $Cu(In,Ga)Se_2$ Marika Edoff, Jes Larsen, Jan Keller, Kostyantin Sopiha, Tobias Törndahl and Lars Stolt; Uppsala University, Sweden

The chalcopyrite family has emerged as a material with many possibilities and has yielded high efficiencies above 23 %[1]. One of the additions to this family is alloying with silver to form $(Ag,Cu)(In,Ga)Se_2$ (ACIGS). Among the features of Ag alloying as compared to $Cu(In,Ga)Se_2$ (CIGS) without Ag, are a lower melting temperature, that leads to large grains also for relatively low deposition temperatures, but also lower voltage losses as compared to the Shockley Queisser limit[2], and a slight increase in bandgap, due to Ag, accompanied by lowering of both the conduction band minimum and of the valence band maximum energy[3]. These advantages open up interesting applications for ACIGS as e.g. top cells in tandem devices, either in combination with low bandgap $CuInSe_2$ (with or withot Ag) or with Si as bottom cells. Due to its electronic band structure, ACIGS with high bandgap up to 1.5 eV yields high efficiencies with a conventional buffer layer like CdS, but also with ZnSnO and Zn(O,S)[4]. In addition to high efficiency, also long-term performance is essential for all applications and there are some questions related to phase stability for the ACIGS material, that need to be investigated further, but where we have obtained new insights with the help of first principle calculations[5]. Among the studies made in our group during the last few years are ACIGS with Ag/(Ag+Cu) ratios varying from 10 to 100 % and with varying Ga/(Ga+In) from 0 to 100 %. We have also applied ACIGS to solar cells with submicron thick absorber layers, as well as investigated the impact of post deposition treatments to this type of materials. In the talk, a short review of the state-of-the art of ACIGS will be given together with some of our insights from this line of research.

The Effect of Damp Heat—Illumination Exposure on CIGS Solar Cells—A Combined XRD and Electrical Characterization Study Mirjam Theelen[1], Ruud Hendrikx[2], Nicolas Barreau[3], Henk Steijvers[1] and Amarante Bottger[2]; [1]TNO Solliance, Netherlands; [2]Delft University of Technology, Netherlands; [3]Institute des Materieaux Jean Rouxel (IMN)-UMR, France

In order to obtain long-term stable and low-cost photovoltaic modules, it is important to know possible degradation mechanisms. In order to identify long term behavior, unpackaged $Cu(In,Ga)Se_2$ solar cells were simultaneously exposed to damp heat and illumination (settings: 85ºC/85% relative humidity and 1000 W/m^2 BAA illumination) [1]. In-situ monitoring of their electrical parameters demonstrated a rapid decrease of the efficiency, mainly driven by changes in the series and shunt resistances. Moreover, non-degraded and degraded solar cells were studied by in-depth XRD and SIMS to investigate the material changes leading to efficiency loss.
SIMS revealed the migration of sodium and potassium, likely leading to a severe decrease in the shunt resistance (from 500±100Ω to 20-30Ω within 200 hours) and voltage. It also displayed the ingression of hydroxide, especially in the ZnO:Al film. Extensive XRD measurements showed that molybdenum oxide was formed, which likely affected the Ohmic contact between Mo and CIGS. Moreover, an in-plane stress increase in the ZnO:Al film from -183±29 to -450±40 MPa was observed. This stress increase is most likely due to the incorporation of species like hydroxides and carbonates in the grain boundaries of the ZnO:Al film. These phenomena could lead to the observed increased series resistance in the solar cells [2].

Late News: Investigation of the Aptness of Pulsed Laser Deposition for the Sequential Fabrication of Cu(In,Ga)Se2-Based Thin-Film Solar Cells Evripides Kyriakides, Panagiotis Ioannou, Christiana Nicolaou, Vasiliki Paraskeva, Maria Hadjipanayi, George E. Georghiou, Paris Papagiorgis, Grigorios Itskos and John Giapintzakis; University of Cyprus, Cyprus

Thin-film photovoltaic (PV) technologies, and $Cu(In,Ga)Se_2$ (CIGS) thin-film solar cells in particular, have been the subject of increasingly rigorous study of late. There are several motivating factors for the development of thin-film photovoltaics, such as the reduction in raw material usage, the decrease in solar cell weight, and the possibility of deposition on flexible substrates. Furthermore, CIGS-based thin-film solar cells hold several advantages compared to rival solar cell technologies. Specifically, they have the highest conversion efficiencies among chalcogenide thin-film PV technologies (23.35% for cells and 17.5% for modules), high radiation resistance, and outstanding stability.

The typical CIGS-based solar cell consists of a soda-lime glass (SLG) substrate, a Mo back contact, CIGS as the p-type absorber layer, CdS as the n-type buffer layer, and i-ZnO/ZnO:Al as the decoupling and transporting window layers, respectively. However, in the state-of-the-art CIGS-based solar cells, each of these layers is deposited with a different method; co-evaporation for the CIGS layer, chemical bath deposition for the CdS layer, and reactive sputtering for the i-ZnO/ZnO:Al bilayer.

This work reports on the utilization of pulsed laser deposition (PLD) as a single technique for the preparation of the aforementioned layers of a complete CIGS-based solar cell stack. Employing a single deposition technique greatly reduces manufacturing complexity. Furthermore, it potentially decreases processing time and associated fabrication costs through streamlined production lines.

The presented results discuss the challenges faced in the completion of this task. The properties of the PLD-grown thin films with respect to structure, composition and morphology are parametrically investigated through

X-ray diffraction (XRD), energy-dispersive X-ray spectroscopy (EDS), scanning electron microscopy (SEM) and atomic force microscopy (AFM). Hence, the influence of PLD process parameters on film growth is evaluated. TCAD simulations realized in Synopsys Sentaurus Device are utilized for the optimization of the function of the cell. Electrical and optical measurements carried out in a solar simulator are used to assess the photovoltaic behavior of the complete structure and, critically, the CdS/CIGS junction heterointerface. The solutions implemented, involving modifications to the typical PLD process, are discussed. Finally, the resulting improvement in conversion efficiency is demonstrated.

High Efficiency Solar Cells Based on Co-Evaporated $CuIn_{0.7}Ga_{0.3}S_2$—Correlation Between Growth Process and Absorber Characteristics Nicolas Barreau; Université de Nantes, CNRS, Institut des Matériaux Jean Rouxel, IMN, France

$CuIn_{0.7}Ga_{0.3}S_2$ semi-conductor has a bandgap energy of 1.7 eV, which is well adapted to applications as top cell in tandem structures with c-silicon bottom cell. Recently, we have shown that solar cells with standard structure, namely Glass/Mo/$CuIn_{0.7}Ga_{0.3}S_2$/CdS/ZnO/AZO, can reach efficiencies above 14 %; the $CuIn_{0.7}Ga_{0.3}S_2$ layer being grown by co-evaporation following a 3-stage process. Determination of compositional depth profile of these absorbers revealed that the distribution of group III elements (*i.e.* In and Ga) is not homogeneous throughout the layers, as expected for films grown by means of sequential process. However, in contrast to V-shaped GGI evolution commonly observed in selenide absorbers, these sulfide films appear composed of two distinct layers, a first with GGI ~ 0.7/0.8 near the back contact and a second with GGI ~ 0.2/0.3 close to the surface; note that the abrupt interface between these layers is located at about half of total film thickness. A large part is the present contribution will focus on the origins for such bilayered compositional structure, which will be discussed accounting relative phase stability while copper content is increased during the second stage. In addition, although optimal bulk material quality could be achieved, device performance still appears limited by dominant interface recombination. To further explore that issue, the first results on epitaxial $CuIn_{0.7}Ga_{0.3}S_2$ layers will be presented.

Development of Ultrathin Cu(In,Ga)Se2 Solar Cells Jessica de Wild[1], Thierry Kohl[1], Gizem Birant[1], Dilara G. Budu[1], Guy Brammertz[1], Marc Meuris[1], Jef Poortmans[2] and Bart Vermang[1]; [1]IMOMEC, Belgium; [2]imec, Belgium

Thin film solar cells have the possibility to be made flexible, semi-transparent and/or may be applied for tandem structures or building integrated. Having multiple usages, it is of interest to make these thin film solar cells as fast and cheap as possible. From the available thin films, Cu(In,Ga)Se2 (CIGS) has one of the best solar cell performance [1]. There are concerns about the usage of indium though when CIGS will be widely applied. Therefore, making the CIGS layer thinner and thereby reducing the amount of In, is an interesting option to explore. When the absorber material becomes thin, interfaces are generally limiting the performance and the path length to absorb all the incoming light may be too short to absorb the longer wavelengths. There are various approaches to tackle these problems. Passivation of the back contact by applying a dielectric is the main route investigated. Not only reduces it the interface recombination at the Mo/CIGS back contact but it also

increases the reflection. We will present here various approaches which are aimed to be industrial viable and easy to make to reduce the losses in ultrathin CIGS solar cells. This also holds for the absorber layers which are made by a single stage coevaporation process. In this case, the Ga gradient at the back is replaced by a passivation layer and no copper rich stage is applied. The effect of the simplified growth is mostly visible in the grain boundaries [2]. As passivation layer, AlOx is often used. As this layer blocks the current flow, it has to be either sufficiently thin to allow tunneling or requires holes allowing for the current to flow to the Mo back contact. We will show that the latter approach can be applied for layers up to 6 nm without lithography steps by simply adding NaF before CIGS growth [3]. When applying a thin Ag layer under the AlOx the cells also show optical improvement. This is likely due to formation of scattering particles, making the CIGS rougher and thereby increasing the optical path length. To improve the absorber layer itself alkali treatments are applied [4]. At the front, the CIGS/buffer interface may also need to be adapted. Application of a passivation layer at the front, either with holes or thin enough for tunneling, is investigated. Before applying a passivation layer on the CIGS surface, cleaning treatments need to be applied [5]. To analyze the effect of the various treatments a combinatorial approach based on bias dependent admittance spectroscopy and (time resolved (TR)) photoluminescence (PL) is developed. Generally, with (TR)-PL a quick analysis whether the treatments are improving the absorber/interface quality before finishing into a device is possible. Features like interference and blue shifts of the spectra may be observed as well and can be related to the emission profile and scale of the potential fluctuations in the absorber layer [6]. However, improvement due the various treatments observed in the (TR)-PL does not necessarily translates into better solar cell performance. This can indicate that the treatments are sensitive to the processing conditions of the window layers for instance and/or that barriers are formed. With bias-dependent admittance spectroscopy losses at interfaces and bulk can be found by introducing a so-called CVf loss map [7]. These maps visualize the losses in the solar cell, which makes it possible to distinguish defects in the bulk from the interface and barriers at front or back interfaces. The bottlenecks observed when developing ultrathin CIGS solar cells will be discussed and possible options to mitigate them are investigated.

Sputtered Gallium Oxide Applied to the Front Side of Cu(In,Ga)Se_2 Thin-Film Solar Cells Wolfram Witte, Wolfram Hempel, Stefan Paetel, Richard Menner and Dimitrios Hariskos; Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg (ZSW), Germany

Oxide-based materials could be candidates for buffer, passivation, or high resistive (HR) layers in Cu(In,Ga)Se_2 (CIGS) thin-film solar cells. In recent years, oxide materials like (Zn,Mg)O, Al_2O_3, Zn_xTi_yO [1], $(In,Ga)_2O_3$ [2] and $Sn_{1-x}Ga_xO_y$ [3] were under investigation. Most of them were deposited by atomic layer deposition. However, from an industrial point of view a very fast method, with deposition times <1 min for a complete layer, would be preferable for buffer, passivation, or HR layer growth.
In this study, we present our results with rf-magnetron sputtered Ga_2O_3 buffer layers as a substitute for our solution-grown CdS buffer in combination with i-ZnO as HR layer and ZnO:Al front contact. So far, best cells achieved efficiencies up to 14% without post-annealing compared to the CdS-buffered reference cells, which exhibit efficiencies up to 17%. As a result of the very high bandgap energy around 4.7 eV of Ga_2O_3, as determined on quartz glass by optical transmittance measurements, and reduced parasitic absorption even higher Jsc values could be achieved compared to the CdS-buffered reference cells. Nevertheless, the difference in efficiency is mainly due to reduced Voc and FF values of the CIGS cells with Ga_2O_3.
The solar cell performance of cells with Ga_2O_3 buffers strongly depends on the deposition conditions as well as

on the thickness of the sputtered Ga_2O_3 layers. We observed poor cell efficiencies for cells with Ga_2O_3 sputtered at room temperature and good values for films grown at elevated substrate temperatures (120 – 200 °C). This result is similar to the behavior we observed for CIGS cells with sputtered Zn(O,S) and In_xS_y buffers [4]. The Ga_2O_3 layers deposited in the relevant temperature range for solar cell applications are X-ray amorphous.
When using CIGS absorber layers with a RbF post-deposition treatment, a wet chemical treatment of the CIGS surface before the Ga_2O_3 deposition has a significant positive impact to achieve decent efficiencies. Non-rinsed samples could exhibit poor efficiencies, mainly due to bad FF values.
In addition, we could achieve a comparable good efficiency of 19.4% (with anti-reflective coating) with Ga_2O_3 applied as an HR layer instead of i-ZnO (19.7%) in combination with CdS as a buffer and ZnO:Al as front contact.

11:10 AM EN07.07.03
Chemical and Electronic Structure of GaO_x/Cu(In,Ga)Se_2 Interfaces in Thin-Film Solar Cells with RbF Post-Deposition Treatment Dirk Hauschild[1,1,2], Elizaveta Pyatenko[1,1], Vladyslav Mikhnych[1], Ralph Steininger[1], Mary Blankenship[2], Dimitrios Hariskos[3], Wolfram Witte[3], Michael Powalla[3], Clemens Heske[1,1,2] and Lothar Weinhardt[1,1,2]; [1]Karlsruhe Institute of Technology (KIT), Germany; [2]University of Nevada, Las Vegas (UNLV), United States; [3]Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg (ZSW), Germany

The introduction of post-deposition treatments (PDTs) has increased the Cu(In,Ga)Se_2-based (CIGSe) thin-film solar cell efficiencies to >23 % on a laboratory scale. Such high-efficiency devices are often processed with a solution-deposited CdS buffer layer. However, the CdS band gap leads to absorption losses in the buffer layer, reducing the solar-cell efficiency. Hence, there is a strong interest to replace CdS with an alternative wide(r) band gap material. In addition to merely increasing the buffer layer band gap, using such an alternative material would also lead to various changes at the buffer/absorber interface, including the electronic and chemical structure. A detailed knowledge of these changes is crucial for further device optimization.

In this contribution, we report on industrially relevant CIGSe absorbers with and without an NH_3-based rinsing step applied after the RbF PDT. Their interface with a wide band-gap GaO_x buffer layer is studied using x-ray photoelectron spectroscopy (XPS), hard XPS (HAXPES) at the synchrotron, and a combination of UV photoelectron spectroscopy (UPS) and inverse photoemission spectroscopy (IPES). The results paint a comprehensive picture of the GaO_x/CIGSe interface and will be discussed in view of the performance of the corresponding CIGSe solar cells.

Late News: Atomic Layer Deposition of Zn1-xMgxO as Transparent Conducting Films for Chalcopyrite Solar Cells Poorani Gnanasambandan[1,2], Mohit Sood[2], Noureddine Adjeroud[1], Renaud Leturcq[1] and Susanne Siebentritt[2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]University of Luxembourg, Luxembourg

We investigate atomic layer deposited zinc magnesium oxide films with varying Mg content as transparent conducting films and as electron transport layers for chalcopyrite solar cells. Optimizing a ternary process by mixing two binary ALD process has its challenges [1]. We achieve high degree of control on composition by optimizing the growth conditions with varying deposition temperatures and supercycle parameters such as pulse ratios and bilayer period. We examine the effect of these films on the performance of high-bandgap solar cells

based on $Cu(In,Ga)S_2$ absorbers.

Previous studies on the impact of $Zn_{1-x}Mg_xO$:Al as transparent electrodes and Mg doped ZnO thin films for the window layer of CIGS $Cu(In,Ga)(S,Se)_2$ solar cells employed co-sputtering , electrodeposition and ALD respectively [2][3][4][5]. With the advantage of low temperature and highly conformal thin film growth, we study ALD grown $Zn_{1-x}Mg_xO$ with x varying from 0.1 to 0.4 and elucidate the effect of doping on the band alignment, electrical and optical properties. With variation in Mg content we were able to achieve 11% efficient $Cu(In,Ga)S_2$ solar cell with an open-circuit voltage of 941 mV.

Solution Processed Bismuth Halide and Chalcohalide Thin-Film Solar Cells David J. Fermin[1] and Devendra Tiwari[2]; [1]University of Bristol, United Kingdom; [2]Northumbria University, United Kingdom

Solution processing of inorganic thin-film solar cells is a key challenge in the growing area of system integrated photovoltaics. The ability of processing high quality materials at temperatures below 200 °C enables the fabrication of devices onto flexible composite materials. Semiconductor compounds with high degree of defect tolerance are an exciting class of materials particularly well-suited to these applications. Indeed, compounds based on Bi^{3+} can lead to attractive opto-electronic properties similar to those observed in Pb^{2+} hybrid perovskites, such as large spin-orbit coupling, dielectric constant and band dispersion.[1]
In this contribution, we will discuss the structure and opto-electronic properties of phase-pure BiI_3 and BiSI obtained by solution based method. BiI_3 is prepared by spontaneous gas-phase iodination of Bi_2S_3 films at 200 °C,[2] while BiSI is generated by thermolysis of a precursor solution composed of $Bi(NO_3)_2$, thiourea and NH_4I.[3] In addition to accurate structure refinement from XRD data of the thin-films, we find excellent correlation between experimental Raman spectra and Raman modes calculated by density functional perturbation theory. Interestingly, BiI_3 exhibits p-type conductivity (acceptor density of the order of 10^{15} cm^{-3}) and a band gap of 1.7 eV, while BiSI is n-type with a donor density in the range of 10^{19} cm^{-3}. Quasi-particle G_0W_0 calculations of both materials show that the conduction band is more dispersed than the valance band due to spin-orbit coupling promoted by Bi^{3+}. Band edge energy values are estimated by electrochemical impedance spectroscopy, enabling the design of PV devices with appropriate band alignment. Devices with the structure $Glass/FTO/TiO_2/BiI_3/F8/Au$ and $Glass/FTO/SnO_2/BiI_3/F8/Au$, where F8 is Poly(9,9-di-n-octylfluorenyl-2,7-diyl), display open-circuit voltage above as high as 600 mV and record power conversion efficiency of 1.32% under AM 1.5G illumination. We will expand the discussion to other complex Bi chalcogenides,[4] addressing the key limiting factor in the PV performance of these materials, i.e. their short carrier lifetimes.

Development and Application of Transparent Back Contacts in CIGSe Solar Cells Roland Scheer[1], Thomas Schneider[1], Johanna Troendle[1], Bodo Fuhrmann[1], Frank Syrowatka[1], Heiko Kempa[1], Torsten Hoelscher[1], Marcel Placidi[2,3] and Alejandro Perez-Rodriguez[2,4]; [1]Martin-Luther-Universität-Halle-Wittenberg, Germany; [2]IREC, Spain; [3]Polytechnic University of Catalonia, Spain; [4]Universitat de Barcelona, Spain

Replacing the established Molybdenum back contact in $Cu(In,Ga)Se_2$ solar cells by a transparent conducting layer would enable a variety of new applications: Bifacial solar modules, semitransparent building integration without back side mirroring, and ultrathin solar cells with scattering back reflector. In this work, we review the status of alternative back contacts for CIGSe solar cells and present own work using ITO. It is shown that for low temperature CIGSe deposition, the ITO back contact is on par with the Mo standard regarding PCE, and may even surpass Mo for ultrathin devices. Admittance measurements on ITO back contacts indicate the absence of a back contact barrier and thus the avoidance of the wellknown reach-through effect. Using bifacial illumination, the back contact recombination velocity is determined to around 10^5 cm/s for the ITO/CIGSe interface formed at around 480°C by co-evaporation of CIGSe on sputtered ITO. Cells of 300 nm CIGSe thickness demonstrate quantum efficiency of 55% if illuminated from the back side. If the ITO layer is grown on top of a reflective back contact of 100 nm Aluminum, ultrathin devices can be constructed. Here, the Aluminum acts as the optical reflector and the ITO serves as a diffusion barrier and electronic back contact. This back contact can be further functionalized by light scattering elements. In experiment, a 300 nm structure element height below a 500 nm CIGS film gives the highest current density, which amounts to 88% of that of a 2.8 µm reference solar cell on Molybdenum.

Bismuth Oxyiodide Solar Cells—Defect Tolerance, Device Engineering and Indoor Light Harvesting
Robert Hoye; Imperial College London, United Kingdom

Lead-halide perovskites have emerged as a leading thin film solar absorber over the past decade. One of the key enabling properties is their tolerance to point defects, which enables them to achieve long charge-carrier lifetimes despite high defect densities when grown by low-temperature, simple fabrication methods. However, the toxicity of the water-soluble lead content may limit their widescale adoption. This talk examines bismuth-based semiconductors as a low-toxicity and stable alternative to lead-halide perovskites, with particular focus on bismuth oxyiodide (BiOI). We show that BiOI replicates the tolerance of lead-halide perovskites to point defects using experimental and computational methods [1,2]. An all-inorganic device structure is developed, and we achieve photovoltaic devices with external quantum efficiencies of up to 80% at 450 nm wavelength. Both the BiOI absorber and devices are stable in air. Although the 1.9 eV band gap is too wide for single-junction devices under 1-sun illumination, this band gap is ideal for indoor light harvesting. We demonstrate BiOI devices with comparable performance to hydrogenated amorphous silicon (the industry standard for indoor photovoltaics) under fluorescent and white LED lighting. We show that these devices, with lab-scale millimetre-squared areas, are sufficient to power carbon nanotube-based inverters [3]. Finally, we discuss the key limiting factors that need to be overcome to achieve further improvements in performance [1,3,4], as well as the potential of the broader family of bismuth-based perovskite-inspired materials for applications in solar energy and indoor light harvesting [3].

Defect Identification and Full Lattice Dynamics of Zinc Phosphide, an Earth-Abundant Semiconductor for Photovoltaics Elias Z. Stutz[1], Diego A. Sandoval Salaiza[1], Alexander P. Litvinchuk[2], Mahdi Zamani[1], Simon Escobar Steinvall[1], Rajrupa Paul[1], Jean-Baptiste Leran[1], Anna Fontcuberta i Morral[1,1] and Mirjana Dimitrievska[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]University of Houston, United States

Zinc phosphide (Zn_3P_2) is an earth-abundant semiconductor material capable of addressing the rising demand for low-cost and efficient optoelectronic devices. Its 1.5 eV direct bandgap, long minority carrier diffusion length (5-10 μm), and high absorption coefficient make it very promising for applications as an absorber in thin films solar cells. Furthermore, it has the added benefit of being a binary phase over more complex multinary materials.
Two crucial challenges need to be overcome to produce high-efficiency devices. First, poor crystal quality when grown on commercially available substrates due to high interface defect densities and high coefficient of thermal expansion. This challenge has been recently solved in our laboratory, as we have demonstrated different fabrication methods of high-quality reproducible thin films, with the possibility of facile transfer onto commercially available substrates.[1] [2] The second challenge is the control of bulk defects and doping, which is crucial for optoelectronic performance. Usually, uncontrolled growth results in p-doped material due to the formation of intrinsic acceptor defects.
To solve the challenge of defect control, we have investigated structural defects in the room-temperature-stable phase of zinc phosphide (α-Zn_3P_2, space group $P4_2/nmc$) using Raman spectroscopy. For that purpose, we have first fully characterized the lattice dynamics of zinc phosphide by combining density functional theory (DFT) calculation with polarized micro-Raman measurements on single-crystalline zinc phosphide. This is the first complete analysis of phonons in Zn_3P_2, essentially providing a reference for further characterization of this material. We identified 33 of the 39 expected Raman lines and have calculated the atomic displacement in all vibrational modes[3].
Then, using factorial and combinatorial studies of Zn_3P_2, along with the micro-Raman spectroscopy and previously mentioned results, has allowed us to probe different structural defects within Zn_3P_2. Systematic changes in the peak position, intensity, and widths in correlation with the presence of Zn and P interstitials and vacancies are presented and discussed. This work demonstrates the possibility of defect engineering in Zn_3P_2, which is of the foremost importance for the improvement of solar cell performance, as well as the potential of Raman scattering for point defect assessment in this system.

Novel Photovoltaic Materials—Multinary Adamantine Phases Derived from Ternary Chalcopyrites Yvonne Tomm[1] and Susan Schorr[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

Adamantine-type compounds, including kesterites, are currently the most promising material for a fully inorganic thin film photovoltaic technology that is free of critical raw materials and thus provides sustainable solutions.

Adamantines are compounds crystallizing in a structure, in which every atom is tetrahedrally bonded to four nearest neighbours [1]. To find new compounds for absorber layers as well as window materials for thin film solar cells, the $A^{I}B^{III}X^{VI}_2$ chalcopyrite compound family, belonging to the Adamantine compounds, can be extended by chemical substitution. Coming from the chalcopyrite-type structure (space group I-42d), one A^{+1} (occupying the structural site 4a) and one B^{+3} cation (occupying the structural site 4b) are replaced by one four-valent cation ($A^{+1} + B^{+3} \leftrightarrow C^{+4}$). This substitution will consequently lead to the formation of cation vacancies. In this way a quaternary "defect adamantine" [1] such as I-[]-III-IV-VI_4 is formed.
.
Here we report on the growth of Cu[]BCX_4 single crystals, with B = Ga, In, C = Ge, Sn and X = S, Se such as $CuGaGeS_4$, $CuInGeS_4$, and $CuGaSnS_4$, and the analysis of their structural as well as optoelectronic properties. The single crystals were grown by chemical vapor transport using iodine as transport agent. The evolved material and the grown crystals were characterized by X-ray fluorescence spectroscopy (XRF) for chemical composition as well as by X-ray diffraction (XRD) at 298K. The obtained powder patterns were analyzed by LeBail refinement to determine the lattice parameter. The chalcopyrite-like crystal structure was used as a structural model in the refinement.
The band gap energy of the material was revealed by solid-state UV/Vis reflectance spectroscopy. The obtained data were analyzed using the Kubelka−Munk pseudo-absorption function and the Tauc-plot method. The structure-property relations of $CuGaGeS_4$ and $CuGaSnS_4$ will be discussed in detail in the presentation.
We present first results on the growth and characterization of the novel compound semiconductor $CuGaGeS_4$ as well as $CuGaSnS_4$. These indicating a potential for future applications.

Towards Defect-Free Thin Films of the Earth-Abundant Absorber Zinc Phosphide Through Nano-Patterning Simon Escobar Steinvall[1], Elias Z. Stutz[1], Rajrupa Paul[1], Mahdi Zamani[1], Nelson Y. Dzade[2], Valerio Piazza[1], Martin Friedl[1], Virginie de Mestral[1], Jean-Baptiste Leran[1], Reza R. Zamani[3] and Anna Fontcuberta i Morral[1,4]; [1]Laboratory of Semiconductor Materials, Institute of Materials, Ecole Polytechnique Fédérale de Lausanne, Switzerland; [2]School of Chemistry, Cardiff University, United Kingdom; [3]Interdisciplinary Centre for Electron Microscopy, Ecole Polytechnique Fédérale de Lausanne, Switzerland; [4]Institute of Physics, Ecole Polytechnique Fédérale de Lausanne, Switzerland

Zinc phosphide (Zn_3P_2) is an earth-abundant semiconductor with optoelectronic properties suitable for photovoltaic applications, such as a direct bandgap (1.50 eV), long minority carrier diffusion lengths (up to 10 μm), and high absorption in the visible range.[1,2] However, applications of the material has been limited due to challenges introduced by the lack of substrate with a matching lattice constant (for epitaxial growth) and thermal expansion coefficient, and the doping due to off-stoichiometry composition resulting in the formation of self-interstitials. Molecular beam epitaxy overcomes this by providing a low-temperature growth route with precise control over the composition, facilitating the fabrication of high-quality zinc phosphide.
A technique which can be used to further improve the material quality is selective area epitaxy (SAE).[3,4] Using a nano-patterned oxide mask on indium phosphide substrates we demonstrate the selective growth in the holes, limiting the interface area to improve its quality.[5] The SAE grown zinc phosphide first grows as nanopyramids. By controlling the growth time and pitch they can be made to overgrow the oxide and coalesce, forming a thin film. The structural properties of the material and the epitaxial relationship were investigated through transmission electron microscopy, which also showed the influence of hole size on the composition of the zinc phosphide and the formation of rotational core-shell structures. Furthermore, using conductive atomic force microscopy (CAFM) and photoluminescence spectroscopy (PL) we evaluated the functional properties of the material. The CAFM measurements showed a diode-like behavior when the zinc phosphide is grown on an n-type substrate, whilst the PL showed clear bandgap emission at 1.53 eV, ideal for photovoltaic applications.

This approach has shown great potential in producing high-quality zinc phosphide, and upcoming studies will use it to transfer the growth to an earth-abundant substrate (silicon), and making prototype photovoltaic devices based on SAE grown zinc phosphide.

Metastability in CIGS Solar Cells with Na and RbF Alkali Treatments with Varitaion in Buffer Layers
Shubhra Bansal; University of Nevada, Las Vegas, United States

The effects of Na and RbF alkali treatment on the metastability behavior of $Cu(In,Ga)Se_2$ solar cells with two different buffers have been investigated with stress factors of heat, junction bias and illumination.

For CdS buffer, four device types with and without Na or RbF treatments have been subjected to heat- and light-soaking under open- and short-circuit (OC, SC) junction bias. Low-Na devices show a higher bandgap due to increased minimum Ga content, higher recombination current and lower open-circuit voltage (V_{OC}). Devices with RbF post-deposition treatment (PDT) show an improvement in net doping density ~ 10^{16} cm^{-3}, V_{OC} and efficiency. Heat- and light-soaking under OC junction bias provokes an increase in net carrier concentration and V_{OC} irrespective of the alkali treatments. After SC stress, a decrease in V_{OC} and net carrier concentration are observed which can be stabilized by RbF-PDT. ToF-SIMS measurements reveal an increase in Na and O concentration in CIGS for baseline and reduced-Na devices, respectively, after OC stress. Oxygen concentration in CdS decreases after heat- and light-soaking for devices without RbF-PDT, whereas it remains unchanged for devices with RbF-PDT. The atomic concentration profiles in CIGS significantly stabilize as a function of stress with the addition of RbF-PDT.

Devices under open-circuit (OC) light soaking show an increase in V_{OC} with CdS buffer, however, V_{OC} decreases for ZnOS buffer devices. All devices show an increase in net carrier concentration after OC light soak irrespective of RbF-PDT or the buffer layers, even though ZnOS buffer devices show degradation. Under short-circuit (SC) light soak CdS buffer devices with RbF-PDT show stabilization of V_{OC} attributed to the increase in ionized acceptors in ordered vacancy compound (OVC) or buffer donor density. ZnOS buffer devices, on the other hand, show a decrease in V_{OC} under both OC and SC light soak irrespective of RbF treatment. A comprehensive discussion of effect of interface defects, conduction band offset and near interface doping density will be presented for ZnOS based CIGS solar cells.

4:25 PM EN07.09.02
Tailoring the Amine-Thiol Solvent System for the Deposition of High Quality Metal Selenide Films to Fabricate $Cu(In,Ga)(S,Se)_2$ Solar Cells Jonathan Turnley, Swapnil Deshmukh and Rakesh Agrawal; Purdue University, United States

The solution processing of thin-film solar cells is of great interest due to the potential of this method to decrease

costs and dramatically increase manufacturing throughput compared to the vacuum analogue. By utilizing hydrazine as a solvent, researchers have fabricated solution-processed $Cu(In,Ga)(S,Se)_2$ devices with efficiencies greater than 17%. However, hydrazine is highly toxic and explosive, potentially limiting its use is large-scale manufacturing. Several alternative solution processing methods are under investigation, though none have matched hydrazine in efficiency. Because of the difficulty in producing a soluble selenium species, these methods will often deposit a nanocrystalline sulfide precursor film. The precursor film is then converted to a large-grain selenide film by heating in a selenium atmosphere. During this conversion, grain growth is achieved as the nanocrystalline sulfide material dissolves in a liquid selenium front and then recrystallizes into micron-scale selenide grains. This process often results in a distinct "fine-grain" layer, particularly as film thickness increases, limiting researchers to absorber layer of 1-1.5μm in thickness.
The amine-thiol solvent system has emerged as one of the most promising alternatives to hydrazine, producing $Cu(In,Ga)(S,Se)_2$ devices with efficiencies above 15%. With its ability to dissolve metals and metal chalcogenides, the amine-thiol solvent system is able to avoid potential anionic impurities that arise when using other metal salts. Additionally, because selenium and many metal selenides can be dissolved in amine-thiol, this system has the potential to tune the sulfur to selenium ratio of the precursor film, as is done in the hydrazine system. One challenge, however, is that the metal-thiolates produced in this dissolution can easily decompose into metal sulfides upon heating, often leading to significant sulfur content in the precursor film, along with some residual carbon.
In this research, we will discuss investigations into amine-thiol dissolutions of metal chalcogenide species through the use of ^{1}H-NMR, Raman, and ESI-MS. By developing a deeper understanding of the chemistry in this reactive dissolution, we can then make carefully controlled modification to the resulting metal complexes. We will present the various methods we have developed to alter the metal-chalcogenide bonding in the soluble precursor species, thereby changing the decomposition products and allowing for additional control over precursor film fabrication. We will also discuss the implications of the precursor film chalcogen composition on the further processing of the absorber layer, particularly as it relates to grain growth and will show how it can help reduce the carbon content in the film. To this end, we have utilized this new chemistry to produce the first ever 2μm-thick, solution-processed absorber films with no fine-grain layer. Finally, we will discuss how these strategies can be implemented to further the ultimate goal of high efficiency, solution-processed solar cells.
In conclusion, this research focuses on developing an understanding of the fundamental chemistry of the metal complexes created with the amine-thiol solvent system and connecting this knowledge with the practical application of solution-processed thin-film PV.

4:40 PM EN07.09.03

Chemical and Electronic Properties of CdS/$Cu(In,Ga)Se_2$ Interfaces with High Ga/(Ga+In) Ratio and Post-Deposition Treatment

Mary Blankenship[1], Dirk Hauschild[1,2,2], Elizaveta Pyatenko[2,2], Wolfram Witte[3], Dimitrios Hariskos[3], Wanli Yang[4], Nan Jiang[1,4], Monika Blum[4,4], Michael Powalla[3], Lothar Weinhardt[1,2,2] and Clemens Heske[1,2,2]; [1]University of Nevada, Las Vegas (UNLV), United States; [2]Karlsruhe Institute of Technology (KIT), Germany; [3]Zentrum für Sonnenenergie- und Wasserstoff-Forschung Baden-Württemberg (ZSW), Germany; [4]Lawrence Berkeley National Laboratory (LBNL), United States

The conversion efficiency of $Cu(In,Ga)Se_2$-based (CIGSe) thin-film solar cells has reached values above 23% on a laboratory scale. To further increase the solar cell performance, higher open-circuit voltages can be achieved by increasing the Ga/(Ga+In) (GGI) ratio to create a larger absorber band gap and/or by applying a post-deposition treatment (PDT) to the absorber surface. Consequently, it is crucial to understand how a high GGI *and* a PDT affects the chemical structure and band alignment at the buffer/absorber interface.

We have investigated in-line deposited and industrially relevant CIGSe absorbers with high bulk and surface GGI ratios. Two sample series, one with and one without RbF PDT, were prepared, and their interfaces with a chemical bath deposited CdS buffer layer were characterized with a combination of electron and soft x-ray spectroscopies. For this purpose, laboratory-based x-ray and UV photoelectron spectroscopy (XPS and UPS, respectively), inverse photoemission (IPES), and x-ray-excited Auger electron spectroscopy (XAES) were combined with synchrotron-based soft x-ray emission spectroscopy (XES). A detailed picture of the electronic

and chemical structure at and near the interface can be painted, which will be discussed in relation to the performance of the corresponding CIGSe solar cells.

5:00 PM *EN07.09.04

Cell-Level Reliability Starring Cu(In,Ga)Se_2 Thin-Film Photovoltaics Lorelle M. Mansfield, Ingrid L. Repins, Stephen Glynn, Christopher P. Muzzillo, Bart Stevens, Peter Hacke, Kent Terwilliger, Steve Johnston, Steven P. Harvey, Matthew R. Young, Helio R. Moutinho, C.S. Jiang, Chuanxiao Xiao, Darius Kuciauskas and Timothy J. Silverman; National Renewable Energy Laboratory, United States

The reliability of photovoltaics is commonly studied at the module level. Many reliability problems do originate from module attributes, such as metal interconnections to cells, junction boxes, etc. However, significant work in reliability can also be done before an entire module is designed. In this talk I summarize how we investigated three reliability concerns in Cu(In,Ga)Se_2 (CIGS) photovoltaics at the cell level. The first is metastability, which in CIGS presents as an increase in V_{OC} over time during prolonged light exposure. Although increasing V_{OC} is not detrimental to module performance, it does complicate accurately measuring a module's performance and subsequent rating. The second is shading-induced hot spots where cells are irreversibly damaged by reverse voltage. This can happen in less than 1 second of partial shading, and the damage is often visible to the eye. Finally, we looked at potential-induced degradation (PID) or a decrease in performance caused by voltage differentials which drive ion diffusion. PID is a growing concern as the number of modules wired in series rises, hence increasing voltage differentials. Examining these perceived problems required developing robust measurement protocols including the fabrication of novel testing structures. These efforts ensured that we were incorporating the right metrics for investigating the phenomena and provided insights for improvement strategies.
NREL is in a unique position to test reliability at the cell level as we are making improvements to PV technology. If we look at reliability earlier in the research cycle, we have the potential to avoid commonly known module reliability problems before cell changes are implemented on a large scale. Cell-level reliability studies could thus lower the rates of module failures in the field and provide confidence to investors that new technologies will perform as advertised.

5:25 PM EN07.09.05

Late News: Enhanced Efficiency of Solution-Processed CuIn(S,Se)2 Solar Cells by *In Situ* Incorporation of Al2O3 Wilman Septina[1], Christopher P. Muzzillo[2], Craig Perkins[2], Anne Curtis Giovanelli[1], Thomas West[1], Kenta Ohtaki[1], Hope Ishii[1], John Bradley[1], Kai Zhu[2] and Nicolas Gaillard[1]; [1]University of Hawaii, United States; [2]National Renewable Energy Laboratory, United States

In recent years, passivation of Cu(In,Ga)Se_2 (CIGSe) surface and/or interfaces with insulator materials has attained lots of attention to further increase efficiency. Such passivation is usually achieved with a thin layer of Al_2O_3 (<50 nm) deposited either before or after fabrication of CIGSe, most predominantly by atomic layer deposition method. The application of Al_2O_3 layer has been shown to reduce the number of electrically active defects at the semiconductor surface, which in turn lowers surface recombination velocities. This led to a decrease in interface recombination and resulted in improved efficiency. Passivation with Al_2O_3 has also been applied successfully to other thin film absorbers such as $Cu_2ZnSn(S,Se)_4$ and CdTe.
In this report, we present a novel approach to improve solution-processed CuIn(S,Se)$_2$ (CISSe) solar cell efficiency by in-situ incorporation of Al_2O_3 . Specifically, $AlNO_3$ was added to inks containing CuCl, $InCl_3$, and thiourea dissolved in methanol. After spin coating of these solutions performed in air, samples were subjected to a selenization process. Our study showed that the Al formed amorphous nanosized-Al_2O_3 covering parts of the film top and bottom surfaces as well as within bulk and grain boundaries. Power conversion efficiency (PCE) as high as 11.6% was measured on cells using CISSe incorporated with Al_2O_3, a value higher than that measured on CISSe fabricated from Al-free ink (maximum PCE: 8.3%). This efficiency boost stemmed primarily from an increase in both in open-circuit voltages and fill factors. Defect passivation via this in-situ formed Al_2O_3 is

thought to play a major role in the improvement of the solar cell performance through defect passivation, while permitting Cd diffusion to take place at the absorber sub-surface. Details of the fabrication process, materials, and photovoltaic characterization will be discussed.

5:30 PM EN07.09.06
Silver Indium Diselenide—A High Mobility, Low-Defect Chalcopyrite Material with Potential for Thin-Film Photovoltaics David J. Rokke, Kyle G. Weideman, Anna Murray and Rakesh Agrawal; Purdue University, United States

An area of interest in the thin film photovoltaics community that has grown in recent years is the alloying of $Cu(In,Ga)(S,Se)_2$ (CIGS) with silver to create $(Ag,Cu)(In,Ga)(S,Se)_2$ (ACIGS). Alloying of silver in CIGS has resulted in favorable device characteristics such as increasing the bandgap to optimize devices for top cells in tandem architectures, reduced structural disorder (observed by lower Urbach energies) and lower open circuit voltage losses. However, we anticipate that the alloying of silver may only complicate the fabrication of CIGS devices by introducing a sixth element that must be controlled in the material. Indeed, a recent report[1] showed that high bandgap ACIGS devices have a low tolerance to off-stoichiometry, and another recent study[2] has suggested that the ACIGS system may be prone to phase segregation at certain temperatures and compositions. These observations foreshadow possible complications in the controlled scale-up of ACIGS devices.
In this work, we propose that some advantages of silver incorporation in chalcopyrite materials could be harnessed differently, by moving away from the complex stoichiometry of ACIGS to the far simpler $AgInSe_2$ (AIS). AIS has been studied only briefly in the literature, but initial findings suggest that the material is worth investigating further as a photovoltaic absorber material. By eliminating copper and gallium, the possibility for phase segregation is greatly reduced and the challenges presented by ACIGS are avoided. In addition, AIS has a direct bandgap in the ideal range for single-junction cells at 1.24eV, has been shown to have a carrier mobility much higher than CIGS, and has been predicted to have higher defect formation energy than CIGS.
To explore the potential of this material, we have fabricated thin films of $AgInS_2$ through the amine-thiol solution processing route by dissolving silver sulfide and metallic indium in a monoamine-dithiol solvent mixture, creating a solution of bis(1,2-ethanedithiolate) indium (III) and oligomeric Ag(I) thiolates. These solutions were cast on to molybdenum-coated glass substrates and annealed to form orthorhombic $AgInS_2$ films. These were then selenized in an elemental selenium atmosphere to create chalcopyrite thin films.
Our preliminary electronic characterization of $AgIn(S,Se)_2$ thin films suggest that the carrier concentration is roughly 1×10^{13} cm^{-3}. In previous literature[3] it has been shown that the carrier concentration can be controlled by changing the concentration of selenium in the annealing atmosphere. We find that carrier mobilities and photoluminescence characteristics are superior to similarly fabricated CIS thin films. From these initial results, we expect AIS to have superior electronic properties and defect characteristics when compared to CIS/CIGS films.
A side effect of the use of silver instead of copper is a change of the majority carriers from holes (p-type) to electrons (n-type). Taking full advantage of AIS will require a redesign in the optimal device architecture, as incorporation in to a heterojunction with CdS or Zn(O,S,OH) (as is done with CIGS) is no longer a viable approach. Our ongoing work is exploring possible junction partners for AIS to propose viable device architectures for further investigation.
In this work, we have developed a solution processing route for the synthesis of $AgIn(S,Se)_2$ thin films and demonstrated exciting electrical properties of this under-studied material. Along with our results, we point out the promise that this material holds for the thin film PV community.

The High Efficiency CZTSSE Solar Cells on Flexible Metal Foils Jin-Kyu Kang[1,2], Dae-Ho Son[1], Seung-Hyun Kim[1], Se-Yun Kim[1,2], Dae-Kue Hwang[1], Shi-Joon Sung[1], Kee-Jeong Yang[1] and Dae-Hwan Kim[1]; [1]Daegu Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of); [2]Kyungnam University, Korea (the Republic of)

The development of flexible solar cells is necessary for achieving market competitiveness through the implementation of low cost solar cells and for applying customized business models, such as building integrated photovoltaics (BIPV) and mobile applications. In addition, low-cost flexible substrates can be used to lower manufacturing costs, which can contribute to the expansion of the renewable energy market by shortening the energy payback time. Solar cells with the CZTS-based (Cu_2ZnSnS_4, $Cu_2ZnSnSe_4$, $Cu_2ZnSn(S,Se)_4$) absorbers are advantageous for lowing the cost, but the development of high efficiency solar cells based on flexible substrates has been relatively unexplored. In this work, flexible CZTSSe solar cells applying the Mo and SUS foil substrate were developed. When we used the metal precursor, double CZTSSe layer, voids and ZnSSe secondary phase were observed. The ZnSSe layer formed during soft annealing plays important role as a layer that blocks the volatilization of Zn. Large void can cause the formation of unwanted secondary phase and non-uniform composition. Applying SnS precursor is a good strategy as a way to suppress void formation. To optimize the processes of the flexible CZTSSe thin film solar cells, Na doping, back contact modifying, blister formation suppression were studied. Applying NaF decreased the defect level and Voc deficit(Eg – qVOC). This improvement can be explained by the associated decrease in defects, which are considered the recombination centers in the CZTSSe absorber layer. The weak adhesion between CZTSSe and Mo layers and the high stress of CZTSSe layer can form blisters. The increase of adhesion between CZTSSe and Mo layers can prevent the formation of blister. The best power conversion efficiency of the prepared CZTSSe solar cell on flexible Mo foil is 11.59%, which is world top efficiency record on flexible substrate.

Tuesday Morning, April 20, 2021
EN07

8:00 AM *EN07.11.01
Grain Boundaries and Dislocations in $Cu(In,Ga)Se_2$ Solar Cells Daniel Abou-Ras; Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Owing to the polycrystalline nature of $Cu(In,Ga)Se_2$ (CIGS) thin films in high-efficiency solar cells, the impact of grain boundaries in these thin films on the photovoltaic performance has always been of concern. The present contribution will give an overview on the current understanding of this matter and show that even in high-efficiency devices, the enhanced nonradiative recombination at CIGS grain boundaries leads to a V_{oc} loss of 20-30 mV. In contrast, nonradiative recombination at dislocations does not seem to be enhanced with respect to the CIGS bulk. Differences between grain boundaries and dislocations will be discussed as well as the issue of potential passivation of grain boundaries by, e.g., alkali metals.

8:25 AM EN07.11.02
Urbach Energy of Alkali-Treated $Cu(In,Ga)Se_2$ Single Crystals Omar Ramirez and Susanne Siebentritt; University of Luxembourg, Luxembourg

Alkali post-deposition treatments in polycrystalline $Cu(In,Ga)Se_2$ absorbers have demonstrated to yield an increase in open-circuit voltage. The origin of such improvement has been attributed to reduced non-radiative recombination in the bulk, where the underlying mechanism has been proposed to be due to passivation of charged defects at grain boundaries as a result of the accumulation of heavy alkali elements conveying a reduction in band bending and tail states[1]. However, the density of tail states is also impacted by disorder in the crystal itself, and in the case of $Cu(In,Ga)Se_2$, prompted by electrostatic potential and bandgap fluctuations. The Urbach energy describes the extension of the states into the band gap, and has recently been proposed as an indictor of the absorber's quality since a correlation between Urbach energy and open-circuit voltage deficit has been observed[2].
In this contribution, we study the influence of different alkali post-deposition treatments on the crystal itself. We measure the Urbach energy and the quasi-Fermi level splitting (qFls) of NaF and KF-treated $Cu(In,Ga)Se_2$ single crystals grown by metalorganic vapor phase epitaxy. Our results show that the post-deposition treatments with NaF, and to a lesser extent KF, can effectively decrease the Urbach energy. In a similar way, an improvement in qFls is obtained after the post-deposition treatments. The fact that alkali incorporation into the grains have an impact on the Urbach energy, suggests that the decrease in tail states observed in polycrystalline absorbers with heavy alkali post-deposition treatments is not exclusively grain boundary-related. Both effects: the reduction of tail states and the increased qFls are explained by increased net-doping due to the alkalis. The effects on grain boundaries have to be complemented by the effects on the grain interiors, to understand the observed improvements and to devise ways for further efficiency improvements.

Band Gap Energy Variations in Chalcogenide Compound Semiconductors: Influence of off-Stoichiometry
Susan Schorr[1,2] and Galina Gurieva[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

The photoactive band gap energy E_g of a solar cell device is determined by the band gap of the absorber layer material which has to be optimized to reach high conversion efficiencies.
One of the reasons for the success of $Cu(In,Ga)Se_2$ (CIGS) based thin film solar cells is the remarkable flexibility of its chalcopyrite crystal structure, accepting large stoichiometry deviations. The structural flexibility is a key for the quaternary kesterite-type compounds too. $Cu_2ZnSn(S,Se)_4$ (CZTSSe) based thin film solar cells reach the highest efficiency with a Cu-poor and Zn-rich composition of the absorber layer. Such deviations from the stoichiometric composition lead to the formation of intrinsic point defects (vacancies, anti-sites, and interstitials) in the compound, which significantly influence the electrical and optical properties of the material.
The existence of off-stoichiometric CZTS, CZTSe and CZTSSe has been shown in extended and systematic studies of powder series [1,2]. The off-stoichiometric composition of the kesterite-type phase corresponds to certain point defects. This correlation is the basis for defining off-stoichiometry types referred to as A–L [2,3]. For example, A-type off-stoichiometric kesterites, which are Cu-poor and Zn-rich, contain copper vacancies (V_{Cu}) and Zn_{Cu} anti-sites. The off-stoichiometry type model has been confirmed experimentally on the basis of neutron diffraction studies [2, 4].
We have determined the band gap energy of these series of off-stoichiometric kesterite-type compounds (powder) by diffuse reflectant spectroscopy. The optical band gap was extracted from Tauc plots obtained by plotting $(F(R)*h\nu)^2$ versus the photon energy [5]. We can show, that in off-stoichiometric CZTS and CZTSe the band gap energy varies strongly in dependence on the off-stoichiometry (which can be expressed by the cation ratios) of the kesterite-type phase. For instance in A-B type CZTSe the band gap energy E_g increases from 0.88 eV to 1.0 eV in dependence on decreasing Cu/(Zn+Sn) and increasing Zn/Sn ratio (Cu/(Zn+Sn) decreases from 0.96 to 0.81 and Zn/Sn increases from 1.04 to 1.15).
Comparing such band gap energy variations in Cu-poor CZTS and CZTSe with those in off-stoichiometric Cu-

poor chalcopyrites (like $CuInS_2$, $CuInSe_2$ and $CuGaS_2$) then surprisingly one finds a different behavior. When looking at the same off-stoichiometry range the band gap energy variations in Cu-poor chalcopyrites are very small.
This can have serious consequences for kesterite-based solar cell device. The absorber layer shows generally an inhomogeneous chemical composition thus different off-stoichiometric kesterite phases, this means different off-stoichiometry types, occur coexisting. This may cause remarkable variations in band gap energy within the absorber layer.

Towards 1V Open-Circuit Voltage and Beyond—Reducing Bulk and Interface Losses in Wide Bandgap Chalcopyrite CuInGaS2 Solar Cell Mohit Sood, Shukla Shukla, Damilola Adeleye, Michele Melchiorre and Susanne Siebentritt; University of Luxembourg, Luxembourg

Bandgap tunability of copper indium gallium disulfide $Cu(In,Ga)S_2$ from 1.55eV ($CuInS_2$) to 2.5eV ($CuGaS_2$) makes it an excellent top cell option for use in a tandem devices.[1] An open-circuit voltage (V_{OC}) of 973 mV and a power conversion efficiency of 15.5% $Cu(In,Ga)S_2$ demonstrates its promises for tandem solar cells in combination with silicon or $Cu(In,Ga)Se_2$. [2,3] However, even the best devices still suffer from a significant V_{OC} deficit (~600 mV) compared to its bandgap owing to non-radiative recombination in the device. Further advancements require a better comprehension of the recombination channels limiting the V_{OC} of the device, whether they lie in the bulk or at the interface.
We present investigation on a composition series of $Cu(In,Ga)S_2$ absorbers grown under different Cu concentration *i.e.* different [Cu]/[In+Ga] (CGI) ratio with bandgap (E_g) around ~1.6 eV, suitable for combination with record efficiency bottom cells. We have shown in the past that a variation in CGI of $CuInS_2$ drastically influences the recombination in the bulk. [4] Here we study higher band gap films with a band gap gradient. The opto-electrical properties are probed with photoluminescence measurements, and the electrical properties by current-voltage and capacitance measurements on solar cells fabricated with either CdS or Zn(O,S) buffer. The results of low temperature photoluminescence demonstrate suppression of deep defects as the CGI is decreased from 1.02 to 0.93, consequently leading to a maximum quasi-Fermi level splitting (qFLs) of 972 meV. Current-voltage measurements of devices prepared with CdS and Zn(O,S) buffer layer exhibit efficiencies close to 13 % with a V_{oc} deficit of 650 mV in Cu-poor (CGI<1) $Cu(In,Ga)S_2$ devices. Temperature dependent V_{OC} measurements show the presence of strong front interface recombinations in all devices, independent of buffer layer used, except one. The device prepared from absorber with CGI < 1 using Zn(O,S) buffer layer, temperature dependent V_{OC} measurements show V_{OC} extrapolation to the bandgap of the absorber at 0 Kelvin, demonstrating front interface passivation in the device. Recently front interface passivated $Cu(In,Ga)S_2$ device with high V_{OC} have been demonstrated, although with a lower bandgap.[5] Our study with higher bandgap allows differentiating between the influence of a defective surface layer and unfavorable band alignment. The findings demonstrate that high qFls and V_{OC} is achieved only with an unetched, i.e. undamaged surface and suitable band alignment. In this case, V_{OC} is limited by bulk recombination. We investigate the deep defects responsible. Finally, capacitance-voltage measurements conclude rather low doping values in Cu poor $Cu(In,Ga)S_2$, an increase in which could lead to further improvement in qFLs and hence the V_{OC} of the device and take it to beyond 1 V.

Sulfides and Selenides, Cu-Rich and Cu-Poor—What is Better for Solar Cells? Susanne Siebentritt and Thomas P. Weiss; University of Luxembourg, Luxembourg

Sulfide chalcopyrites have suitable band gaps to be used as top cells in tandem photovoltaic devices. Traditionally the sulfide solar cells were made from Cu-rich absorbers, i.e. absorbers grown under Cu-excess. The latest record device with an efficiency of 15.5% however, was made from Cu-poor material - which also results in the better solar cells in selenide chalcopyrite. Yet, in contrast to the selenides, the quasi-Fermi level splitting, i.e. the internal voltage of the absorber is higher in Cu-rich CuInS2 than in Cu-poor CuInS2. We will discuss the similarities and differences between sulfide and selenide material, in particular in terms of Cu dependent properties, as well as the defect spectra.

On the Surface Properties of CIGSe Absorbers Alex Redinger; University of Luxembourg, Luxembourg

In this contribution, I will present an overview of the most important scanning probe microscopy results acquired on Cu(In,Ga)Se_2 (CIGSe) absorber surfaces over the last years. Then I will summarize some of our latest results acquired on polycrystalline and epitaxial CIGSe with different Cu-content. I will present a scanning tunneling microscopy (STM) study, where we analyzed the electronic effect of Cd^{2+} pre-electrolyte treatment [1]. I will show how Cd-ions effectively passivate defects and increase surface band bending. Then I will critically discuss the current status of Cu-rich CISe and present a detailed STM and Kelvin Probe Force Microscopy study, which we carried out on the rear-surface of the absorbers [2]. We do find strong evidence for a Cu_xSe precipitation at the back of Cu-rich absorbers. Finally, I compare measurements aquired on polycrystalline and epitaxial absorbers before and after K deposition and show how a short air exposure alters the work function distribution and the interpretation of grain boundary band bending.

Late News: Nanocrystalline Silicon Tunnel Junctions in High Efficiency Solar Cells—Characterization

and Deep Insight Apolline Puaud[1], Laurie-Lou Senaud[2], Delfina Muñoz[1] and Bertrand Paviet-Salomon[2]; [1]CEA-INES, France; [2]PV-Center CSEM, Switzerland

With the increasing use of nanocrystalline silicon layers and tunnel junctions in high-efficiency tandem and single-junction solar cells, the understanding of the transport mechanisms in these layers becomes mandatory. Moreover, some solar cells can be composed of an NPN junction: (n)nc-Si:H/(p)nc-Si:H/n-type transparent conductive oxide (TCO) with complex intern mechanisms not explained in the state-of-the-art. In this work, two approaches of tunnel junction from CSEM [1] and CEA [2] are compared and deeply characterized in a cross experiment.
We performed dark I-V measurements under variable temperature on several heterojunction test-structures. We used different n-type TCOs and nanocrystalline silicon layers to decorrelate the mechanisms at the interface with the TCO and at the interface between n-type and p-type nanocrystalline silicon layers. Structures without front-side TCO and with Aluminum metallization are also used to help this decorrelation. Moreover, we calculated contact resistivity (ρ_c) of each possible stack and corresponding contact activation energies.

Each test-structure is composed of a (n)c-Si wafer, a known and Ohmic backside and a variable frontside. By measuring symmetrical structures (with equivalent backside and frontside) and using the expanded Cox and Strack Method presented by Wang Et al. [3], we extracted the backside resistances and corresponding contact resistivity. With the poor lateral conductivity of amorphous silicon layers compared to the c-Si(n) bulk, we assume that the current spreading only occurs in the bulk, so we calculate the backside resistance, R_{back} with the following equations: $R_{back}=(R_{tot} - R_{bulk})/2$ with $R_{bulk}=(\rho/d\pi).\arctan(4t/d)$ where d is the front-side circular electrode diameter, t the wafer thickness and R_{tot} the total resistance extracted from I-V curves. By plotting the contact resistivity on an Arrhenius plot, we obtained contact activation energies.

Same analysis were performed for the whole test-structures of the study by using the equation $R_{front}=R_{tot}-R_{bulk}-R_{back}$ to obtain frontside resistances. Stuctures without TCO on the frontside and Aluminum metallization on (n)nc-Si:H presents a good Ohmic behaviour, with contact resistivity under 250 $m\Omega.cm^2$ at ambient temperature, which confirms a good contact between n-type nanocrystalline silicon layer and Aluminum. Contrariwise, for structures with the stack (n)nc-Si:H/(p)nc-Si:H/Al, Ohmic contacts are only obtained at high temperatures with the two thinner tunnel junctions and contact resistivities are larger than 400 $m\Omega.cm^2$.
For the thicker tunnel junction, Ohmic behaviors were observed at all temperatures in all test-structures, which results in very low contact resistivity (under 40 $m\Omega.cm^2$). Moreover, in this case, we observed a very low front-resistance variation from 200K to 290K and an increase of this resistance from 275K to 350K when the bulk resistance becomes dominant. The differences in thermal behavior could be explained by a huge contribution of transport via tunneling, which is a mechanism less temperature dependent than thermoionic emission. In fact, with the vertical nanocrystalline growth, thicker is a layer; the better is the vertical conduction that permits the current to flow through the junction. A complete analysis of transport mechanisms and the results with the different front-side TCOs will be presented in the full study.

12:25 PM EN07.12.03
Assessing the Defect Tolerance of Kesterite-Inspired Solar Absorbers Andrea Crovetto[1], Sunghyun Kim[2], Moritz Fischer[1], Nicolas Stenger[1], Aron Walsh[2], Ib Chorkendorff[1] and Peter Vesborg[1]; [1]Technical University of Denmark, Denmark; [2]Imperial College London, United Kingdom

Various thin-film I_2–II–IV–VI_4 photovoltaic absorbers derived from kesterite have been synthesized, characterized, and theoretically investigated in the past few years. The availability of this homogeneous

experimental/computational dataset is an opportunity to examine trends in the defect properties of kesterite-derived materials and identify criteria to (hopefully) find new defect-tolerant semiconductors in this vast chemical space.

First, we find that substitutions on the Zn site lead to a smooth decrease in band tailing as the ionic radius of the substituting cation increases. Unfortunately, this substitution strategy does not ensure the suppression of deeper defects and non-radiative recombination [1].

Then, we argue that Gaussian and Urbach band tails in kesterite-inspired semiconductors are two separate phenomena caused by two different antisite defect types. Deep Urbach tails are correlated with the calculated band gap narrowing caused by the ($2I_{II} + IV_{II}$) defect cluster. Shallow Gaussian tails are correlated with the energy difference between the kesterite and stannite polymorphs, which points to the role of ($II_I + I_{II}$) defect clusters involving Group IB and Group IIB atoms swapping across different cation planes. This finding can explain why in-plane cation disorder and band tailing are uncorrelated in kesterites.

Finally, we will discuss some PV-relevant properties of two relative newcomers to the I_2–II–IV–VI_4 family (Cu_2SrSnS_4 and Cu_2BaSnS_4) in a more detailed manner. The properties are: bulk defect landscape, band tailing, absolute band positions, and surface band bending [2].

12:30 PM EN07.12.05
Hole Transport Across Graphene Electrodeposited Cu_2O Interfaces Himanshu Singh; Indian Institute of Technology, India

Growing demand for energy sources that are cleaner and economical lead to intensive research on alternative materials for solar cells which does not require energy intensive fabrication procedures. Cuprous oxide (Cu_2O) is the among earliest semiconductor to be evaluated for photo-voltaics which is still being investigated for its earth abundant composition, cost effectiveness and bandgap. Cu_2O, a p-type semiconductor with a direct band gap of 2-2.2eV, is an attractive semiconductor material for photovoltaic conversion due to its high optical absorption coefficient in the visible range and can also be used as anode material in thin film lithium batteries. To maximize the photocurrent efficiency, it is coupled to charge transfer and transport pathways of Inorganic materials such as Vanadium pentoxide (V_2O_5),Molybdenum trioxide (MoO_3) and Nickel oxide (NiO). However, such realization requires cost intensive high vacuum plasma enhanced deposition processes and graphene is an ideal alternative to such hole transport layers.

Graphene is a transparent conductor which can be roll to roll processed in a cost effective fashion. These hole extraction layer requires a high work function to allow for the built-in electric field across the active layer and for holes to transport toward the anode. Graphene and it's derivatives, due to their ambipolar behaviour allowing work function tunability, are suitable candidates for hole transport layer (HTL). The most important character of such an implementation is the contact resistance between P-Cu2O and the graphene film. Here we study the interface conductivity of graphene and Cu_2O films grown using electrochemical methods.

A compact, non-porous, stoichiometric Cu_2O was electrodeposited on graphene coated glass plates. The contact resistance of the Cu_2O thin film with commonly used metals such as Au, Pt, Ti was measured using a standard transfer length measurement technique. The contact resistance of graphene with the same set of metals were also measured. Finally, the crucial contact resistance of graphene-Cu_2O interfaces were measured for the first

time. We draw conclusions on the electrodeposited doping density, Schottky barrier between the Cu_2O thin films and the metals and finally the efficiency of graphene as an efficient hole injector.

Atomistic Approach to the Doping of Compound Semiconductors Olivier C. Gagné; Carnegie Institution for Science, United States

Activation and tuning of the useful properties of semiconductors intended for photovoltaic, electronic and/or electrochemical applications hinges on their successful release of charge carriers, a process typically achieved in appreciable quantity via substitutional incorporation of foreign ions into the host crystal structure, i.e. extrinsic doping. As it stands, the rate-limiting step in designing efficient semiconductors is the identification of the most viable dopant ions to achieve n- and/or p-type conductivity – a process that is severely clouded by our incomplete understanding of chemical bonding behavior in solids. Today, doping studies rely exclusively on resource-intensive first-principles calculations, with little chemical guidance available to computationalists regarding where to focus their resources. Below, we argue that an atomistic understanding of the factors underlying ion substitutions in solids would provide such guidance, and would allow proactive calculations to be made for host/dopant combinations prior to their synthesis in lieu of expanding costly resources in low-return compositional spaces.

Three major factors underlie doping difficulties in semiconductors: [1] dopant insolubility, where defect formation energies are prohibitively high, [2] un-ionizability of dopant, where the charge carrier is not released to the system at operating temperature, and [3] compensated dopants, where formation of an opposite-charge native defect negates the effect of the intentional dopant. Factor [3] is terminal whereby formation of compensated defects is caused by the charge carrier itself, and not the identity of the dopant. However, difficulties associated with factors [1] and [2] may be circumvented via appropriate dopant selection, whose ease of substitution in the host crystal structure (in the form of defect formation energies) dictates dopant level depth in the band structure. Factors known to influence dopant level depth include similarities in atomic orbital energies, local atomic geometry (crystal-chemical behavior), and size of the substituting ions – all of which amenable to guidance via an adequate, systematized understanding of crystal-chemical behavior. Substantial discrepancy between the dopant and substituted ions for any of these parameters results in deep dopant levels, which are generally undesirable as they provide uncontrolled recombination channels.

Systematic investigation of crystal-chemical behavior begins with wide-scale analysis of chemical bonding in solids, in the form of bond-length dispersion analyses. Results from the largest bond-length dispersion analysis for inorganic solids were recently reported for cations bonded to O^{2-} and N^{3-},[1] covering 177,446 reliable bond lengths hand-picked from 9210 crystal-structure refinements for oxides, and 6,770 bond lengths from 720 crystal-structure refinements for nitrides; equivalent analysis for cations bonded to S^{2-}, Se^{2-} and Te^{2-} is underway. We use these data to systematically identify structural, electronic and/or bond-topological effects underlying anomalous bonding behavior across the periodic table. Considering that the chemical insight derived from these bonding data holds at the local scale, our analyses enable an atomistic understanding of dopant behavior at point defects which we use to investigate and model the fundamental principles underlying the coexistence of ions in crystallographic sites, taking us one step closer to a quantitative assessment of dopant viability in compound semiconductors – and an atomistic resolution to the doping bottleneck.

An Investigation of Doping and Quasi-Homojunction Thin–Film Solar Cells Based on Sb_2Se_3

Donglou Ren, Michel Cathelinaud, Hongli Ma and Xianghua Zhang; Université de Rennes, France

The development of traditional commercial thin film solar cells based on copper indium gallium selenide (CIGS) and cadmium telluride (CdTe) in large-scale production is limited due to the scarcity of In, Ga and Te and the toxicity of Cd.

Earth-abundant and low-toxic antimony chalcogenides Sb_2X_3 (X = S, Se, S/Se) have received an increased attention from the photovoltaics community thanks to their excellent optoelectronic properties. After only 7 years of research, the record power conversion efficiency (PCE) of Sb_2Se_3 based solar cells has reached 10.5%[1]. Consequently, they are more and more considered as a promising next generation absorber materials. Despite the huge progress, the efficiency is still far lower than the values reported for CIGS and CdTe, largely owing to the absorber's low carrier density and high defects concentration[2]. Doping is an effective method to improve the properties of semiconductors, however, only few works have been reported in this field.

In this work, we investigated the effects of several dopants (Na, In, Cu, I, and Te) on the electric and electronic properties of Sb_2Se_3 prepared using melt-quenching method. Different techniques including X-ray diffractions and observation under high-resolution electronic microscopes have been used to observe that the elements of Na and In are not doped into Sb_2Se_3 lattice, leading to phase separation. Surprisingly, two novel heterojunctions Sb_2Se_3/$NaSbSe_2$ and Sb_2Se_3/β-In_2Se_3 were successfully in-situ synthesized and they exhibited interesting photocatalytic activity for methyl orange degradation, taken as an example, due to the effective separation and transport of photo-generated carriers.

Most importantly, the effective p-type doping (Cu) and n-type doping (I and Te) are obtained, remarkably enhancing the photoelectric properties of Sb_2Se_3. Quasi-homojunction thin film solar cells using doped Sb_2Se_3 with Cu and I, have been fabricated via radio frequency (RF) magnetron sputtering technology. Encouraging PCE of 2.41%, fill factor (FF) of 41%, J_{sc} of 20 mA/cm^2, and V_{oc} of 294 mV have been achieved. The preparation, characterization, and loss mechanisms of these solar cells will be presented and discussed. This is the first work on homojunction solar cells based on Sb_2Se_3.

Late News: Origin of Low Conversion Efficiency of Cu2ZnSnS4 Kesterite Solar Absorber—The Actual Role of Cation Disorder

Wei Chen[1], Diana Dahliah[1], Gian-Marco Rignanese[1] and Geoffroy Hautier[1,2]; [1]Université catholique de Louvain, Belgium; [2]Dartmouth College, United States

As an emerging class of nontoxic and earth-abundant solar absorbers, kesterite $Cu_2ZnSn(S,Se)_4$ has been the focus of much attention from the photovoltaic community. However, despite years of optimization, the kesterite solar cells struggle to attain a power efficiency higher than 13%, far behind the other thin-film technologies such as CIGS and perovskites. The open-circuit voltage (V_{OC}) is in particular low given the material's band gap. The low efficiency and the low V_{OC} of kesterite solar cells are often attributed to the Cu-Zn cation disorder, although such an assignment is still a subject of debate. Here, the controversial role of cation disorder in the extraordinarily low V_{OC} of Cu_2ZnSnS_4 (CZTS) kesterite absorber is examined through a statistical treatment of disorder within the cluster-expansion method. It is demonstrated that the extensive Cu-Zn disorder alone cannot be responsible for the large Urbach tails observed in many CZTS solar cells. While the band gap is reduced as a result of the Gaussian tails formed near the valence-band edge due to Cu clustering, band-gap fluctuations contribute only marginally to the V_{OC} deficit, thereby excluding Cu-Zn disorder as the primary source of the low efficiency of CZTS devices. On the other hand, the extensive disorder stabilizes the formation of Sn_{Zn} antisite and complexes, which as nonradiative recombination and minority carrier trapping centers dominate the

V_{OC} loss in CZTS. Our analysis indicates that current CZTS devices might have already approached the maximum conversion efficiency given the limited growth conditions and the remnant cation disorder even after post-annealing. In view of the improved efficiency achieved with CZTS-derived kesterite absorbers, the methodology presented in this work offers an avenue to understanding and optimizing these emerging kesterite solar devices towards higher efficiency.

Cu/Zn Disorder vs Solar Cell Efficiency—The $Cu_2ZnSn(S_xSe_{1-x})_4$ Monograin Case Galina Gurieva[1], Alexandra Franz[1], Sergiu Levcenko[1], K. Muska[2], Kaia Ernits[2] and Susan Schorr[1,3]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]crystalsol OÜ, Estonia; [3]Freie Universität Berlin, Germany

In the last years quaternary chalcogenides have gained a lot of attention; especially the kesterite type semiconductor compounds $Cu_2ZnSn(S,Se)_4$ which consist mostly of earth abundant and non-toxic elements. These compounds are a promising low cost alternative absorber material for thin film solar cells due to its suitable criteria for photovoltaic applications: *p*-type semiconductor behavior, direct band-gap between 1.0-1.5 eV and absorption coefficient $>10^4$ cm^{-1} [1]. The record conversion efficiency of 12.6 % reported for a $Cu_2ZnSn(S,Se)_4$ based thin film solar cell was reached when the polycrystalline CZTSSe absorber layer exhibits an off-stoichiometric composition [2]. Deviations from stoichiometry cause intrinsic point defects (vacancies, anti-sites, interstitials), which determine the electronic properties of the semiconductor significantly [3]. It is agreed in literature that large band tailing observed in Cu-based kesterite-type semiconductors causes voltage losses limiting the efficiency of kesterite-based devices. The Cu/Zn disorder (Cu_{Zn} and Zn_{Cu} anti-sites in Cu-Zn planes at z=¼ and ¾), which is always present in these compounds [4, 5], is discussed as a possible reason for band tailing. Conventional structural characterization is done with X-ray diffraction, but in case of isoelectronic cations, like Cu^+ and Zn^{2+}, they are difficult to distinguish. Nevertheless, the neutron scattering length of Cu and Zn is different, by neutron diffraction we can distinguish between Cu^+ and Zn^{2+} site occupation in the crystal structure [4, 5]. Kesterite-type based thin films solar cell technologies are mainly based on polycrystalline absorber layers, which makes it quite hard to correlate the crystallographic structure (determined via neutron diffraction) to the performance of these materials. A promising low cost alternative technology uses $Cu_2ZnSn(S,Se)_4$ (CZTSSe) monograins (single crystals of 50-100 μm size) which are fixed in a polymer matrix to form a flexible solar cell [6].

The experimental determination of the order parameter Q which is a quantitative measure of the degree of Cu/Zn disorder [7] requires a differentiation between the isoelectronic cations Cu^+ and Zn^{2+}. An in depth analysis of neutron diffraction data provides information on the cation distribution in the crystal structure allowing the determination of type and concentration of intrinsic point defects including a distinction between Cu and Zn [5]. On the other hand neutron diffraction requires large sample volumes, thus kesterite monograins offer the unique possibility to correlate structural disorder in kesterite-type absorbers with device performance parameters.

We will present a detailed structural investigation of CZTSSe monograins based on neutron powder diffraction experiments, the influence of the purity of the starting material as well as small changes in the chemical composition on the Cu/Zn disorder resulting in different power conversion efficiencies of the respective devices. A further investigation of the effect of the disordering procedure and the long low temperature – "ordering" annealing on the Cu/Zn disorder and optical properties of the CZTSSe monograins will be presented as well.

Late News: Modulus Spectroscopic Estimation of Two Local Built-In Potentials in CZTSe: Ge Bi-Layers Solar Cells Sanghyun Lee[1] and Kent Price[2]; [1]Indiana State University, United States; [2]Morehead State University, United States

Kesterite or CZTSSe ($Cu_2ZnSnS_xSe_{4-x}$) solar cells has been steadily emerging third-generation thin-film solar cells as cost-effective CZTSSe solar cells have shown <12.6 % efficiency. In particular, we reported that CZTSe Ge bi-layers devices have shown greatly improved performance with the enhanced grain and grain boundary properties. CZTSe: Ge bi-layers devices consist of several different functional parts such as carrier generation and carrier separation, associated with electric field in the depletion region. The current-voltage (I-V) measurements can provide the device performance of photovoltaic devices (DC characteristics), but the electrical property associated with each interface junction of CZTSe: Ge bi-layers devices cannot be readily accessed with DC characteristics. Conversely, AC characteristics (modulus spectroscopy) can provide each interface junction's properties in the frequency domain as a certain range of frequency separately reveals them. In this study, we fabricated and analyzed CZTSe: Ge bi-layers devices to accurately evaluate the electrical structure at hetero and back contact junctions by modulus spectroscopic characteristics. Moreover, we studied the dependence of light and voltage biases with respect to impedance and modulus behaviors of hetero and back contact junctions. We used an equivalent circuit model for CZTSe: Ge bi-layers devices that describes the junction modulus and impedance characteristics. This model is utilized to extract the most appropriate device parameters under various voltage bias conditions, which agrees with Sentaurus TCAD numerical simulation results.
Fabricated devices are analyzed with an equivalent circuit model, and LEVM/LEMW software resolved two different parallel circuit branch components. Modeling with LEVM/LEMW software accurately fits our model to modulus spectroscopy combined with impedance spectra in the given testing frequency domain. Using TCAD numerical simulations, we examine a variety of device models with a set of built-in potentials for appropriate parallel circuits with two capacitance and two resistance (R^2=0.99). Our study shows that heterojunction built-in potential is 801 meV, which is ~10 % smaller than a theoretical value, 894 meV. Conversely, the built-in potential of the back contact junction is 428 meV. The total built-in potential is 373 meV. All in all, modulus data combined with impedance spectra agree well with modeling and numerical simulation results.

Unraveling the Chemistry and Transport of Multi-Valent Cations in the Bulk and at Interfaces Karl Mueller[1], Venkateshkumar Prabhakaran[1], Grant E. Johnson[1], Linda Wangoh[1], Yingge Du[1], Kee Sung Han[1], Jian Zhi Hu[1], Ying Chen[1], Rajeev Surendran Assary[2] and Vijayakumar Murugesan[1]; [1]Pacific Northwest National Laboratory, United States; [2]Argonne National Laboratory, United States

The design and achievement of superior battery systems (i.e., those that are more efficient, higher in energy density, safer, more environmentally friendly, etc.) requires knowledge of fundamental chemical and physical properties of the system and its components while under true operating conditions. Such advanced knowledge can be obtained through both modeling and experimental efforts. In the case of battery systems designed to replace the well-known lithium ion battery systems, new chemistries in particular are being explored, classified, and improved using state-of-the-art characterization and computational tools. New analytical tools have been developed for the study of these advanced battery systems in destructive, post-mortem modes as well as while the battery is under operating conditions. Further, certain aspects of the battery chemistry and operation can also be modeled and reproduced with varying degrees of fidelity through computational studies that cross scales from the atomic and molecular to the sizes of pores and beyond. The combination of these experimental techniques and computational tools will eventually lead to predictive understanding of battery components and their operation in the complete battery system. This presentation will focus on progress in merging both post-mortem and operando studies that use advanced spectroscopies and computational methods to understand components of complex battery systems. In this work, we focus on enabling the prediction and creation of bespoke interfaces and transformative interphases for energy storage through atomistic- and molecular-level understanding of the role of interface structure and composition on interphase properties, as well as the design and discovery of novel interface constructs for facile charge transport.

10:55 AM *EN08.01.02
Exploring Transition Metal-Complexes as Redox Mediators in Li-O_2 Battery Aninda J. Bhattacharyya and Subhankar Mandal; Indian Institute of Science, India

Identification of oxygen as a high energy density storage material marked a paradigm shift from solid-state intercalation chemistry form of energy storage such as Li-ion batteries. Nearly three decades ago, Abraham and co-workers demonstrated a rechargeable metal-oxygen (Li-O_2) battery. Li-O_2 batteries display a theoretical energy density of over 3505 Wh. Kg^{-1}, much higher than Li-ion batteries. However, Li-O_2 electrochemistry is non-trivial. The electrolyte, electrocatalysts, and solid-porous O_2-scaffold influences the multistep O_2 Û Li_xO_y reaction. The reversibility of the transformation of O_2 Û Li_xO_y is crucial for stable battery performance, and this is directly associated with the kinetics of oxygen evolution reaction (OER) and the formation of insoluble oxides (Li_xO_y) during oxygen reduction reaction (ORR). There has been intense research on the Li-O_2 battery system's different components over the last two decades. Our strategy here is to develop efficient soluble redox mediators/electrocatalysts that reside at porous O_2-electrode|electrolyte interface. This is in contrary to the conventional approach of immobilization of electrocatalyst(s) on the porous cathode (O_2)-scaffold. The

efficiency of the redox-mediator is finely determined by the redox reversibility of the transition metal site and oxygen binding capability of the complex. While this strategy may lead to efficient metal-oxygen batteries, it will also pose new and non-trivial challenges on interfacial charge transfer and transport. This presentation will discuss porphyrin (bare hemin and heme proteins, Rudra N. Samajdar et al. *J. Phys Chem. C* 2019) and phthalocyanines (Pc) (Subhankar Mandal et al. *submitted*, 2021) from groups 6-12, e.g., MnPc, FePc, CoPc, NiPc, CuPc, ZnPc, and MgPc (d^0 system, group 2) as the redox mediators in Li-O_2 batteries. Due to the redox mediator's residence at the electrode | electrolyte interface, the insulating Li-oxides do not form on the air-cathode scaffold and block the pores. In the context of the porphyrin, due to their superior ability to combine with O_2, the protein performs better than the bare heme. In the case of the Pcs, the electrochemical processes are observed to be highly dependent on the metal centre. The experimental findings in case of the Pcs are additionally supported by theoretical studies based on DFT.

11:20 AM EN08.01.03

Insights into the Functionality of an Alkylated $Li_xSi_yO_z$ Interphase for High Energy Cathodes from High Sensitivity NMR Spectroscopy Shira Haber[1], Rosy Sharma[2,3], Arka Saha[2,3], Arava Zohar[1], Malachi Noked[2,3] and Michal Leskes[1]; [1]Weizmann Institute of Science, Israel; [2]Bar-Ilan University, Israel; [3]Bar-Ilan Institute of Nanotechnology and Advanced Materials, Israel

Deposition of thin protective films on the cathode surface is an efficient approach to overcome interfacial degradation processes and control ionic mobility across the interface. An essential requirement of a good coating layer is that in addition to surface passivation, it will enable unimpeded ion transport between the electrode and electrolyte. To date, the rational design of such protective layers is limited, mostly due to the lack of sensitive characterization tools that can provide atomic-molecular level insight into both the *structure* and *function* of thin amorphous layers.

Here I will present a new approach to examine thin interphases and gain atomic level insight into their composition, 3D structure and lithium ion transport properties by using **solid state nuclear magnetic resonance** (ssNMR) spectroscopy. The approach is based on (i) 10-10^4 fold increase in ssNMR sensitivity provided by **Dynamic nuclear polarization** (DNP), a process in which the high electron spin polarization is transferred to surface nuclei in the sample, enabling the detection of otherwise invisible nanometer-thick layers, and (ii) tracking ^{6}Li-^{7}Li isotope exchange processes across the electrode-electrolyte interface.

I will describe the application of this approach to a novel surface treatment for high energy cathodes, lithium rich $LiNi_xMn_yCo_zO_2$ (NMC), which leads to substantial improvements in rate performance and capacity retention. Specifically, I will show how the combination of DNP and ssNMR provides a detailed chemical map of the surface composition and structure of this lithium-silicate protection layer. The permeability of the coating and the role of lithiated interphases was assessed by ^{6,7}Li exchange experiments on coated and uncoated NMC and further compared to Electrochemical Impedance Spectroscopy (EIS) results.

The combination of structural insight from high sensitivity ssNMR and lithium exchange brings us closer to understanding the functionality of electrode surface layers.

Solvation Structures, Molecular-Level Dynamics and Evolution of Electrolytes in Solution and at Interfaces Using Advanced NMR Techniques Jian Zhi Hu[1], Ying Chen[1], Kee Sung Han[1], Nathan Hahn[2], Kevin R. Zavadil[2], Kristin Persson[3], Vijayakumar Murugesan[1] and Karl Mueller[1]; [1]The Joint Center for Energy Storage Research (JCESR), Pacific Northwest National Laboratory, United States; [2]Sandia National Laboratories, United States; [3]Lawrence Berkeley National Laboratory, United States

Nuclear magnetic resonance (NMR), a quantitative and non-destructive atomic-isotope specific tool, is idea for studying a system without compromising control of both pressure and temperature. We will show how NMR and associated capabilities (1D and 2D solid/liquid state NMR spectroscopy, pulsed-field-gradient-NMR, and DFT computational modeling of NMR parameters) combined with molecular dynamics simulations can be utilized to study the solvation structures and the molecular-level dynamics of electrolytes in solution and at the solid-electrolyte interface. The following examples will be highlighted to demonstrate the power of our

combinations of approaches: (i) Mechanisms of desolvation associated with $Mg(TFSI)_2 + G_2$ on surfaces of nano-sized MgO solids; (ii) Role of solvent rearrangement on Mg^{2+} solvation structures in dimethoxyethane solutions; and (iii) Origin of unusual acidity and Li^+ diffusivity in a series of water-in-salt electrolytes.

Multivalent Electrolytes: Controlling Interfacial Resiliency Through Selective Cation Coordination

Nathan Hahn[1,2] and Kevin R. Zavadil[1,2]; [1]Sandia National Laboratories, United States; [2]Joint Center for Energy Storage Research, United States

While several multivalent battery working ions such as Mg^{2+} or Ca^{2+} present the theoretical promise of high pack-level energy density, numerous challenges stand in the way of their successful development to commercialization. One of the key challenges is maintaining electrolyte stability during the working ion (de)solvation and charge transfer events at the potential extremes of the anode and cathode electrified interfaces. Stability under these conditions is heavily influenced by the interactions of the strongly polarizing multivalent cation of interest with the supporting salt or solvent species. In this work, we evaluate the efficacy of using selective coordination strategies to tune interfacial stability at magnesium and calcium battery electrodes. A combination of electrochemical, solvation, and surface analyses will be presented to provide a holistic view of the extent to which targeted salt or solvent additives mitigate electrolyte decomposition. These findings help guide electrolyte design efforts aimed at achieving high voltage multivalent batteries.

Ion Clustering in Electrolytes—Implications on Electrochemical Stability and Transport Properties Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Bosch Research, United States

Electrochemical stability windows of electrolytes largely determine the limitations of operating regimes of lithium-ion batteries, but the degradation mechanisms are difficult to characterize and poorly understood. Using computational quantum chemistry to investigate the oxidative decomposition mechanisms that govern voltage

stability of multi-component organic electrolytes, we find that electrolyte decomposition is a process involving the solvent and the salt anion and requires explicit treatment of their coupling. We find that the ionization potential of the solvent-anion system is often lower than that of the isolated solvent or the anion. This mutual weakening effect is explained by the formation of the anion-solvent charge-transfer complex, which we study for 16 anion-solvent combinations relevant for Li-ion battery electrolytes. This understanding of the oxidation mechanism allows to formulate a simple predictive model that explains experimentally observed trends in the onset voltages of degradation of electrolytes near the cathode. This model opens opportunities for rapid rational design of stable electrolytes for high-energy batteries. [1]
Our charge complex model suggests an explanation of why ionic liquids are typically found to be more electrochemically stable at high voltage than conventional organic solvent-based electrolytes. At the same time, ion complexes in ionic liquids affect ionic transport due to correlation effects. Using molecular dynamics simulations of transport properties, we find that strong ionic interactions result in significant deviations from ideal solution behavior. By adopting rigorous concentrated multicomponent solution theory, we show that anomalously low and even negative Li transference numbers emerge in vast range of different ionic liquid chemistries, suggesting a universal behavior of this class of electrolytes. Finally, we propose chemical strategies for mitigating the detrimental effects of clustering and for increasing transference number and conductivity. [2-4]

1:25 PM EN08.02.02
ALD Niobium Oxide for Improved Rate Capability and Cycle Life of Cathode Films for Li-Ion Batteries
Abdessalem Aribia, Jordi Sastre-Pellicer, Xubin Chen, Gilshtein Evgeniia, Ayodhya Tiwari and Yaroslav Romanyuk; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Layered oxide cathode materials are widely used in modern Li-ion batteries. However, during device operation they suffer from surface degradation, transition metal oxide dissolution and destructive phase transitions at the cathode-electrolyte interface. One way to suppress the chemical instability and reactivity of the cathode with the electrolyte is to coat the cathode surface with inert oxides.

We investigate niobium oxide cathode coatings with an intention of improving performance at ultra-high C rates and long-term cyclability of Li-ion batteries. The effect of the coating was evaluated in a thin-film $LiCoO_2$ model system. The niobum oxide was deposited by atomic layer deposition (ALD), which enables a conformal coating over the cathode material. The niobium oxide film was lithiated by annealing it together with the cathode. The electrochemical properties could be significantly improved compared to uncoated samples by systematically investigating the battery performance as a function of coating thickness. Thereby, 47 % remaining initial capacity was observed at 100 C for 30 nm niobum oxide-coated cathode films. For the same coating thickness, the cells retained 80% of the initial capacity after 493 cycles at 10 C, more than doubling the cycle life of the uncoated cathode. Impedance investigation indicated a strong retardation of the interfacial resistance growth during cycling. Elemental analysis revealed a bulk and surface contribution of the niobium oxide coating. These results suggest that ALD as coating method can also have a strong impact for high rate discharging of bulk cathode powders.

1:40 PM *EN08.02.03
Mechanisms of Diffusive Charge Transport and Surface Adsorption in Redox-Active Polymer Solutions

Liliana Bello and Charles E. Sing; University of Illinois at Urbana-Champaign, United States

Redox-active polymers (RAPs) are a promising material for energy storage in flow batteries due their large size preventing detrimental redox material crossover and adjustable molecular chemistry and architecture for optimized performance. There has been a recent effort to understand the physics governing charge diffusion in RAPs, both in the bulk and near surfaces. We use simulations and theory to show how a variety of molecular charge transport mechanisms affect diffusive motion in RAP solutions. To simulate these RAP solutions, we employ a hybrid Brownian dynamics and kinetic Monte Carlo model that accounts for both the conformational degrees of freedom and charge hopping dynamics. This model uses a coarse-grained representation that can be altered to reflect a variety of physicochemical properties of RAPs, in particular using the molecular charge hopping kinetics as either a tunable variable or an input parameter. We perform these simulations for both isolated, single-chain and interacting, multi-chain systems to demonstrate the interplay between a variety of transport mechanisms (e.g. intra-polymer self-exchange, polymer segmental motion, inter-polymer collisions). We develop theoretical scaling arguments to describe the diffusive motion of charge via these mechanisms, showing excellent agreement with simulations. Our predictions suggest the existence of three charge transport regimes, which distinguish between inter- and intra-molecular processes and dilute and semi-dilute solutions. We extend our understanding of these solution dynamics to model of the kinetics of surface adsorption, providing a molecular connection between surface interactions and charge transport.

2:05 PM EN08.02.04
Cooperative Anion Effects for Reversible Plating/Stripping of Divalent Metals Justin Connell, Milena Zorko, Garvit Agarwal, Mengxi Yang, Chen Liao, Rajeev Surendran Assary, Dusan Strmcnik and Nenad Markovic; Argonne National Laboratory, United States

One of the biggest challenges facing the development of multivalent batteries is the fact that the majority of promising electrolytes demonstrated to date are incompatible with either metallic anodes or high voltage cathodes, both of which are required for multivalent systems to compete with existing Li-ion technologies. For example, many electrolytes shown to exhibit reversible plating/stripping of Mg metal rely on the presence of significant concentrations of Cl^-, precluding their use with oxide cathode materials due to parasitic reactions that take place at high voltage. In light of this limitation, it is imperative that a more complete understanding be developed of the specific role of Cl^- in promoting reversibility in multivalent systems in order to develop design rules for synthesizing new electrolytes that can avoid the use of Cl^- altogether. Through systematic rotating disk and ring-disk electrode (RDE and RRDE) investigations of metal plating/stripping in multivalent electrolytes utilizing the bis-(trifluoromethane sulfonyl) imide ($TFSI^-$) anion with varying concentrations of Cl^-, a cooperative effect is observed between both anions that yields the overall more reversible behavior of mixed $TFSI^-/Cl^-$ electrolytes relative to electrolytes containing only $TFSI^-$. This effect is shown to be general across multiple multivalent systems (i.e., Mg, Zn and Cu), and mechanistic understanding of the role of Cl^- in improving reversibility of TFSI-based electrolytes is provided through the combination of R(R)DE experimental results with computational evaluation of the activity and stability of various TFSI- and Cl-based solution complexes. The cooperative anion effect can be further generalized to other electrolyte systems, suggesting a set of general design principles for developing new multivalent electrolytes.

2:20 PM EN08.02.05
Realizing Reversible Magnesium Plating/Stripping by Interface Controls Hui Wang[1,2], Jaegeon Ryu[1,2] and Yuyan Shao[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]Joint Center for Energy Storage Research, United States

Rechargeable Mg batteries hold a great potential for a new low-cost, high energy density energy storage solution due to the high volumetric capacity (3,833 mAh cm^{-3}) and natural abundance (2.33% in earth crust) of Mg. Despite its promising electrochemical metrics, the absence of proper electrolytes that enable reversible Mg plating-stripping and compatible pairing with cathode materials hindered the practical use of Mg metal anodes. More importantly, there is very limitedfundamental understanding of the critical factors to drive the reversible

Mg anodes at the Mg/electrolyte interface. Here, we investigated the interfacial chemistry between Mg and modified Mg cationic clusters in $Mg(TFSI)_2$ with $Mg(BH_4)_2$ cosalt through operando electrochemical analyses to rationalize the improved reversibility of Mg plating-stripping. Meanwhile, the electrochemically evolved artificial film was developed to stabilize the fresh Mg deposits, which showed ultrafast charge transfer and low film resistance in the conventional electrolyte of $Mg(TFSI)_2$-$MgCl_2$.

4:00 PM *EN08.03.01
Optimizing Bulk and Interfacial Kinetic Limitations in Nanostructured Battery Materials Sarah Tolbert; University of California, Los Angeles, United States

In bulk battery materials, solid-state diffusion of ions frequently limits rate capabilities, and phase transitions or phase separation processes often limit stability. Many of these limitations can be overcome by moving to the nanoscale, as diffusion distances are shortened, and phase transitions or phase separation can either be suppressed, or occur on much shorter length-scales. Nanoporous materials, in particular, are very promising, as they offer reduced diffusion lengths without significantly reducing electrical conductivity, as often occurs in nanocrystal based materials. While the advantages of nanostructured electrode materials can be significant, they have the marked disadvantage of increased interfacial area that can lead to increased SEI formation and reduced coulomb efficiency. In this talk, we explore a number of systems where we seek to optimize the trade-off between bulk kinetic limitations and interfacial or charge transfer limitations, with a specific focus on how nanoscale architecture can be tuned to produce an ideal balance between these limitations. Systems that will be addressed include high rate nanoporous cathodes based on both conventional oxides, using $LiNi_{0.80}Co_{0.15}Al_{0.05}O_2$ (NCA) as a prime example, and on metal phosphates, using $LiVPO_4F$ (LVPF) as an example. In both cases, nanoporous materials are produced by combining polymer templating with sol-gel methods. For both systems, in addition to optimizing nanoscale size, we find that the key to high rate behavior is incorporation of a conductive artificial SEI layer. In the oxide cathodes, in particular, conjugated polymers can be highly effective at increasing stability and rate capabilities, a process that should derive from a combination of enhanced electrical conductivity and reduced SEI formation. A variety of new conjugated polymer binders will be discussed. Finally, we will consider nanostructured alloy anodes produced by selective etching of metals. In these systems, dramatic structural changes upon lithiation require the use of nanophase materials to achieve stable cycling. Here, the interplay between nanoscale architecture, material composition, and surface layers will be explored using *operando* transmission X-ray microscopy (TXM), which allows us to directly image the evolution of the nanoscale pore structures during battery operation. Taken together these results demonstrate the rich design space that is available when nanoscale architecture and interfacial engineering are combined to optimize the performance of battery materials.

4:25 PM *EN08.03.02
Probing Local Ion Intercalation Processes Through Electro-Chemo-Mechanical Coupling Behaviors Nina Balke and Wan-Yu Tsai; Oak Ridge National Laboratory, United States

Electrode deformations during charging and discharge process are directly related to the power performance and cyclability of the energy storage devices. Understanding the electrode deformation and changes in mechanical responses during electrochemical events and their impact on devices' performance is crucial for achieving high

power and high energy storage devices. In-situ atomic force microscopy (AFM) is well suited to tackle this task as it allows tracking local sub-nanometer volume changes and other mechanical responses. With a spatial resolution of tens of nanometer, this approach is capable of mapping the electro-chemo-mechanical behavior under the conditions close to the device operation and access information about local redox mechanisms and investigate its heterogeneity.

In this work, the local electro-chemo-mechanical coupling behaviors of proton insertion into WO_3 electrodes is studied. The concept of mechanical cyclic voltammetry (mCV) curves is introduced, and the relationship between electrochemical current and strain are discussed in the context of simplified models. The results show that different mechanical responses are involved during ion insertion and extraction. The mechanical CV mapping highlighted the local heterogeneity and showed that the charging mechanisms varied across the electrode. These local variations could be further corelated to local morphology, crystal orientations or chemical compositions. Besides providing information of redox heterogeneity, the mCV methodology allows us to circumvent the common issues that are often encountered in the global electrochemical characterizations, for example cell resistance and unwanted parasitic reaction. We further demonstrate that the mCV approach is applicable to a variety of energy storage materials with increasing complexity of current-deformation relationships.

The work was supported by the Fluid Interface Reactions, Structures and Transport (FIRST), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences. Measurements were performed at the Center for Nanophase Materials Sciences (CNMS), which is sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division, Office of Basic Energy Sciences.

4:50 PM EN08.03.03
Advanced Electrode/Electrolyte Interphases for High Voltage Lithium Metal Batteries Xiaodi Ren, Xianhui Zhang, Ji-Guang Zhang and Wu Xu; Pacific Northwest National Laboratory, United States

Rechargeable batteries with high energy density are of significant importance to the energy storage market, especially for portable electronics and electric vehicles. Although the use of lithium (Li) metal anode and high capacity cathode at high operation voltage can achieve the high energy density of batteries, the development of Li metal batteries is greatly limited by the inferior performances because of the issues related to the Li metal anode (dendrite growth and low Coulombic efficiency) and the intercalation cathode under high voltages and challenging temperatures. The main reason is the electrode/electrolyte interphases on both Li metal anode and the high voltage cathode are not stable and effective enough to protect the two electrodes from the continuous side reactions with the electrolyte. In this presentation, we report to design and in situ generate highly stable electrode/electrolyte interphases on both Li anode and $LiCoO_2$ cathode with an advanced electrolyte, with which greatly improved cell performances of Li||$LiCoO_2$ batteries are achieved under a high charge voltage of 4.5 V and a wide temperature range from -30 to 55 °C. More details will be discussed at the presentation.

Designing Stable Electrode/Electrolyte Interphases for Lithium-Ion Batteries with Low-Flammability Electrolytes Hao Jia, Yaobin Xu, Xianhui Zhang, Sarah Burton, Mark Engelhard, Peiyuan Gao, Chongmin Wang and Wu Xu; Pacific Northwest National Laboratory, United States

As the energy density of lithium ion batteries (LIBs) increases, safety of the battery is raising intensive concern. Flammability of the electrolyte is a critical link of the overall safety property of LIBs. The conventional approach to reduce the flammability of liquid electrolytes is to introduce a certain amount of a miscible organic phosphate solvent as flame retardant (FR) additive or co-solvent into the $LiPF_6$-organocarbonates electrolytes.[1] However, due to the intercalation of the phosphate molecules into the graphite electrode, the introduction of such FR usually induces incompatibility between the FR and the graphite electrode and deterioration in battery cycling performance. Moreover, as the FR is gradually consumed by the parasitic

reactions at the electrode/electrolyte interfaces, the flame retarding effectiveness of the FR decays.[2] In response to these challenges, the concept of localized high-concentration electrolyte (LHCE) with an organic phosphate solvent FR is utilized to adjust the electrode/electrolyte interphases on both graphite anode and high voltage cathode. By adopting the unique solvation structure of LHCE and the incorporation of a small amount of electrolyte additive, the electrode/electrolyte interphases can be designed and tuned. Consequently, the graphite||$LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ cells using such phosphate-based LHCEs can achieve the capacity retention of 85.5% after 500 charge/discharge cycles, being significantly higher than that of conventional $LiPF_6$-organocarbonate electrolyte (75.8%). Meanwhile, ignition test shows that these LHCEs are much less flammable than the conventional $LiPF_6$-organocarbonate electrolytes. More details will be reported during the presentation.

Ion Clustering and Transport in $MgCl_2$-Based Electrolytes for Rechargeable Magnesium Batteries

Vallabh Vasudevan[1], Mingchao Wang[1], Nick Birbilis[2] and Nikhil Medhekar[1]; [1]Monash University, Australia; [2]The Australian National University, Australia

Non-aqueous Rechargeable Mg batteries (RMBs) represent a safer, cheaper and more powerful alternative to lithium ion battery technology.[1, 2] However, the high charge density of Mg^{2+} ions triggers the formation of ion impermeable deposits with solvents at electrode/electrolyte interfaces called Solid-Electrolyte Interfaces (SEIs). To overcome the stability and reversibility issues caused by SEIs, the electrolytes used must be stable against reductive reactions at the anode/electrolyte interface during charge/discharge cycles in RMBs.[3, 4] Magnesium halide salts are an exciting prospect as stable and high-performance electrolytes for RMBs. By nature of their complex equilibria, these salts exist in solution as a variety of electroactive species (EAS) in equilibrium with counter ions such as $AlCl_4^-$. Here we investigated ion agglomeration and transport of several such EAS in $MgCl_2$ salts dissolved in ethereal solvents under both equilibrium and operating conditions using large scale atomistic simulations.[5] We find that the solute morphology is strongly characterized by the presence of clusters and is governed by the solvation structures of EAS. Specifically, the isotropic solvation of Mg^{2+} results in slow formation of bulky cluster, compared with chain-like analogues observed in the Cl-containing EAS such as $Mg_2Cl_3^+$, $MgCl^+$ and $Mg_2Cl_2^{2+}$. We further illustrate these clusters can reduce the diffusivity of charge-carrying species in the $MgCl_2$ based electrolyte by at least an order of magnitude. We highlight the role of the solvent in determining cluster morphology and ion mobility by controlling ion diffusion pathways and ion coverage. Our findings of the cluster formation, morphology and kinetics can provide useful insight into the electrochemical reactions at the anode/electrolyte interface in RMBs.

Single Molecule Charge Transport at Electrode Interfaces Charles M. Schroeder and Jialing Li; University of Illinois at Urbana-Champaign, United States

The development of new energy storage systems has attracted substantial attention in the scientific community. The overall performance of energy storage in batteries, including rates of charge/discharge and system reliability, largely depends on the resiliency of the electrode/electrolyte interface. Despite recent progress, major challenges lie developing new electrolytes and electrodes for redox-flow batteries to enhance charge transfer rates and to achieve extended operation lifetimes. In recent years, bulk-scale methods have been used to characterize and understand redox-active electrolyte behavior at interfaces, however, bulk measurements tend to 'average out' and obscure charge transport events at the molecular level. In this work, we use single molecule methods to directly characterize charge transport at the electrode interface. In particular, we use a custom electrochemical scanning tunneling microscope-break junction (ECSTM-BJ) instrument to understand interfacial charge transport and redoxmer degradation at the molecular level. ECSTM-BJ enables the direct measurement of molecular charge transport and conductance as a function of applied bias, external gate voltage, and the chemical identity of the redox-active species or supporting electrolytes. Materials with different chemical structures and charge transport channels are identified as different molecular subgroups, thereby revealing otherwise hidden molecular sub-populations that underlie bulk-scale behavior. Using this approach, we investigate two different redox-active systems: viologen-based molecules and mesolytic cleavage of redoxmers. Electrostatic gating is used to tune charge transport in viologen-based molecules by adjusting the potential drop across the double layer and the associated redox states in the electrochemical environment. In contrast to non-redox-active counterparts, our results show that the conductance of viologen-containing molecules is a strong function of the gate voltage as the viologen redox center is reduced. Moreover, the reduced state of the molecules weakens the interaction between the molecules and the electrode, which is indicated by changes in junction length. In a related study, we show that intermolecular charge transport is effectively regulated by the formation of a pH-responsive supramolecular host-guest complex. In this way, we present intriguing new avenues for intermolecular complexation for controlling the charge transport process. Finally, we discuss the direct molecular characterization of self-immolating redoxmers that degrade upon being damaged via mesolytic cleavage. Interestingly, our results show that strong electric fields near electrode interfaces induce mesolytic cleavage, followed by the dimerization of the reaction products, which is detected by single molecule conductance. Overall, our results highlight the use of single molecule techniques to characterize charge transport at the electrode/electrolyte interface.

8:40 PM EN08.04.02
Interfacial Solvation Dynamics of Multivalent Cations—Peculiarities and General Principles of Ion Solvation Engineering Artem Baskin[1,2], David Prendergast[2] and John Lawson[1]; [1]NASA Ames Research Center, United States; [2]Lawrence Berkeley National Laboratory, United States

The essential electrochemical processes at electrode interfaces are closely related to the changes of coordination environments and solvation structures of cations. The thermodynamics of these processes including reactivity and stability of interfaces are largely determined by the spatial speciation profile in the interfacial regions whereas kinetics of the charge transfer is governed by the stiffness of solvation spheres of cations and their coordination states. However, the atomistic details and thermodynamic characteristics of ion (de-)solvation process in the confined environment (e.g., near an electrode) remain largely unknown. Specifically, for multivalent cations that are prone to the formation of ion-pairs and neutral aggregates in low dielectric solvents and show a non-trivial concentration dependence of population of various ionic species these characteristics are

very difficult to probe both experimentally and computationally. The key questions we want to address are the following: 1) how different the population of ionic/neutral species at the interface is as compared to the bulk electrolyte at various electrode potentials; 2) in which form the active matter (metal cations) is delivered to the interface; 3) what is the dynamics of the cation solvation and coordination environment along the most thermodynamically favorable pathways of a cation that approaches the interface from a bulk electrolyte; and finally 4) what is the locus and a particular cation solvation/coordination state at which the charge transfer occurs.
Using a multiscale methodology based on classical and *ab initio* free energy sampling techniques we analyze a solution of $MgTFSI_2$ in THF next to graphene and show that the anion-coordinated species are the vehicle that delivers the Mg-cation to the interfaces at shorter distances and in lower coordination states. This allows us to formulate the key and general interfacial descriptors that can be used to control the balance between the chemical stability of an interface and the overpotential associated with the charge transfer kinetics. We identified the optimal free energy pathways and a generalized coordinate that describe the (de-)solvation dynamics of the Mg-cation. Finally, we show how the interfacial solvation dynamics can be manipulated using the ion solvation multiplicity.

Atomic-Scale Insight into Charge Transfer Processes at Electrochemical Interfaces Donald Siegel; University of Michigan–Ann Arbor, United States

Interfacial charge transfer processes strongly influence the performance of elecrochemical enenergy storage devices in many different ways. For example, ion deposition from electrolytes onto electrodes influences the efficiency, morphology, and stability of anodes based on high-capacity metals. Electronic transfer between electrodes and solid eletrolytes can impart undesirable electrical conductivtity and precipitate harmful chemical reactions. Ion transport in solid electrolytes can be highly sensitvie to internal interfaces such as grain or particle boundaries. This presentation will summarize recent computational studies of the atomic-scale phenomena that underlie charge transfer processes on electrode surfaces, between elecrodes and electrolytes, and at internal interfaces in solid electrolytes. Multiple computational techniques, ranging from large scale classical MD to many-body perturbation theory, are used to tackle the different length scales spanned by these systems.

Interfacial Reactivity of Electrolytes in Multivalent Batteries—Insights from Density Functional Theory Calculations and XPS Experiments Garvit Agarwal[1], Swadipta Roy[2], Venkateshkumar Prabhakaran[2], Grant E. Johnson[2], Vijayakumar Murugesan[2] and Rajeev Surendran Assary[1]; [1]Argonne National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States

Multivalent batteries, particularly Mg-metal batteries, are promising technology for next-generation energy storage applications due to their theoretically high volumetric energy density. One of the critical challenges in multivalent batteries is to create a stable and functional electrochemical interphase (solid electrolyte interphase) that facilitates reversible plating and stripping of charge carrying ions and impedes electronic transport to limit electrolyte degradation. This requires fundamental understanding of the reactivity of electrolyte (solvent and salt) species with Mg-metal anode. To address this, we employ in-operando X-ray photoelectron spectroscopy (XPS) experiments in combination with density functional theory (DFT) calculations to elucidate the decomposition mechanisms of two commonly used ethereal solvents, diglyme (G2) and tetrahydrofuran (THF) on the Mg-metal anode surface. The solvent molecules are exposed to sputter cleaned Mg-metal surface and high-resolution XPS spectra are collected at different temperatures to analyze the reaction products. DFT calculations are performed to model the adsorption and to compute the reaction energy profiles to elucidate decomposition reaction pathways of G2 and THF on pristine Mg (0001) surface. The decomposition pathways are modeled as a series of C-O and C-H bond cleavage reactions. The climbing image nudge elastic band (CI-

NEB) calculations are carried out to compute the transition states and energy barriers for the various C-O and C-H bond cleavage reactions. Further, Bader charge analysis is performed to estimate the effect of charge transfer on the stability of intermediate species formed during the surface decomposition reactions. The computed reaction energy profiles indicate higher reactivity of diglyme molecule compared to a THF molecule at Mg (0001) surface, in agreement with experimental observations. Our approach enables a detailed atomic-level understanding of the reaction mechanisms and explain the nature of key reaction products of solvent decomposition on Mg-metal anode surface.

Elucidating Cation Electrodeposition—The Roles of Electrolyte Composition and Surface Structure Perla Balbuena, Stefany Angarita-Gomez and Fernando A. Soto; Texas A&M University, United States

The use of lithium metal anodes is expected and desired in the new generation of high energy density batteries. However, the high reactivity of Li metal electrodes creates a series of issues that keep them away from practical applications. For example, electrolyte degradation reactions due to electron transfer from the surface induce the formation of a solid-electrolyte interphase (SEI) film, that starts at open circuit conditions. This multicomponent SEI film has different passivation properties and morphologies depending on the electrolyte. However, during battery charge, another phenomenon takes place simultaneously with SEI growth, and this is cation electrodeposition and metal nucleation or “plating”. As expected, at fixed current rate, phenomena such as cation diffusion and desolvation depend strongly on the type of electrolyte and the stage of formation of the SEI. Here we analyze cation electrodeposition from first principles simulations, including ab initio constrained molecular dynamics coupled to thermodynamic integration in the Blue Moon ensemble. We characterize the possible free energy pathways of the cation in various environments and the influence of the electrolyte composition and its decomposition, and the surface structure.

Effects of Functionalized Cathode and Electrolyte Composition on Structure and Dissolution of Polysulfide Species in Li-S Batteries Rasha Atwi and Nav Nidhi Rajput; Stony Brook University, The State University of New York, United States

A major breakthrough in battery materials is required to meet the ever-increasing proliferation of portable electronic devices, electric vehicles and their variants, as well as the need for incorporating renewable energy resources into the main energy supply [1]. In this context, lithium-sulfur (Li-S) batteries are promising candidates due to their very high energy density (2,600 Wh kg^{-1}) and specific capacity (1,675 mAh g^{-1}) and significantly lower weight and cost, compared to lithium-ion batteries (LIBs) [2]. Fully packaged, it is expected that future Li-S batteries can operate at close to 500 Wh kg^{-1}, which is more than twice the energy density of LIBs (200 Wh kg^{-1}) [3]. However, several issues including the dissolution of Li-Polysulfide (PS) species into the electrolyte have prevented this technology from being broadly commercialized [4]. In this talk, I will present our computational approach of attaching functional groups to the cathode surface to create thermodynamic barriers to the dissolution of PS in an electrolyte. Beginning with theoretical analysis of the structure and interactions of generic LiPS moieties and a large set of functional groups via high-throughput density functional theory (DFT) calculations, I show that it is possible to identify functional groups that anchor to the cathode and

exert high enough binding affinity to LiPS formed near electrode/electrolyte interface to prevent their loss to the solution. The selected candidates are used in detailed molecular dynamics (MD) studies to develop a fundamental understanding of the effect of various electrolyte variables (components, PS chain length, salt concentration) on structural and dynamical properties at the functionalized interface [5, 6]. In addition, I show how we are applying such a multi-scale modeling approach using our group's newly developed computational infrastructure that combines DFT calculations with MD simulations, resulting in a database of well-characterized materials to be used for building machine-learning models as well as for testing computationally identified structures in experiments. This work provides crucial information to mitigate the dissolution of PS species during cycling, which is the main reason for rapid capacity decay in Li-S batteries.

Understanding Ion Transport and Interfacial Stability in Fluorine Containing Lithium Argyrodite Electrolytes for Solid-State Lithium-Sulfur Batteries Varun Shreyas, William Arnold, Saransh Gupta, Jacek Jasinski, Gamini Sumanasekera, Hui Wang and Badri Narayanan; University of Louisville, United States

Rechargeable all solid-state lithium-sulfur batteries (ASLSBs) hold tremendous promise for use in electric vehicles due to their high theoretical capacity (~1675 Ah/kg; ~5-6 times higher than state-of-the-art Li-ion batteries), high promised energy density (400 Wh/kg) and cycle life, and low costs owing to natural abundance of sulfur. Lithium argyrodites (e.g., Li_7PS_6, and its halogen-doped derivatives) have emerged as a lucrative class of solid-state electrolytes (SSEs) for ASLSBs; owing to their high Li-ion conductivity (~10^{-3} S/cm), good elastic stiffness (~30 GPa), and low flammability. Despite their promise, ASLSBs (even using argyrodite SSEs) remain far from commercialization due to paucity of fundamental understanding of physical factors underlying key electrochemical phenomenon including ion-conduction, charge transport, structural evolution, and interfacial reactions (e.g., dendrite growth, electrolyte decomposition etc.). Specifically, such knowledge gap has thwarted development of high-performance SSEs that provide rare combination of superionic Li conduction and interfacial stability. Here, we integrate *ab initio* molecular dynamics (AIMD) simulations, density functional theory (DFT) calculations, liquid-phase synthesis and characterization methods to advance the understanding of lithium-ion conduction and interfacial reactions in fluorine (F) containing lithium argyrodites. The choice of F-containing argyrodites was motivated by recent reports indicating that F (or LiF) could suppress formation of deleterious dendrites at the Li-anode. Our AIMD simulations showed that lithium argyrodite doped with F alone, Li_6PS_5F possesses much lower Li-ion conductivity (~0.32 mS/cm) as compared to state-of-the-art Li_6PS_5Cl electrolytes (~0.9 mS/cm). Interestingly, we found that simultaneous doping of argyrodites with two dissimilar halogens (e.g., F and Cl) results in much higher Li^+ ion conductivity as compared to the counterparts doped with one halogen. For instance, we found that the Li^+ ion conductivity of $Li_6PS_5F_{0.5}Cl_{0.5}$ electrolyte (2 mS/cm) is ~2.2 times higher than that of Li_6PS_5Cl (0.9 mS/cm) and ~6 times that of Li_6PS_5F (0.32 mS/cm); consistent with our experimental measurements. Careful analysis of our AIMD trajectories, and DFT calculations indicate that this enhanced Li-ion diffusion can be attributed to the unique

defect structure stabilized by F ions, and halogen-mediated hopping of Li ions across the SSE. More importantly, we found that such mixed halogen doping enhances stability of SSE against Li-anode, as evidenced by our galvanostatic Li stripping/plating experiments that show flat voltage profile and low polarization voltage for $Li_6PS_5F_{0.5}Cl_{0.5}$ even at current density of 0.2 mA/cm^2; in contrast, the cells with Li_6PS_5F and Li_6PS_5Cl electrolytes die at 0.05 mA/cm^2 and 0.1 mA/cm^2 respectively. AIMD simulations show that this enhanced interfacial stability in $Li_6PS_5F_{0.5}Cl_{0.5}$ SSE is enabled by formation of strong Li-F bonds at the anode/electrolyte interface, which reduce the dissociation of PS_4^{3-} tetrahedra. These results will be discussed in the context of developing novel solid-state electrolytes for high-performance all solid-state lithium-sulfur batteries.

9:10 AM EN08.05.05
Late News: DFT Sampling Study on Ion Transfer at Heterogeneous Solid-Solid Interfaces in Batteries
Yoshitaka Tateyama[1,2], Keitaro Sodeyama[1,2] and Bo Gao[1]; [1]National Institute for Materials Science, Japan; [2]Kyoto University, Japan

Interfacial charge-transfer processes in batteries govern their performance and stability, where both electronics and ionics play crucial roles. However, the electronic and atomistic understanding of such interface processes is still difficult in the conventional computational as well as experimental approaches. From theoretical side, we have addressed this issue based on the first-principles density functional theory (DFT) calculations of the explicit solid-solid interfaces. Firstly, we explored techniques to obtain the energetically probable disordered solid-solid interfaces. If soft materials consist of the interface, one can use the DFT molecular dynamics (MD) sampling. We applied this procedure for the Li-intercalated graphite LiC_x anode / Li_2CO_3 inorganic solid electrolyte interphase (SEI) [1]. For the solid electrolyte (SE) - cathode interfaces in all-solid-state batteries (ASSBs), we developed, “Heterogeneous Interface (HI)-CALYPSO method”, allowing systematic sampling of heterogeneous solid-solid interface structures, based on the particle swarm optimization (PSO) [2].

With the obtained probable interfaces, we calculated the free/potential energy profiles of the Li-ion transfer across the interfaces. For the LiC_x anode / Li_2CO_3 SEI interface, we demonstrated that the Li-ion energy (a sort of electrochemical potential) in the anode is much higher than in the SEI [1]. The energy difference is attributed to the negative-charge environment surrounding the Li-ions. The obtained energy profiles correspond to the discharge process where Li-ions flow into the electrolyte side. To explain the charging process, we proposed that the energy profiles are modulated by the electric field by the excess electrons. These results also suggest a continuous energy profile model for Li-ion in the whole battery. We have also examined the energy profiles across the β-Li_3PS_4 (LPS) SE / $LiCoO_2$ (LCO) cathode interfaces in ASSB, which supports the current profile model. Though several hypotheses still exist, the present results will give a novel and useful insight into the Li-ion transport in batteries.

The work was partly supported by MEXT as “Program for Promoting Researches on the Supercomputer Fugaku” (Fugaku Battery & Fuel Cell Project) and JSPS KAKENHI “Interface IONICS” Grant Number JP19H05815.

Controlling Interphase Generation and Interfacial Charge Transfer at Magnesium Anode–Electrolyte Interfaces Brett A. Helms[1], Sung-Ju Cho[1], Benjamin Cousineau[2], Jingbo Zhao[1], Emily Carino[3], Julian Self[1], Kristin Persson[1,2], Rajeev Surendran Assary[3], Garvit Agarwal[3] and Kevin R. Zavadil[4]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Argonne National Laboratory, United States; [4]Sandia National Laboratories, United States

The inherent reactivity of magnesium metal toward electrolytes promotes the formation of insulating surface films which inhibit ionic charge transfer at the anode-electrolyte interface of magnesium metal batteries. It remains a significant challenge to realize reversibility with high energy efficiency due to the exceedingly high overpotential to plate and strip the anode at high current densities. Here, we will discuss recent efforts in our group to control interphase generation at the magnesium anode-electrolyte interface with de novo designed materials. We find that tailoring the solvation environment of magnesium in the interphase is a critical factor and explains both successes and failures in rechargeable cells. We further find that both structure and dynamics play important roles, which we elucidate by comparing molecular dynamics simulations with Raman, IR, and X-ray spectroscopic studies as well as X-ray scattering. Together, these colective insights feed back into the design of artificial interphases, which have decidedly different design rules than those that are used in alkali metal batteries (i.e., Li-metal, Na-metal, or K-metal). We will also highlight how computational materials design and high-throughput screens becomes indispensible tools to quickly navigate important structure–transport relationships in artificial interphses for magnesium metal batteries.

12:10 PM EN08.06.02
Sodium Stripping and Plating from Na-β"-Alumina Ceramics beyond 1000 mA/cm² Daniel Landmann, Gustav Graeber, Meike Heinz and Corsin Battaglia; Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Sodium-nickel chloride batteries are based on abundant, non-critical raw materials (namely rock salt, nickel, and alumina). These batteries have a proven track record for backup power applications, but also show great potential for large-scale stationary electricity storage. To enable increased deployment of this battery technology, charge and discharge rate capabilities need to be improved (>1C), and cell production cost needs to be reduced.
While lithium-ion battery cells are currently developed towards generation 3b, the current sodium-nickel chloride cell design stems from the early 1990s. In this study, we assess the rate limiting processes in state-of-the-art sodium-nickel chloride cells and propose measures to improve their performance. We deconvolute the battery's performance into anode and cathode processes in order to develop next-generation sodium-nickel chloride batteries with enhanced cell design and chemistry. By these measures, we target to improve nominal discharge current rates from currently C/3 to 1C (200 mA/cm^2), and maximum pulse discharge rates from currently 1.5C to 3C (600 mA/cm^2) [1].
On the anode side, we investigate plating and stripping of liquid sodium metal from a ceramic Na-β"-alumina electrolyte at 250 °C, applying a specially designed high-temperature electrochemical cell. Employment of a porous carbon electrode coating allows us to (1) prevent dewetting of plated liquid sodium from, and (2) to supply liquid sodium upon stripping to, the sodiophobic Na-β"-alumina surface. By this measure we are able to eliminate the mass transport limitations at the sodium/ Na-β"-alumina interface and demonstrate current densities above 1000 mA/cm^2 at cumulative plated capacity of 10 Ah/cm^2 without dendrite formation [2]. These values are two orders of magnitude higher than the corresponding values measured at room temperature [3] and exceed practical continuous current densities by a factor of 5.
On the cathode side, we characterize the chlorination and de-chlorination reaction of nickel by cyclic voltammetry, galvanostaic techniques, and electrochemical impedance spectroscopy. We deconvolute the cathode behavior into single processes by dedicated experiments. We identify the rate-limiting processes and link the overall electrochemical performace of the battery to the local degree of chlorination. By enhancing the general understanding of the working principles in sodium-nickel chloride cells, we strive to enhance cycle-life and increase charge and discharge rates for next-generation sodium-nickel chloride batteries.

Kinetic- vs Diffusion-Driven Three–Dimensional Growth in Magnesium Metal Battery Anodes Janna Eaves-Rathert[1], Kathleen Moyer[1,1], Murtaza Zohair[1,1] and Cary Pint[1,1,2]; [1]Vanderbilt University, United States; [2]Iowa State University of Science and Technology, United States

Until now, a key barrier toward realizing a high energy density Mg^{2+} battery has been the limited understanding of mechanisms governing multivalent metal electrodeposition. This, compounded with recent observations of Mg dendrites, highlights the need for better fundamental insight into multivalent systems. We present a comprehensive study of electrodeposition in practical coin cell configurations to evaluate the mechanisms of growth from common $Mg(TFSI)_2$-based electrolytes. Our findings indicate a transition from charge transfer-limited to diffusion-limited electrodeposition processes that govern the morphological evolution of Mg deposits. We observe the signature of cell shorting under a wide range of current densities which we attribute to 3-D hemispherical growth of Mg deposits that form under mixed diffusion and kinetic control and are distinguished from traditional fractal dendrites. Our results highlight synergy with classical electrochemical theories for growth and lay groundwork for future approaches to achieve stable electroplated multivalent metal electrodes.

Dendrite Formation during Charging of Li-Metal Batteries: Transport Limitations within the SEI Control Dendrite Initiation Adam M. Maraschky and Rohan Akolkar; Case Western Reserve University, United States

High-energy density batteries are the critical component which could enable electric aircraft and more powerful portable devices. The Li metal anode offers the highest theoretical specific capacity among the available anode materials. The most significant barrier to the development of secondary Li-metal batteries is the dendritic electrodeposition of Li during the battery charging process. In this presentation, we will characterize the onset time of dendritic growth that occurs when charging Li-metal anodes. Using a combination of electrochemical techniques and optical microscopy, we observe that Li dendrites initiate at a time when the surface overpotential during galvanostatic electrodeposition reaches a maximum value. The dendrite onset time (τ_{onset}) is shown to increase with increasing temperature and decrease with increasing current density and initial solid electrolyte interphase (SEI) thickness. These observations form the basis of an analytical transport model wherein the Li^+ concentration available for Li plating decreases gradually within the SEI as the layer becomes thicker during electrodeposition. At $t = \tau_{onset}$, the mobile Li^+ concentration at the Li–SEI interface approaches zero. Due to this Li^+ concentration depletion, the roughness of the Li electrode amplifies, eventually producing dendrites. Once dendrites form, they rupture the SEI, lowering the surface resistance for Li plating. Model predictions of how τ_{onset} varies with current density, initial SEI thickness, and temperature are found to be in qualitative agreement with experimental observations. The analytical model explains mechanistically how transport limitations within the SEI control the onset time of dendrites during Li electrodeposition. Our results highlight the need for stable SEI materials that suppress or eliminate solid-state Li^+ concentration depletion, which is shown herein to be the key process controlling the formation of dendrites during Li-metal battery charging.

Superior Lithium Metal Anode Composed of Porous Carbon Electrodes Layered with Metal-Organic Framework Juran Noh, Wenmiao Chen, Yutao Huang, Peng Wu, Jian Tan, Hong-cai Zhou and Choongho Yu; Texas A&M University, United States

Lithium-based energy storage system has faced a critical limit of gravimetric/volumetric capacity in commercial

graphite anode (340 mAh g^{-1}). Lithium metal is a holy grail for the next generation anode with high specific capacity (3850 mAh g^{-1}), but still has big challenges caused by lithium dendrites and large volume changes particularly at high current density and capacity. Three-dimensional (3D) lithium host materials may compensate for the volume change with pores in the host material but limited lithium-ion diffusion through porous media has resulted in clogging at the pore inlet and thereby initiated lithium dendrite growth on the surface. While artificial solid-electrolyte interphase (SEI) coated lithium metal anode could avoid lithium dendrite growth on the surface but repeated large volume change may cause the detachment of the SEI layer. In this study, a two-dimensional metal-organic framework (MOF) has been attached to carboxylated CNTs via strong coordination bonding. We observed that MOF-layered 3D CNT scaffolds stored a large amount of lithium metal without dendrite growth and volume expansion until a high capacity of 24 mAh cm^{-2} at a high current density of 8mA cm^{-2}. With the utilization of inner void space to store lithium, high volumetric capacity (~1000 mAh cm^{-3}) and gravimetric capacity (~1690 mAh g^{-1}) was achieved, which are much higher than those of commercial graphite anode (570 mAh cm^{-3} and ~340 mAh g^{-1}). This study discloses a promising approach for a high-energy-density anode with lithium metal, which has been arduous in utilizing lithium metal for Li batteries in practice.

Late News: High-Performance Low-Temperature Molten Sodium Batteries Enabled by Improved Charge Transfer Across Interfaces Martha M. Gross, Stephen Percival, Rose Lee, Amanda Peretti, Mark Rodriguez, Erik Spoerke and Leo Small; Sandia National Laboratories, United States

Managing electrochemical interfaces in molten sodium batteries is key to achieving high battery performance. Traditional molten sodium batteries operate a high temperature (~300 °C) which facilitates charge transfer at the interfaces between molten sodium and solid electrolyte, solid electrolyte and catholyte, and catholyte and current collector. Dramatically lowering the operating temperature to near the melting temperature of sodium (97.8 °C) introduces substantial charge transfer resistances at these key interfaces. To enable high battery efficiency, longevity, and resiliency, the molten sodium battery must be re-engineered from the bottom up to improve charge transfer and lower interfacial resistances. Here, we describe a low-temperature molten sodium battery capable of high performance, long-term operation at the low temperature of 110 °C. This is achieved by the modification of battery interfaces and materials design of the metal-halide sodium iodide molten salt catholyte. The use of engineered Sn-based coatings on the solid electrolyte surface at the interface with molten sodium to increase sodium wetting on NaSICON is shown to dramatically lower interfacial resistance, allowing battery operation at higher current densities. The activation of the cathode current collector to enhance charge transfer at the catholyte-current collector interface further reduces resistance at this interface, enabling high cyclability of the battery. Materials design of the metal-halide sodium iodide molten salt catholyte results in further improvements in interfacial resistance, resulting in a high-performance, low-temperature molten sodium battery of great promise for large-scale electrochemical energy storage. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Late News: Electrochemistry of the NaI-AlBr3 Low Temperature Molten Salt System—Implications for Applied Battery Performance Stephen Percival, Rose Lee, Martha M. Gross, Amanda Peretti, Leo Small and Erik Spoerke; Sandia National Laboratories, United States

Development of a new class of redox active, fully inorganic, low temperature (c.a. 100 °C) molten salt electrolytes is necessary for the continued development of safe, low cost sodium battery technologies. The discussed, redox active, NaI-$AlBr_3$ system demonstrates many physical properties that are desirable for the use in a battery system. These properties have been investigated and experimentally evaluated with focus to energy storage considerations, including the conductivity and melting point of various compositions at different temperatures allowing the construction of a simple phase diagram. The electrochemical properties of the various

molten salt composition showed lower than expected iodide oxidation current density along with variable diffusion coefficients of reactant. Choice of electrode material was found to significantly affect the reaction kinetics, where carbon is found to hinder reaction rate as compared to tungsten, potentially dictating battery cell engineering and cost.

This work was supported by the U.S. Department of Energy's Office of Electricity through the Energy Storage Research Program, managed by Dr. Imre Gyuk. Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC, a wholly-owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525. This paper describes objective technical results and analysis. 2:15 PM EN08.07.01
Lithium Interface Dynamics in Coated $LiFePO_4$ Nanoparticles Peter Benedek[1], Xueyan Zhao[1], Emanuel Billeter[2], Elisabetta Nocerino[3], Ola Forslund[3], Nami Matsubara[3], Andreas Borgschulte[2], Fanni Juranyi[4], Martin Månsson[3] and Vanessa Wood[1]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]KTH Royal Institute of Technology, Sweden; [4]Paul Scherrer Institute, Switzerland

During the last decade, the (dis)charge behaviour of $LiFePO_4$ (LFP) particles has been widely studied. While LFP typically charges in a phase separation reaction forming $LiFePO_4$ and $FePO_4$-rich domains, these domains vanish into a single Li_xFePO_4 solid solution at faster rates or smaller particle size.[1] Using phase-field modelling, an involvement of the interface has been proposed where autocatalytic reactions and resistances may affect the LFP charging dynamics and hence the rate-limiting steps.[2,3] However, due to the lack of understanding of the $LiFePO_4$ interfaces, existing experiments do not suffice to validate this model.

Here, we rationalize the interface dependent delithiation mechanism in LFP particles by introducing coatings that affect ion dynamics and hence the resistances.[4] With a combination of electronic structure calculations and *ab-intio* molecular dynamics modelling, we show that insulating oxide coatings such as ZnO hamper lithium ion interface diffusion, whereas carbon coatings lead to faster Li ion transport. We validate our models by synthesizing coated $LiFePO_4$ nanoparticles and measuring their electronic structure using ultraviolet absorption and x-ray photoemission spectroscopy. Measuring lithium ion interface diffusivity on the coated LFP nanoparticles via muon spin spectroscopy confirms our calculations.[5] Finally, using operando x-ray diffraction, we can track interface dependent changes in the delithiation behaviour. Based on our findings, we offer a rational design strategy for interfaces in lithium ion batteries that homogenize the current density and reduce the strain throughout the battery materials providing longer battery lifetime at increased rate capabilities.

Using *Operando* SQUID Magnetometry to Monitor Charge Transfer Processes in Li- and Na-Ion Battery Cathodes Stefan Topolovec[1], Gregor Klinser[1], Heinz Krenn[2] and Roland Würschum[1]; [1]Graz University of Technology, Austria; [2]University of Graz, Austria

Further development in the field of modern battery materials requires advanced characterization techniques that can yield insights into the atomic and chemical processes occurring during charging and discharging. Therefore, over the last years, a variety of in situ/operando methods were developed, probing the transfer of ions and electrons mainly at the electrode-electrolyte interface [1,2]. To achieve a complete picture of the processes in the electrodes, additional bulk sensitive methods, probing the whole volume of the material, would be beneficial. By developing an operando SQUID magnetometry technique, our group has established such a method, which enables a continuous monitoring of the oxidation states of the transition metal ions and therefore an identification of the redox active ions [3]. In this talk, first the electrochemical cell that enables operando measurements in a SQUID magnetometer will be presented and then an overview about recent results obtained with this new characterization technique will be given.

Measurements of the variation of the magnetic susceptibility of the technologically important class of NMC cathode materials have shown that different charge transfer processes occur for the two compositions $LiNi_{0.33}Mn_{0.33}Co_{0.33}O_2$ and $LiNi_{0.6}Mn_{0.6}Co_{0.2}O_2$. For $Li_xNi_{0.33}Mn_{0.33}Co_{0.33}O_2$ first Ni acts as redox active ion and changes its oxidation state stepwise from Ni^{2+} to Ni^{3+} and then from Ni^{3+} to Ni^{4+}. Upon extracting more than 66% of Li, a simultaneous oxidation of Co^{3+} and O^{2-} ions was observed that is associated with irreversible capacity losses [4]. The charge compensation process for $Li_xNi_{0.6}Mn_{0.6}Co_{0.2}O_2$ could also be divided into three steps. First a simultaneous oxidation of Ni^{2+} and Co^{2+} ($1 \geq x > 0.53$), followed by a sole Ni^{3+} oxidation ($0.53 > x > 0.21$), and finally by a contribution of Ni^{3+} and Co^{3+} or by Co^{3+} and O^{2-} ($x < 0.21$) [5].

The potential of the developed operando technique will also be demonstrated for post Li-ion batteries. Studies on $NaV_2(PO_4)_3$ cathodes revealed that vanadium is the only ion undergoing oxidation and reduction upon battery operation and that parasitic side reactions take place in the first charging cycle [6].

All in all, we could proof that operando magnetic susceptibility measurements can serve as a sensitive fingerprint for the charge compensation processes taking place in Li-ion and Na-ion battery cathodes. Therefore, this technique is highly suitably as complementary method for the characterization of the electron transfer reactions at electrode interfaces.

Atomic-scale Computational Study of the Solid Electrolyte Interphase in Na-Ion Batteries with a Nanoporous Hard Carbon Anode Emilia Olsson and Qiong Cai; University of Surrey, United Kingdom

The solid electrolyte interphase (SEI) is known to have a direct impact on sodium ion battery performance. The composition of the SEI has been shown to have a compositional dependence upon electrolyte, cycling time, anode material, and sodium salt. For hard carbon anodes with organic solvent and $NaPF_6$ there are a number of

common features. These involve the fluoridation of the hard carbon surface suggested to result from the salt dissociation, in addition the breakdown of the electrolyte molecules can result in carboxyl, carbonyl and carbonate motifs being observed, together with both inorganic and organic SEI constituents.[1,2] This make the atomic scale understanding of the anode electrolyte interphase, and its influence on both charge transfer and electrochemical performance challenging.

In this study, we combine atomic scale computational modelling with experimental characterisation of anode electrolyte interphases to investigate the structure, charge transfer, and electronic processes at the hard carbon anode electrolyte interphase in Na-ion batteries.[3,4] Hard carbons are complex disordered carbon structures with randomly oriented graphene sheets, closed and open pore systems, and turbostratically stacked graphitic stacks. Adding to their complexity, these anode materials are also prone to defects and oxygen functionalities. This complex anode material structure leads a plethora of different anode electrolyte interphase structures, which all can have different influence on the electrochemical performance.[4–7] Here, we construct, based on experimental guidance, a number of different interphase models to capture the effect of anode surface termination, roughness, defects, functional groups, pore size, and combinations of these on the electrochemical performance and charge transfer across the electrolyte anode interphase. Through a combination of ab initio molecular dynamics, and density functional theory simulations, the electronic structure, ionic diffusion, and electrolyte dissociation products can be investigated. These simulations showed, using an organic solvent based electrolyte that the local structure of the anode surface directly influences the solvent molecule breakdown and interphase immobile solvent molecule layer. Introducing carbon vacancy defects, and oxygen functionalities, together with different pore systems were further shown to affect the organic solvent molecule breakdown and lead to irreversible capacity loss. Similarly, the sodium ion transfer from the electrolyte bulk to the anode (both through intercalation and surface adsorption) was probed at different interphases to explore the effect of morphology, the liquid phase composition, and electronic structure on charge transfer.

Synchrotron Characterization of Chemo-Mechanical Transformations in All-Solid-State Batteries Kelsey B. Hatzell and Marm Dixit; Vanderbilt University, United States

Transportation accounts for 23% of energy-related carbon dioxide emissions and electrification is a pathway toward ameliorating these growing challenges. All solid state batteries could potentially address the safety and driving range requirements necessary for widespread adoption of electric vehicles. However, the power densities of all-solid state batteries are limited because of ineffective ion transport at solid|solid interfaces. New insight into the governing physics that occur at intrinsic and extrinsic interfaces are critical for developing engineering strategies for the next generation of energy dense batteries. However, buried solid|solid interfaces

are notoriously difficult to observe with traditional bench-top and lab-scale experiments. This talk will discuss opportunities for tracking phenomena and mechanisms in all solid state batteries *in-situ* using advanced synchrotron techniques. Synchrotron techniques that combine reciprocal and real space techniques are capable of tracking multi-scale structural phenomena from the nano- to meso-scale. This talk will discuss the role microstructure plays on transport and interfacial properties that govern adhesion. Quantification of salient descriptors of structure in solid state batteries is critical for understanding the mechanochemical nature of all solid state batteries.

3:25 PM EN08.07.05
Phase Controlled Synthesis and Properties of Mn_3O_4 Spinel Oxides Electrodes for Multivalent Batteries Using Molecular Beam Epitaxy Linda Wangoh, ZhenZhong Yang, Le Wang, Mark Bowden, Karl Mueller, Vijayakumar Murugesan and Yingge Du; Pacific Northwest National Laboratory, United States

Rechargeable multivalent batteries have attracted extensive research due to their low cost and higher energy density compared to Li-ion batteries. However, most cathode materials have several major challenges such as slow charge/discharge cycle and irreversible phase transitions that hinder their practical use as multivalent cathodes. Therefore, identifying and synthesizing the ideal electrode material is therefore essential in advancing multivalent battery technology. Furthermore, fundamental nature of the diffusion mechanism and its effects on the host structure is necessary to improve the performance of these systems.
Manganese-based spinel oxides are a particular class of promising materials for multivalent electrodes due to their increased energy density and higher specific capacity. However, their performance is highly dependent on their synthesis conditions and phase purity due to the existence of a multiple Manganese oxidation states (Mn^{2+}, Mn^{3+}, Mn^{4+}). In this presentation, we highlight the use of epitaxial thin films, grown using Molecular Beam Epitaxy (MBE), a technique that provides precise control over interface structure and thickness, to study host structures for multivalent cathodes. We begin with epitaxial Fe_3O_4 thin film as a model system to highlight the utility of well-defined interfaces and smooth surfaces to perform fundamental studies in cation diffusion. In addition, we investigate the electronic and structural properties of Mn_3O_4 spinel epitaxial films. In particular, we highlight the phase selective growth of phase pure Mn_3O_4 is highly dependent on the growth parameters such as flux rate and oxygen partial pressure. Furthermore, to understand the evolution of Mn_3O_4, thermal annealing of the material is performed to promote cation diffusion and structural transitions. These changes are monitored using high-resolution *in-situ* and *ex-situ* characterization techniques such as x-ray photoelectron spectroscopy, x-ray absorption near edge structure and x-ray diffraction.

5:15 PM *EN08.08.01
Identifying Intact Electrode Interfaces with Cryogenic Electron Microscopy Katherine L. Jungjohann[1], Daniel Long[1], Steven Randolph[2], Renae Gannon[3], Luara Merrill[4], Subrahmanyam Goriparti[4] and Katharine Harrison[4]; [1]Center for Integrated Nanotechnologies, United States; [2]Thermo Fisher Scientific, United States; [3]University of Oregon, United States; [4]Sandia National Laboratories, United States

Increasing the energy storage capacity of portable, rechargeable Li-ion batteries would find the most gains by implementing a Li-metal anode. Li-metal anodes at high-charging rates are needed for high power applications, such as for electric vehicles. However, Li-metal anodes experience significant capacity losses and limited

lifetimes as a result of the uncontrolled Li morphology during plating and stripping, especially at high-charge rate. The resultant morphology is commonly seen as high aspect ratio grains, which have a large surface area that can react with the electrolyte and form the solid electrolyte interphase (SEI) layer. The SEI layer is a determinant factor of the performance of the Li anode, as cyclic Li plating and stripping steps produce significant surface volume changes that present fresh surfaces for further SEI formation. This causes the SEI to continuously grow over the lifetime of the battery. This is a barrier for implementation of Li-metal anodes into commercial batteries, as the continuous formation of SEI consumes the Li inventory (resulting in capacity loss) and electrolyte (reducing pathways for Li-ion transport through the cell).
The visualization of the Li/SEI/electrolyte interfaces allows for understanding the co-dependence of the different stacked materials within a battery and the failure mechanisms that result from effects of stack pressure, electrolyte, separator, and cycling rate. Cryogenic electron microscopy techniques allow for the intact characterization of solid-liquid interfaces from atomic-scale resolution [1], up to complete cross-sectional visualization of frozen coin-cell batteries. We present analysis of SEI/Li metal interfaces using cryogenic focused ion beam (FIB) cross-sectional imaging in a scanning electron microscope, and the subsequent lamella preparation for cryo-scanning/transmission electron microscopy analysis [2]. Additionally, using a cryo stage on a laser plasma-FIB [3], we visualize a complete coin cell in cross section at representative areas of a millimeter in width. Both structural mapping methods are combined with elemental mapping using x-ray spectroscopy for identification of the electrode/electrolyte interfaces. We propose a mechanism for Li plating through a separator based on our analysis, as it is known that Li metal itself does not have the mechanical integrity to puncture the polymeric material unassisted [4,5].

5:40 PM EN08.08.02
The Effect of Anions in the Calcium Solvation Under Operando Conditions Probed by *In Situ* Soft X-Ray absorption spectroscopy
Feipeng Yang[1], Xuefei Feng[1] and Jinghua Guo[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Santa Cruz, United States

While there is considerable interest in multivalent batteries, calcium has not attracted much attention compared to magnesium or aluminum until a recent work showing that calcium can be plated and stripped at room temperature with good capacities and stabilities. Additionally, because of the higher mobility of Ca^{2+} compared to that of Mg^{2+} as a result of the lower charge density of Ca^{2+}, the interest in calcium batteries has been growing rapidly. The problem now inhibiting the development of calcium batteries is the understanding of the solvation and charge transfer mechanism at the electrode/electrolyte interface and how different types of anions will affect the calcium solvation at this interface while under in-situ/operando electrochemical conditions. It has been reported that when $Ca(BH_4)_2$ is substituted by the more weakly coordinated calcium hexafluoroisopropoxyborate ($Ca(BHFIP)_2$), ionic conductivity increases by an order of magnitude, which demonstrates the strong coordination of BH_4^- compared to Ca^{2+} in THF. To probe the calcium coordination chemistry difference at the electrode/electrolyte interface as a function of the type of anions, total electron yield (TEY) mode soft X-ray absorption spectroscopy (XAS) was employed under operando electrochemical conditions. It was observed that the $Ca(BHFIP)_2$ in THF shows a small shoulder on the right side of the L_2-edge and a pre-edge peak on the left side of the L_2-edge peak. A less prominent pre-edge peak is also observed on the left side of the L_3-edge peak. These signatures become more prominent when the potential is swept negatively

and are not reversible when the potential is swept positively in a cyclic voltammetry cycle. On the other hand, the $Ca(BH_4)_2$ in THF is more reversible, and no shoulder peak on the right side of the L_2-edge peak was observed. The detailed solvation structure of the calcium still needs to be resolved with the DFT calculations but such TEY spectra indicate their differences in the calcium coordination chemistry at the electrode/electrolyte interface as a result of the anions and it will guide the future development of electrolytes for calcium batteries.

Unveiling a New Facet in Magnesium Battery Electrochemistry Rana Mohtadi and Oscar Tutusaus; Toyota Research Institute of North America, United States

The pursuit of eco-friendly battery technologies that meet the industrial requirements for portable, stationary and automotive applications in terms of safety, cost, energy density, performance reliability and sustainability has propelled research efforts toward battery chemistries beyond Li-ion. Thus far, none of the battery chemistries that promise high energy densities such as those based on Li metal (Li-S, Li-air) and multivalent batteries such as Mg have demonstrated their potential owing to intrinsic material challenges. For example, Li-S and Li-air suffer from complex cathode conversion reactions and dendrite prone Li metal. On the other hand, issues in multivalent batteries like Mg stem from the high polarizability of Mg^{2+} that results in strong interaction with solvents and host solid state structures. [1,2,3,4] This unfortunate phenomena has often resulted in sluggish diffusion kinetics and high overpotentials, which undermine the practicality of Mg batteries. Herein, we will discuss how fundamental studies we conducted inspired a potential path forward towards overcoming these challenges and allowed us to discover new possibilities towards enabling Mg rechargeable batteries.

Multimodal Characterization of Electrodeposited Calcium Metal and Its Native Interphases for Next-Generation Battery Applications Scott A. McClary, Daniel Long, Paul Kotula, Mark Rodriguez, Timothy Ruggles, Katherine L. Jungjohann and Kevin R. Zavadil; Sandia National Laboratories, United States

Rechargeable batteries based on divalent Ca anodes have attracted considerable research attention due to their high theoretical energy densities, reduction potentials approaching lithium's, high crustal abundance, and low propensity for dendrite formation [1,2]. The highly reductive nature of calcium means that a solid-electrolyte interphase (SEI) layer spontaneously forms to protect the growing deposit from parasitic reactions. Many SEI components formed from typical calcium electrolytes (e.g. CaF_2) are poor ionic conductors [3], leading to failure upon cycling [4], but a select few (e.g. borate species, CaH_2) support limited calcium transport, enabling more extensive cycling [3,5]. To date, the formation mechanisms and transport properties of interphases in Ca electrodeposits have been sparsely studied.

In this contribution, we present multimodal characterization of electrodeposited and cycled Ca metal from $Ca(BH_4)_2$-THF and related electrolytes, with emphasis on the properties of native interphases. We identify primary and secondary phases in electrodeposits using techniques including XRD, SEM, and ToF-SIMS. We discuss the transport properties of key interphase components as determined through electrochemical methods. We then show results of characterization of thin calcium lamellae including TEM and STEM imaging, selected-area diffraction, and EDS and EELS mapping, revealing the chemical identity, nano-scale structure, and spatial distribution of interphases, while drawing connections to bulk microstructure when possible. We also discuss the use of cryogenic techniques to freeze the native electrolyte in place, allowing for insight into an evolving

calcium deposit under realistic battery operating conditions.

Our results are an important step towards the rational design and engineering of favorable protective interphases required for high efficiency plating and stripping of calcium metal anodes [6].

Late News: Scanning Electrochemical Cell Microscopy Based Nanoscale Electrochemistry Study Jiali Zhang and Byong Kim; Park Systems, Inc., United States

The objective in electrocatalysis and energy storage is to correlate electrochemical activity with nanostructured electrochemical interfaces (electrodes) [1]. However, it is challenging to quantify the heterogeneity of electrode structures or study the local structure-activity relationship for these interfaces using conventional macroscopic electrochemical techniques. Scanning electrochemical cell microscopy (SECCM) is a new nanoelectrochemical scanning probe technique designed to investigate the local electrochemical properties of electrode surfaces. In this study, the electrochemically reversible $[Ru(NH_3)_6]^{3+/2+}$ electron transfer process at a highly ordered pyrolytic graphite (HOPG) surface was recorded with SECCM technique using Park NX12 AFM system. A single barrel glass nanopipette with a Ag/AgCl quasi-reference counter electrode(QRCE) is utilized [2]. Using previous successful experience in commercializing pipette-based electrochemical microscopy [3], Park Systems's hardware and software enable localized nanoscopic cyclic voltammetry each time the meniscus contacts the surface. The redox process at the HOPG surface is detected with high reproducibility and robustness, with a current limit as minute as a few pA. Position dependence electrochemical current mapping is demonstrated. These results suggest that the effectiveness of Park Systems's commercial SECCM option for quantitative electroanalysis at the nanoscale. This capability could also facilitate the rational design of functional electromaterials with potential applications in energy storage (battery) studies and corrosion research.

Accessible Electrode Surface Area and Its Impact on Redox Flow Battery Performance Fikile Brushett[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Joint Center for Energy Storage Research, United States

Carbon-fiber electrodes exhibit many desirable material properties including conductivity, porosity, and chemical stability, and, accordingly, are employed in a range of electrochemical technologies.[1] These electrodes are particularly important in redox flow battery (RFB) systems, as they support multiple critical functions including providing surface area for electrochemical reactions, distributing liquid electrolytes, and conducting electrons and heat. While commercial materials possess suitable permeability and conductivity, the performance of pristine substrates is limited and oxidative treatment prior to use is common practice.[2,3] Partial oxidation of the electrode surface has been shown to introduce a range of oxygen functional groups, which improve hydrophilicity and, in some cases, catalyze redox reactions, as well as to increase surface area available for the electrochemical reactions.[4,5] Both effects are posited to improve electrode performance but their relative importance and effectiveness remains unclear.[6]

Here, we critically assess the nature of the surface area generated by thermal pretreatment in air and its role on RFB electrode performance. Using Freundenberg H23 as a model substrate, we systematically vary pretreatment time and temperature to create different surface morphologies and develop structure-function relations. First, we use Brauner Emmanuel Teller gas adsorption (e.g., N_2, Kr, Ar/CO_2) and mercury porosimetry to estimate physical surface area and pore size distribution. In parallel, we use voltammetry and impedance spectroscopy to determine electrochemically active surface area with different electrolyte compositions. In general, we find that only a fraction of the physical surface area is accessible for electrochemical redox reactions due, in large part, to the nanoscopic dimensions of the added surface area. Second, we develop a simple mathematical model to assess the effectiveness of the available surface area of carbon fibers for Faradaic reactions. We find that, under typical RFB operating conditions, external mass transfer limitations govern performance, limiting the utilization of recessed areas generated during pretreatment. Ultimately, these results highlight the potential limits of performance improvement strategies based on increasing surface area of fibrous substrates and motivate new approaches for electrode development.

Mechanisms Underlying the Electrochemical Oxidation of Nitroxide Radicals in Ethaline Deep Eutectic Solvent Nora A. Shaheen[1], Mahesh Ijjada[1], Miomir B. Vukmirovic[2] and Rohan Akolkar[1]; [1]Case Western Reserve University, United States; [2]Brookhaven National Laboratory, United States

Deep eutectic solvents (DESs) are emerging as promising electrolytes for electrochemical energy storage applications. Electroactive nitroxide-radical-containing organics can be dissolved in DESs to facilitate redox reactions; however, mechanistic insight of their charge transfer kinetics at the electrode surface is limited. Here, we investigate the mechanism underlying the electrochemical oxidation of 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) and 4-hydroxy2,2,6,6-tetramethylpiperidine-1-oxyl (4-hydroxy-TEMPO). Using polarization measurements on a platinum rotating disk electrode (RDE) and micro-electrode, we show that the anodic charge transfer coefficient (α) for one-electron transfer oxidations of TEMPO and 4-hydroxy-TEMPO approaches 0.9 in DES as well as in aqueous electrolytes, i.e., a significant deviation from $\alpha \approx 0.5$ expected for symmetric redox behavior. To explain this observation, a two-step oxidation mechanism is proposed wherein the nitroxide-containing species undergo fast charge transfer at an electrode surface followed by slow rate-limiting desorption of the adsorbed oxidized species. Numerical simulations are reported to characterize how the proposed two-step mechanism manifests in transient electrochemical behavior of the 4-hydroxy-TEMPO oxidation reaction, and good agreement with experiments is noted. Further evidence, based on voltammetry coupled with gravimetry (e-QCM), will be presented in support of the surface adsorption-desorption phenomena. Ramifications of the mechanistic understanding gained to the design of future high-performance DES electrolytes for energy storage will be discussed.

8:55 PM *EN08.09.03
Reaction Rate Mapping at Electrodes for Redox Flow Batteries—Impacts of Adsorption and Electrode Structure Dipobrato Sarbapalli[1], Michael Counihan[1], Tylan Watkins[2], Kevin R. Zavadil[2] and Joaquin Rodriguez-Lopez[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Sandia National Laboratories, United States

Long-lasting, high performance redox flow batteries (RFBs) will require robust electrode interfaces capable of enabling thousands of cycles while sustaining high rates of charge transfer. In this context, understanding the mechanisms of charge transfer as affected by processes such as precipitation/adsorption, molecular or electrode degradation, and the distinct reactivity of heterogeneous surface features, seems of great relevance to develop electrodes that ensure sustained RFB performance. We posit that to achieve this understanding, a versatile approach that achieves a quantitative evaluation of electron transfer rates and relates them to these chemical processes and structural attributes is necessary.

In this presentation, we will discuss how we have combined the redox imaging capabilities of scanning electrochemical microscopy (SECM) with other in-situ and ex-situ characterization techniques such as atomic force microscopy (AFM) and secondary-ion mass spectrometry (SIMS), as well as with versatile multi-layer graphene (MLG) electrodes to elucidate reaction attributes of model redox-active dialkoxybenzene derivatives, 2,5-di-*tert*-butyl-1,4-bis(2-methoxyethoxy)benzene (C1) and 2,3-dimethyl-1,4-dialkoxybenzene (C7).[1] Specifically, during cycling of the redox mediators, we observed the formation of interfacial films with distinct redox and mechanical properties compared to those of cleaved graphitic surfaces, and exclusively during reduction of electrogenerated radical cations. These films modified the rate and distribution of the electron transfer rate constants causing a significant deviation from Butler-Volmer kinetics. However, their impact was also found to be highly dependent on the surface features investigated, which were conveniently probed using the spatially-resolved capabilities of SECM. Bolstered by our findings with C1 and C7, we have also investigated other molecules used as catholytes in RFBs as well as the impact of redox-active concentration on the observed rate constants. The diversity of effects observed through our electrochemical imaging methodology highlights the importance of understanding how heterogeneous reactivity might impact RFB performance.

Binding Energies and Electronic Coupling Calculations of Redox Flow Molecules at the Carbon Surface
Jason D. Howard and Larry Curtiss; Argonne National Laboratory, United States

For charge transfer to occur in a redox flow battery the molecules must come in proximity to the electrode surface and because of this the binding energy of the constituent molecules is a crucial aspect of the net charge transfer of the system. In this work the process of computing charged binding energies is discussed along with theoretical ambiguities. The methods of using either cluster or periodic models are compared. The results overall suggest that charged redox flow molecules can bind strongly to a carbon surface. Results also show that binding energies are strongly affected by an applied potential. For cases where spontaneous charge transfer occurs within standard density functional theory simulations, constrained density functional theory is used to get a more physical binding energy. Finally some results of the electronic coupling for diabatic states prepared with constrained density functional theory are presented in the context of Marcus theory.

Understanding and Addressing the Fundamental Challenges in Rechargeable Lithium Metal Batteries Jie Xiao; Pacific Northwest National Laboratory, United States

To significantly boost the energy of the state-of-art lithium ion (Li-ion) batteries, one of the most effective approaches is to replace graphite anode with Li metal which is ultralight but energy concentrated. However, its thermodynamically instable nature in liquid electrolytes cuases many well-known problems such as dendrite formation which plagues the implementation of the proposed technology. Although many approaches have been

proposed to rescue Li metal anodes, most of the work are performed in small-scale coin cells and tested in the conditions drastically different from the reality. A full knowledge of Li metal activities at the cell level is lacking but extremely critical for the success of developing next-generation rechargeable Li metal batteries. This talk will discuss the fundamental challenges of utilizing Li metal anode in at cell-level. A Li metal prototype pouch cell with 350 Wh/kg energy with more than 350 cycles will be demonstrated. The key fundamentals that enable the long-term cycling of Li metal anodes in pouch cells are discussed and the root causes of the poor cycling of realistic Li metal pouch cells have been revisited. A series of fundamentally new insights have been provided to inspire scientific innovations to tackle the real challenges of developing next-generation battery technologies.

The Effects of Applied Interfacial Compression on Lithium Metal Cycling Behavior Katharine Harrison, Subrahmanyam Goriparti, Daniel Long, Benjamin Warren, Luara Merrill, Zachary Casias, Brad L. Boyce, Brian Perdue and Katherine L. Jungjohann; Sandia National Laboratories, United States

Conversion cathode materials have traditionally been paired with lithium metal for use in non-aqueous primary batteries to enable high energy density. Due to the demand for high energy density rechargeable batteries, there is great interest in replacing conventional lithium insertion materials currently used in lithium-ion batteries with conversion cathodes and lithium metal anodes. Essentially, these batteries are similar to lithium primary batteries but with the added complication of recharge. Rechargeability is extremely challenging due to the need to chemically convert species with large volume expansion and multiple discharge products back to their original forms during charge. In conjunction, these already challenging battery systems also rely on repeatable and efficient electroplating and stripping of lithium metal. Despite decades of research, efficient and reliable lithium-metal anode cycling remains a major challenge in commercializing rechargeable batteries based on conversion chemistries.

Interfacial stack pressure in cells consisting of conversion cathodes and lithium-metal anodes is a critical parameter to tune and control. The large volume changes associated with cycling high capacity conversion cathodes and lithium-metal anodes will likely cause significant pressure changes in cells during cycling, unlike the small volume changes typically observed for intercalation electrodes. Furthermore, our previous studies suggest that the absence of interfacial compression greatly impacts lithium-metal anode morphology and Coulombic efficiency during cycling.[1] In an effort to understand these impacts more systematically, we fabricated lithium versus copper pouch cells and subjected them to varied applied interfacial compression.

We cycled pouch cells at high and low current densities in 4 M lithium bis(fluorosulfonyl)imide in 1,2-dimethoxyethane (4 M LiFSI in DME) for 50 cycles at a variety of pressures ranging from 0-10 MPa. This very promising electrolyte was used because it has been shown to enable lithium-metal anode cycling with high Coulombic efficiency, a dense morphology, and a compact solid electrolyte interphase.[2] We disassembled pouch cells after the first and 51st plating cycles to understand morphology of the lithium deposits using cryo focused ion beam and cryo electron microscopy techniques. We confirm through these experiments that interfacial compression plays an important role in lithium-metal anode plating and stripping behavior. Lithium morphology and Coulombic efficiency can be improved through tuning the applied interfacial compression.

9:05 AM DISCUSSION TIME

9:20 AM *EN09.01.06
Functional 2D Materials and Devices for High-Power Energy Storage Xinliang Feng; Technische Universität Dresden, Germany

High-power electrochemical energy storage devices are important components for various industrial applications, ranging from individual electronics to grid storage. The demand for power and energy supply is equally imperative in actual use and is keen to expand in the future. Thus, it is highly desirable to design new electrochemical batteries and supercapacitors to mitigate the trade-off between power density and energy density. On the other hand, as growing requirements for intelligent electronic devices and internet-of-things, extensive attentions have been attracted to functional (particularly, smart and stimuli-responsive) energy storage devices, which are rapidly responsive to the variations of devices or the external environment, *e.g.*, configuration, voltage, deformation, light, and temperature, etc. Meanwhile, the portable, implantable, and wearable electronics are advancing toward miniaturization as well as ultralight, and safe, long-term, and high-speed operation, thus stimulating the urgent pursuit for miniaturized energy storage devices.
In this lecture, we will present our recent efforts in developing functional graphene and 2D materials for high-power energy storage devices, especially for the flexible/micro-supercapacitors with smart functions. Electrochromism, thermo-response, and photo-response can be integrated into such devices which provide the possible means to monitor the electrochemical process using external stimulus, thus opening up windows for realizing the power systems for intelligent electronic devices. Towards realizing high-power electrochemical batteries, we will discuss our recent progress in the development of dual-ion energy storage devices, which involve different charge storage chemistry in contrast to the conventional “rocking-chair” mechanism.

Deeply Rechargeable Zinc Anodes for Ultra-Safe High-Energy Rechargeable Batteries Nian Liu; Georgia Institute of Technology, United States

Metallic zinc as a rechargeable anode material for aqueous batteries has gained tremendous attention with merits of intrinsic safety, low cost, and high theoretical volumetric capacity (5,854 mAh/cm3). Among zinc-based batteries, Zn-air batteries are promising with the highest theoretical volumetric energy density (4,931 Wh/L). Rechargeable zinc anode has recently achieved progress in neutral electrolytes, yet developed slowly in alkaline electrolytes, which are kinetically favorable for air cathodes. Passivation, dissolution, and hydrogen evolution are three main reasons for irreversibility of zinc anodes in alkaline electrolytes, which limits the rechargeability and usable energy density. In this talk, I will present our recent works on using nanoscale material design to overcome passivation, dissolution, and hydrogen evolution issues of zinc anode, towards a deeply rechargeable zinc-based battery. I will also introduce the battery-gas chromatography quantitative analysis, as well as in situ microscopy methodologies we have developed, to quantify gas evolution side

reaction, as well as visualize the reaction on electrodes during operation.

12:10 PM EN09.02.02
3D- Printed Zinc-Carbon Composite Anode for High Performance Zinc-Ion Battery Stephen Amoko, Sanket Bhoyate, Narendra Dahotre, Yijie Jiang and Wonbong Choi; University of North Texas, United States

Recently, aqueous Zinc ion batteries have caught research attention due to intrinsic safety, low cost, and high theoretical volumetric capacity. However, insufficient utilization of Zn ions from anode can result in an inferior battery performance and limit practical application. Using 3D printed structures, the active surface area of Zn anode can be increased efficiently utilizing the Zn ions from anodes for battery reactions. Here, we develop a 3D printable zinc-carbon composite anode using direct ink writing (DIW) method to obtain porous anode structure with an increased surface area for high performance Zn ion batteries. Porous anode structure exhibits an increased electrochemical performance as compared to commercial Zn plate anodes resulting in higher specific capacity. By varying filament distancing and path, we can 3D print the zinc anode with different active surface areas, area to volume ratio, and porosity. Carbon in the composite improved conductivity, and mechanical stability of 3D printed zinc anode. Our 3D printed composite anodes allows flexible designing of batteries surpassing conventional battery designs such as coin cells or pouch cells and can be used to design printed energy storage systems.

12:25 PM EN09.02.03
High Performance Printed AgO-Zn Rechargeable Battery for Flexible Electronics Lu Yin, Jonathan Scharf, Joseph Wang and Y. Shirley Meng; University of California, San Diego, United States

The rise of flexible electronics calls for cost-effective and scalable batteries with good mechanical and electrochemical performance. In this presentation, we report on our development of printable, polymer-based AgO-Zn batteries that feature flexibility, rechargeability, high areal capacity, and low impedance. Using elastomeric substrate and binders, the current collectors, electrodes, and separators can be easily screen-printed layer-by-layer and vacuum-sealed in a stacked configuration. The batteries are customizable in sizes and capacities, with the highest obtained areal capacity of 54 mAh/cm2 for primary applications. Advanced micro-CT and EIS were used to characterize the battery, whose mechanical stability was tested with repeated twisting and bending. The batteries were used to power a flexible E-ink display system that requires a high-current drain and exhibited superior performance than commercial coin-cell batteries. The developed battery presents a practical solution for powering a wide range of electronics and holds major implications for the future development of practical and high-performance flexible batteries.

Advances in Alkaline Conversion Batteries for Grid Storage Applications Timothy N. Lambert[1], Noah B. Schorr[1], David J. Arnot[1], Matthew Lim[1], Nelson S. Bell[1], Andrea M. Bruck[2], Jonathon N. Duay[1], Maria Kelly[1], Rachel Habing[1], Logan Ricketts[1], Julian Vigil[1], Joshua W. Gallaway[2], Igor Kolesnichenko[1], Stephen Budy[1], Elijah Ruiz[1], Gautam G. Yadav[3], Meir Weiner[3], Aditya Upreti[3], Jinchao Huang[3], Michael Nyce[4], Damon Turney[4], Sanjoy Banerjee[4,3], Birendra Magar[5], Nirajan Paudel[5], Igor Vasiliev[5], Erik Spoerke[1] and Babu Chalamala[1]; [1]Sandia National Laboratories, United States; [2]Northeastern University, United States; [3]Urban Electric Power, United States; [4]The City University of New York, United States; [5]New Mexico State University, United States

For energy storage to become ubiquitous in the grid, safe, reliable low-cost electrochemical storage technologies that can be manufactured at high volumes with low capital expenditures are needed. Rechargeable alkaline batteries based on the use of a Zinc conversion anode are well suited due to Zn's high capacity (820 mAh g^{-1}), elemental abundance and established materials supply chain resulting in low production costs. Alkaline-based cells are also inherently safe and do not have the temperature limitations of Li-ion or Pb-acid batteries, thereby removing the need for complicated thermal management control strategies, and providing for simpler systems with lower integration costs. To realize the highest energy density batteries Zn needs to be

coupled with a similarly low cost, abundant and high capacity conversion electrode. Historically Zn/MnO_2, Zn/CuO and Zn/S are primary battery chemistries; however, MnO_2 (616 mAh g^{-1}), CuO (674 mAh g^{-1}) or S (1675 mAh g^{-1}) conversion cathodes are enticing candidates and if a reversible battery can be proven.

This talk will cover recent endeavors to develop cost effective and reliable energy dense alkaline batteries for grid storage applications in a Department of Energy, Office of Electricity (OE) funded program, whose success depends on the ability to effectively pair Zn anodes with a high capacity conversion cathode. This presentation will include an introduction into the OE funded program and the recent developments of rechargeable Zn/MnO_2. Progress towards rechargeable Zn/Cu_2S and Zn/CuO batteries, which have now been demonstrated at commercially relevant areal capacities (~ 10-40 mAh cm^{-2}) and energy densities (~ 100-250 Wh/L), and aspects of their battery chemistries and cycling properties will also be provided.

This work was supported by the U.S. Department of Energy, Office of Electricity, Energy Storage Program, Dr. Imre Gyuk, Program Manager, and the Laboratory Directed Research and Development program at Sandia National Laboratories. 1:05 PM *EN09.02.05
Wiring Electrons and Ions Throughout Architected Zinc Anodes Enables Rechargeable Aqueous Zinc Batteries Debra R. Rolison, Brandon J. Hopkins, Ryan H. DeBlock, Christopher N. Chervin, Nathaniel L. Skeele, Megan B. Sassin, Jeffrey W. Long and Joseph F. Parker; U.S. Naval Research Laboratory, United States

The inherent safety issues of Li-ion batteries and the high-risk supply chain of necessary elements in their active materials provides ample reason to revisit safer aqueous-based batteries. In terms of the specific energy of the system (not the single cell) and the system cost per kW h^{-1}, zinc-based batteries can outshine Li-ion and are undergoing a 21st-century renaissance. We have demonstrated that a monolithic three-dimensional (3D) aperiodic form factor zinc “sponge” developed at the U.S. Naval Research Laboratory (NRL) suppresses formation of dendrites, even when cycling the cell versus nickel, silver, or air cathodes at high rate and to deep utilization of all the zinc in the cell. This performance breakthrough arises because the entire electrode volume is directly wired to the current collector through an inner core of always-present metallic zinc thereby improving uniformity of electroreaction. The co-designed feature of through-connected porosity in 3D plays an important role in ensuring within the confined volume that the ultimate end-product of discharge in alkaline electrolyte, zinc oxide, precipitates onto that internal electrified interface. The historic limitations of zinc anodes in alkaline electrolyte are now history paving the road to next-generation, safer electrochemical energy storage.

Mechanistic Role of Dopants in Conversion Reactions of Layered Birnessite MnO_2 Joshua W. Gallaway, Andrea M. Bruck, Matthew A. Kim, Tristan Owen, Erick Ruoff and Katelyn Ripley; Northeastern University, United States

Rechargeable alkaline Zn-MnO_2 batteries have become the subject of a large research effort because they provide a pathway to high energy density rechargeable batteries that are potentially low cost (<$50/kWh) and have a non-flammable electrolyte. Since aqueous batteries are more limited in voltage than non-aqueous systems, achieving high reversible capacity is key to increasing energy density and lowering cost. A full two-electron reaction of MnO_2 from its layered birnessite form to the layered hydroxide pyrochroite results in a theoretical capacity of 617 mAh/g.

(1) $\delta\text{-}MnO_2 + 2H_2O + 2e^- \leftrightarrow Mn(OH)_2 + 2OH^-$

However, discharge of reaction (1) proceeds through a mixed mechanism: initially the layered structure is maintained and charge is compensated by insertion of ions; later the layered structure breaks down through dissolution and a new layered structure is formed. The charging reaction is similar in nature, but not necessarily a simple reversal of the same path. Furthermore, side reactions can permanently reduce the capacity, as material is instead converted to a stable and resistive spinel form Mn_3O_4 that results in electrode failure. Layered birnessite, which has the ideal structure $\delta\text{-}MnO_2$, can accommodate foreign cations in the interlayer as well as interlayer water. For example K-birnessite incorporates some K^+ from the electrolyte as well as some neutral H_2O as $\delta\text{-}(K_x)MnO_2 \bullet wH_2O$. However, the K^+ charge is compensated by some reduction of Mn^{IV} to Mn^{III}, and because K^+ is not electrochemically active in the stability window of water, this results in a theoretical capacity much lower than 617 mAh/g. If the inserted cations are instead electrochemically active (as with some transition metals) they can themselves participate in the electrochemical reaction and provide capacity. It has long been known that doping $\delta\text{-}MnO_2$ with Bi^{3+} reduces or eliminates the detrimental side reactions resulting in Mn_3O_4, producing a rechargeable electrode. This doping is most effective in thin electrodes of low areal capacity. However, a dual-doping strategy involving both Bi^{3+} and Cu^{2+} extends the effect to high areal capacity electrodes that are thick, have high mass loading, or both. In such a case there are many electrochemically active species in the material, and the sequential electrochemistry of Mn(IV/III), Cu(II/I), Mn(III/II), Cu(I/0), and Bi(III/0) have all been observed on the surface of an MnO_2 particle using operando μ-XANES during electrode discharge.

Here we present findings concerning the mechanistic role of intercalated cations in the conversion reactions of doped $\delta\text{-}MnO_2$, with a particular focus on the part played by Bi^{3+}. Bi-doped MnO_2 can be prepared in a number of ways, and is often treated in the literature as a single interchangeable material. However, there is evidence that different synthesis methods result in materials that differ in morphology, crystallinity, and in amount and site of Bi-doping. In this study we prepare a series of crystalline $\delta\text{-}(K_x, Bi_y)MnO_2 \bullet wH_2O$ materials in which y is systematically varied, and these model compounds allow the structural effect of Bi^{3+} to be observed. Operando characterization of these compounds during cycling reveal the dynamic effect of Bi dopants and their interaction with Mn during reaction (1). A multimodal study of synchrotron X-ray diffraction (XRD) and quick X-ray absorption (QAS) shows that during charging of Bi-doped MnO_2 there is an extended period of overlapping electrochemical activity of Bi(0/III) and Mn(II/III), and that this period corresponds to the disappearance of the discharge product, crystalline $Mn(OH)_2$, but no corresponding charge product is observed by diffraction. Operando Raman spectroscopy reveals that during this period the vibrational signature of $\delta\text{-}MnO_2$ is present, which indicates a disordered $\delta\text{-}MnO_2$ is the initial charge product. Without Bi^{3+} this disordered material is not observed.

Novel Materials and *Operando* Methods for Electrical Energy Storage Technologies Héctor D. Abruña; Cornell University, United States

This presentation will deal with the development of novel materials and *operando* methods for the study and characterization of battery materials. The presentation will begin with a brief overview of the methods

employed. Particular emphasis will be placed on the use of X-ray diffraction (XRD), X-ray absorption spectroscopy (XAS) X-ray microscopy and tomography and confocal Raman under active potential control. The utility of these methods will be illustrated by selected examples including Li/S, Li/Se batteries and Li metal deposition and dendritic growth, as well as the use of organic based materials. The presentation will conclude with an assessment of future directions.

3:30 PM EN09.03.04
Reaction Heterogeneity in High-Energy Lithium–Sulfur Pouch Cells Lili Shi, Chaojiang Niu, Cassidy Anderson, Shuo Feng, Dianying Liu, Dongping Lu, Jie Xiao and Jun Liu; Pacific Northwest National Laboratory, United States

Lithium sulfur (Li–S) battery as one of the most promising next generation energy storage technologies has been extensively studied because of the high theoretical energy, low cost, and environmental friendliness of sulfur.[1] Significant progresses have been made on new materials and advanced characterization techniques for mechanism understandings.[2] However, further commercialization is currently hindered by the limited cell energy and cycle life of realistic batteries.[3] To close the gap between the material-level discoveries to the practical cell-level demonstration, we designed and fabricated realistic Li–S pouch cells, compared the key parameters required for high energy batteries, investigated the reaction processes and their correlations to the cycle behaviors and failure mechanisms. It is found in addition to the electrolyte depletion, heterogeneous electrolyte diffusion and redistribution are dominant factors of the high energy cell decay at electrolyte extremely lean conditions.[4] Utilization of spatially resolved characterization and theoretical simulation on the practical pouch cells provides a full spectrum view of the dynamic interactions of key cell components in Li–S batteries. New finding of the research will be presented and discussed at the meeting.

Improving Cell Resistance and Cycle Life with Solvate/Thiophosphate Hybrid Electrolytes in Lithium Metal and Lithium Sulfur Batteries Andrew Gewirth; University of Illinois at Urbana-Champaign, United States

Solid electrolytes (SEs) have become a practical option for lithium ion and lithium metal batteries due to their improved safety over commercially available ionic liquids. The most promising of the SEs are the thiophosphates whose excellent ionic conductivities at room temperature are comparable to those of the commercially-utilized ionic liquids. Hybrid solid-liquid electrolytes exhibit higher ionic conductivities than their bare solid electrolyte counterparts due to decreased grain boundary resistance, enhanced interfacial contact with electrodes, and decreased degradation at the interface.
In this study, we evaluate a series of hybrid electrolytes made from a ‘solvate’ electrolyte in both Li-Li symmetric cells and in a full cell with a Li_2S cathode relative to their bare Li/SE/Li counterparts. Interestingly, hybrid electrolytes made by combining HFE-modified solvates and SE exhibit all the benefits of the interlayer modified SEs, without the necessity of pellet manufacture. The solvate-integrated cathode layer is additionally beneficial for achieving high active material utilization, maintaining intimate interfacial contact, and providing buffer space for volume contraction and expansion. The hybrid Li_2S cell exhibited superior cycling performance compared to the solid-state cells in terms of Li2S loading, utilzation, and cycling stability. Finally, we discuss the use of hybrid electrolytes to enable other cathode chemistries, particularly those involving conversion.

Enhanced Performance of Iron-Based Material for Aqueous Rechargeable Battery Fenghua Guo, SaeWon Kim, Xiaoqiang Shan, SathyaNarayanan Jagadeesan and Xiaowei Teng; University of New Hampshire, United States

Electrochemical energy storage has always been an essential part of the application of electricity, as electricity itself cannot be stored. Aqueous electrochemical energy storage is one of the most important and long-lasting research fields due to its cost-effective and environmentally benign nature. The utilization of transition metal oxides/hydroxides in rechargeable batteries has attracted increasing research interests over the years for their multiple valence states, making it possible to have one or more redox couples and the relatively high abundance of transition metal on earth. Among them, the iron as the fourth most abundant element on the earth crust saw its application in the energy storage as early as when Thomas Edison developed the famous Nickel-Iron Battery in 1901.
Our study was devoted to bringing further understanding of the electrochemical behavior of lepidocrocite (γ-FeOOH) in the alkaline system and its application as the anode in full cells. Unlike commonly used alkaline solution with high concentration, we focus on a mild environment (pH=12, 13). By bringing in additional anion group into the system, we observed enhanced capacity with a different redox behavior, which was attributed to the formation of the green rust phase by *in-situ* X-ray Diffraction measurements. Full cell data showed that the capacity retention was also improved significantly by enabling the anion intercalation . Our study opens a way to improve the performance of iron-based electrode materials in an alkaline system.

Multiple Sulfur Reduction Pathways and Hidden Lithium Storage Mechanisms for Extra Discharge Capacity Revealed by First Principles Simulations Perla Balbuena and Saul Perez Beltran; Texas A&M University, United States

Lithium-Sulfur batteries are among the most promising for desired high energy density applications such as electric vehicles. The batteries are usually configured with a Li metal anode and a sulfur-carbon (S-C) cathode electrode, in addition to an electrolyte typically composed by an ether solvent, a salt, and some additives. However, the formation of soluble polysulfide species during discharge reactions, and their migration to the anode side create severe problems that result in drastic reduction of the battery capacity during cycling. One possible solution is to modify the structure and chemical composition of the S-C cathode, by creating chemical S-C bonds. One of the best materials that contain such S-C bonds results from special thermal treatments (under an excess of sulfur) of polyacrylonitrile (PAN), that results in a new material called SPAN. During discharge, this material does not generate long-chain polysulfides, thus avoiding one of the main problems of this type of batteries. However, the underlying microscopic mechanisms occurring in the cathode during lithiation are not yet fully understood. In this work, we use ab initio molecular dynamics simulations to model a cathode material that reproduces experimental data of SPAN's graphitization and conjugated ordering, sulfur-carbon covalent bonding, sulfur loading, and elemental composition, including nitrogen doping. Our study reveals atomistic details regarding voltage profiles including the roles of S, N, and C atoms during lithiation, and provides new insights into the origins of irreversible capacity loss between the first and second cycles.

Rational Design of Sulfur Cathode for High-Energy Lithium-Sulfur Batteries Shuo Feng[1,2], Lili Shi[1],

Cassidy Anderson[1], Yuehe Lin[2], Jie Xiao[1], Jun Liu[1] and Dongping Lu[1]; [1]Pacific Northwest National Laboratory, United States; [2]Washington State University, United States

A crucial prerequisite for a high energy lithium-sulfur (Li-S) battery is the integration of a high-loading sulfur cathode, a lean amount of electrolyte, and a limited Li anode 1-4. However, simultaneous application of these parameters often leads to the rapid deterioration of the cell performance. Fundamental mechanisms of the cell failure are still not very clear; materials that can fulfill both high energy density and long cycle life of the Li-S batteries are still facing significant challenges. Highly porous and nanosized carbon materials are widely explored as effective sulfur hosts to improve Li-S battery's performance. However, these nano materials tend to form extremely porous and thick sulfur cathodes which require a large amount of electrolyte for pore filling, and thus a very high electrolyte to sulfur ratio (E/S ratio > 10 μL/mgs) is usually used for cell test. To address those issues, rational designs for both materials and electrode structures are urgently needed to enable the operation of low porosity sulfur cathodes (<50%) under lean electrolyte condition (E/S ratio < 4 μL/mgs), conserving more proportion of electrolyte for cell cycling. In this research, sulfur/carbon composite with controllable secondary particle sizes were synthesized and used as example materials to understand the impacts of materials and electrodes on sulfur reactions at realistic conditions. It is found that the larger sulfur/carbon particles (> 90 μm) demonstrate significant superiorities over the smaller ones (< 20 μm) in terms of electrolyte permeability, sulfur utilization rate, electrochemical polarization, and shuttling effect. As a result, at an extremely low electrode porosity of 45%, the high loading sulfur cathode (>4 mg/cm2) can deliver a high initial discharge capacity of 1001 mAh/g under lean electrolyte conditions (E/S ratio = 4 μL/mgs) with a much improved cycling stability. New findings of the research will be presented and discussed at the symposium.

High Donor Electrolytes for Lithium-Sulfur Batteries with Lean Electrolyte Conditions Jang Wook Choi; Seoul National University, Korea (the Republic of)

Li-S batteries have experienced remarkable progress in the past decade, mainly in terms of cycle life. The shuttling process, the main capacity fading mechanism, was addressed by a variety of strategies targeting all of sulfur electrode, electrolyte, and separator. Nonetheless, the main progress was based on ether-based electrolytes that have a certain level of compatibility with Li metal counter electrode. To achieve more competitive energy density, electrolyte amount should be controlled to be low thus satisfying the necessity of lean electrolyte conditions. In this talk, I will introduce recent progress in identifying high donor electrolytes. High solubility of polysulfides contributes directly to boosting the volumetric energy density. I will also discuss how to secure the compatibility with Li metal anode so that high donor electrolytes can be adopted in commercially viable conditions.

6:20 PM *EN09.04.04
The Role of Superoxide Solvation and Crystal Growth in Enabling Rechargeable, High Capacity Metal

Oxygen Batteries Naga Phani B. Aetukuri; Indian Institute of Science, India

Batteries with energy density higher than that of state-of-the-art Li-ion batteries are considered critical for mass adoption of electric automobiles. Alkali metal-X batteries such as Li-O_2, Na-O_2, K-O_2 and Li-S batteries have been extensively researched over the past few years as high energy density alternatives to Li-ion batteries. Amongst these battery types, metal-oxygen batteries afford the highest energy density for a given alkali metal. Elementary steps that are common to all alkali metal-oxygen batteries are, i) the electrolyte crystal growth during discharge and ii) dissolution of alkali metal peroxides such as Li_2O_2 (in Li-O_2 batteries) or superoxides such as NaO_2 or KO_2 (in Na- or K-O_2 batteries, respectively). In general, at least one of these steps was found to be slow or inefficient in aprotic metal-oxygen batteries. However, the parameters that limit the rate of crystal growth and dissolution, and therefore the ultimate practical energy densities and rechargeability attainable in these batteries, are poorly understood. For example, Li_2O_2 and NaO_2, the discharge products in Li- and Na-O_2 batteries respectively, are both electronic insulators. Therefore, electrochemical deposition of Li_2O_2 and NaO_2 might lead to battery electrode passivation and to low practical specific energy. However, electrode-passivation limited capacities were observed in Li-O_2 batteries, but not in Na-O_2 cells. In this talk, we will present experimental results backed by theoretical calculations that suggest the capacity limitations in alkali metal-oxygen batteries can be overcome by suitable electrolyte design that enhances solution-mediated electrochemical deposition of Li_2O_2 and NaO_2. This mechanism leads to a higher specific energy than that limited by electrode passivation. Further, we will discuss the role of ion-pairing on the growth of crystals in metal-oxygen batteries and propose suitable additives to enhance crystal growth in metal-oxygen batteries. Finally, we will also discuss design rules for selecting electrolyte solvents that favor the solution deposition of discharge products while also being electrochemically stable.

6:45 PM EN09.04.05

Competition of Intercalation and Conversion Reactions for FeOF Cathode—A Combined Study with Atomic Simulations and Experiment Qisheng Wu[1], Haotian Wang[2], Gary Rubloff[2], Chuan-Fu Lin[2,3] and Yue Qi[1]; [1]Brown University, United States; [2]University of Maryland, United States; [3]The Catholic University of America, United States

The iron oxyfluoride (FeOF) cathode has been attracting great research interests since it inherits both the high output voltage of fluorides (FeF_x) and the good kinetics of oxides (FeO_x). The lithiation of the rutile FeOF starts with intercalation up to a certain concentration ($Li_{0.6}FeOF$) followed by conversion reaction to form new phases (e.g., rock salt $LiFeO_x$, LiF, and Fe metal). It is not surprising that the thermodynamically favorable conversion reaction does not happen in the very beginning due to kinetic barriers for solid-state phase transformation. The atomistic mechanism of the competition between the intercalation *vs.* conversion for FeOF is yet to be understood. In this work, a combined study with atomic simulations and experiments is performed to resolve this issue.

We propose by density functional theory (DFT) calculations a new intermediate rock salt structure, which has lower interface energy with the dominating converted phases ($LiFeO_2$ and FeO). Therefore, the intermediate rock salt structure will have a smaller barrier for conversion reactions. It is identified from the transition state calculations via NEB method that phase transition from the intercalated rutile structure to the intermediate rock salt structure is accompanied by a volume expansion. Therefore, compression stress imposed by a coating layer can prevent the transformation to the intermediate rock salt structure and delay the onset of the conversing reaction. This explained the previous experimental observation that a thin solid electrolyte (LiPON) deposition on the FeOF cathode extended the Li insertion process to higher concentrations ($Li_{1.0}FeOF$). Since the intercalation process is more reversible than the conversion reaction, the LiPON coated FeOF cathode retained 89% of its capacity for more than 100 cycles. This suggests that mechanical constraints can be used to control the competition of intercalation and conversion reactions to design durable high capacity conversion-type cathode materials for Li-ion batteries.

Density Functional Theory and Experimental Investigation of Voltage Profile and Rechargeability in CF_x Batteries Kevin Leung[1], Noah B. Schorr[1], Matthew Mayer[2], Timothy N. Lambert[1], Y. Shirley Meng[2] and Katharine Harrison[1]; [1]Sandia National Laboratories, United States; [2]University of California at San Diego, United States

Graphite Fluoride (CF_x) exhibits one of the highest theoretical energy capacities among primary batteries, and has recently been reported to be rechargeable in Na/CF_x cells[1]. Although CF_x is widely used, key aspects of CF_x cell operations remain poorly understood. For example, the practical operational voltage is far below the theoretical (thermodynamic) average of 4.66 V for Li/CF_x [2] (Fig. 1a). The discharge rate is slow, and rechargeability for Li/CF_x, which can lead to high energy density secondary batteries, has yet to be demonstrated. A deeper understanding of the CF_x discharge mechanism, which is still disputed, will improve battery capabilities. In this presentation, we will report ab initio molecular dynamics (AIMD) simulations of CF_x defluorination by a Li-droplet on CF_x edges (i.e., under short-circuit conditionS). We also perform static, zero temperature Density Functional Theory (DFT) calculations of equilibrium voltages motivated by insights obtained in these AIMD simulations. From these predictions, we propose a discharge mechanism with a voltage range which is in broad agreement with our Galvanostatic Intermittent Titration Technique (GITT) measurements. We also calculate defluorination energy barriers associated with C-F bond breaking and relate these predictions to kinetic values estimated from experiments. Finally, solvent effects and constant-voltage electrochemical (including "overpotential") conditions will be considered in DFT calculations.

Screening Interfaces of Energy Materials Using First-Principles Calculations Pieremanuele Canepa; National University of Singapore, Singapore

In 2000, during his noble prize lecture Prof. Herbert Kroemer stated ``The interface is the device"[1]; he was referring to the phenomenal success in design and application of semiconductor heterojunction devices in microelectronics. Arguably, Kroemer's statement has an ever-increasing relevance across a range of technologies far beyond transistors, where heterojunctions found their initial success. Researchers are increasingly finding that interfaces between materials represent a rich space for the exploration of exotic properties that are not present in bulk materials, such as two-dimensional electron gases (or liquids) and quantum topological states. It is clear that the importance of the interface can only grow with the evolution of modern technological applications. Simultaneously, progress in computational materials science in describing complex interfaces is critical for improving the understanding and performance of energy materials, including rechargeable batteries and catalysts [2].
In this talk, I will elucidate how first-principles calculations, based on density functional theory, can be applied to large pools of materials to rationalize their behaviors when forming functional interfaces [3–7]. Focus will be given to topical materials in rechargeable batteries, where controlling interfaces is paramount to curb degradation phenomena [3–7].

Tutorial EN10: Interfaces in Energy Storage and Water-Energy Nexus Systems
Session Chairs: Seth Darling, Zhenxing Feng and Kang Xu
Saturday Morning, April 17, 2021
EN10

9:00 AM *
Interfacing Electrolytes in Batteries Kang Xu; U.S. Army Research Laboratory, United States

This tutorial provides a colloquial introduction to the interface science in electrochemistry, and the central role played by interfaces and interphases in the advanced batteries. It will also cover the recent advances in the field of high energy battery chemistries and materials.

10:30 AM BREAK

10:45 AM *
Interfaces in Water-Energy Systems Seth Darling; Argonne National Laboratory, United States

Interfaces between materials and water or aqueous fluids are central to the performance of almost all water-energy systems. In this tutorial, Dr. Darling will first introduce global-scale challenges related to the water-energy nexus and then reveal how the properties of water/solid interfaces are interconnected with these challenges. He will present various strategies that are used by researchers to manipulate interfacial properties, ranging from mussel-inspired dopamine chemistry to atomic layer deposition and related techniques. He will provide examples of applications implementing such approaches, including anti-fouling surfaces, catalytically active materials, membranes with unusual transport properties, selective sorbents, and photothermal systems for solar steam generation.

SESSION EN10.01: Electrocatalysis in General

Sunday Morning, April 18, 2021
EN10

8:00 AM *EN10.01.01
Probing Buried Electrochemical and Catalytic Interfaces Under Working Conditions Robert Weatherup; University of Oxford, United Kingdom

Revealing the chemical reactions that occur at catalytic and electrochemical interfaces under realistic conditions is critical to selecting and designing improved materials for chemical synthesis, energy storage, and corrosion prevention. Obtaining chemical information with nm-scale interface sensitivity is however a significant challenge given these interfaces are typically buried between a bulk support and dense reaction environment. [1,2]

Here we introduce and apply several complementary methods based on soft X-ray spectroscopies and neutron reflectometry for studying electrochemical and catalyst interfaces under realistic liquid- and gas-phase environments. This includes *membrane-based* approaches which we have been involved in developing over recent years that enable *operando* x-ray photoelectron and absorption spectroscopy (XPS/XAS) of solid-liquid and solid-gas interfaces at atmospheric pressures and above.[2-5] These rely on reaction cells sealed with X-ray/electron-transparent membranes such as thin (<100 nm) silicon nitride or graphene membranes that remain impermeable to gases and liquids.

We demonstrate how these approaches can track the chemical evolution of solid-gas interfaces such as copper surfaces during methanol oxidation,[6] and supported nanoparticle catalysts in atmospheric pressure environments.[4] We also show how total electron yield (TEY) mode XAS can monitor the evolution of solid-liquid interfaces under electrochemical control, including the oxidation/reduction of Ni electrodes in aqueous media, and solid-electrolyte interphase (SEI) formation on Li-ion battery anodes.[5] This is complemented by neutron reflectometry which reveals the precise thickness of the layers formed on electrode surfaces with sub-nm depth resolution, even for light elements such as Li, C, O. We are thus able to follow the chemical and structural evolution of the solid-electrolyte interphase during its formation under realistic electrochemical conditions. We further introduce some promising new methods for accessing the chemistry of electrode-electrolyte interfaces in solid-state batteries,[7] using Hard X-ray Photoelectron Spectroscopy.

We expect these methods to be valuable in understanding a wide range of interfacial reactions across the electrochemical and catalytic sciences, and will summarize outstanding challenges in this area that are still to be overcome.

Intermetallic PtCo Catalysts with Enhanced Stability Jacob Spendelow[1], Chenyu Wang[1] and David Cullen[2]; [1]Los Alamos National Laboratory, United States; [2]Oak Ridge National Laboratory, United States

Polymer electrolyte fuel cell performance is limited mainly by the cathode, where poor oxygen reduction reaction (ORR) kinetics and slow transport of O_2 to active sites lead to large overpotentials. State-of-the-art high surface area Pt alloy catalysts also suffer from poor durability due to loss of surface area (particle growth) and leaching of base metals. We have recently demonstrated that the use of intermetallic nanoparticle catalysts such as $L1_0$-PtCo can enable significant improvements in long-term performance due to improved stabilization of base metal in the ordered lattice. We have also demonstrated a strong role of the catalyst support in determining catalyst performance and durability, providing additional opportunities to control and tune catalyst properties through control of support morphology, porosity, and graphitization. New catalysts based on $L1_0$-CoPt combined with advanced support structures have shown excellent durability in fuel cell membrane electrode assemblies (MEAs), meeting DOE targets for accelerated stress tests (30K voltage cycles in MEA) with minimal performance degradation. Recent results and future directions for this catalyst research will be discussed.

8:50 AM EN10.01.03
Highly Dispersed RuOOH Nanoparticles on Silica Spheres—An Efficient Photothermal Catalyst for Selective Aerobic Oxidation of Benzyl Alcohol Qilin Wei and Yugang Sun; Temple University, United States

Photothermal catalysis represents a promising strategy to utilize the renewable energy source (e.g., solar energy) to drive chemical reactions more efficiently. Successful and efficient photothermal catalysis relies on the availability of ideal photothermal catalysts, which can provide both large areas of catalytically active surface and strong light absorption power simultaneously. Such duplex requirements of a photothermal catalyst exhibit opposing dependence on the size of the catalyst nanoparticles, i.e., smaller size is benefcial for achieving higher surface area and more active surface, whereas larger size favors the light absorption in the nanoparticles. In this article, we report the synthesis of ultrafine RuOOH nanoparticles with a size of 2–3 nm uniformly dispersed on the surfaces of silica (SiOx) nanospheres of hundreds of nanometers in size to tackle this challenge of forming an ideal photothermal catalyst. The ultrasmall RuOOH nanoparticles exhibit a large surface area as well as the ability to activate adsorbed molecular oxygen. The SiOx nanospheres exhibit strong surface light scattering resonances to enhance the light absorption power of the small RuOOH nanoparticles anchored on the SiOx surface. Therefore, the RuOOH/SiOx composite particles represent a new class of efficient photothermal catalysts with a photothermal energy conversion efficiency of 92.5% for selective aerobic oxidation of benzyl alcohol to benzylaldehyde under ambient conditions.

9:05 AM DISCUSSION TIME

9:20 AM EN10.01.05
Aging and Recovery of Fe-Ni-Co Electrocatalysts for the Alkaline Oxygen Evolution Reaction (OER) Elizabeth Podlaha-Murphy; Clarkson University, United States

Earth-abundant Fe-Ni-Co oxide are recognized electrocatalysts for the oxygen evolution reaction (OER) in water splitting. In the present work, Fe-Ni-Co alloy thin films are electrodeposited onto copper substrates and surface oxides generated by voltammetry in 1 M KOH. The electrocatalysts are aged until changes in the OER are observed at different applied current densities. Regenerated catalysts occur via a cathodic post-treatment.

Stability of the electrocatalysts are examined with voltammetry, chronopotentiometry and XANES analyses. Fresh, unaged samples show predominately Fe(III), Ni(II) and metallic Co states present in the oxide. Changes of the electron density distribution were observed upon aging of the electrocatalysts that could be reversed through the regeneration step. The Fe-Ni-Co thin films were fabricated by electrodeposition from a boric acid-containing electrolyte onto rotating cylinder electrodes. The OER activity of the electrodeposits in 1 M KOH was a function of deposit composition, as expected although alloys with a small amount of Co maintained a constant Tafel slope over a larger range than a comparable Fe-Ni electrocatalyst. Chronopotentiometric aging during an anodic current density of 10 mA/cm^2 for 30 hours, was followed by a cathodic post treatment current density, that fully recovered the OER activity, and the limits of the cathodic post treatment with more extreme aging conditions will be discussed.

Operando 3D Imaging of Electrodes and Electric Double Layers at the Atomic Scale Yingjie Zhang; University of Illinois at Urbana-Champaign, United States

The interconversion between chemical energy and electricity relies critically on electrode-electrolyte interfaces, which consists of the electrode surface regions and the solvation layers, also called the electric double layers (EDLs). While the electrode structures have been extensively studied using in-situ characterization techniques, to date the structure of EDLs remains largely unexplored. This is not surprising, considering the weakly ordered, partially mobile, and vacuum-incompatible nature of the liquid molecules in the EDL. To address this challenge, we have developed a novel technique, electrochemical three-dimensional atomic force microscopy (EC-3D-AFM), to directly image both the electrode surface and EDLs under operando conditions. Utilizing ultrasensitive force detection techniques, we are able to achieve atomic and molecular resolution. I will discuss our recent findings on the potential-dependent EDLs of graphitic and other van der Waals electrodes using the EC-3D-AFM method. In addition, I will also discuss our efforts on operando spectroscopy of electrode-electrolyte interfaces, as well as joint experiment-theory approaches to understand the hidden mechanisms of interfacial electrochemical energy conversion processes.

10:55 AM EN10.02.02
Lithium–Ion Battery Separators—The Influence of Separator Structure on Battery Performance
Christina Sauter, Raphael Zahn and Vanessa Wood; ETH Zürich, Switzerland

Separators in Lithium Ion Batteries (LIBs) are electronically isolating membranes that prevent physical contact between the two electrodes while allowing ionic transport. Therefore, they are considered to be a crucial part in battery safety.[1] In commercially available LIBs, separators are predominately made from porous polyolefin films such as polypropylene (PP) or polyethylene (PE). They can be coated with thin layers of ceramics (e.g., Al_2O_3, MgO_2, …), which improves their stability against shrinking under thermal stress and their resistance to electrochemical oxidation by high voltage positive electrodes.[3]
Traditionally, the effective transport coefficient (ratio between porosity and tortuosity) is used for the characterization of LIB separator performance. However, to fully capture all aspects of battery performance, additional structural parameters like pore space connectivity are necessary.[4] [5] Here, we show how the 3D structure of the separator pore space directly influences separator wetting and thereby battery performance. Our research group developed an approach to visualize and quantify LIB separators with focused ion beam scanning electron microscopy (FIB-SEM).[2] Using FIB-SEM we acquired the 3D tomographic data of

commercial coated and uncoated PE separators. Comparing the effective transport coefficients, pore connectivity and mechanical stability of the two different separators, we quantify the influence of the ceramic coating on structure and performance.
The 3D data sets also allow us to simulate the wetting of the separator membranes with liquid electrolyte. We see that during this so-called imbibition-process up to 30% gas is entrapped in the separator. Using partial wetting theory, we show that the specific 3D structure of the separator is responsible for this incomplete wetting. Comparing the wetting simulations to separator performance measurements, we demonstrate, that incomplete wetting can explain the discrepancy between theoretically predicted and experimentally measured transport coefficients. We also show that quasi-static wetting models overestimate the amount of residual gas in the membranes and that realistic wetting models have to consider both, the physico-chemical properties of the liquid electrolyte and the 3D structure of the separator pore space.[6]

Enhanced Voltage Generation Through Electrolyte Flow on Liquid Filled Surfaces Bei Fan, Prab Bandaru and Li Cheng; University of California, San Diego, United States

The generation of electrical voltage through the flow of an electrolyte over a charged surface may be used for energy transduction. Here, it is shown that enhanced electrical potential differences/streaming potential (V_s) may be obtained through the flow of salt water on *LFS* (liquid filled surfaces) infiltrated with lower dielectric constant liquid, such as oil, harnessing electrolyte slip and associated surface charge. A record large figure of merit, in terms of the voltage generated per unit applied pressure, of 0.043 mV/Pa, was obtained through the use of the *LFS*, greater by a factor of 1.4, when compared to air filled surfaces (*AFS*). These results lay the basis for innovative surface charge engineering methodology for the study of electrokinetic phenomena at the microscale with applications to new electrical power sources.

We will also discuss a methodology for substantially indicating the magnitude of the electrokinetic streaming potential (V_s) from ~ 0.02 V to ~ 1.6 V, based on experimental results. The underlying idea is to use textured *LFS*, filled with low viscosity oils, for electrolyte flow. The charge density at the electrolyte-oil interface as well as the enhanced slip is thought to be responsible for the enhancement of the V_s. The specific influence of the filling oil viscosity on the V_s was probed with respect to the viscosity. It was found, through experimental analysis as well as computational simulations, that the fluid slip length was inversely proportional to the filling oil viscosity, and influences the V_s. The obtained results provide new perspectives related to complex electrolyte flow conditions as may be relevant to chemical and biological separations.

New Long Life/ Safer Lithium Ion Battery with Low Cost/Li-Corrosion Resistant Ultrananocrystalline Diamond-Coated Components Elida I. de Obaldia[1,2], Orlando Auciello[2,3] and Jesus J. Alcantar-Peña[4]; [1]Universidad Tecnológica de Panamá, Panama; [2]The University of Texas at Dallas, United States; [3]Original

Biomedical Implants, LLC, United States; [4]Center for Engineering and Industrial Development, Mexico

Novel low cost/electrically conductive/corrosion resistant nitrogen-doped ultrananocrystalline diamond (N-UNCD) coating provides excellent chemically robust encapsulation of commercial natural graphite (NG)/copper (Cu) anodes and new textured Si-based anodes, currently under development for Li-ion batteries (LIB), providing a solution to the problem of LIBs' anode materials degradation due to chemical corrosion induced by Li ions. The N-UNCD encapsulating coating allows for good conductivity of both electrons and Li-ions while exhibiting outstanding chemical and electrochemical inertness to Li ions-induced corrosion, eliminating de Li-induced chemical corrosion of graphite powder in current commercial graphite/copper composite anodes, which result in degradation of the capacity energy after undesirable relatively short numbers of charge/discharge cycles of LIBs. In addition, the electrically conductive N-UNCD coating produce a substantial increase in the mechanical strength of the anode's graphite powder and will also produce the same results for structured Si anodes, resulting in the formation of robust Solid-Electrolyte Interface (SEI) films, which effectively eliminate unceasingly cracking of SEI, observed in graphite/copper anodes, which expose fresh graphite anode surface, thus, repairing of the SEI by electrochemical reduction of the electrolyte and the formation of additional SEI compounds, which increase the impedance for the lithium ion diffusion and causes the electrolyte to be prematurely depleted in anodes without the N-UNCD coating. In addition to the excellent protection to chemical attack of anodes, new preliminary R&D will be presented indicating that electrically conductive N-UNCD coatings can also be used to coat LIB's oxide cathodes to protect them from Li-induced corrosion, as well, and that insulating/corrosion resistant UNCD coating can be used to coat the inner walls of novel metallic aluminum LIB's cases and membranes to protect them from corrosion induced by the Li-based battery environment, and thus enabling to use aluminum as a LIB's case, thus to replace current more expensive partially corrosion resistant metals. The pathway to commercialization of the new UNCD coating technology for LIBs and other LI-based batteries, like thermal Li-sulfur batteries will be discussed.

The Use of Synchrotron Techniques to Characterize Oxide-Supported Catalysts Richard L. Kurtz; Louisiana State University, United States

Synchrotron-based characterization methods can provide valuable information on the nature of catalyst/adsorbate interactions and a number of soft X-ray based techniques will be reviewed in this presentation. We will focus our discussion on systems involving catalyst clusters supported on single-crystalline oxides, particularly TiO_2, ZnO, and Fe_2O_3. The examples that we will present include studies related to electrochemistry as well as environmental chemistry.

With synchrotron ultra-violet light one can provide information on occupied valence electronic structure and charge-transfer mechanisms occurring during reaction and adsorbate bonding using ultra-violet photoemission (UPS) and by tuning the photon energy it's possible to use excitation resonances to enhance sensitivity to defect states. Synchrotron-based X-ray photoelectron spectroscopy (XPS) is another valuable tool for probing surface reactions and cross-sections for core-level excitations can also be tuned with photon energy. Since XPS involves photoexcitation from a core level to a plane-wave final excited state far above E_F, the measured binding energies reflect potential shifts in the *occupied* core levels reflecting the chemistry of the atomic

bonding. Another valuable measurement is to probe the *empty* electronic states just above the Fermi level by monitoring the X-ray absorption near edge structure (XANES). This can provide further information on the changes induced by chemical bonding and the hybridization of empty electronic states and we will show that it provides valuable information that is complementary to the UPS/XPS probes of the occupied states. In the case of the L edges (2*p* states), the dipole-allowed transition to empty 3*d* states are very sensitive to details of the changes in the empty-state electronic structure, crystal-field splitting, and other effects induced in the interfaces on chemical adsorption and reaction.

It is helpful to combine this data with models to better understand the local atomic and electronic states and density-functional theory (DFT) calculations allow one to model surface structures and compute electronic band structures, including empty states. A Bader analysis can provide information on charge-transfers that are involved, and methods have been developed to compute the XANES spectra directly, including spectra considering the presence of the (*2p*) core hole. We will contrast data with predictions to show how progress is being made in understanding the underlying chemistry involved. We will conclude with a summary of how synchrotron studies, combined with DFT calculations, will provide valuable information on the atomic and electronic origins of interface structures.

1:25 PM *EN10.03.02
Revealing Coupled Surface Transformation and Reorganization on Metal Oxide in Oxygen Evolution Reaction Hua Zhou; Argonne National Laboratory, United States

Electrocatalysts are materials designed to provide a facilitating environment for electrochemical conversion and synthesis of materials and fuels from atmospheric molecules, which is one of the most important challenges facing societal need of energy in 21st century. One of the major hurdles developing electrocatalysts is the lack of holistic information of the evolving surface structure of materials during electrochemical operation. This is particularly formidable for oxygen evolution reaction (OER), where the oxidizing environment is corrosive and can significantly rearrange the electrocatalyst surface structure. Therefore, identifying how the surface structure of materials evolves during the OER is essential to the development of more active and stable electrocatalysts and broadly to the prospect of materials and energy sustainability. Surface-sensitive X-ray probes from modern synchrotron sources including surface X-ray scattering and grazing incidence X-ray spectroscopy provide a very powerful suite of toolkits to decipher the surface subtlety and evolution. If utilizing these techniques in a well-coordinated approach, one can deliver thorough and deep fundamental insights of surface transformations (e.g. structural, chemical and electronic) during the electrocatalytic process.

In this talk, I will firstly render a brief survey of various surface sensitive X-ray techniques to specifically probe structural and chemical aspects of electrocatalytic materials, in particular the combined approach to differentiate the contribution from surface and bulk layers. In particular, I will introduce the high energy surface X-ray diffraction technique which facilitates fast capturing of structural evolution of less stable surface under electrocatalytic conditions. Following the survey, I would like to present a comprehensive study of the emergent surface transformation of $SrIrO_3$, the most active OER electrocatalyst reported to date, especially the amorphous boundary layer that forms from the pristine crystalline structure on the surface with OER cycling. In virtue of multimodal X-ray probing, a step-by-step transformation mechanism of the amorphization process could be explicitly illuminated. Our X-ray results show that the amorphization is triggered by the lattice oxygen activation and the structural reorganization facilitating coupled cation and anion diffusions is key to the realization of the OER active structure in the final Sr_yIrO_x form which exhibits stronger disorder than conventional amorphous IrO_x, partially explaining its champion OER activity.

1:50 PM EN10.03.03
The Active Sites of *In Situ* Generated CoOx Catalyst for Electrochemical Water Splitting Maoyu Wang and Zhenxing Feng; Oregon State University, United States

The high-efficiency and low-cost catalysts for oxygen evolution reaction (OER) are critical for electrochemical

water splitting to generate hydrogen as the clean fuel for sustainable energy conversion and storage. The development of those catalysts relies on discovering their active sites and understanding of their catalytical states so that rational design strategies can be applied. Transition metal sulfides are an emerging type of OER catalyst that exhibits superior activity even better than commercial standards such as RuO2. However, they undergo structural and compositional change during the reaction, which adds difficulties in studying catalytic active sites. Here, we use cobalt sulfide, Co9S8, as a representative example. Utilizing multimodal operando characterizations including Raman spectroscopy, X-ray absorption spectroscopy, and X-ray reflectivity, we find that Co9S8 ultimately converts to oxide cluster (CoOx) containing six oxygen coordinated Co as the basic unit which is the true catalytic center to promote high OER activity. The density functional theory (DFT) calculations verify the in-situ generated CoOx consisting of di-μ-oxo Co-Co motifs in CoO6 octahedral clusters as the actual active sites. Our results also provide insights to design other transition metal X-ides (X: C, P, N, S, etc.) as efficient electrocatalysts that experience a similar restructuring in OER.

2:05 PM EN10.03.04
Tuning Metal Nanoparticle Exsolution on Perovskite Surface with Strain-Modified Point Defect Formation Jiayue Wang[1], Jing Yang[1], Alexander K. Opitz[1,2] and Bilge Yildiz[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Technische Universität Wien, Austria

A central theme in renewable energy technologies today is to design nanostructured catalysts at the solid/gas and solid/liquid interfaces towards desired reactions. A recent advance in materials for electrochemical energy and fuels conversion is to synthesize oxide supported metal nanoparticles in a process termed “exsolution”. Exsolution generates stable and catalytically active metal nanoparticles via phase precipitation out of a host oxide. Unlike traditional nanoparticle infiltration techniques, the nanoparticle catalysts from exsolution are anchored in the parent oxide. This anchored structure makes the exsolved nanoparticles more resistant against particle agglomeration as compared to the infiltrated ones. As a promising technique, exsolution has now been successfully implemented to produce stable supported nanoparticle catalysts in a wide range of applications, including H_2O and CO_2 splitting, three-way catalysts, solid oxide fuel cells, and ceramic membrane reactors.

The current exsolution studies typically report metal nanoparticles of 10s of nm size and separation of 10s-100s of nm. While the obtained improvement in reaction kinetics is already promising, there is *plenty of room at the bottom* to increase the density and dispersion of exsolved nanoparticles to achieve higher catalytic activities. In this work, we propose that point defect formation in the oxide lattice to be the fundamental knob to control exsolution and demonstrate this approach in epitaxial $La_{0.6}Sr_{0.4}FeO_3$ (LSF) thin films. By quantifying surface defect states with ambient pressure X-ray spectroscopy (APXPS), we identify the initial oxygen vacancy formation and the following Schottky defect formation as the primary defect reactions in exsolution. Then, by tuning the formation energy of these two defects in LSF with biaxial lattice strain, we examined their impacts on metallic iron (Fe^0) exsolution. Lattice strain tunes the formation energy, and thus, the abundance of these defects, and alters the amount and size of the resulting exsolution particles. As a result, the LSF surface that has more of these point defects, also has the highest Fe^0 concentration, the largest particle density, as well as the finest particle size. Finally, with the aid of density functional theory (DFT), and Monte Carlo (MC) calculations, we suggest surface oxygen vacancy clusters to be the nucleation sites for the exsolved particles. These observations highlight the critical role of surface point defects in controlling the size and density of the exsolved nanoparticles on the perovskite surfaces.

2:20 PM EN10.03.05
Probing the Initial Stages of Iron Surface Corrosion Using AP-XPS Chathura de Alwis[1], Mikhail Trought[1], Slavomir Nemsak[2], Ethan J. Crumlin[2] and Kathryn A. Perrine[1]; [1]Michigan Technological University, United States; [2]2Advanced Light Source, Lawrence Berkeley National Laboratory, United States

Iron-based materials, prevalent in steel infrastructures as well as soils and minerals, participate in chemical reactions in the water cycle. Iron surfaces undergo corrosion, an electrochemical redox process, with oxidation of the iron anode and the cathodic reaction driven by O_2 and water. The surface corrosion occurs in ambient

conditions and in complex environments, where ions are known to catalyze the rate of oxidation. Metallic iron readily transforms in the presence of water and O_2 to form a complex mixture of iron oxides, hydroxides and oxyhydroxides, known as rust. Therefore, to understand the surface processes and changes in oxidation states, decreasing the reaction rate is required to measure factors on the surface oxidation mechanism.
Ambient pressure X-ray photoelectron spectroscopy (AP-XPS) was used to measure surface oxidation of iron. An iron substrate with and without NaCl, was exposed to varying partial pressures of O_2 and H_2O vapor. The O1s, C1s, Fe2p, Na2s, and Cl2p regions were analyzed in comparison to the pristine iron surface. The evolution of oxide species in the O1s and C1s regions were observed with increasing O_2 pressure, which we interpreted as an irreversible formation of carbonates and bicarbonates at the surface. The results were corroborated by the lab-based *ex situ* XPS following the air exposure. Combination of the experiments helped to understand the fundamental steps of oxidation and the role of O_2 for changing surface composition in the corrosion reaction. The ions from NaCl play a significant role in surface oxidation, during the initial stages of surface corrosion, impacting surface chemistry in energy processes, mineral cycling and material degradation.

2:25 PM EN10.03.06
Valence Band Spectra Reveals Phase Transformations of Fe_3O_4(001) During Ambient Pressure Reduction and Oxidation Mikhail Trought[1], Slavomir Nemsak[2], Ethan J. Crumlin[2] and Kathryn A. Perrine[1]; [1]Michigan Technological University, United States; [2]Lawrence Berkeley National Laboratory, United States

Iron oxide surfaces play a significant role in catalytic reactions such as water splitting, the Haber process, and in mineral cycling in naturally-occurring environmental processes. These processes rely on the change of the oxidation state of the iron oxide surface by oxidation-reduction reactions. Many of these transformations occur in the high-pressure regime, which makes these reactions difficult to investigate at the atomic level due to extraneous factors affecting the surface at the equilibrium/reactive conditions. However, it is still important to identify the phase transformation of iron oxide materials *in situ* during these processes.
In this study, iron oxide surface transformations are investigated using ambient pressure - X-ray photoelectron spectroscopy (AP-XPS). The Fe_3O_4(001) surface was exposed to reducing and oxidizing conditions by dosing hydrogen and oxygen gases, respectively at various temperatures and pressures. AP-XPS was used to measure changes in the surface electronic structure and oxidation states of the Fe_3O_4(001) surface near ambient pressure conditions in the Fe 2p, O 1s, and valence band regions. The shape of the valence band spectra was used to track changes in the surface electronic structure during the reactions. These studies suggest that Fe_3O_4(001) reduces when annealed in ultra-high vacuum and exposed to H_2 and upon oxidation, Fe_2O_3 is produced. These experiments are compared with α-Fe_2O_3(0001) that reduces to Fe_3O_4 when annealed in ultra-high vacuum. This study gives an important insight to the *in situ* surface redox chemistry and phase transformations of iron oxide surfaces relevant for catalytic and environmental processes.

Tuning the Catalyst Microenvironment for CO_2 Gas-Diffusion Electrolysis Xiaofeng Feng; University of Central Florida, United States

Electrochemical reduction of CO_2 provides a promising route for sustainable production of fuels and chemicals such as multi-carbon hydrocarbons and oxygenates. While most efforts are focused on developing catalytic

materials for CO_2 electroreduction, it is also critical to understand other factors beyond catalytic materials such as the local environment of the catalysts, which can mediate the transport and local concentration of reaction species and influence reaction pathways. Here we present our recent study of catalyst microenvironment for CO_2 electroreduction in flow cells with gas-diffusion electrodes (GDEs). For proof-of-concept, we use commercial Cu nanoparticles and homogeneously disperse polytetrafluoroethylene (PTFE) nanoparticles in the catalyst layer, which created a hydrophobic microenvironment of the Cu catalysts. The Cu/C/PTFE electrode showed a significant improvement in the activity, Faradaic efficiency, and C_{2+} product selectivity for CO_2 reduction compared to a regular Cu/C electrode without added PTFE. Moreover, the CO_2 reduction activity on the Cu/C/PTFE electrode increased with the CO_2 gas flow rate, suggesting a gas-phase transport of CO_2 inside the catalyst layer. The improved performance is attributed to the reduced diffusion layer thickness that accelerates CO_2 mass transport, increases the local concentration of CO_2 near the catalyst surface, and enhances CO_2 adsorption for the reaction. Compared to regular GDEs, the electrode with added PTFE creates a balanced gas/liquid microenvironment and solid-liquid-gas interfaces inside the catalyst layer, which can enhance the mass transport and kinetics of CO_2 electrolysis, providing a general approach to improve gas-involving electrocatalysis.

Spatially Resolved Analysis of Degradation in Polymer Electrolyte Fuel Cells and Novel Electrode Designs for Improved Efficiency of Polymer Electrolyte Water Electrolysis Severin Vierrath and Matthias Breitwieser; Universität Freiburg, Germany

Fuel cells and electrolysis based on a polymer electrolyte membrane (PEM) are key technologies for a hydrogen society to produce green hydrogen, store large amounts of energy or electrify heavy-duty vehicles. However, durability and efficiency of the membrane electrode assembly is still a major focus of research. This talk gives two examples on investigating ageing phenomena in a fuel cell electrode. The first examines carbon corrosion in the electrode via Focused-Ion-Beam (FIB) tomography, showing that the major mechanism of this degradation phenomenon is loss of active catalyst [1]. In the second investigation, the polymer degradation in the membrane is studied via Raman, showing that the polymer degradation is favored on the anode side [2].
The second part of the talk deals with reducing the iridium catalyst loading in the anode of PEM water electrolysis. In the effort of reducing the catalyst, a major problem arises in the in-plane conductivity of the electrode, which leads to poor efficiencies [3]. Two alternatives are presented, which counter this problem by increasing the electrical conductivity. Employing a nanofiber interlayer enabled an 80% reduction of catalyst material without compromising efficiency or durability[4]. In the second more simplistic approach, blending the polymeric binder in the electrode with PEDOT:PSS, an electronically conductive polymer, yielded a similar effect [5].

Late News: Variable Temperature Raman Spectroscopic Analysis of the Formation of Harmful Defects in Photoanodes During Synthesis Rodney Smith; University of Waterloo, Canada

Semiconducting photoelectrodes may possess numerous types of structural defects, with each exerting influence over material properties and photoelectrochemical performance. We previously demonstrated that Raman spectroscopy can identify distortions within the crystal lattice of hematite electrodes that were synthesized by the annealing of lepidocrocite. The distortion inhibited photoelectrocatalysis and was tentatively attributed to protohematite, a form of hematite where hydroxyl ligands are trapped within the crystal lattice. Here, the mechanism of hematite formation while annealing lepidocrocite is probed through *in-situ* variable temperature Raman spectroscopy and conventional thermal analysis. Results show a branching pathway, where protohematite forms between 200 and 400 °C in a reaction environment-dependent fashion. Once formed, the protohematite is remarkably persistent and harmful to photoelectrocatalysis. These results demonstrate a powerful method to study solid state phase transitions and provide insight into the formation of a harmful defect in hematite photoanodes that was previously not considered.

5:05 PM EN10.04.04
Modulation of Surface Electronic States in Ferroelectrics for Enhanced Hydrogen Evolution Activity
Pedram Abbasi, Tod A. Pascal and David Fenning; University of California, San Diego, United States

Traditionally, catalysts are limited by adsorbate-surface interactions that lead to a "volcano" behavior of activity as a function of binding energy, qualitatively described by the Sabatier principle. Thus one of the grand challenges in modern catalysis is the rational design of systems that can surpass this optimum. Ferroelectric perovskites are an interesting class of nanomaterials since they can present two distinct chemical surfaces depending on the polarization direction. This dual presentation potentially frees catalyst design from the constraints of a simple Sabatier framework, where on any single catalytic surface the adsorbates involved in the reaction must bind neither too weakly nor too strongly. Here we demonstrate a polarization-dependent electrochemical performance of ferroelectric $BaTiO_3$ (BTO) thin films for the hydrogen evolution reaction (HER).

A combination of detailed surface sensitive, core-level spectroscopy and first-principles computation are used to gain insight into the catalytic effects of a change in the polarization state of the BTO. The model BTO catalyst is grown by molecular beam epitaxy and exhibits an excellent ferroelectric response in Piezo-force microscopy (PFM) and polarization-filed (P-E) hysteresis measurements. We use electrochemical poling to control the polarization direction of the single-crystal thin film, enabling sensitive measurements of the catalytic surface in both up and down polarization states. Angle-resolved X-ray photoelectron spectroscopy and Ultra-violet Photoelectron spectroscopy reveal a lower work function and high valence band density of states at the surface of BTO when poled up.
These measurements are complemented by density functional theory (DFT) calculations, employed to gain insights into the localized density of states in BTO slabs, as well as the effect of polarization switching on the HER reaction barriers. Our calculations demonstrate that upward polarized samples have a higher density of electrons near the solid-electrolyte interface and predict a lower barrier for proton adsorption as the rate-limiting step for HER reaction. Experimentally, we observe a higher exchange current density on the upward polarized BTO, consistent with the first-principles result.

By leveraging model single-crystal thin film catalysts in experiments with well-defined polarization, we gain insights into the effects of ferroelectric polarization at the catalytic surface, paving the way for further development of ferroelectric-enhanced electrocatalysis.

Transformation, Reaction and Organization at Functional Interfaces for Sustainable Energy Systems Using Microreactor-Assisted Nanomaterial Deposition Process Chih-Hung Chang; Oregon State University, United States

Microreactor-Assisted Nanomaterial Deposition (MAND) process combines the merits of microreaction technology and chemical synthesis of nanomaterials. This technique uses continuous flow microreactors for the synthesis, assembly, and deposition of nanomaterials. In synthesis, microreactor technology offers large surface-area-to-volume ratios within microchannel structures to accelerate heat and mass transport. This accelerated transport allows for rapid changes in reaction temperatures and concentrations, leading to more uniform heating and mixing in the deposition process. The possibility of synthesizing nanomaterials in the required volumes at the point-of-application eliminates the need to store and transport potentially hazardous materials while providing new opportunities for tailoring novel nanostructures. MAND processes control the heat transfer, mass transfer, and reaction kinetics using well-defined microstructures of the active unit reactor cell that can be replicated to produce higher chemical production volumes. This critical feature opens a promising avenue in developing scalable nanomanufacturing. Furthermore, the continuous flow microreactor opens up the opportunity to conveniently assemble unique nanostructures and nanostructured thin films. There are many innovative solution-based routes towards syntheses of nanomaterials. The majority of these syntheses, however, were carried out using small-batch reactors. Results-to-date demonstrates the possibility to control the reacting flux, including small intermediate-reaction molecules, nanoclusters, nanoparticles, and structured assembly of nanomaterials.
I will discuss recent progress in using continuous microreactors to control the chemical transformation, reaction, and organization of functional nanomaterials and the applications of these functional nanomaterials for sustainable energy systems (e.g., solar photovoltaics). There is a significant opportunity to improve all solar PVs to maximize annual energy yield and increase service lifetime by engineering the interface. First, a portion of the light is reflected when light encounters an abrupt change in the refractive index. Thus, it is essential to reduce reflection for improving efficiency. Besides, the accumulated mass (i.e., soils, dust, pollutants, and air particles) on a cover can significantly reduce the power output of a solar PV module ranges from 1% to as much as 70% in some areas without cleaning. One way to mitigate the soiling effect is to regularly clean the solar arrays, which increase the LCOE and requires water. We have investigated the use of MAND to control the interfaces on installed solar modules in the field to mitigate these issues.

6:55 PM EN10.05.02
Durable and Washable Paper-Based Electronics for Wearable Applications Su Yang, Xiaoming Tao, Su Liu and Xujiao Ding; Hong Kong Polytechnic University, China

Nowadays wearable electronics are playing a more and more important part in daily life. Therein, paper-based electronics stand out by virtue of various advantages like low-cost, lightweight, and high flexibility. Nevertheless, it is still challenging to achieve long-term use of paper-based electronics due to their poor electromechanical durability and washability. This work adopts a novel high-performance polyimide paper as substrate and compact parylene encapsulation as a protective and reinforced layer, simultaneously enhancing electromechanical durability and machine-washability for the first time. The result shows parylene-encapsulated PI paper-based electronics show greatly electromechanical performance, abrasion resistance, bending durability, and outstanding machine washability. Moreover, such paper-based electronics demonstrates outstanding stability over different harsh environments. With 1D circuit board assemblies design and fabrication, the resultant electronic yarns are easily integrated into fabrics for wide wearable applications. Such water-resistant

paper-based electronics show great feasibility for wearable applications other than dry disposable electronics.

7:10 PM EN10.05.03
Development of Polymer Nano-Composite Based Aerogels via Supercritical Drying Ying Mu, Xiaoli Li and Marilyn L. Minus; Northeastern University, United States

Since the development of aerogels in the 1930s, they have attracted much attention due to their unique porous structure and lightweight properties. Such structures are useful for many applications including thermal and sound insulation, energy storage, waste-water treatment, and flame retardant materials. To date, silica-based aerogels have dominated the industry and research interests, although, while limited, some polymeric-based materials exists. More recently, polymer-based aerogels have drawn much attention, but to date have primarily been processed via freeze drying methods. While this method is more tunable for polymer-based aerogels, the resultant morphology and properties are inferior to aerogels processed using super critical drying (SCD). In this work, SCD process optimization and process-structure-property studies on polymer nano-composite based aerogels will be presented. The mechanisms of solvent exchange and diffusion during gel and aerogel processing will also be investigated and discussed. Boron nitride nanotubes (BNNTs) have been chosen as a filler candidate for these composite aerogels due to their lightweight, oxidative, structural, and radiation shielding properties. Current work has shown that the composite precursor gels exhibit enhanced mechanical and thermal performance. To this end, a fundamental study regarding these materials will be presented and include multi-scale characterization results and analyses.

7:25 PM EN10.05.04
Ultrasensitive Electrochemical Sensors Based on van der Waals Materials Fujia Zhao, Shan Zhou and Yingjie Zhang; University of Illinois at Urbana-Champaign, United States

Dissolved oxygen (DO) and hydrogen peroxide are important indicators of water quality. Hydrogen peroxide is also widely used in water and pollutant treatment as an excellent oxidizer. Thus, an aqueous oxygen and hydrogen sensor with high sensitivity, rapid response and good selectivity is in high demand. However, previously reported sensors, which are mainly based on enzymes, noble metals or metal oxides, have drawbacks of either high cost or weak response. Here, we introduce a novel electrochemical sensor based on van der Waals materials. Our sensors exhibit ultrahigh sensitivity and low detection limit for oxygen and hydrogen peroxide detection, outperforming typical noble metal-based electrochemical sensors. Through electrochemical kinetic analysis and simulations, we quantify the reaction kinetics and find that the high performance can be attributed to the facile charge transfer at the electrode-aqueous solution interface.

7:40 PM EN10.05.05
Conceptualization, Proof-of-Concept and Material Challenges of the Brayton Electrochemical Refrigeration Cycle Aravindh Rajan; Georgia Institute of Technology, United States

One path towards mitigating the global warming consequences of the rising global cooling demand is the search for alternative refrigeration technologies. We have identified one such technology that has electrochemical origins and remains to be experimentally demonstrated. The entropy of carefully chosen cathodic and anodic reactions may be utilized to induce refrigeration by employing them in either Brayton or Stirling type cycles. In this work, the concept of the Brayton Electrochemical Refrigeration (BECR) cycle will be first introduced. This will include an overview of the working of the system, the governing material properties and operating parameters, and predictions of its performance. Then, the development and results of the experimental proof-of-concept of the BECR cycle will be discussed. Finally, the material level challenges to a commercial product will be discussed. Arguments will be made as to why the commonly leveraged solvation entropy is not a promising pathway to commercialize the BECR cycle and thermally regenerative electrochemical systems in general. A less explored alternative mechanism of entropy change is proposed.

7:55 PM EN10.05.07

Realization of Entire Substrate Area Selective Emitters via Thin Film Interference Minsu Oh, Emily Carlson and Thomas Vandervelde; Tufts University, United States

Selective thermal emitters have attracted researchers due to their utility in applications such as gas sensing or thermophotovoltaic (TPV) energy harvesting. Depending on the application, the desired emission spectrum of an emitter can vary. For example, in TPV applications, a broadband emitter can increase the output power density of the diode at the cost of lower energy conversion efficiency due to excess energy in higher energy photons being lost to thermalization of the carriers. Meanwhile, a narrowband emitter can improve the conversion efficiency via reduced thermalization of the diode, resulting in lowered output power density. A narrowband selective emitter designed with its absorption energy spectrum placed just above the bandgap could also be paired with a TPV diode for cases where the diode heating needs to be minimized. For this reason, a balance between the output power density and conversion efficiency is needed for the optimal performance of a TPV system. As such, one of the approaches to optimizing a TPV system's performance is utilizing a selective emitter with multiple narrowbands and stacking of a number of TPV diodes whose bandgaps correspond to the different peak emission wavelengths of the emitter. Photonic crystals (PhCs)/metamaterials (MMs) have been used to create selective emitters with different peak emission wavelengths and bandwidths. However, most PhC/MM emitters are limited to a single band emission spectrum, and only a few MMs have been reported with a multiband emission spectrum. Moreover, PhC/MM emitters that work at shorter wavelengths such as the visible or near-/mid-infrared are based on nanometer scale feature sizes where it is challenging to write the pattern over a large area and fabrication imperfections can lead to lowered performances. The thermal stability of a nano-patterned emitter could also decrease at high temperatures. In this work, we report multiband selective emitters that are built with a planar, thin layer of a dielectric material deposited on top of a metallic layer. The multiple emission bands of these emitters directly result from the inteference fringes in reflectance, as the transmittance of the structure is zero over the wavelength spectrum studied. The peak emission wavelengths of these emitters can be tuned by varying the thickness of the dielectric layer due to the dependence of reflectance on the film's thickness. Compared to PhC/MM emitters, the thin-film emitters reported here do not need nano/micro patterning, which makes the fabrication process longer and more complicated, and can be fabricated over the entire area of the substrate with ease. Therefore, we believe that our work can provide a path forward for optimizing thermal applications such as TPV energy harvesting via selective emitters with a large working area, fabrication ease, and multiple emission bands.

Entropy-Maximized Materials for Electrocatalysis Applications Sheng Dai[1,2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, United States

Until recently the design and synthesis of heterogeneous catalysts have been dominated through enthalpic factors (e.g., charge-charge interactions, charge-transfer interactions). With emergence of high entropy materials (HEMs), another avenue to design and synthesize catalytic materials has opened up. The definition of HEMs is any material that consists of the solid solution of more than five components that allow great flexibility in tuning surface compositions and interfacial functionalities. Here we present the synthesis of high entropy electrocatalysts that potentially outperform the traditional catalysts in energy-related catalysis reactions. The synthesis strategies through entropy maximization will be discussed.

9:25 PM *EN10.06.02
Chemical Design of Colloidal Copper-Based Nanorod Electrocatalyst Xingchen Ye and Soojin Jeong; Indiana University Bloomington, United States

In this talk, I will discuss our recent progress on the development of heterometallic seed-mediated synthesis for monodisperse penta-twinned Cu nanorods using Au nanocrystals as seeds. The nanorod aspect ratio can be readily adjusted from 2.8 to 13.1 by varying the molar ratio between Au seeds and Cu precursor, resulting in narrow longitudinal plasmon resonances tunable from 762 to 2201 nm. The growth pathway features coevolving shape and composition whereby nanocrystals become progressively enriched with Cu concomitant with nanorod growth. The nanorods possess active surface sites for the high-rate electrochemical reduction of carbon dioxide into liquid fuels.

9:50 PM EN10.06.03
Transition Metal Sulfide-Based Electrocatalysts for Water Oxidation Reaction Brian Muhich and Zhenxing Feng; Oregon State University, United States

Water splitting reactions represent a promising future avenue for clean energy storage and fuels, and the development of inexpensive and commercially friendly electrocatalysts is essential for the widespread utilization of such processes. Oxygen evolution reaction (OER), also known as water oxidation reaction, is a key component of the overall water splitting reaction, and currently, the most effective catalysts for OER are RuO_2 and IrO_2. Due to the scarcity of noble metals like Ru and Ir, effective catalysts composed of more abundant transition metals are desired. Among these transition metal catalysts, (Ni, Co)S materials have shown significant promise as effective OER catalysts. In this project, we explore the enhanced OER activity through the use of (Ni, Co)S catalysts and also explore different means by which to optimize these catalysts through different NiCo compositions. Through the use of electrochemical tests, we have observed favorable reaction kinetics at higher concentrations of Co and lower overpotentials at higher concentrations of Ni, with good stability overall. We attribute these characteristics to the *in-situ* development of NiOOH active sites and the higher conductivity of Co. This work provides insights in the development of efficient and noble metal free OER electrocatalysts based on the optimization of transition metal compositions, and future physical characterization can advance our understanding of a catalyzed water splitting mechanism and the development of chemically stable electrocatalysts.

CeO_2-TiO_2 Nanoparticle—Nanorod Heterojunction for Efficient Photoelectrochemical Water Splitting Sutapa Dey and Somnath C. Roy; Indian Institute of Technology Madras, India

Limited fossil fuel reserves and green house emissions have driven intense research activities over the past few decades on the development of clean and renewable energy sources. Hydrogen is one such source with a high gravimetric energy density and the combustion of which does not generate carbon contained products. However, hydrogen needs to be generated from sources such as water or hydrocarbons, and such processes become viable only when input energy is supplied through renewable sources. Photoelectrochemical (PEC) water splitting is such a suitable pathway to generate hydrogen from water using solar energy. In this process, a semiconductor based material generates electron-hole pair by harvesting solar energy, which paves the way to produce hydrogen mediated by chemical reactions through decomposition of water. However, in spite of about 50 years since its discovery by Fujishima and Honda, PEC water splitting remains a challenging task because of a lack of suitable material. In general, metal oxide such as Titanium dioxide (TiO_2) acts as an excellent photocatalyst material[1], but suffers from limited light absorption window (in ultra violet region which is only 5% of full solar spectrum) and relatively higher recombination of the photogenerated charges. In this regard , CeO_2, a rare earth metal oxide with a more negative conduction band position and lower band gap is one of the most efficient companion of TiO_2 leading to suitable band alignment in a CeO_2-TiO_2 heterojunction[2]. Moreover, CeO_2 shows visible light sensitivity and good electron transfer ability mediated by its variable Ce valences such

as Ce^{3+} and Ce^{4+}, high capacity for oxygen storage, capture and release and high thermal stability[3]. Here we demonstrate that by using TiO_2 nanorods functionalized with CeO_2 nanoparticles, photocurrent density enhances 3 times over that obtained from the bare TiO_2 nanorods. The TiO_2 nanorods are fabricated on FTO coated glass substrates by hydrothermal technique. The size and distribution of the CeO_2 nanoparticles grown over these nanorods can be precisely controlled by optimizing the deposition/growth parameters and at an optimum condition, an effective heterojunction forms enabling easy transfer of photogenerated charges. This is also confirmed by Electrochemical Impedance Spectroscopy (EIS), where lowest charge transfer resistance is observed for CeO_2-TiO_2 heterojunction photoanodes. Further, Applied Bias Photo-to-current Efficiency (ABPE %) shows a 2.52 times enhancement for the heterojunctions compared to that of bare TiO_2 nanorods. In addition to expected effect of heterojunction in assisting charge separation, visible light absorption by CeO_2 (marked by a 50 nm red-shift in the absorption spectra) also helps in achieving better performance in the PEC operation. We conclude that such heterojunctions made with all oxide components (CeO_2 and TiO_2) may serve better for PEC applications by virtue of their chemical stability under aqueous media. The results of this work with extensive details will be presented.

D–Band Contraction of Metal Nitride Nanosheets for Highly Efficient and Stable Electrochemical Oxidation of Ammonia Shi He, Yufeng Cheng, Mengdi Wang, Peter Novello, Siyuan Zhu and Jie Liu; Duke University, United States

Ammonia is a promising hydrogen carrier as it reduces the cost of long–range transportation of hydrogen. Ammonia electrolysis provides a convenient method to extract hydrogen from ammonia at end users. However, the conventional platinum carbon electrode suffers from fast degradation and electrode fouling at electrode–electrolyte interface during the ammonia electrochemical oxidation〈AOR〉. Here, we report that nitriding electrochemical deposited nickel cobalt layered double hydroxide nanosheets can achieve high electrocatalytic activity for AOR in non–aqueous solution. The AOR onset overpotential of $NiCo_2N$ nanosheets is 0.55 V which is about 0.25 V lower than that of the platinum carbon electrode. Ultraviolet–visible and Mass spectroscopy studies reveal $NiCo_2N$ nanosheets can suppress the formation of metal amine complex and preferentially oxidize ammonia to N_2 with a faradic efficiency of over 90 percent. DFT calculation indicates that the downshift of the metal d–band center on $NiCo_2N$ nanosheets surface accelerated the generation of NH^+_X cations and desorption of final N_2*, boosting ammonia electrochemical oxidation toward N_2. Overall, this work introduces a practical strategy for synthesizing an active and stable electrocatalyst for AOR.

A p-type Transparent Conducting Oxide with 2D Superconductivity Akira Ohtomo and Takuto Soma; Tokyo Institute of Technology, Japan

We report on epitaxial synthesis, excellent p-type transparent conductivity, and two-dimensional superconductivity of the layered lithium niobate [1]. The superconducting films were prepared through the following three steps. Amorphous films of the stoichiometric $LiNbO_2$ were first deposited on (111) spinel substrates, and then heated to high temperatures for obtaining highly crystalline epitaxial films. A fraction of Li ions were removed from the films by immersing in an iodine solution so that the equivalent amount of hole carriers were introduced. The obtained films showed superconductivity below 4.2 K, and averaged transmittance to the visible light of 77% despite large number of hole carriers. Moreover, we found that the normal-state conductivity and the transmittance simultaneously increased with increasing hole carriers. This behaviour is unusual because higher conductivity usually leads to larger free-carrier absorption. We explained it in terms of strongly correlated electrons at the largely isolated Nb $4d_{z2}$ band. The two-dimensional superconductivity in $Li_{1-x}NbO_2$ will be briefly discussed in terms of the observed BKT transition and the electronic phase diagram that was established by electrochemical doping experiments [2].

8:25 AM *NM01.01.02
High Temperature Superconductivity in Monolayer Cuprates Yuanbo Zhang; Fudan University, China

The two-dimensional CuO2 plane plays a fundamental role in the physics of cuprates. Indeed, cuprates (and all other families of high temperature superconductors) adopt a layered atomic structure. In BSCCO, the weak van der Waals interaction between adjacent bismuth-oxygen layers makes the crystal easily cleavable, making atomically-thin BSCCO an ideal system for investigating high temperature superconductivity in the two-dimensional limit. By fabricating samples in an inert atmosphere, we are able to obtain half-unit-cell-thick single crystals (referred to as monolayer) of BSCCO samples and to probe the evolution of superconductivity as the dimensionality is reduced. We probe the electronic structure of monolayer Bi2Sr2CaCu2O8+δ (Bi2212) and Bi2Sr2CuO6+δ (Bi2201) with electronic transport measurements, as well as scanning tunneling microscopy (STM) and scanning tunneling spectroscopy (STS) techniques.

Local Moment Pairing in the Heavy-Fermion Superconductor $CeCoIn_5$ Laura Greene; Florida State University, United States

The heavy-fermion superconductor $CeCoIn_5$ has a pairing symmetry of $d_{x^2-y^2}$ but the pairing mechanism

remains unknown. Our planer tunneling spectroscopy measurements on single crystals into the three major crystallographic orientations as a function of temperature down to 20 mK and fields up to 18 T are reproducible, and our diagnostics show transport across the barrier is predominately single-step elastic tunneling. [1] At low temperatures, on the (100) and (001) faces, we find sharp coherence peaks with an estimated gap of 0.65 meV, and on the (110) face, a broad zero-bias peak. Previously published STM work reports observing pair potentials above $T_c = 2.3$ K [2]; we also find pre-formed pairs up to $T_p \sim 5$ K. Below T_p, with increasing applied field, the pairing gap evolves smoothly to a field-induced gap, that grows linearly up to 18 T, the highest field measured. At higher temperatures, no field-induced gap is observed, showing that pairing and the field-induced gap exist concomitantly. Kondo scattering plays a role in the pairing mechanism, and omposite pairing remains a possible explanation. [3]

9:15 AM NM01.01.04
Cavity Probes and Control of Antiferromagnetic Fluctuations in a Mott Insulator Jonathan Curtis[1], Andrey Grankin[2], Nicholas Poniatowski[1], Prineha Narang[1], Victor Galitski[2] and Eugene Demler[1]; [1]Harvard University, United States; [2]University of Maryland, United States

Using THz electromagnetic cavities to probe and control correlated phases of matter has recently seen a surge in activity, in large part due to remarkable advances in experimental techniques. Some of the most interesting compounds from this point of view are the cuprate high-temperature superconductors and their Mott-insulating parent compounds, which often exhibit long-range antiferromagnetic order. In this work, we present a mechanism by which the electromagnetic field of such a THz cavity can be coherently coupled to the quantum fluctuations of this antiferromagnetic order in a simplified model of an undoped cuprate. In addition to the direct magnetic-dipole interaction between the electromagnetic field and the local moments, we also consider a more elaborate coupling which exploits spin-orbit effects to produce coupling between the antisymmetric spin-exchange interaction and the electric field. Within linear spin-wave theory, we show how these terms can lead to the formation of Neel magnon-polariton resonances, as well as allow for optical parametric driving of spin-waves in the insulating phase. We identify clear experimental signatures to look for and argue these are within experimental reach. Finally, we conclude by speculating on what happens once the system is hole-doped with charge carriers, in light of our outlined coupling scheme.

9:30 AM NM01.01.05
Ultra-High Critical Current Density at the Quantum Critical Point of $YBa_2Cu_3O_{7-d}$ Superconducting Thin Films Teresa Puig[1], Alex Stangl[1], Anna Palau[1], Guy Deutscher[2] and Xavier Obradors[1]; [1]Insititut de Ciencia de Materials de Barcelona-CSIC, Spain; [2]Tel Aviv University, Israel

Doping is one of the most relevant paths to tune the functionality of cuprates, it determines carrier density and the overall physical properties of these impressive superconducting materials. We present an oxygen doping study of $YBa_2Cu_3O_{7-d}$ (YBCO) thin films from underdoped to overdoped state, correlating the measured charge carrier density, n_H, the hole doping, p, and the critical current density, j_c. Our results show a continuous increase

of j_c with charge carrier density, reaching 90 MA/cm^2 at 5 K for p-doping at the Quantum Critical Point (QCP), linked to an increase of the superconducting condensation energy. The ultra-high j_c achieved corresponds to a third of the depairing current, i.e. a value 60% higher than ever reported in YBCO films. The overdoped regime is characterized by a sudden increase of n_H, associated to the reconstruction of the Fermi-surface at the QCP. Pulsed laser and chemical solution deposited films have been studied. Overdoping YBCO, therefore, opens a promising route to extend the current carrying capabilities of REBCO coated conductors for applications.

Late News: Electrochemically-Induced Insulator-Metal Transition in Ionic-Liquid-Gated NiS2 Single Crystals Sajna Hameed, Bryan Voigt, William Moore, John Dewey, Bhaskar Das, Bing Luo, Nicholas Seaton, Chris Leighton and Martin Greven; University of Minnesota Twin Cities, United States

Motivated by the existence of superconductivity in pyrite CuS_2 [1], we explore the possibility of ionic-liquid-gating-induced superconductivity in the related antiferromagnetic Mott insulator pyrite NiS_2. A clear gating-induced insulator-metal transition is observed, with progressively decreasing low temperature sheet resistance with increasing positive gate bias. We deduce an electrochemical gating mechanism through formation of S vacancies, however, which is entirely non-volatile and irreversible. This is in striking contrast to the completely reversible, volatile electrolyte-gating-induced insulator-metal transition in pyrite FeS_2 [2]. We attribute the difference in behaviors to the much larger S diffusion coefficient in NiS_2 compared to FeS_2 [3,4], analogous to the situation in electrolyte-gated oxides [5].

10:30 AM *NM01.02.01
Higher T_cs Beyond That Predicted by the Universal T_c-Dopant Relation Paul C. W. Chu[1,2], Liangzi Deng[1], Yongping Zheng[3], Zheng Wu[1], Shuyuan Huyan[1], Hung-Cheng Wu[1], Yifan Nie[3] and Kyeongjae Cho[3]; [1]University of Houston, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]The University of Texas at Dallas, United States

Achieving higher transition temperature (T_c) is a primary goal in superconductivity research. T_c and doping have been found to have a dome-like universal relation where the peak position is the maximum T_c ($T_{c\text{-}max}$), which is consistent with previous experimental results in the lower pressure range. By using our newly developed ultra-sensitive magnetization measurement technique under high pressure, we have discovered a universal resurgence of T_c passing the peak predicted by the general T_c-*p* (doping) or -P (pressure) relation for the BSCCO cuprate high temperature superconductors and have attributed the resurgence to a pressure-induced

electronic transition, which is supported qualitatively by our density functional theory calculations. This offers a new path to raise the T_c of the layered cuprate high temperature superconductors to a new height.

We have investigated the bulk superconducting state *via* dc magnetization measurements by deploying our newly developed HP-DAC/MPMS technique. We discovered a common resurgence of the T_cs of the monolayer $Bi_2Sr_2CuO_{6+\delta}$ (Bi2201) and the bilayer $Bi_2Sr_2CaCu_2O_{8+\delta}$ (Bi2212) to beyond the respective $T_{c\text{-}max}$s predicted by the universal relation between T_c and p or P at higher pressures. The T_c of underdoped Bi2201 initially increases from 9.6 K at ambient to a peak at ~ 23 K at ~ 26 GPa and then drops as expected based on the universal T_c-P relation. However, at pressures above ~ 40 GPa, T_c rises rapidly without any sign of saturation up to ~ 30 K at ~ 51 GPa. Similarly, the T_c for the slightly overdoped Bi2212 increases after passing a broad valley at 20-36 GPa and reaches ~ 90 K without any sign of saturation at ~ 56 GPa. We have therefore attributed this T_c-resurgence to a possible pressure-induced electronic transition in the cuprate compounds due to a charge transfer between the Cu $3d_{x^2-y^2}$ and the O $2p$ bands projected from a hybrid bonding state, leading to an increase in the density of states at the Fermi level, in agreement with our density functional theory calculations. Similar T_c-P behavior has also been reported previously in the trilayer $Bi_2Sr_2Ca_2Cu_3O_{10+\delta}$ (Bi2223). These observations suggest that higher T_cs than those previously reported for the layered cuprate high temperature superconductors can be achieved by breaking away from the universal T_c-P relation through possible electronic transitions induced by the application of higher pressures.

Temple Foundation, the John J. and Rebecca Moores Endowment, and the State of Texas through the Texas Center for Superconductivity at the University of Houston.

10:55 AM *NM01.02.02
Hot Superconducting Superhydrides Russell Hemley; University of Illinois at Chicago, United States

Realizing superconductivity in the vicinity of room temperature in hydrogen-rich materials under pressure is a topic of great current interest. Specifically, high-pressure experiments motivated by density-functional theory and conventional electron-phonon coupling models have uncovered new classes of hydrogen-rich metal hydrides, or superhydrides, with superconducting critical temperatures (Tc) in the vicinity of room-temperature at megabar pressures (i.e., >100 GPa). Original calculations for the rare-earth hydrides predicted that LaH10 and YH10 would form dense hydride clathrate structures exhibiting Tc's of 257-326 K at pressures of 200-300 GPa.1,2 X-ray diffraction experiments on the La-H system confirmed the formation and stability of the LaH10 structure near the predicted pressures,3 and subsequent electrical conductivity and critical current measurements confirmed the very high-temperature superconductivity of the phase.4,5 Experiments that used ammonia borane (NH3BH3) as the hydrogen source indicated Tc's beginning at 260 K, including conductivity onsets as high as 290 K that have been confirmed in more recent work.6 It was proposed that the high and variable Tc arises from incorporation of N and/or B in the structure from the ammonia borane starting material.5,6 Moreover, in experiments that confirmed the structure7 and high-temperature superconductivity5,6 of LaH10, Drozdov et al.8 reported a slightly lower maximum Tc of 250 K in experiments conducted without ammonia borane. Using methods developed previously and applied to H3S, B and N doping of the La-based superhydride increases the Tc of the material to room temperature. These techniques were also used to examine the doping of C on the superconductivity of H3S. As found for the La-based superconductor, low-level substitution of C for S can fine-tune the Fermi energy to match the peak in the electronic density-of-states peak, thereby maximizing the electron-phonon coupling and boosting the critical temperature from the original 203 K to 289 K at 260 GPa for 4% doping of C for S in H3S.9 The results provide an explanation for the recent experimental observation of room-temperature superconductivity in a highly compressed C-S-H mixure.10 The above findings open new avenues for creating 'hot' hydrogen-rich superconductors with Tc's above room temperature.

Topological States and Transport Properties in Iron Chalcogenide Superconductors Qiang Li[1,2]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

Superconducting iron chalcogenides $FeSe_xTe_{1-x}$ (FST) have attracted a great deal of interest in both fundamental physics and potential applications. While very high upper critical fields make FST an excellent candidate for high-field magnets and energy applications, Majorana zero-modes identified in FST superconductors hold promise for topological quantum computing. In this talk, we discuss multiple topological states and possible broken time reversal symmetry in FST, and their impacts to charge transport, which we studied in both FST single crystals and thin films having a broad range of superconducting transition temperature driven by strain or gating.

11:45 AM *NM01.02.04
Low Temperature Emergence of an Orbital-Selective Mott Phase in $FeTe_{1-x}Se_x$ Ming Yi; Rice University, United States

Electronic correlation is of fundamental importance to high temperature superconductivity. Iron-based superconductors are believed to possess moderate correlation strength, which combined with their multi-orbital nature makes them a fascinating platform for the emergence of exotic phenomena. Previously, it has been reported that iron-chalcogenide superconductors exhibit strong orbital-dependent correlation effects and that by raising temperature they crossover into an orbital-selective Mott phase. Here, we report spectroscopic evidence of the reorganization of the Fermi surface from FeSe to FeTe as Se is substituted by Te. This evolution is observed to be accompanied by a redistribution of the orbital-dependent spectral weight near the Fermi level together with a divergent behavior of a band renormalization in the d_{xy} orbital. All of our observations are further supported by our theoretical calculations to be salient spectroscopic signatures of such a non-thermal evolution from a strongly correlated metallic phase towards an orbital-selective Mott phase in $FeTe_{1-x}Se_x$ as Se concentration is reduced.

12:10 PM NM01.02.05
Nematic Fluctuations in Iron-Based Superconductors $BaFe_2(As_{1-x}P_x)_2$ Zhaoyu Liu, Qianni Jiang, Yue Shi, Zaiyao Fei, Paul Malinowski, Josh Mutch and Jiun-Haw Chu; University of Washington, United States

Nematicity is a many-body quantum phase that breaks rotational symmetry while preserving translational symmetry. It has been discovered in the phase diagrams of both iron-based and cuprate high-temperature superconductors [1-3]. In the iron-based superconductors, the optimal doping of superconducting phase coincides with the putative nematic quantum critical point, suggesting the possibility of superconducting pairing enhanced by nematic quantum fluctuations [2,4]. However, a comprehensive study of the nematic fluctuations is still absent in the $BaFe_2(As_{1-x}P_x)_2$, which exhibits the cleanest signature of quantum criticality among all the iron-based superconductors. In this talk, I will present a detailed study of the nematic fluctuations of $BaFe_2(As_{1-}$

$_xP_x)_2$ using the elastoresistivity measurement. I will also present the study of strain dependence of superconducting Tc, which shed light on the intricate relations between nematicity and superconductivity.

Phase-Dependent Dissipation in SNS Junctions—Topology and Non-Equilibrium Dynamics Meydi Ferrier; Universite of Paris-Saclay, France

An (SNS) junction with two superconductors coupled by a normal metal hosts Andreev bound states whose energy spectrum is phase-dependent and exhibits a minigap, resulting in a periodic supercurrent. However, phase-dependent dissipation also appears due to finite-time relaxation of Andreev bound states, providing an ultra-sensitive tool for the carrier dynamics.
In the weakly driven regime, we have measured dissipation in a phase-biased junction built around a bismuth nanowire, a second order topological insulator which was previously shown to host one-dimensional ballistic edge states. We have found absorption peaks at the Andreev level crossings in accordance with predictions of telltale signs of topological junctions [1,2].
I will also present our most recent results on SNS junctions strongly driven out of equilibrium by microwave field where novel physics emerges due to redistribution of quasiparticles, whose understanding is still incomplete. Strong driving power can significantly modify the distribution function from thermal equilibrium, activating additional transitions. We have measured the evolution of both the supercurrent and dissipation, extracted simultaneously from the ac magnetic susceptibility of a phase-biased graphene-superconductor ring driven out of equilibrium by microwave irradiation [3]. Increasing the frequency beyond the system relaxation rate has several measurable consequences: Firstly, the phase dependence of supercurrent is modified. In particular, the Fourier coefficients dependence on power deviates from the Bessel function expected in the adiabatic ac Josephson effect in qualitative agreement with time-dependent Usadel equations. Secondly and more interestingly, the dissipation with irradiation frequency higher than the minigap shows a distinct enhancement around $j = 0$ where the minigap is the largest and the dissipation is very weak in equilibrium. Using Kubo formalism, we explain this effect by the nonequilibrium distribution function with partial occupation above the minigap permitting transitions between levels on the same side of the minigap (intraband). More generally, our results demonstrate that phase dependent dissipation measurement allows a much deeper understanding of the relaxation mechanisms than supercurrent in superconducting junctions.

2D Platforms for Majorana States and Phase Measurement of Topological Superconductivity Igor Zutic[1], Tong Zhou[1], Jong Han[1], Matthieu C. Dartiailh[2], William Mayer[2], Andrew Kent[2], Javad Shabani[2], Narayan Mohanta[3] and Alex Matos-Abiague[3]; [1]University at Buffalo, The State University of New York, United States; [2]New York University, United States; [3]Wayne State University, United States

Topological transition transforms common superconductivity into an exotic phase of matter, which holds promise for fault-tolerant quantum computing [1]. A hallmark of this topological transition is the emergence of Majorana bound states (MBS), quasiparticles that nonlocally store a single electron. Their non-Abelian

exchange statistics allows for the implementation of quantum gates through braiding operations [1]. While most of the MBS proposals were focused on 1D systems [2], their geometry has inherent difficulties for technological implementation and realizing braiding. MBS detection typically relies on the measurement of zero-bias conductance peak [2,3] that could also arise in topologically-trivial systems. To overcome these challenges, we propose 2D platforms, which could support scalable MBS and their braiding. First we discuss how spin valves, common in spintronics, can be used through their fringing fields [4,5] to proximitize two-dimensional electron gas to implement MBS and their braiding [6,7]. Next we show our measurements of topological superconductivity in epitaxial Al/InAs Josephson junctions [8]. The closing and reopening of the superconducting gap with increasing magnetic field is simultaneously accompanied by the measurement of p-jump in the superconducting phase [8]. Remarkably, this topological transition can be controlled by gate voltage. We propose X-shaped topological junctions [9] in which the observed topological transition can be used to realize scalable MBS and their braiding.

Josephson Coupling Between Topological Superconducting Surfaces Guo-Xing Miao; University of Waterloo, Canada

The proximity effect from superconductors is . Inducing superconductivity on topological insulator surface states through proximity effect is an attractive approach to realize topological superconductivity, and provides great freedom in potential device engineering. Here we aim to look at the coupling between the opposite surfaces of a topological insulator thin film. Using high quality BiSbTe thin films as the tunnel barrier and MgB2 to induce superconductivity, the top and bottom surfaces of the same topological insulator can readily couple between themselves. Other than Josephson coupling between bulk superconductors, one can also identify signatures from the coupling between surface zero-modes, while other modes are largely suppressed due to the opposite spin textures. Interestingly, the edges of the micro sized pillars offer another channel of conductance across the junction. When unfolded, the device is practically equivalent to an in-plane junction with a 1D channel between two topological superconductors and a periodic boundary condition. This circular 1D edge channel can potentially become a host for Majorana-like edge modes on vertical pillar structures.

Controlling Vortex Matter in Superconductors with Nano-Textured Structures Wai-Kwong Kwok; Argonne National Laboratory, United States

Advances in nanofabrication has opened new venues for controlling vortex matter, which is responsible for the electro-magnetic response of all applied superconductors. For example, nano-hole and blind-hole structures with innovative patterns have emerged as a versatile platform for controlling and optimizing vortex pinning and dynamics in superconductors for enhanced critical current. Magnetic field pinning of vortices with nanoscale structures has also shown great potential for in-situ manipulation of vortex behaviour. Moreover, magnetic pinning is relatively temperature independent compared with core pinning. I will present recent highlights of our work on tailoring vortex dynamics with magnetic texturing. Namely, we use nano-magnetic patterned structures based on spin-ice rules to explore the effect of pinning, dynamic rectification and geometric frustration in a flux quanta system. In addition, we demonstrate that magnetic pinning can be used to ‘pin’ vortices in the liquid state in high temperature superconductors.

Late News: An Epitaxial GaN/NbN Heterostructure Exhibiting Concurrent Superconductivity and Quantum Hall Effect Phillip Dang[1], Guru Khalsa[1], Celesta S. Chang[1], D. Scott Katzer[2], Neeraj Nepal[2], Brian Downey[2], Virginia Wheeler[2], Alexey Suslov[3], Andy Xie[4], Edward Beam[4], Yu Cao[4], Cathy Lee[4], David A. Muller[1], Huili Xing[1], David Meyer[2] and Debdeep Jena[1]; [1]Cornell University, United States; [2]U.S. Naval Research Laboratory, United States; [3]National High Magnetic Field Laboratory, United States; [4]Qorvo, Inc., United States

Superconductivity is a phenomenon that allows for lossless electrical transport and exceptional precision in voltage due to flux quantization, while the quantum Hall effect (QHE) is a paragon of topological protection in electronic states that allows for part-per-billion precision in resistance. Creating seamless heterostructures harboring these two unique electronic phases is highly desirable for the discovery new physics as well as the application of these electronic phases to topological quantum computing. Unfortunately, the quantum Hall state and the superconducting state are typically thought to be incompatible because the same magnetic field that creates the quantum Hall state destroys the superconducting state. In this work, we show that by using growth advances to develop a heterostructure of superconducting NbN and a GaN two-dimensional electron gas (2DEG), the two electronic phases can be seen concurrently in the same structure.

The epitaxial nitride structure begins with a 50 nm NbN layer, which is grown on a 3-inch diameter semi-insulating 6H-SiC wafer by plasma-assisted molecular beam epitaxy (PAMBE). We then use metal organic chemical vapor deposition (MOCVD) to grow a 20 nm AlN nucleation layer, a 1.5 μm GaN buffer layer, and an AlN spacer/AlGaN barrier/GaN cap stack that defines the 2DEG. Gated Hall bar devices were fabricated by using 15 nm of Al_2O_3 as a gate insulator and Ti/Al/Ni/Au annealing for ohmic contacts to the 2DEG. Resistivity and Hall-effect measurements were taken on the gated Hall bars in magnetic fields up to 45 T and at temperatures as low as 350 mK. Over the range of gate voltages used, the 2DEG densities vary from less than 1.1×10^{12}/cm^2 to 6.7×10^{12}/cm^2, and the 2DEG mobilities vary from 1200 cm^2/Vs to 8500 cm^2/Vs at 390 mK. The GaN 2DEG was able to enter the integer QHE regime in magnetic fields as low as 15 T. We then made electrical contact to the buried NbN layer to extract the superconducting critical temperature and critical fields via resistance measurements. The T_c is 16.5 K with a sharp transition of $\Delta T = 0.16$ K in width, and the maximum out-of-plane H_c is 17.8 T. Therefore, superconductivity and the integer QHE are concurrent in this structure for $T < 1$ K and 15 T < μH < 17.8 T. Analysis of these results shows that this window of temperatures and magnetic fields can be significantly expanded, suggesting that the nitride material system could potentially become an industrially viable platform for robust quantum devices based on topologically protected transport.

Neutron Scattering Studies in Quasi- One-Dimensional Superconducting Systems Clarina R. dela Cruz and Keith M. Taddei; Oak Ridge National Laboratory, United States

Quasi-one-dimensional A2Cr3As3 (with A=K, Cs, Rb) is an intriguing new family of superconductors which exhibit many similar features to the cuprate and iron-based unconventional superconductor families. Yet in contrast to these systems, no charge or magnetic ordering has been observed which could provide the electronic

correlations presumed necessary for an unconventional superconducting pairing mechanism - an absence which defies predictions of first principles models. We report the results of neutron scattering experiments on polycrystalline K2Cr3As3 (Tc∼7K) which probed the low temperature dynamics near Tc . Neutron diffraction data evidence a strong response of the nuclear lattice to the onset of superconductivity while inelastic scattering reveals short-range magnetic fluctuations.These observations suggest that K2Cr3As3 is in close proximity to a magnetic instability and that the incipient magnetic order both couples strongly to the lattice and competes with superconductivity - in direct analogy with the iron-based superconductors. Further studies of charge doping of KCr3As3 via H intercalation revealed very interesting results. We show that the previously reported ethanol bath deintercalation of K2Cr3As3 to KCr3As3 has a secondary effect whereby H from the bath enters the quasi-one-dimensional Cr6As6 chains. Furthermore, we find that - contrary to previous interpretations - the difference between non-superconducting as-grown KCr3As3 samples and superconducting hydrothermally annealed samples is not a change in crystallinity but due to charge doping with the latter treatment increasing the H concentration in the CrAs tubes effectively electron-doping the 133 compound. These results suggest a new stoichiometry KHxCr3As3, that superconductivity arises from a suppressed magnetic order via a tunable parameter and paves the way for the first charge-doped phase diagram in these materials.

Superconductivity in Infinite Layer Nickelates Harold Hwang[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Ever since their discovery, superconductivity in cuprates has motivated the search for materials with analogous electronic or atomic structure. Here we present how soft chemistry approaches can be used to synthesize superconducting infinite layer nickelates from their perovskite precursor phase, using topotactic reactions [1,2]. We will present the synthesis and transport properties of the nickelate superconductors, and our current understanding of aspects of the electronic structure, including the unusual role of rare-earth hybridization [3,4]. A particular focus will be on the observation of a doping-dependent superconducting dome in (Nd,Sr)NiO_2, similar to cuprates [5]. However, while cuprate superconductivity is bounded by an insulator for underdoping and a metal for overdoping, here we observe weakly insulating behavior on either side of the dome. Furthermore, the normal state Hall coefficient is always small and proximate to a continuous zero crossing in doping and in temperature, in contrast to the ~1/x dependence observed for cuprates. This suggests the presence of both electron- and hole-like bands, consistent with band structure calculations.

Synthetic Route Towards Higher-Crystallinity Superconducting Infinite-Layer Nickelates Kyuho Lee[1,2], Danfeng Li[1,2], Motoki Osada[1,2], Bai Yang Wang[1,2], Berit H. Goodge[3,4], Lena Kourkoutis[3,4] and Harold Hwang[1,2]; [1]SLAC National Accelerator Laboratory, United States; [2]Stanford University, United States; [3]Cornell University, United States; [4]Kavli Institute at Cornell for Nanoscale Science, United States

The recent discovery of superconductivity in the infinite-layer nickelates $Re_{1-x}Sr_xNiO_2$ (*Re* = Nd, Pr)[1,2] has

sparked significant interest in the investigation of the intrinsic superconducting and normal-state properties of this new superconducting system. However, the non-trivial inclusions of defects and structural imperfections in this thermodynamically unstable material[3,4] remain a major materials challenge. The main factors contributing to these imperfections include the unusually high formal nickel valence in the perovskite precursor phase due to the chemical doping of strontium, the unavoidable epitaxial mismatch with the substrate due to the large in-plane lattice change during the topotactic transition, and the decomposition and secondary-phase formation issues arising during the soft-chemistry reduction step.[3-5] Upon careful optimization of the growth and reduction conditions, we have identified the key parameters for achieving higher crystallinity and established a reproducible method to stabilize high-quality $Nd_{1-x}Sr_xNiO_2$ (001) epitaxial thin films on $SrTiO_3$ (001) substrate by pulsed-laser deposition and CaH_2-assisted topochemical reduction. In particular, x-ray diffraction and scanning transmission electron microscopy measurements of the newly optimized samples reveal that the Ruddlesden-Popper-type faults prevalent in the previous generation of samples (Ref. 3) are now largely eliminated, indicating major improvements in the crystallinity of this material. The optimization process and the resultant evolution of the structural properties of the nickelate films will be discussed. In addition, the improvement in the crystallinity affects the transport properties and the superconducting dome[5,6] of this material, the details of which will be discussed.

Electronic Structure and Interface Effects in Superconducting Nickelate Thin Films Berit H. Goodge[1,1], Danfeng Li[2,3], Kyuho Lee[2,3], Motoki Osada[2,3], Bai Yang Wang[2,3], Harold Hwang[2,3] and Lena Kourkoutis[1,1]; [1]Cornell University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Stanford University, United States

The stabilization of superconducting infinite-layer nickelate thin films [1,2] presents a long-awaited platform for experimental comparison to the analogous cuprate superconductors and exploration of the underlying physical mechanisms. Unlike the bulk-synthesized cuprates, however, the thin film geometry of the superconducting nickelates has important implications for both the materials physics and the experimental methods used to probe it. Here, we harness atomic-scale scanning transmission electron microscopy (STEM) and localized electron energy loss spectroscopy (EELS) to explore both the lattice and electronic structure with high real-space resolution across a wide series of nickelate thin films. State-of-the-art electron spectroscopy reveals key electronic differences between the nickelate and cuprate superconductors [3]. Beyond the experimental considerations, the thin film geometry of the nickelate superconductors has also raised speculation about possible phenomena at the nickelate-substrate interface [4-6]. Harnessing the ability of cross-sectional measurements by atomic-resolution STEM and EELS, we discuss the details of both lattice and electronic structure in these materials across the substrate-film interface.

Penetration Depth Measurements of Infinite-Layer Nickelates Shannon Harvey, Bai Yang Wang, Danfeng Li, Motoki Osada, Kyuho Lee, Varun Harbola, Sam Crossley and Harold Hwang; Stanford University, United States

The discovery of superconductivity in infinite-layer nickelates [1] has the potential to help reveal the origins of high-temperature superconductivity. To do this, we must first develop an understanding of superconductivity in nickelates by measuring their fundamental properties. In this talk, I will present our measurements of the in-plane penetration depth of $(Nd,Sr)NiO_2$ thin films across the doping-dependent superconducting dome [2]. The penetration depth provides information about the superfluid density and pairing symmetry of the superconducting state, which will help to inform our understanding of the nature of superconductivity in these materials.

5:32 PM NM01.04.07
Isotropic Pauli-Limited Superconductivity in the Infinite-Layer Nickelate $Nd_{0.775}Sr_{0.225}NiO_2$ Bai Yang Wang[1,2], Danfeng Li[1,2], Berit H. Goodge[3], Kyuho Lee[1,2], Motoki Osada[1,2], Shannon Harvey[1,2], Lena Kourkoutis[3], Malcolm Beasley[1] and Harold Hwang[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States; [3]Cornell University, United States

The recent observation of superconductivity in thin film infinite-layer nickelates [1] offers fresh terrain for investigating superconductivity in layered oxides. A wide range of perspectives [2-4], emphasizing single- or multi-orbital electronic structure, Kondo or Hund's coupling, and analogies to cuprates, have been theoretically proposed. Clearly, further experimental characterization of the superconducting state is needed to develop a foundational understanding of the nickelates. In this talk, I will discuss using magnetotransport measurements to probe the superconducting anisotropy in $Nd_{0.775}Sr_{0.225}NiO_2$. We find that the upper critical field is surprisingly isotropic at low temperatures, despite the layered crystal structure. We deduce that under magnetic field, superconductivity is strongly Pauli-limited, such that the paramagnetic effect dominates over orbital de-pairing. Underlying this isotropic response is both an enhanced electronic magnetic moment, the measurement of which can serve as a critical test of our interpretation and a substantial anisotropy in the superconducting coherence length, at least four times longer in-plane than out-of-plane. A prominent low-temperature upturn in the upper critical field indicates the likelihood of an unconventional ground state.

Superconductivity, Topological Edge States and Electron-Hole Pairing in a Single Monolayer Material, WTe_2 David H. Cobden; University of Washington, United States

In the semimetal WTe_2, low symmetry, band inversion, heavy carrier mass, near-perfect compensation, strong electron-phonon interactions and strong spin-orbit coupling all combine to provide a promising setting for correlated and topological phenonema. Undoped, a monolayer of WTe_2 behaves as a two-dimensional topological insulator with helical conducting edge states. Anisotropic magnetoresistance measurements of the edge conduction reveal the direction of the spin polarization, and surprisingly it is found to be independent of the edge termination. We infer that it is inherited from the bulk bands which are also spin polarized along a special axis, and show that this is consistent with theory. In addition, several lines of evidence indicate that the insulating behavior involves electron-hole pairing, with the possible formation of an excitonic insulator state near the compensated state. Meanwhile, at a surprisingly low level of electrostatic doping the insulating state converts into a metal which superconducts about 0.8 K. It is therefore quite likely that the superconductivity is tilted-Ising like and competes with excitonic ordering. Multi-terminal measurements also suggest that the topological edge states persist while being very weakly coupled to the bulk superconductivity.

Majorana Corner Modes in Superconducting Topological Metals—A Case Study of Monolayer WTe2 Yi-Ting Hsu; University of Notre Dame, United States

Monolayer WTe2, an inversion-symmetric transition metal dichalcogenide, has recently been established as a quantum spin Hall insulator and found superconducting upon gating. It is therefore natural to wonder whether this discovered superconductivity is topological. In this talk, I will first show that gated monolayer WTe2 is a promising candidate for a ``higher-order" topological superconductor, which features Majorana zero modes localized at sample corners. Then I will present a general recipe for realizing superconductors hosting such Majorana corner modes without utilizing proximity effect. Finally, I will discuss systematic searches for new material candidates in databases guided by topological invariants that are applicable to ab initio band structures and can diagnose Majorana boundary types.

7:18 PM DISCUSSION

7:42 PM *NM01.05.04
Half-Quantum Flux in Topological Superconductors Yufan Li; Johns Hopkins University, United States

Spin-triplet superconductors (SCs) are highly desirable but rarely realized. On the other hand, there are surging interest in the spin-triplet p-wave pairing due to its close relevance to topological superconductivity and noise-resilient quantum computing. The superconducting gaps of triplet and singlet SCs with odd and even parity respectively can be exploited for unequivocal identification. We show that the magnetic flux quantization, one of the defining characteristics of a superconductor (SC), is a decisive phase-sensitive method to distinguish triplet-pairing SCs from the more common spin-singlet SCs. A superconducting ring with triplet pairing may demonstrate half-integer flux quantization $(n + ½)\ \Phi_0$, where n is an integer, i.e., half flux quanta with half-integer quantum numbers of 1/2, 3/2, 5/2, *etc*. instead of the exclusive integer quantization $n\Phi_0$ observed in singlet SCs. We have observed half-quantum flux in mesoscopic rings of superconducting β-Bi_2Pd thin films [1]. The result provides conclusive evidence for spin-triplet *p*-wave pairing in β-Bi_2Pd as a leading candidate of intrinsic topological SCs. We have also observed half-quantum flux in noncentrosymmetric α-BiPd, where an admixture of singlet and triplet pairing is expected from the absence of parity symmetry [2]. Our findings establish a new paradigm for identifying spin-triplet pairing, and usher in new venues for studying topological superconductivity.

Superconductivity and Topological Phases in Two-Dimensional Materials Kam-Tuen Law; The Hong Kong University of Science and Technology, Hong Kong

In recent years, superconductivity and topological phases (such as quantum spin Hall and anomalous Hall phases) have been discovered in atomically thin two-dimensional materials such as in transition metal dichalcogenides (TMDs) and twisted bilayer graphene. These materials exhibit novel physical properties due to their crystal symmetries, band structures and interaction effects.

In this talk, I would like to discuss:

1. The properties of superconducting 2H-structure TMDs which we called Ising superconductors. In the case of gated 2H-structure MoS2 for example, superconductivity can survive even in the presence of an in-plane magnetic field up to 60 Tesla. We showed that this is due to a special form of spin-orbit coupling (SOC) which we called Ising SOC. We will also discuss how Ising superconductors can be used to realize Majorana fermions which are important for topological quantum computation. [1-4]

3. The current-induced magnetization switching in twisted bilayer graphene. Recently, quantum anomalous Hall effect with spontaneous ferromagnetism was observed in twisted bilayer graphenes (TBG) near 3/4 filling by Goldhaber-Gordon's group at Stanford [6] and Young's group at UCSB [7]. Importantly, it was observed that an extremely small current can switch the direction of the magnetization. This offers the prospect of realizing low energy dissipation magnetic memories. However, the mechanism of the current-driven magnetization switching is poorly understood as the charge currents in graphene are generally believed to be non-magnetic. In this talk, the observed current-induced magnetization effect will be explained [8].

Topological Superconductivity and Majorana Zero Mode in Iron-Based Superconductors Hong Ding;
Institute of Physics, Chinese Academy of Sciences, China

In this talk I will report our recent discoveries of topological superconductivity and Majorana zero mode in iron-based superconductors. We have observed a superconducting topological surface state of Fe(Te, Se) with Tc ~ 14.5K by using low-temperature ARPES [1], and a pristine Majorana zero mode (MZM) inside a vortex core of this material by using low-temperature STM [2]. We have also observed a half-integer level shift of vortex bound states [3] and quantized Majorana conductance [4] in this material, which are hallmarks of MZMs. In addition, we have also found that most of Fe-based superconductors [5], including monolayer Fe(Te, Se)/STO [6], have similar topological electronic structures. One of them, $CaKFe_4As_4$, an Fe-As bilayer superconductor (Tc ~ 35K), is found to possess MZM and other bound states that can be well reproduced by a simple theoretical model [7]. Our observations offer a new, robust platform for realizing and manipulating MZMs, which can be used for quantum computing at a relatively high temperature.

Novel Physics Induced by Dimensional Reduction from 3D to 2D in Layered Materials Xianhui Chen;
University of Science and Technology of China, China

Two-dimensional (2D) materials have attracted plenty of interests due to the novel physical properties induced by the reduction of dimension compared to three-demensional (3D) system, and the practical and potential application of revolutionary current technologies as well. It is of great significance to extensively investigate the fundamental physics of the related materials in the two-dimensional limit. The success of 2D materials is based on the development of suitable synthesis methods, mainly including exfoliation, chemical vapour deposition and various solution-phase methods. New and more efficient methods are under developing. Recently, we have successfully intercalated organic ion cetyltrimethyl ammonium (CTA^+) and tetrabutyl ammonium (TBA^+) into several layered crystals via electrochemical intercalation method, realizing two-dimensionalization of the related functional layers and observing some intriguing new physical phenomena. We intercalated CTA^+ and TBA^+ into the FeSe single crystal by the electrochemical method, achieving high superconducting transition temperature (T_c) to be 45 and 50 K for $(CTA)_{0.3}FeSe$ and $(TBA)_{0.3}FeSe$, respectively. By measuring Knight shift and nuclear spin-lattice relaxation rate, we unambiguously observed a pseudogap behavior below $T_p \sim 60$ K in these two kinds of layered FeSe-based high-temperature superconductors, and revealed that the pseudogap behavior is related to strong superconducting fluctuations due to the quasi-2D nature induced by the organic-ion intercalations. With intercalating the same organic ions into an intrinsic semiconductor $SnSe_2$, superconductivity with T_c to ~6.4 (TBA^+) and 7.1 K (CTA^+) was achieved. We also synthesized an organic-ion intercalated transition-metal dichalcogenides $(TBA)_{0.3}VSe_2$, where the metallic charge-density-wave (CDW) state with transition temperature (T_{CDW}) of 110 K in the pristine system was changed to an insulating CDW state

with T_{CDW} of 165 K by the intercalation. With TBA^+-intercalation, the insulating ferromagnetic van der Waals material $Cr_2Ge_2Te_6$ with Curie temperature T_{curie} of 67 K was altered to a metallic ferromagnet with T_{curie} of 208 K, accompanied by the magnetic easy axis changing from <001> direction to the *ab* plane. Our work indicated that the 3D-to-2D crossover induced by intercalation of the large organic ion CTA^+ and TBA^+ between functional layers plays a key role in the dramatic changes of the physical properties in the several material systems, and demonstrated that the intercalation of organic ions with large size can serves as a convenient and efficient approach to explore and manipulate the versatile electronic and magnetic properties in the layered crystals.

Late News: Fermi-arc Criterion for Surface Majorana Modes in Superconducting Time-Reversal Symmetric Weyl-Semimetals Rauf O. Giwa and Pavan Hosur; University of Houston, United States

A Majorana-fermion is an exotic particle that is its own anti-particle and can occur in superconductors, where charge conjugation is realized as a particle-hole symmetry. In recent years, many clever realizations of Majorana-fermions in condensed-matter have been predicted. Many have been verified by exploiting the interplay between superconductivity and band topology in metals and insulators. On the other hand, Weyl-semimetals are three-dimensional materials in which the bulk band-gap closes at an even-number of discrete points (Weyl nodes) in the Brillouin zone. Weyl-summits are characterized by topologically protected surface states consisting of disjoint, open Fermi-arcs, projected from bulk Weyl-nodes to the surface.

Realizations of Majorana-fermions in semimetals remain less explored. We ask, ”under what conditions do superconducting vortices in time-reversal symmetric Weyl-semimetals trap Majorana-fermions on the surface?” If each constant-kz plane, where z is the vortex axis, contains equal numbers of Weyl nodes of each chirality, we predict a generically gapped vortex and derive a topological invariant ν in terms of the Fermi arc structure that signals the presence or absence of surface Majorana fermions. In contrast, if certain constant-kz planes contain a net chirality of Weyl nodes, the vortex is gapless.

We analytically calculate the topological invariant ν within a perturbative scheme and provide numerical support with an orthorhombic lattice model. Using our criteria, we predict phase transitions between trivial, critical and topological vortices by simply tilting the vortex. Finally, we propose Li(Fe0.91Co0.09)As with broken inversion symmetry as a candidate for realizing our proposals.<gdiv></gdiv><gdiv></gdiv><gdiv></gdiv>

Phenomena and Physics in Pressurized Superconductors Revealed by Our Recent Studies Liling Sun[1], Jing Guo[1], Yazhou Zhou[1], Genda Gu[2], Cheng Huang[1], Qi Wu[1], Tao Xiang[1] and Robert J. Cava[3]; [1]Institute of Physics, Chinese Academy of Sciences, China; [2]Brookhaven National Laboratory, United States; [3]Princeton University, United States

It has been established that the superconductivity in a material is dictated by its degrees of freedom of electronic charge, orbital, spin and crystallographic structure, which can be manipulated by the control parameters such as pressure, magnetic field and chemical composition. Pressure is a 'clean' way to tune basic electronic and structural properties without changing the basic chemistry, and can help to search for new phenomena and understand the corresponding physics. In this talk, I will present some interesting phenomena obtained by our recent high-pressure studies, including crossover from two-dimensional to three-dimensional superconducting states in bismuth-based cuprate superconductor [1] and discovery of the *RSAVS* superconductors [2-5].

Clathrate Superhydrides Under High Pressure—A Class of Extraordinarily Hot Conventional Superconductors Yanming Ma; Jilin University, China

Room-temperature superconductivity has been a century long-held dream of mankind and a focus of intensive research. In an effort to search for room-temperature superconductors, we proposed in 2012 the first-ever clathrate superhydride CaH61 stabilized at an extreme pressure
150 GPa that shows a potential of high temperature superconductivity at Tc about 235 K. In 2017, we extended the superconducting clathrate structures into rare earth (RE, e.g., Sc, Y, La, Ce, Pr., etc) superhydrides at high pressure conditions that commonly have three clathrate
structured stoichiometries of REH6, REH9, and REH10, some of which exhibit extraordinarily high-temperature superconductivity2. Subsequent experiments synthesized the as-predicted clathrate superhydrides YH6, YH9, and LaH10 and measured Tc values at 224, 243, and 260 K, respectively, setting up new Tc records among known superconductors. These discoveries open up the door of achieving superconductors that could work at room temperature (300 K) in superhydrides under high pressures. In the talk, I will give an overview on the current status of research progress on superconductive superhydrides, and then discuss the design principle for achieving room temperature superconductor. Our prediction on a hot superconductor (Tc = ~400 K) in a clathrate Li2MgH16 superhydride found in a ternary Li-Mg-H system3, and other recent results on clathrate superhydrides together with future research direction along this line will be discussed.

8:00 AM *NM02.01.01
New Opportunities for Nanostructured Coated Conductors: Solution Derived Ultrafast Transient Liquid Assisted Growth Xavier Obradors[1], Teresa Puig[1], Juri Banchewski[1], Silvia Rasi[1], Albert Queraltó[1], Kapil Gupta[1], Lavinia Saltarelli[1], Diana Garcia[1], Adrià Pacheco[1], Roxana Vlad[1], Laia Soler[1], Júlia Jareño[1], Ziliang Li[1], Roger Guzman[1], Natalia Chamorro[1], Bohores Villarejo[1], Cornelia Pop[1], Max Sieger[1], Susagna Ricart[1], Jordi Farjas[2], Pere Roura[2], Cristian Mocuta[3], Ramon Yañez[4] and Josep Ros[4]; [1]ICMAB - CSIC, Spain; [2]University Girona, Spain; [3]Solieil Synchrotron, France; [4]Universitat Autònoma de Barcelona, Spain

Coated conductors of $YBa_2Cu_3O_7$ (CC-YBCO) have emerged as the most attractive opportunity to reach unique performances in an extended range of temperatures and magnetic fields making them attractive for power and magnet applications. Reducing the cost/performance ratio, however, continues to be a key objective. Chemical solution deposition (CSD) is a competitive cost-effective technique which has been used to obtain nanocomposite films and CCs. However, the typical growth rates (0.5-1 nm/s) of the fluorine-based CSD approach remain too low thus limiting its throughput.
We will show in this talk how CSD-based nanocomposite YBCO films can be obtained using metalorganic colloidal solutions including preformed $BaMO_3$ (M=Zr, Hf) nanoparticles. This approach can be easily combined with Inkjet printing and other scalable deposition techniques for thick film preparation.
Transient Liquid Assisted Growth (TLAG) is a novel growth approach [1] allowing to combine the already well established CSD methodologies with ultrahigh growth rates based on a non-equilibrium liquid-mediated approach (100-1000 nm/s). This novel approach uses fluorine-free metalorganic precursors and is also compatible with the colloidal solution approach to nanocomposite coated conductors. We will show that using properly TLAG requires to generate new knowledge about kinetic phase diagrams that we have reached using fast in-situ XRD analysis (100 nm/frame) under synchrotron radiation. Critical current densities up of 5 MA/cm^2 at 77K are already realized in thin films and the suitability of using IBAD buffered metallic substrates will be also demonstrated. A modified nanostructure is demonstrated based on epitaxial $BaMO_3$ nanoparticles thus generating a new opportunity to deeply analyse the key influence of defect structure on vortex pinning of nanocomposite superconductors.

We acknowledge funding from EU-ERC_AdG-2014-669504 ULTRASUPERTAPE and EU-PoC-2020-IMPACT projects, and the Excellence Program Severo Ochoa SEV2015-0496

Strong Pinning at High Growth Rates in Rare Earth Barium Cuprate (REBCO) Superconductor Films

Grown with Liquid-Assisted Processing (LAP) During Pulsed Laser Deposition Judith L. MacManus-Driscoll[1], John Feighan[1], May Lai[1], Ahmed Kursumovi[1], Haiyan Wang[2], Di Zhang[2], Jae Hun Lee[3] and Seung Hyun Moon[3]; [1]University of Cambridge, United Kingdom; [2]Purdue University, United States; [3]sunam, Korea (the Republic of)

We present a simple liquid assisted processing (LAP) method, to be used in-situ during pulsed laser deposition growth to give both rapid growth rates (>250 nm/min and strong pinning. Achieving these two important features simultaneously has been a serious bottleneck to date. LAP enhances the kinetics of the film growth so that good crystalline perfection can be achieved at up to 60 x faster growth rates than normal, while also enabling artificial pinning centres to be selfassembled into fine nanocolumns. In addition, LAP allows for RE mixing (80% of Y with 20% of Yb, Sm, or Yb+Sm) to create effective point-like disorder within the REBCO lattice and which leads to strongly improved pinning at 30 K and below. Overall, LAP is a simple method which could be adopted by other in-situ physical or vapour deposition methods (i.e PLD, MOCVD, evaporation, etc) to significantly enhance both growth rate and performance.

8:50 AM *NM02.01.03
Advanced Second Generation Wire Development at AMSC Martin W. Rupich[1], Qiang Li[2], Vyacheslav Solovyov[3] and Amit Goyal[4]; [1]AMSC, United States; [2]Brookhaven National Laboratory, United States; [3]Brookhaven Technology Group, United States; [4]University of Buffalo, United States

AMSC is exploring the development of advanced wire architectures which can double the I_c of the standard Second Generation (2G) high temperature superconducting (HTS) wire and significantly enhance performance in the presence of magnetic fields. The Second Generation HTS wires are generally based on a composite architecture consisting of a thin YBCO superconducting layer deposited on one side of a thin, flexible metal substrate. This composite HTS/substrate structure is typically surrounded by an electroplated Cu layer or laminated between metal strips to provide mechanical and electrical stability. AMSC has been developing an alternative architecture consisting of 2 distinct HTS layers deposited on each side of a metal substrate. This double HTS layer composite is then surrounded by an electroplated Cu layer or laminated between two metal strips, resulting in a wire package nearly indistinguishable from the standard single HTS layer wire. The novel architecture results in a 2G wire with double the critical current of the standard single layer wire.
The enhanced pinning performance of the wire is achieved by the introduction of a uniform defect structure produced by a reel-to-reel irradiation of the HTS layers by ions such as Au^{5+}. The ion irradiation produces an extremely uniform distribution of pinning defects that enhances I_c by a factor of up to 3 times. By controlling the irradiation process, the performance can be engineered for the temperatures and fields of the targeted applications.
In this presentation, we will review the performance of the novel 2G wire architecture and describe the structure and properties of the irradiation induced pinning landscapes.
This work is supported by EERE under contract DE-EE0007870.

Late News: Reel to Reel BZO-Doped REBCO Coated Conductors by Direct-Resistance Heating Technique in Advanced MOCVD Reactor Mahesh Paidpilli, Kalyan Boyina, Eduard Galstyan, Goran Majkic and Venkat Selvamanickam; University of Houston, United States

Advanced metal organic chemical vapor deposition (A-MOCVD) has been developed to grow long-length, thick film REBCO coated conductors in a single pass with superior in-field performance. Multiple long-length 5% Zr doped REBCO coated conductors with film thickness ranging from 1-4µm have been produced in A-MOCVD Reactor. The critical current density of these conductors has been examined by scanning hall probe microscopy. REBCO coated conductors with ~4µm thickness exhibit magnetization critical current density (J_c) over 1.5 MA/cm^2 at 65 K, 1.5 T and 5.4 MA/cm^2 at 4.2 K, 13 T. The microstructure, out-of-plane and in-plane texture of REBCO coated conductors will also be presented.

9:30 AM NM02.01.05
Fast Screening of TLAG-CSD REBCO Superconductors Fabrication by High-Throughput Experimentation Albert Queraltó[1], Juri Banchewski[1], Kapil Gupta[1], Adrià Pacheco[1], Lavinia Saltarelli[1], Diana Garcia[1], Cristian Mocuta[2], Susagna Ricart[1], Xavier Obradors[1] and Teresa Puig[1]; [1]Institut de Ciència de Materials de Barcelona, Spain; [2]European Synchrotron Radiation Facility, France

High-throughput screening of materials is a novel development strategy that is envisaged to accelerate discovery, development, and optimization of materials. Chemical solution deposition (CSD) techniques such as drop-on-demand inkjet printing (DoD IJP) are ideal to perform high-throughput studies through the fabrication of complex combinatorial samples with locally-uniform or graded compositions, and high spatial precision that enables parallel investigations on morphological, structural and functional properties.

The current work shows the implementation of such approach to expedite the optimization of REBCO superconducting films fabricated with the newly developed transient-liquid assisted growth chemical solution deposition (TLAG-CSD) method, which has been able to attain growth rates 100 times larger than with other fabrication methods. The preparation of combinatorial samples was done through mixing different rare earth cuprate precursor solutions with DoD IJP to explore the influence of rare-earth and liquid phase compositional changes on the epitaxial growth characteristics. The use of computational methods allowed the successful merging of precursor inks and high sample homogeneity, as confirmed by EDX and high-resolution XRD.

Epitaxial growth studies were then conducted for the fast identification of the best ranges of processing conditions and compositions. We use the advantages of this strategy to rapidly analyze different compositions in one single step by in-situ XRD synchrotron radiation experiments. Finally, we combined this knowledge with machine learning approaches to widen the understanding and rapid optimization of epitaxial growth of high-temperature REBCO superconducting films.

9:45 AM NM02.01.06
A Microstructural Perspective of the Ultrafast Transient Liquid Assisted Growth of High Current Density YBCO Superconducting Films Kapil Gupta[1], Lavinia Saltarelli[1], Albert Queraltó[1], Laia Soler[1], Júlia Jareño[1], Juri Banchewski[1], Roger Guzman[1], Silvia Rasi[1], Adrià Pacheco[1], Diana Garcia[1], Susagna Ricart[1], Jordi Farjas[2], Pere Roura-Grabulosa[2], Xavier Obradors[1] and Teresa Puig[1]; [1]Institut de Ciència de Materials de Barcelona (ICMAB-CSIC), Spain; [2]University of Girona, Spain

The outstanding ability of $YBa_2Cu_3O_{7-x}$ (YBCO) films to carry high currents at high magnetic fields offers an unparalleled opportunity to be used in large scale superconducting power applications and high field magnets. In an essential need of high performance, high throughput, and low cost manufacturing, chemical solution deposition (CSD) has become a very competitive cost-effective and scalable methodology to produce epitaxial thin films, with enhanced performance at high magnetic fields by the incorporation of secondary phase nanoparticles (NPs) [1]. However, their growth rates are rather small (0.5-1 nm/s). In this regard, we have developed a novel growth approach, entitled, Transient Liquid Assisted Growth (TLAG) [2], which is able to combine CSD methodologies for fluorine-free metalorganic precursors with ultra-fast growth rates (100 nm/s) by facilitating a non-equilibrium liquid-mediated approach and several intermediate reactions. Critical current densities up of 5 MA/cm^2 at 77K are already realized in TLAG-CSD grown YBCO thin films. In order to further improve the thin film's crystal quality and superconducting properties, understanding of initial nano-phases in pyrolysis process and all the intermediate reactions during growth, as well as, fine tuning of growth parameters is essential. For this purpose, the microstructure of pyrolyzed YBCO thin films and the intermediate

phases of quenched thin films along with grown YBCO thin films, investigated via high resolution transmission electron microscopy (HRTEM), scanning transmission electron microscopy (STEM), electron energy loss spectroscopy (EELS) and energy dispersive X-ray spectroscopy (EDX), will be presented.
Furthermore, the current-carrying capabilities of high temperature superconductors (HTS) are determined by its microstructure and it can be enhanced by the presence of well-controlled nano-defects inside the epitaxial superconducting matrix acting as vortex pinning centers. TLAG-CSD has demonstrated the growth of nanocomposites to increase flux pinning at high magnetic fields by incorporating pre-formed NPs to the metaloganic initial inks. Therefore, using aberration-corrected STEM combined with high angle annular dark field (HADDF) and EELS, we explore the detailed microstructure of grown TLAG-CSD YBCO films and nanocomposites, with a focus on new defects landscape at the atomic level, secondary phases, and strain effects. An additional advantage of TLAG-CSD is that preformed NPs can be incorporated to the metalorganic ink to prepare superconducting nanocomposites with enhanced vortex pinning, which will also be presented. Finally, the recent progress in TLAG-CSD, in terms of microstructure correlation with growth mechanisms and growth rate will be discussed.

Revealing the Second-Order Topological Character of Bismuth-Based Josephson Junction Sophie Gueron and Helene Bouchiat; Université Paris Saclay et CNRS Laboratoire de Physique des Solides, France

In Second-Order Topological Insulators (SOTI), bulk and surfaces are insulating while the edges or hinges conduct current in a quasi-ideal (ballistic) way, being insensitive to disorder. Crystalline bismuth has been shown to belong to this class of materials [1,2,3]. Just like the case of Quantum Spin Hall edges of 2D Topological Insulators, current is expected to be carried without dissipation by counter-propagating ballistic helical states, with a spin orientation locked to the momentum. Such edge or hinge states open many possibilities, from dissipationless charge and spin transport to new avenues for quantum computing. We have investigated Crystalline Bi nanowires based Josephson junctions and found that they exhibit saw-tooth current phase relations robust in high magnetic field which is the signature one-dimensional ballistic edge states. We also demonstrate the topological nature of Andreev states in these junctions when coupled to a microwave resonator in a phase-biased configuration. We find absorption peaks at the Andreev level crossings, whose temperature and frequency dependencies point to protected topological crossings with an accuracy limited by the electronic temperature of our experiment.

Josephson Junctions with Topological Interlayers Alexander Brinkman; University of Twente, Netherlands

In order to study Majorana and parafermionic quasiparticles a platform is needed that combines superconductivity and topology. A candidate platform is a Josephson junction with standard s-wave superconductors as leads and a topological interlayer in which electron spin is coupled to momentum direction.

We will show results for junctions based on topological materials with transport in 3D bulk Dirac semimetals, 2D topological surface states as well as 1D higher order topological hinge states, progressively trying to reduce the number of non-topological additional modes.

For the Dirac semimetal $Bi_{0.97}Sb_{0.03}$ we revealed that the required spin-momentum locking is present for the bulk carriers and that the degeneracy of the Dirac cone can be lifted in parallel electric and magnetic fields [1]. Indeed, Josephson junctions with this material reveal that part of the supercurrent is carried by bound states that are 4pi-periodic, as evidenced from microwave irradiation experiments [2]. The g-factor of the interlayer turns out to be gigantic [3]. We will discuss in what sense these bound states can be considered topological despite their degeneracy in spin.

Going one dimension lower, the spin momentum locking of 2D topological surface states can be used. For the Dirac semimetal Cd_3As_2 we show that part of the supercurrent is carried by the Fermi arc surface states [4]. For the use of the surface states of topological insulators we developed technology that allows for in-situ fabricated interfaces and in-situ defined nanostructures [5]. The use of selective area growth is especially promising for the purpose of reducing the number of modes in the nanodevices by size quantization, in order to maximize the 4pi signal.

In order to avoid any non-topological Andreev modes in the junctions at all, the 1D situation is preferred. For this purpose we focused on higher order topological 1D hinge states that might exist in Dirac semimetals. For Cd_3As_2 we showed that this is indeed the case by analyzing the supercurrent modulation by magnetic field and electric gating [6].

Late News: Circuit-QED Probing of Majorana Bound States in TI Nano Josephson Junctions Thilo Bauch[1], Ananthu Pullukattuthara Surendran[1], Gunta Kunakova[2,1], Jana Andzane[2], Donats Erts[2] and Floriana Lombardi[1]; [1]Chalmers University of Technology, Sweden; [2]University of Latvia, Latvia

The interest in hybrid Topological Insulator (TI) Josephson junctions was boosted after the prediction by Fu and Kane of an unconventional chiral p-wave symmetry of the proximity induced order parameter into the topological surface states. The chiral induced p-wave is a prerequisite for the nucleation of localized Majorana states in a tri-junction geometry, which is instrumental for topological quantum computation. In a multimode hybrid TI Josephson junction with two terminal geometry, Majorana physics manifests as peculiar properties of a part of the Andreev bound states carrying the Josephson current: they give rise to an unconventional 4p periodic current phase relation (CPR) coexisting with a 2p periodic CPR of the conventional Andreev bound states. The relative weight between the 4p and 2p periodic Andreev bound states increases with the transparency

of the junction and, in general, by reducing the number of channels. A direct way to achieve a low number of transport channels is to use TIs with reduced dimensionality like very thin and narrow nanoribbons. Indeed, quite recently, various theoretical proposals have shown the advantage to using Josephson junctions with TI nanoribbons, with suppressed bulk conduction, to realize Majorana fermions.
To obtain information about the bound state spectrum we have implement a circuit-QED readout scheme for our Al-Bi2Se3-Al hybrid junctions. Here we embedded a TI Josephson junction-based RF SQUID in a superconducting resonator. The dispersive microwave read out of the resonator/RF-SQUID setup allows us to extract information about the bound state spectrum of the TI junction. In fact, the low amplitude microwave readout ensures a relative low perturbation of the junction (in respect to the critical current) as compared to typical "Shapiro step" measurements, where the large microwave drive can cause undesirable population of higher lying bound states. Moreover, the dispersive readout enables us to characterize decoherence sources eventually affecting the performance of a TI junction based topological quantum bit. Finally, we present preliminary results of two-tone spectroscopy envisaged to extract the phase dispersion of single bound states directly.

Late News: Unconventional Current Phase Relation of Topological-Insulator Nanoribbon-Superconductor Hybrid Junctions Ananthu Pullukattuthara Surendran[1], Gunta Kunakova[1,2], Jana Andzane[2], Donats Erts[2], Floriana Lombardi[1] and Thilo Bauch[1]; [1]Chalmers University of Technology, Sweden; [2]University of Latvia, Latvia

Hybrid material systems with a conventional superconductor in proximity to a semiconductor or an unconventional conductor have recently acquired a vast interest due to their potential to hoist exotic phenomena.[1-3] Current studies on superconductor-topological insulator (TI)-superconductor junctions based on exfoliated film and nanoribbons have shown unconventional current phase relations (CPR) that could be associated with Majorana fermions, which may help realize topologically protected quantum computing.[4-8] In a 3D TI based junction, the Majorana modes should appear in the surface modes as a doublet of gapless Andreev bound states whose energy varies 4π periodically with the phase across the junction alongside the normal 2π periodic Andreev bound states. But in most of the studies on these systems, there is an unavoidable contribution from the bulk, and experiments based on 3D-TI nanoribbons (TINRs) with a reduced number of transport modes are much needed. We make use of Al-Bi_2Se_3-Al junctions fabricated using TINRs grown by physical vapor deposition. [9-11]To extract the current phase relation of our TI-junction, we utilize an asymmetric dc-SQUID measurement technique. The TI-junction to be studied is connected parallel to a reference junction on the same TINR with a higher critical current, typically 10-15 times more, thus forming a SQUID device. This asymmetry in critical current is achieved by varying the TI-junction width, keeping the distance between the electrodes constant. Now, considering a large ratio between the critical currents and a small SQUID loop inductance (i.e., screening parameter much less than one), the phase across the reference junction stays constant on the application of magnetic flux while the phase across the test junction is changing linearly with the applied magnetic flux. From the modulations of the SQUID critical current, we directly determine the CPR of the small TI-junction. We observe clear deviations from standard sinusoidal CPR of typical tunnel junctions in all our devices. This skewed CPR at low temperatures results from highly transparent modes in our TI junctions. For increasing temperature and one obtains the sinusoidal current phase relation consistent with the thermal population of the Andreev bound states.

Late News: Giant Fractional Shapiro Steps in Anisotropic Josephson Junction Arrays Ritika Panghotra[1], Clécio C. de Souza Silva[2], Bart Raes[1], Ivo Cools[1], Wout Keijers[1], Jeroen E. Scheerder[1], Victor V. Moshchalkov[1] and Joris Van de Vondel[1]; [1]Quantum Solid-State Physics, Department of Physics and Astronomy, KU Leuven, Belgium; [2]Departamento de Física, Universidade Federal de Pernambuco, Brazil

The current phase relationship (CPR), describes the relation between the supercurrent, I_S, through a Josephson junction (JJ) and the gauge invariant phase difference across the junction, $\Delta\theta$. The exact relation, is determined by the details of the Andreev bound state spectrum that exists in the junction. For conventional SIS junctions, the CPR is sinusoidal, $I_S=I_C\sin(\Delta\theta)$, where I_C is the junction critical current. With the advances in materials sciences and the realization of novel link materials, exhibiting non-conventional CPRs, JJ with new functionalities arise having a tremendous potential for applications.

The harmonic content of the CPR in these novel weak link materials can be revealed by experiments relying on detecting the phase-locked response of a current driven Josephson junction when subjected to a high frequency radiation field of frequency, ν_{rf} [1]. In case the weak link is characterized by a conventional sinusoidal CPR, this resonant response manifests itself as constant voltage plateaus, so called Shapiro steps, in the VI-characteristics at voltages $V_n=n\Phi_0\nu_{rf}$, where n is an integer number and Φ_0 the flux quantum. However, for a weak link having a non-sinusoidal CPR, the response exhibits, in addition to the conventional integer Shapiro steps, steps at fractional values $V_{n/q}=(n/q)\Phi_0\nu_{rf}$, where the q^{th} ($q \neq n$) fractional step originates from the phase-locked response with the q^{th} harmonic of the CPR.

Despite the experimental accessibility of these techniques, the detailed interpretation of such experiments is complicated by the non-linear nature of the Josephson response. Moreover, the use of a single junction makes these experiments challenging mainly due to its low response. Josephson junction arrays (JJAs) containing many junctions provide the natural alternative to provide the necessary enhancement of the coherent response. Although JJAs hold a strong promise to study the CPR, the impact of the particular CPR on the high frequency response remains until now unexplored.

We investigate the potential of anisotropic JJAs to study the harmonic content of the CPR in a broad frequency range (down to 50 MHz). Introducing anisotropy results in a giant collective high frequency phase-locked response that reflects the properties of a single junction. We demonstrate experimentally the appearance of giant fractional Shapiro steps in anisotropic JJAs as unambiguous evidence of a skewed current phase relationship. This in contrast to prior observations of giant fractional Shapiro steps in JJAs as resulting from magnetic flux quantization in the two-dimensional array.

Making the High-Pressure-Induced High-T_c Phases Practical for Applications Paul C. W. Chu[1,2], Liangzi Deng[1], Trevor Bontke[1], Melissa Gooch[1], Shuyuan Huyan[1], Rabin Dahal[1] and Zheng Wu[1]; [1]University of Houston, United States; [2]Lawrence Berkeley National Laboratory, United States

Raising T_c and setting new T_c records by discovering new compounds, modifying known compounds, and/or developing novel mechanisms to meet new challenges in science and technology have lured many scientists and engineers to superconductivity ever since its discovery. Great progress has been made in the last three decades in both the stable compounds, such as cuprates and iron-pnictides and -chalcogenides, and the unstable compounds of hydrogen-rich molecular solids. Both have T_cs within practical ranges: air-conditioning for the former and cryogen-free ambient for the latter. While the temperature barrier has been brought down, the pressure becomes a formidable obstacle to practical applications. Should this obstacle be overcome by retaining these high pressure (HP)-induced high-T_c phases at ambient, their technological impact would be profound and limited only by the imagination. We have thus explored the possibility of retaining these HP phases at ambient *via* pressure-quenching following appropriate thermodynamic paths like those for diamond from graphite and black phosphorus from red phosphorus. Model material systems of Sb, Bi, FeSe, and Cu-doped FeSe have been chosen for the study. We have successfully retained at ambient many superconducting and non-superconducting phases induced under HP up to 64 GPa in these materials. The thermal stability of the pressure-quenched phases has also been resistively examined. The experimental details are briefly described below:

I. Non-superconducting Sb and Bi Single Crystals

1. Determined resistively the phase diagrams, R-P and Tc-P, of the superconductors investigated and compared them with existing ones when available.
2. Identified the HP-induced phases with their different T_cs to retain at ambient.
3. Pressure-quenched these HP-induced phases by rapid removal of the pressure at 77 K.
4. Cooled the pressure-quenched phases from 77 K down to 1.2 K to determine whether each superconducting phase has been quenched in. If so, warmed up the sample to room temperature and cooled it down again to 1.2 K. The superconducting transition will disappear if the superconducting phase is associated with pressure-quenching and if the thermal stability of this phase ceases to exist at 300 K.
5. By repeating such R-T measurements on cooling to 1.2 K after warming to various temperatures above 77 K, the thermal stability of each pressure-induced superconducting phase quenched at 77 K is determined.
6. An anomaly in the R-T curve is also detected in the temperature region when the superconducting transition disappears.
7. Indeed, some of the HP-induced superconducting phases have been successfully pressure-quenched at ambient at 77 K with different thermal stability ranges.

II. Superconducting FeSe Single Crystals

Following the same steps taken for Sb and Bi, we have shown that the HP-induced superconducting phases, as well as the non-superconducting phases, can be pressure-quenched at ambient with a thermal stability up to 300 K.

III. Non-superconducting Cu-Doped FeSe Single Crystals

Following the same protocol for the above compounds, we have unambiguously pressure-quenched in at ambient the HP-induced superconducting and non-superconducting phases.

We have thus demonstrated that the superconducting and non-superconducting phases in Sb, Bi, FeSe, and Cu-doped FeSe single crystals induced under HP up to 64 GPa can be pressure-quenched in at 77 K and ambient pressure with different thermal stabilities up to 300 K. The observations hold great promise for practical applications of the high-temperature superconducting cuprate HBCCO with a T_c of 164 K at ~ 31 GPa and of C-S-H with a T_c of 287 K at 267 GPa.

Significantly Enhanced Pinning Efficiency of 1D $BaZrO_3$ Artificial Pinning Centers with Coherent Interfaces with $YBa_2Cu_3O_{7-x}$ Matrix Judy Z. Wu; University of Kansas, United States

One-dimensional c-axis aligned $BaZrO_3$ (BZO) nanorods are regarded as strong one-dimensional artificial pinning centers (1D-APCs) in $YaBa_2Cu_3O_{7-x}$ (YBCO) films. However, a microstructure analysis has revealed a highly defective, oxygen-deficient YBCO column of 2-3 nm in thickness around the BZO 1D-APCs due to the large lattice mismatch of ~7.7% between the BZO (3a=1.26 nm) and YBCO (c=1.17 nm). A hypothesis of reduced pinning potential height due to this defective YBCO column has been confirmed recently on much lower pinning efficiency of the BZO 1D-APCs as compared to $BaHfO_3$ (BHO) 1D-APCs that form a coherent interface with YBCO. Herein, we report a dynamic Ca/Cu replacement approach on tensile strained YBCO lattice immediately after the BZO 1D-APCs formation to induce c-axis elongation of the YBCO lattice near the BZO 1D-APC/YBCO interface to prevent the interfacial defect formation by reducing the BZO/YBCO lattice mismatch. An YBCO elongated c-axis up to 1.24 nm via Ca/Cu replacement and a defect-free, coherent BZO 1D-APC/YBCO interface are confirmed in transmission electron microscopy and elemental distribution analyses. Excitingly, up to five-fold enhancement of J_c (H) at magnetic field H=9.0 T//c-axis and 65-77 K was obtained in the ML samples as compared to their BZO/YBCO single-layer counterpart's. This has led to a record high pinning force density F_p together with significantly enhanced H_{max} at which F_p reaches its maximum value $F_{p,max}$ for the BZO 1D-APCs at H//c-axis. At 65 K, $F_{p,max}$ ~157 GN/m^3 and H_{max} ~ 8.0 T in the 6 vol.% BZO/YBCO ML samples represent a significant enhancement over $F_{p,max}$ ~36.1 GN/m^3 and H_{max} ~ 5.0 T on the 6 vol.% BZO/YBCO SL counterparts. This result not only illustrates the critical importance of the BZO 1D-APC/YBCO interface in the pinning efficiency, but also provides a facile scheme to repair this interface for higher pinning efficiency of the BZO 1D-APCs.

Late News: Anisotropic Superconductivity in the Spin-Vortex Antiferromagnetic Superconductor $CaK(Fe_{0.95}Ni_{0.05})_4As_4$ Beilun Wu; Instituto Nicolás Cabrera and Condensed Matter Physics Center (IFIMAC), Universidad Autónoma de Madrid, Spain

$CaKFe_4As_4$ is a newly discovered iron pnictide superconductor which shows optimal critical temperature T_C of 38 K at the stoichiometric compound. Electron doping with Ni or Co atoms induces a decrease in T_C and the onset of a particular hedgehog antiferromagnetic order, without sign of structural instability or nematicity. The influence of this new form of magnetic order on the superconducting state has been till now poorly investigated. Here, we present quasiparticle interference study on $CaK(Fe_{0.95}Ni_{0.05})_4As_4$ using scanning tunneling microscope at dilution fridge temperature[1]. Unlike in the undoped system[2], we reveal in the Ni doped system a four-fold highly anisotropic superconducting state, in association with the hedgehog antiferromagnetic order present in this system.

Late News: Superconducting Properties of 1144-type Iron-Based Superconductors by Mechanochemically Assisted Synthesis Andrea Masi[1,2], Achille Angrisani Armenio[2], Andrea Augieri[2], Giuseppe Celentano[2], Chiarasole Fiamozzi Zignani[2], Aurelio La Barbera[2], Francesco Rizzo[2], Alessandro Rufoloni[2], Enrico Silva[1], Angelo Vannozzi[2] and Francesca Varsano[2]; [1]Università degli studi Roma Tre, Italy; [2]ENEA, Italy

Iron-based superconductors (IBSC) represent a group of superconducting materials that attracted significant attention in recent years both for academic research and practical applications due to the exotic coupling of magnetism and superconductivity and to their large critical current densities at high magnetic fields. All iron-based superconductors are based on a common structural element, namely a layer composed by Fe atoms tetrahedrally coordinated by pnictogen (P,As) or chalcogen (S,Se,Te) atoms. Several elements and molecules can be intercalated among these planes, giving rise to the different families of the IBSCs. Among these, the so called "1144" compounds are obtained when alternate layers of alkaline and alkaline-earth metals are intercalated among Fe-As planes. These group of IBSCs is characterized by critical fields and critical currents among the highest for what concerns IBSCs single crystals, hence, being very attractive in perspective of high field applications.
In previous works, we have demonstrated the appeal of a mechanochemically assisted synthesis route as opposed to the common high temperature (e.g. T ~ 900 °C) process, allowing a finer control of the experimental variables. In particular, we exploit High Energy Ball Milling (HEBM), a low cost and easily scalable mechano-chemical powder processing methodology, to ensure the intimate mixing of the elemental powders, and therefore a high degree of homogeneity and reactivity in the starting reactants. Coupling the HEBM with intermediate temperature (e.g. T ~ 700 °C) thermal treatments represents an effective strategy to drop the issues related to volatile compounds (e.g. As, K) and ensure at the same time the required homogeneity.
In this work we focus on the properties of Ca/K-1144 polycrystalline materials obtained by the mechanochemically assisted synthesis route. The materials have been characterized in their structure and morphology by means of X-ray diffraction and scanning electron microscopy techniques. Superconducting properties are evaluated by means of electrical resistance and magnetization measurement carried out in different magnetic field conditions up to 18 T. High field measurements allow to highlight granularity phenomena – often observed in these class of compounds – most likely due to weak links at grain or grain aggregates boundaries and to the random orientation of the crystallites that characterizes these bulk samples.

Late News: Investigating the Impact of Magnetism on Superconductivity in the Magnetic-Superconductor RbEuFe4As4 via Scanning Hall Probe Microscopy David Collomb[1], Simon Bending[1], Alexei Koshelev[2], Mathew Smylie[2,3], Liam Farrar[1], Jin Ke Bao[2], Duck-Young Chung[2], Mercouri G. Kanatzidis[2,4], Wai-Kwong Kwok[2] and Ulrich Welp[2]; [1]University of Bath, United Kingdom; [2]Argonne National Laboratory, United States; [3]Hofstra University, United States; [4]Northwestern University, United States

The possible coexistence between magnetism and superconductivity has fascinated scientists ever since the latter's discovery over 100 years ago. New insights into the interaction between these two forms of order may lead to the realisation of exciting new applications including superconducting spintronics, skyrmionics and fluxonic devices for the next generation of computing hardware. $RbEuFe_4As_4$ is a recently-discovered spin-singlet iron-based superconductor with a superconducting transition temperature of T_c = 37K and a magnetic transition temperature of T_m, = 15K, below which both superconductivity and magnetism are present. This large coexistence temperature window makes $RbEuFe_4As_4$ an ideal material in which to study the interactions between the two forms of order in detail. Magnetic force microscopy and optical conductivity measurements on $RbEuFe_4As_4$ have suggested a weak suppression of superconductivity in the vicinity of T_m [1], while angle-resolved photoemission spectroscopy measurements indicate a more complete isolation of the two sublattices [2]. Here we use quantitative scanning Hall probe magnetic imaging of superconducting vortices in $RbEuFe_4As_4$ to probe changes in key superconducting parameters near the magnetic ordering temperature. Model fits to the vortex profiles as a function of temperature reveal a significant increase in the penetration depth near T_m, followed by a gradual reduction at lower temperatures, revealing that the magnetic ordering

leads to a significant reduction in the superfluid density [3]. We corroborate these results with a recently-developed model describing the suppression of superconductivity by correlated magnetic fluctuations [4]. The qualitative agreement between our data and the model suggests that the coupling between the Eu moments and Cooper pairs is weak enough that superconductivity is never destroyed, yet still strong enough to substantially weaken superconductivity. Our results have important implications for understanding coexistence phenomena in other materials systems, which could pave the way to exploiting such materials in future hybrid applications.

3:50 PM NM02.03.06

Late News: Direct-Writing of Advanced 3D Nano-Superconductors Rosa Córdoba[1], D. Mailly[2], A. Ibarra[3], Roman O. Rezaev[4], E. Smirnova[4], Oliver G. Schmidt[4], Vladimir M. Fomin[4], Uli Zeitler[5], I. Guillamón[6], Hermann Suderow[6] and JM De Teresa[7]; [1]Molecular Science Institute (ICMol), Spain; [2]Centre de Nanosciences et de Nanotechnologies, France; [3]University of Zaragoza, INA, LMA, Spain; [4]Institute for Integrative Nanosciences, Germany; [5]High Field Magnet Laboratory (HFML-EFML), Radboud University, Netherlands; [6]Universidad Autónoma de Madrid, Spain; [7]Instituto de Nanociencia y Materiales de Aragón (INMA), Spain

Nowadays, superconductors are commonly utilized in several applications such as energy generators and storage due to their unique capability of transferring electricity without energy losses. In some applications, their nanoscale patterning enhances their performance and gives rise to new physical phenomena. Innovative schemes have taken advantage of the third dimension (3D) for the development of advanced electronic components. The fabrication of complex 3D nano-architectures opens fascinating novel routes in the fields of material science, physics and nanotechnology. Thus, 3D nano-superconductors could be implemented in the next generation of energy efficient electronic devices. Nevertheless, their fabrication and characterization are still challenging and only a few works addressing the growth of real 3D nanosuperconductors have been reported so far [1–4].

In this contribution, we introduce a direct-write nanolithography method to fabricate at-will advanced 3D nano-superconductors. This specific technique called focused ion beam induced deposition (FIBID) is based on chemical vapour deposition process assisted by a charged particle beam focused to a few nanometers. Particularly, we have prepared 3D superconducting W-C hollow nanowires by decomposing tungsten hexacarbonyl molecules with a highly-focused He^+ ion beam, with outer diameters down to 32 nm and inner ones down to 6 nm [5]. In addition, by modifying the ion beam current, hollow nanowires with controllable inner and outer diameters have been achieved [6]. The growth of the vertical W-C nanowire occurs around the ion beam spot, mainly due to the interaction of secondary electrons with the adsorbed precursor molecules, whereas a cavity at the center of the nanowire is created due to the He^+ beam milling effect on the growing material. As shown by transmission electron microscopy, nanowires microstructure displays grains of large size fitting with face-centered cubic WC_{1-x} phase. In addition, we have grown nanohelices with at-will geometries, with dimensions down to 100 nm in diameter, and aspect ratio up to 65. These nanotubes and nanohelices become superconducting at 7 K and show large critical magnetic field and critical current density. Particularly, these nanohelices display superconductivity up to 15 T depending on the direction of the field with respect to the nanohelix axis. This suggest that their helical 3D geometry and their orientation in a magnetic field play a

significant role in the superconducting phase transition, which can be qualitatively explained using an approach for the properties of thin-film superconductors. Moreover, fingerprints of vortex and phase-slip patterns are experimentally identified and supported by numerical simulations based on the time-dependent Ginzburg-Landau equation [7].
The fabrication of such advanced 3D nanomaterials with outstanding properties makes this technique at the cutting edge of nanofabrication methods based on focused beams of charged particles.

Late News: Topological Transitions in Superconductor Nanomembranes Under a Strong Transport Current Roman O. Rezaev[1,2], E. Smirnova[1], Oliver G. Schmidt[1,3,3] and Vladimir M. Fomin[1,4]; [1]Leibniz IFW Dresden, Germany; [2]Tomsk Polytechnic University, Russian Federation; [3]TU Chemnitz, Germany; [4]National Research Nuclear University MEPhI, Russian Federation

Topological defects such as vortices and phase slips in a superconductor system manifest spatial patterns and dynamics that are closely associated with the geometric design in curved micro- and nanostructures of superconductors [1]. This study is motivated by the recent progress in fabrication of complex 3D nanoarchitectures (e.g., open nanotubes and nanohelices) by using the advanced 3D roll-up self-organization and nanowriting techniques based on focused ion beams. To simulate the superconducting properties of complex nanoarchitectures, a numerical platform has been developed based on a set consisting of the time-dependent Ginzburg-Landau equation coupled with the Maxwell equations [2].

The topological transitions between vortex-chain and phase-slip transport regimes unveiled in curved superconductor nanostructures as a function of the applied magnetic field under a strong transport current [3] open up a possibility to efficiently tailor the superconducting properties of nanostructured materials by inducing a nontrivial topology of superconducting screening currents. We report on a topological transition between superconducting vortices and phase slips under a strong transport current in an open superconductor nanotube with a submicron-scale inhomogeneity of the normal-to-the-surface component of the applied magnetic field. When the magnetic field is orthogonal to the axis of the nanotube, which carries the transport current in the azimuthal direction, the phase-slip regime is characterized by the vortex/antivortex lifetime $\sim 10^{-14}$ s versus the vortex lifetime $\sim 10^{-11}$ s for vortex chains in the half-tubes, and the induced voltage shows a pulse as a function of the magnetic field. This non-monotonous behavior is attributed to the occurrence of a phase-slip area at such magnetic fields, when the quasi-stationary pattern of vortices changes from single to double chains in each half-turn, followed by reentrance of the superconducting state with a chain of moving vortices when the magnetic field further increases. A three-fold voltage peak occurs in an ultrathin open Nb tube of radius 400 nm at the magnetic field about 10 mT. The topological transition between the vortex-chain and phase-slip regimes determines the magnetic-field–voltage and current–voltage characteristics of curved SC nanomembranes to pursue high-performance applications in advanced electronics (e.g., as novel superconductor switching-based detectors) and quantum computing.

5:15 PM NM02.04.01
Late News: Significant Progress in MgB2 Transport Jc and n Value with Vapor-Solid Reaction Route and C/Dy2O3 Additions Mike D. Sumption and Fang Wan; The Ohio State University, United States

In this work a vapor-solid reaction route was developed for MgB2 conductors with a multifilamentary structure of subelements with a Mg infiltration-based subelement design. The individual subelements consisted of Mg rods surrounded by B powder, all encased in a Nb chemical barrier. This design, used previously for liquid infiltration routes, was used for a lower temperature vapor-solid reaction route, with significant improvements in layer Jc, conductor Ic, and conductor n-value. This result is explained in terms of a two process model, including percolation through the strand, and local reactive diffusion to form the MgB2 phase. The model show that much deeper infiltration and a more complete reaction is possible with a vapor-solid route. Whole conductor Je values of 9 x 104 A/cm2 are obtained at 4 T, 4.2 K, (Ic = 500 A in our 0.83 mm OD, 18 filament conductor). Index values above 30 were obtained at 6 T. These conductors had co-additions of 2 mol% C and 2 wt% Dy2O3. A variety of C doping fractions and Dy2O3 additions are compared, and the best properties are found in samples with co-additions. It is seen that Dy2O3 suppresses Tc more slowly than C doping and thus is a useful co-additive at elevated temperatures. Co-additions are in every case superior to single additive designs, although the optimal amount of Dy2O3 additions depends on the intended temperature of use. This result is explained in terms of the relative fraction of inter- and intra-band scattering with C doping and Dy2O3 additions.

Late News: Cryogenic/Superconducting Considerations for Electric Aircraft Drivetrains Mary Ann Sebastian[1,2], Timothy Haugan[2], Mike D. Sumption[3] and Bang-Hung Tsao[1]; [1]University of Dayton Research Institute, United States; [2]Air Force Research Laboratory, United States; [3]The Ohio State University, United States

Transportation is a leading source of green-house gas emissions, with aircraft contributing to 10% of the CO_2 emissions at 900 million metric tons of CO_2/yr. Employing electric aircraft drivetrains would greatly diminish CO_2 emissions. However, implementation of all-electric, hybrid, and turboelectric propulsion systems does present many difficult challenges in regards to power capability, specific power, and specific energy. Superconducting power transmission and cryogenic machines have unique properties that can help overcome these challenges. Superconducting power transmission has no ohmic losses, lower transmission voltage, and utilizes smaller, lightweight conductors. Cryogenic machines utilizing superconducting wire possess very high

efficiency and supply a large current density. This presentation discusses cryogenic/superconducting considerations for electric aircraft drivetrains and provides an analysis of mass and heat loss scaling laws for various components of the electric drivetrain: such as metal conductors, busbars, current leads, metal/superconducting T-joints, HTS cables, and cryoflex tubing.

5:45 PM NM02.04.03
Late News: Current Sharing, Stability and Thermal Management in an Extremely Low AC Loss MgB2 Conductor Christopher Kovacs[1], Timothy Haugan[2], Mike D. Sumption[3], Mike Tomsic[4] and Matt Rindfleisch[4]; [1]National Academies of Sciences, Engineering, and Medicine, United States; [2]Air Force Research Laboratory, United States; [3]The Ohio State University, United States; [4]Hyper Tech Research Inc., United States

In the push to develop high power electric aircraft, superconducting technology promises to significantly reduce mass and volume of motors and generators. However, challenges related to AC Loss and thermal management are a significant factor in preventing the proliferation of aerospace superconducting technologies. Increasing the resistance of the metal matrix stabilization has only gone so far in reducing coupling currents for higher frequency applications. In this research, Multiphysics simulations were used to investigate using a very high thermal conductivity electrical insulator replacing the main slightly resistive metal matrix of an MgB_2 composite wire. The insulator separates the MgB_2 filaments entirely, only allowing transient current sharing to occur with the high purity (typically Niobium) diffusion barrier. The results of these simulations and a process to make this composite in a realistic manner using a molten salt impregnation process are then presented.

Prediction of Flux Pinning Properties of APC-Doped REBCO Coated Conductor by TDGL Method
Kaname Matsumoto; Kyushu Institute of Technology, Japan

Optimizing the critical current density *Jc* of REBa2Cu3O7-x (REBCO, RE = rare earth) coated conductors at a given temperature *T* and magnetic field *B* is particularly important in applications such as high magnetic field coils. To that end, it is necessary to know more about how the introduced artificial pinning centers (APCs) immobile the motion of quantized vortices. In order to solve this problem, we fabricated coated conductor samples in which BaMO3 (BMO : M=Hf, Zr, Sn) APCs were introduced into REBCO thin films and investigated in detail the effect on *Jc* under 4.2 – 20 K and *B//c*, 0-25 T magnetic fields. The thin film preparation conditions were adjusted to change the size and density of the BMO nanorods, and to control the concentration of random pinning centers such as oxygen vacancies. Information on nanostructures including BMO-APCs was obtained from REBCO samples by TEM observation, and vortex pinning simulation was performed by large-scale time-dependent Ginzburg-Landau (TDGL) equations for high kappa limit, with nanostructure information as input parameters. Thereafter, the predicted *Jc* and the measured *Jc* were compared. According to the experimental results, the maximum value of the global pinning force *Fp* (= *Jc* x *B*) of the sample varied from 0.7 to 1.7 TN/m3 depending on the concentration of BMO. When the concentration of BMO was high, the *Fp* value reached a peak of 1.7 TN/m3 at 8-10 T and formed a plateau. The plateau continued to the high magnetic field region of 25 T, the upper limit of the present experiment. When the concentration of BMO was low, the maximum value of *Fp* decreased to about half and gradually increased toward the high magnetic field side. On the other hand, according to TDGL simulation, when the concentration of BMO was high, *Fp* reached about 1.7 TN/m3 in the vicinity of 8-10 T (strong pinning regime), and then the *Fp* value was saturated to form a similar plateau (collective pinning, plastic pinning regime). In addition, when

the BHO concentration was halved, Fp decreased to about half, and the experimental results were successfully reproduced almost accurately. Large-scale TDGL simulations were expected to have splendid *Jc* prediction power, but now it is clear that the experimental *Jc* values of REBCO coated conductors with APCs can be simulated almost accurately. Additional random pin effects such as oxygen vacancies can be also incorporated into the TDGL simulation. The optimal structure of APC that maximizes *Jc* can be predicted under given *T* and *B* conditions by these methods, which can help improve the performance of coated conductors with real complex microstructures.

Development of High-tc Superconducting DC Cable System and Related Basic Studies Noriko Chikumoto, Hirofumi Watanabe, Yury Ivanov, Hirohisa Takano and Satarou Yamaguchi; Chubu University, Japan

For the social implementation of superconducting cables, the key point is how long the liquid nitrogen used to cool the superconducting cables can be circulated maintaining a predetermined temperature. In order to obtain the properties required to get a future prospect for longer length cable system, we participate a national project called Ishikari project that include the construction of two dc power lines, “Line 1” with 500m-length (5kA, 100 MVA) and “Line 2” with 1000m-length (2.5 kA, 50 MVA) and the circulation and current test using the system. The project had been started from 2013 and successfully ended on 2016 [1,2]. From the analysis of various data we have got the prospect that we can circulate the LN2 for more than 20 km. [3]. However, there are issues to be considered for the realization of 10-20 km system, such as improvement of thermomechanical characteristics, simplification of cable connection, weight reduction, and further improvement of cooling efficiency. We will discuss about these technical issues and show some of the basic research concerning them.

9:05 PM *NM02.05.03
Development of High-Performance $Ba_{1-x}K_xFe_2As_2$ Tapes for High-Field Magnet Applications Yanwei Ma[1,2]; [1]Institute of Electrical Engineering, Chinese Academy of Sciences, China; [2]University of Chinese Academy of Science, China

Iron-based superconductors exhibit high upper critical fields and low electromagnetic anisotropy, making them particularly attractive for high-field applications. IEE-CAS continues to address iron-based wire development and fabricating methods to improve characteristics and performance of the wires and tapes. The highest J_c value has reached 0.15 MA/cm^2 at 4.2 K and 10 T with a combination of densification and texturing processes in mono-core silver sheathed $Ba_{1-x}K_xFe_2As_2$ (Ba-122) tapes. By employing high strength Cu/Ag and stainless steel/Ag as sheath materials, larger than 0.1 MA/cm^2 at 4.2 K in an external magnetic field of 10 T was recently achieved for Ba-122 tapes by the scalable flat-rolling process. Furthermore, transport J_c of 100 m long tapes was further enhanced, higher than 30000 A/cm^2 (4.2 K, 10 T). We will show a summary of the recently achieved properties and give an outlook on the next development steps on our program roadmap.

9:30 PM NM02.05.04
Late News: Evidence of Ambient Superconductivity in Engineered Au-Ag Nanostructures Anshu Pandey; Indian Institute of Science, India

We had recently proposed the existence of room temperature, ambient pressure superconductivity in Au-Ag nanostructures. This presentation will provide an overview of the structural, electronic, magnetic and optical properties of these materials. It is shown that below a certain critical temperature that is dependent on sample structure and composition, these materials show transitions to a diamagnetic, zero resistance state. We further show that along with emergence of unusual magnetic and electrical properties, these materials also exhibit unconventional optics. In particular, we observe the suppression of usual metallic plasmon resonances and the appearance of a broad dissipation less resonance. A theoretical framework for correlating and explaining some

of these material properties is described.

SESSION NM02.06: Superconductors Wires/Tapes and Applications

8:00 AM *NM02.06.01
Frontiers of Nb_3Sn and REBCO Conductor Technology for Future Applications in High Magnetic Fields
Carmine Senatore[1], Florin Buta[1], Gianmarco Bovone[1], Marco Bonura[1], Tommaso Bagni[1], Davide Matera[1], Amalia Ballarino[2], Simon Hopkins[2], Bernardo Bordini[2] and Lucio Rossi[2]; [1]University of Geneva, Switzerland; [2]CERN, Switzerland

Low Temperature Superconductors (LTS) have today more widespread application than ever, with a large market pulled by Magnetic Resonance Imaging (MRI), Nuclear Magnetic Resonance (NMR) spectroscopy and large-scale science projects. In particular, Nb_3Sn is the prime candidate to develop accelerator magnets for the post-LHC collider, where unprecedented collision energies in the region of 100 TeV are envisaged. This goal has led to a baseline configuration requiring dipoles generating 16 T in a 100 km tunnel that translates into a requirement for critical current densities substantially beyond state-of-the-art for commercial Nb_3Sn wires and eventually close to the ultimate limit of the material. On the other hand, High Temperature Superconductors (HTS) were intended at the beginning as a vehicle for a new class of applications in the electric utility network. However, the game changing opportunity now coming from HTS and, in particular, from REBCO tapes results from the possibility to operate at high current densities in very high magnetic fields and at high cryogenic temperature. These properties raised the interest of both high-energy physics and fusion communities. High fields beyond the reach of LTS, in the range of 20 T, would enable a further increase of the collision energy in the next generation hadron colliders and are making possible the conception of compact fusion devices, which are crucial for the fusion's commercial realization. Moreover, the low sensitivity of the critical current to temperature, apart from the obvious simplification of the refrigeration system, would bring an improved stability of the magnet system, which is an essential requirement both in a particle collider and in a dynamic fusion environment. In this talk, I will address the current state and the directions in which the technology needs are driving the property evolution of Nb_3Sn and REBCO with a particular focus to the recent developments at UNIGE.

8:25 AM *NM02.06.02
Challenges in Designing Superconducting Magnets for the European DEMOnstration Fusion Power Plant Valentina Corato; ENEA, Italy

Fusion power offers the prospect of an almost inexhaustible source of energy for future generations. The design and R&D of future fusion reactor concepts is expected to benefit largely from the experience gained in the design, construction and operation of ITER. However, harnessing fusion energy and deploying reliable magnetic confinement fusion power plants, requires to overcome the design challenges and to address the remaining readiness gaps.

Many realizations of the DEMOnstration Fusion Power Plant (DEMO) are proposed in the world, featuring different concepts and approaches. In this framework Europe is starting the Conceptual Design Phase for building a superconducting tokamak and starting operations around the middle of the century. The aim is demonstrating the production of 500 MWs of net electricity, the feasibility of operation with a closed tritium fuel cycle, and maintenance systems capable of achieving adequate plant availability.
Superconducting magnets have the crucial role to produce high magnetic fields used for initiating, confining, shaping and controlling the fusion fuel in the form of plasma. The main challenges related to magnets regard the design layout (pancakes vs. layers), the superconducting materials (Low-Temperature vs. High-Temperature Superconductors) and technology (React&Wind vs. Wind&React manufacturing approach) and the possible use of radial plates.
An overview of the state-of-the-art and the main perspectives of the superconducting magnet technology considered for DEMO will be illustrated.

8:50 AM NM02.06.04
Late News: Angular Dependence of Pinning Unfolds the Difference Between YBCO and Fe(Se,Te) Films
Gaia Grimaldi[1], Antonio Leo[2,1], Angela Nigro[2,1], Masood Khan[2], Valeria Braccini[1], Carlo Ferdeghini[1], Francesco Rizzo[3], Andrea Augieri[3] and Marina Putti[4]; [1]CNR, Italy; [2]University of Salerno, Italy; [3]ENEA, Italy; [4]University of Genova, Italy

The study of pinning landscape is crucial to implement any coated conductor technology based on superconducting materials. In particular, the race to obtain a more isotropic material among High Temperature Superconductors has been pursued by the introduction of effective pinning centers in HTS. The advance of Iron-Based Superconductors can be boosted not only by the fact that Fe-chalcogenides are some of the most isotropic superconductors but also overcoming some conventional beliefs. The Fe(Se,Te) thin films, indeed, are very weak anisotropic superconductors with low values of both the anisotropy factors γ_j and γ_H, in the critical currents and critical fields, respectively. Nevertheless, a common feature with HTS is their layering crystallographic structure. Therefore a puzzling issue arises from the angular dependence of pinning in Fe(Se,Te) compared with YBCO films. We measure the irreversibility field $H_{irr}(\theta)$ and the activation pinning energy $U_p(\theta)$ as a function of the angle between the *c*-axis of the films and the applied magnetic fields up to 16 T. $H_{irr}(\theta)$ experimental data reveal similarities and differences between YBCO and Fe(Se,Te) films. Owing to their common material layered structure they both show an anisotropic *2D* behavior of the intrinsic pinning contribution, whereas the extrinsic pinning component unveils the *3D* isotropic pinning of Fe(Se,Te) against the *2D* pinning anisotropy of YBCO. A stronger endorsement comes from $U_p(\theta)$ data that show a steep peak around $\theta=0°$ (*H* paralell to the *ab*-planes) for both YBCO and Fe(Se,Te) films, which is the fingerprint of their flux pinning ability into the layering structure. By continuously rotating θ towards 90° degrees, only YBCO shows a smooth spread peak around $\theta=90°$ (*H* paralell to the *c*-axis), whereas no peak is observed for Fe(Se,Te). All these features promote Fe-chalcogenide superconducting material as the right candidate for coated conductor technology.

9:05 AM NM02.06.05
Late News: Improved Properties in Gd-Doped YBCO Film Grown by Chemical Solution Deposition
Valentina Pinto[1], Angelo Vannozzi[1], Achille Angrisani Armenio[1], Francesco Rizzo[1], Andrea Masi[1,2], Andrea Augieri[1], Antonino Santoni[1], Alessandro Rufoloni[1], Antonella Mancini[1], Laura Piperno[1,2], Valentina Galluzzi[1], Massimo Tomellini[3], Silvia Orlanducci[3] and Giuseppe Celentano[1]; [1]ENEA, Italy; [2]Roma Tre University, Italy; [3]Tor Vergata University, Italy

The replacement of Y^{3+} in $YBa_2Cu_3O_{7-\delta}$ (YBCO) by rare earth elements (*RE*s) such as Gd^{3+} to form alternative *RE*BCO compounds has been extensively studied and demonstrated to be very effective for the preparation of materials with enhanced superconducting properties. Chemical Solution Deposition (CSD) of GdBCO is widely adopted for the production of films, but film growth is more sensitive to process parameters with respect to YBCO synthesis. With the aim of overcoming this limitation and improving superconducting properties, mixed $Y_{1-x}Gd_xBa_2Cu_3O_{7-\delta}$ compounds have been successfully studied. To our knowledge,the introduction of Gd in the

form of Gd_2O_3 or GdBCO, added in excess with respect to YBCO, has been reported only by two papers (on bulk or film grown by sol-gel) and demonstrated to have a positive influence on superconducting properties. In this work, we propose a similar study applied to YBCO film deposited by CSD. The aim is to obtain the advantages related to the presence of Gd using the robust and reproducible process adopted for YBCO.In particular, when Gd is added in excess with respect to Y, it can form oxides as Gd_2O_3 or it can substitute Y to form GdBCO, whereas Y can form other oxides such as Y_2O_3. In both cases, many different defects might originate and act as artificial pinning centers, contributing to the overall improvement of superconducting properties.
CSD of Gd-doped YBCO (YBCO-Gd) film was carried out following the metal organic decomposition approach and *in-situ* route. Three dopant concentrations, i.e. 5, 10 and 20mol%, were studied. Film morphology and crystalline structure were deeply investigated by scanning and transmission electron microscopy (SEM and TEM), X-ray diffraction and photoelectron spectroscopy (XRD and XPS). In general, a well *c*-axis oriented grain structure was observed through XRD. However, YBCO-Gd5% and 10% samples show, with respect to pure YBCO, improved film coalescence and an increase of stacking faults number, as recognized by TEM. XPS allowed verifying the Gd distribution in the film and which phase Gd formed. Superconducting properties, assessed through electrical and magnetic measurements, were evaluated at different temperatures, magnetic field directions and intensities. Higher zero-field critical current densities were measured in the temperature range from 10 K to 77 K with 5% and 10% Gd concentrations (i.e. 28, 27 and 13 MA/cm^2 respectively for YBCO-Gd5%, YBCO-Gd10% and YBCO at 10K). This improvement by a factor two remains up to 12T and from 10 K to 65 K.
Preliminary data on YBCO-Gd20% evidenced the need for further process optimization aimed at reducing the porosity and the *a*-axis content well evident in the studied films. Nevertheless, the in-field superconducting properties were better than pure YBCO and comparable to YBCO Gd5% and YBCO Gd10%, although a different pinning strength acting in YBCO Gd20% samples could be recognized.
The obtained results confirm the efficacy of Gd addition for the enhancement of transport properties and the existence in YBCO-Gd films of a pinning mechanism particularly significant at low temperatures and different with respect to pure YBCO. The possible origin of such outcomes will be proposed and discussed.

9:20 AM NM02.06.06
Late News: Intrinsic Anisotropy and Pinning Anisotropy as Revealed by Surface Impedance Measurements in YBa2Cu3O7-d and FeSexTe1-x Thin Films Enrico Silva[1], Jorge Alcala[2], Andrea Alimenti[1], Andrea Augieri[3], Elena Bartolomé[4], Valeria Braccini[5], Giuseppe Celentano[3], Xavier Obradors[2], Anna Palau[2], Valentina Pinto[3], Nicola Pompeo[1], Teresa Puig[2], Marina Putti[6], Francesco Rizzo[3] and Kostiantyn Torokhtii[1]; [1]Università Roma TRE, Italy; [2]Institut de Ciència de Materials de Barcelona, Spain; [3]ENEA, Italy; [4]Escola Universitaria Salesiana de Sarrià, Spain; [5]CNR-SPIN, Italy; [6]Università degli Studi di Genova, Italy

Anisotropy is fundamental in layered superconductors $YBa_2Cu_3O_{7-\delta}$ (YBCO) and Fe-based compound like $FeSe_xTe_{1-x}$(FeSeTe). The sources of anisotropy are many. The unavoidable anisotropic electron effective mass (whence the anisotropic coherence length) gives rise to what we call here *intrinsic anisotropy* γ. The layered structure and extended defects like twin planes, grain boundaries, columnar or other linear defects such some artificial pinning centres (APC) introduce additional directional and a complex *pinning anisotropy*.

In magnetic-field dependent measurements all sources of anisotropy contribute to the overall response, with a difficult identification of the different contributions. Microwave measurements are able to disentangle the intrinsic from pinning anisotropy: high-frequency oscillating vortices experience the effect of vortex drag (the usual mechanism of flux-flow resistivity ρ_{ff}, which depends on the anisotropy through the effective vortex mass), pinning recall force (given by the pinning constant k_p), and flux-creep jumps (quantified by a normalized dimensionless parameter χ) [1]. By measuring the complex surface impedance $Z=R+iX$ as a function of the applied dc magnetic field H and the field orientation θ, possibly at different frequencies, all these contributions can be singled out, gaining separately access to the intrinsic and pinning anisotropy [2].
We perform measurements of $Z(H,\theta)$ with different dielectric resonator setups [3], operating at 16, 27 and 47 GHz, in dc fields up to 1.3 T at different field orientations. We investigate and compare the behaviour of YBCO thin films grown by Chemical Solution Deposition [4] and Pulsed Laser Deposition (PLD) [5], with and without APC in the shape of nanoparticles and nanorods, to the results obtained in pristine $FeSe_xTe_{1-x}$ thin films grown by PLD from $FeSe_{0.5}Te_{0.5}$ targets [6]. We extract the intrinsic anisotropy γ of the various samples, obtaining in YBCO consistent values $\gamma = 5.0\pm0.5$ [7] irrespectively of the kind of APC, and $\gamma \approx 2$ in FeSeTe. On the other hand, we obtain very different pinning anisotropies in all compounds. In YBCO, the pinning anisotropy is related in a complex fashion to the different directional APC, while in FeSeTe we do not measure in the angular dependence of the pinning constant significant departures from the effective mass effect.

This work has been carried out within the framework of the EUROfusion Consortium and has received funding from the Euratom programme 2014–2018 and 2019–2020 under Grant Agreement No. 633053. Late News: MgB2—A Promising Material for Large Scale Applications of Superconductivity Jacques Noudem[1,2], Yiteng Xing[1,2] and Pierre Bernstein[1,2]; [1]Normandie University, France; [2]ENSICAEN, France

While most applications of bulk superconductors are based nowadays on REBCO (RE: Rare earth) or BSCCO materials, the possibility to use liquid hydrogen as a fuel for airplanes and other applications on the one hand and the availability of powerful cryo-coolers on the other hand make light MgB_2 superconductors very attractive for large scale applications. The low density of this light material and its strong mechanical hardness are well suited to its possible use in electric aircrafts and windmill generators. Using the Spark Plasma Sintering technique, bulks can be manufactured in much less time than cuprates and the bulks can be given complex shapes. This is much more difficult with cuprates. These advantages make already MgB_2 a privileged material for the investigation of functional superconducting properties. As an example, we'll report the results of our studies on i) the effect of the thickness and the diameter of cylindrical superconductors on the levitation force and the condition for stability in superconducting magnetic levitation and ii) the role of the starting material on the critical current density of MgB_2 bulks and its dependence on the applied magnetic field.

Understanding Sources of Decoherence In Superconducting Quantum Devices with High Quality Factor Superconducting Resonators Sebastian de Graaf[1], Tonias Lindstrom[1], Alexander Tzalenchuk[1], Lev Ioffe[2,3], Lara Faoro[4], Andrey Danilov[5] and Sergey Kubatkin[5]; [1]National Physical Laboratory, United Kingdom; [2]University of Wisconsin–Madison, United States; [3]Google Inc, United States; [4]Sorbonne Université, France; [5]Chalmers University of Technology, Sweden

Despite the promises of superconducting qubits, their performance is presently limited by short coherence times due to defects intrinsic to materials. As a result, future quantum computers would require massive error correction circuits, which seem to be very challenging to build. Another more promising path would be to improve this coherence time, which would relax the constraints on the quantum error correction circuits and would thus make a quantum computer more feasible. This task is considered one of the main challenges in the field, and we contribute to its solution by measurements on high quality factor superconducting resonators [1,2]. Our approach gave vital clues to the long-standing problem of noise and decoherence in superconducting devices: a technique for on-chip Electron Spin Resonance (ESR) allowed to identify the chemical species responsible for the flux noise in superconducting circuits [3]. Furthermore, the noise measurements in superconducting resonators point to the link between charge and flux noise in superconducting circuits [4]: a mild sample treatment has led to tenfold reduction of the density of the surface spins, responsible for the flux noise, as evidenced by ESR, and this treatment has also lead to tenfold reduction of the low frequency noise in superconducting resonator, usually associated with charge noise.

Another major challenge comes from non-equilibrium quasiparticles (QPs) that result in qubit relaxation and dephasing. We reveal a previously unexplored decoherence mechanism in the form of a new type of Two-Level Systems (TLS) originating from trapped QPs, which can induce qubit relaxation. Using spectral, temporal, thermal and magnetic field mapping of TLS-induced fluctuations in frequency tunable resonators [2], we identify a highly coherent subset of the general TLS population with a low reconfiguration temperature around 300 mK, and a non-uniform density of states. These properties can be understood if the TLS are formed by QPs trapped in shallow subgap states formed by spatial fluctuations of the superconducting order parameter. This implies that even very rare QP bursts will impact coherence over exponentially long timescales. Summarizing this part, some spurious two-level systems observed in superconducting devices are attributed to long-lived quasiparticles trapped in gap inhomogeneities [5].

Finally, we study a single highly coherent environmental two-level system. We trace the in-time spectral diffusion of this individual TLS and demonstrate that it originates from the TLS coupling to a countable number of low energy incoherent fluctuators (TLF). From the analysis of these fluctuations, we can access relevant parameters of these otherwise elusive low energy TLFs including TLF-TLF interaction energies. Our approach opens up for deriving the macrosocopic observables of glassy media from direct measurements of local TLF dynamics at microscopic level - a route towards substantiating commonly accepted models for a decohering environment.

In summary, the use of high-Q superconducting resonators contributes to the construction of full microscopic model for interacting TLS and will then present a solid foundation for building up an ensemble level description of a glassy TLF media. Such a development, in turn, will provide so much needed understanding of decoherence mechanisms at microscopic level and indicate approaches for mitigation of decoherence.

Temperature Dependence of Quasiparticle Tunneling as a Probe of Transmon Quality Cihan Kurter; IBM T.J. Watson Research Center, United States

Non-equilibrium quasiparticles are possible sources for decoherence in superconducting qubits because their tunneling across the Josephson junction can lead to relaxation. In this talk, we will present the impact of intrinsic properties of our transmons on quasiparticle tunneling (QPT) and discuss how this affects the device quality and performance. We find that the QPT rate to be sensitive to the choice of materials and to the geometry of the capacitive pads shunting the Josephson junctions in transmons. In some of our devices, we observe an anomalous temperature dependence of the QPT rate below ~ 100 mK that deviates from a flat background associated with non-equilibrium quasiparticles. One hypothesis for this trend which will be discussed is that sites of high transparency in the Josephson junction give rise to such behavior.

11:20 AM NM02.07.03
Late News: Investigate Microwave Losses of Materials with Superconducting Resonators Chan U Lei[1], Suhas Ganjam[1], Lev Krayzman[1], Ignace Jarrige[2], Luigi Frunzio[1] and Robert Schoelkopf[1]; [1]Yale University, United States; [2]Brookhaven National Laboratory, United States

Improving the coherence of superconducting circuits is one of the biggest challenges in superconducting quantum computing. Superconducting quantum circuits are built from materials such as dielectrics and superconductors. The microwave dissipations from these materials limit the coherence of the circuits. Since the dissipated power of the constituent materials combines in parallel, the materials' quality of all the dominating loss channels needs to be improved simultaneously to enhance the coherence. Therefore, identifying and quantifying materials' microwave losses in superconducting circuits is crucial to developing quantum circuits with very high coherence. In this talk, we will present how to use superconducting resonators to characterize and measure microwave losses of materials in superconducting circuits.

Late News: Low Frequency AC Josephson Effect in Ultrasmall Josephson Junctions Hermann Suderow; Universidad Autónoma de Madrid, Spain

The Josephson effect is the consequence of coupling between two superconducting electrodes and consists of a Cooper pair current flowing between the two superconductors at zero bias voltage V=0 and coherent emmission of photons with energy eV at a finite bias voltage V>0. Here we show that ultra small Josephson junctions embedded in a circuit with a feedback oscillate between zero and finite voltage states. We measure the resulting AC oscillations in Pb-Pb, Al-Al and Pb-NbSe$_2$ atomic size Josephson junctions with a millikelvin Scanning Tunneling Microscope (STM). We discuss prospects and applications of the newly found AC behavior.

11:50 AM NM02.07.05
Late News: Direct Ion Beam Writing of Josephson Junctions in Superconducting Nitrides Aki Ruhtinas and Ilari Maasilta; University of Jyvaskyla, Finland

Direct writing of Josephson junctions using focused ion beam was recently demonstrated in YBCO [1] and MgB2 thin films [2]. This method can simplify and extend the fabrication of Josephson junctions for superconducting devices. We use this approach for superconducting nitride thin films, and show how disorder-driven superconductor-insulator transition (SIT) can be used in Josephson junction fabrication using a helium ion beam. We use high quality superconducting thin films of NbN, TiN and NbTiN that we grow with an infrared pulsed laser deposition technique [3], and demonstrate that in all of the studied nitrides superconductivity can be suppressed by helium ion irradiation, with a higher helium ion fluence resulting in a lower critical temperature Tc. This controllable Tc suppression combined with the high spatial resolution of the

helium ion microscope enables us to successfully fabricate SNS-type Josephson junctions with highly tunable weak links. First results indicate that the most promising candidate among the three superconducting nitrides studied is NbTiN, because of its high Tc (~ 15 K), low resistivity and easily controllable SIT transition. In addition, we demonstrate that NbTiN thin films can be pushed to the insulating side of the SIT transition with a high enough helium ion fluence. Thus, we also managed to fabricate insulating barrier SIS Josephson junctions with NbTiN, in addition to SNS- type devices.

12:05 PM NM02.07.06
Superconducting rf-SQUIDs Based Metamaterials Operated in 3WM and 4WM Regimes for Travelling Microwaves Luca Fasolo[1,2], Angelo Greco[1,2], Alessio Rettaroli[3], Luca Piersanti[3], Giovanni Maccarrone[3], Carlo Ligi[3], Daniele Di Gioacchino[3], Claudio Gatti[3], Matteo Beretta[3] and Emanuele Enrico[1,2]; [1]Istituto Nazionale di Ricerca Metrologica, Italy; [2]Piemonte Quantum Enabling Technologies Laboratory - PiQuET, Italy; [3]Istituto Nazionale di Fisica Nucleare - Laboratori Nazionali di Frascati, Italy

At microwave frequencies, Josephson parametric amplifiers (JPA), based on a resonant architecture, have demonstrated quantum-limited noise and are currently used in emerginng fields like axion search or solid state qubits read out. Despite significant advances allowing improved bandwidth and saturation power JPAs are however still insufficient for addressing the needs of the above-mentioned applications. Traveling Wave Parametric Amplifiers (TWPAs) represent a potential solution. At microwave frequencies, a TWPA is designed as a nonlinear metamaterial that exploits the signal response of reactive parts (typically inductance) in a superconducting circuit. A large pump tone modulates this inductance, coupling the pump (f_p) to a signal (f_s) and idler (f_i) tone via frequency mixing such that $2f_p = f_s + f_i$ (4-wave mixing, 4WM) or $f_p = f_s + f_i$ (3-wave mixing, 3WM).
Parametric amplifiers are currently the only known method to achieve quantum-limited sensitivity to microwave signals but achieving a large enough and sufficiently flat bandwidth over the entire needed band is still a challenging task. Worldwide, research efforts are under way to solve these problems, by developing several prototype functional amplifiers. TWJPA appear as the ultimate microwave amplifiers since they promise large gain, wide bandwidth, high saturation power and low noise approaching the quantum limit, making it robust, easily integrable into experimental setups, and cost-effective application in detectors read out and in quantum information sciences.
In recent times, the concept of a parametric amplifier with microwaves travelling along a transmission line with embedded Josephson junctions (TWJPA) was developed in several groups. These devices have already demonstrated quantum-limited noise and are used to readout superconducting qubit. TWJPA are classically designed for operating only in the 4WM regime. In this approach, the necessary phase matching of the travelling microwaves requires sophisticated dispersion engineering which still cannot ensure perfect phase matching in a sufficiently wide frequency range. This results in undesirable resonance dips and considerable ripple in the gain versus frequency dependence. Recently, a wide-band parametric amplifier operating in the regime of 3WM, has been proposed. The proposed design consists of a 3WM TWJPA based on microwave transmission line formed by a serial array of non-hysteretic rf-SQUIDs. This one-dimensional metamaterial possesses large quadratic nonlinearity and nominally zero (unwanted) cubic (Kerr-like) nonlinearity. Proof-of-principle measurements performed at a temperature T = 4.2 K on Nb/AlOx/Nb trilayer samples have demonstrated the validity of the concept of this practical TWJPA with great promise for quantum-limited performance. It is expected that TWJPA devices operating in the three-wave mixing mode will outperform state-of-the-art parametric amplifiers with respect to simultaneously achieving large gain and high bandwidth. In the present work several characterizations of TWJPAs based on Al standard Josephson junctions technology will be presented. The DC current tunability of such a rf-SQUIDs based metamaterial will be investigated by focusing on the 4WM and 3WM regimes. Single tone transmission spectroscopy and signal gain evaluation by means of the so-called pump-on-pump-off method will be discussed with particular attention to real devices

non-idealities that introduces a complex behaviour of the amplifier response.

Late News: Large Fluctuations of T1 in Long-Lived Transmons Kungang Li, Sudeep Dutta, Rui Zhang, Zachary Steffen, Dylan Poppert, Shahriar Keshvari, Jeffery Bowser, Benjamin Palmer, Christopher Lobb and Frederick Wellstood; University of Maryland, United States

As the relaxation time T_1 of transmons has increased in recent years, apparently so has the size of the fluctuations in T_1. To investigate the cause of these fluctuations we measured the T_1 of transmons made with an electrode layer of pure aluminum and a counter-electrode layer made with either pure Al or oxygen-doped granular Al. The superconducting energy gap of the counter-electrode depends on the layer's thickness and the grain size, which depends on the oxygen doping. At 20 mK an oxygen-doped device showed T_1 variations between about 80 μs and a maximum of 300 μs, while an un-doped device on the same chip showed uncorrelated T_1 variations between about 50 and 100 μs. Measurements of the fluctuations versus temperature reveal that the standard deviation of T_1 is proportional to T_1, even above 150 mK, where the transmon relaxation is dominated by thermally generated quasiparticles. We discuss why this behavior is not consistent with the two most commonly proposed mechanisms, fluctuations in two-level-system dielectric loss or fluctuations in the density of non-equilibrium quasiparticles and propose an alternative mechanism that is consistent with this behavior.

SESSION NM02.08: REBCO Films and Coated Conductors
Session Chairs: Fedor Gomory and Joffre Gutierrez
Thursday Afternoon, April 22, 2021
NM02

1:00 PM NM02.08.01
$REBa_2Cu_3O_{7-x}$ Coated Conductors Integration in High-Energy Physics Applications Joffre Gutierrez[1], Artur Romanov[1], Patrick Krkotic[2,3], Guilherme Telles[1], Joan O'Callaghan[3], Francis Perez[2], Montse Pont[2], Xavier Granados[1], Ilya Korolkov[4], Sergio Calatroni[5] and Teresa Puig[1]; [1]Institut de Ciència de Materials de Barcelona, Spain; [2]ALBA Synchrotron, Spain; [3]Universitat Politècnica de Catalunya, Spain; [4]Institut de Física d'Altes Energies, Spain; [5]CERN, Switzerland

On the 19th of June 2020, the European Strategy Group announced the 2020 update of the European Strategy for Particle Physics, identifying the ambition to operate a proton-proton collider (FCC-hh) at the highest achievable energy as long term future priority. CERN's FCC-hh is the most ambitious scenario for a post LHC machine. It will operate as an 80-100 km acceleration ring where 16-18 T magnets will steer proton bunches producing center-of-mass collision energies of 100 TeV. In order to protect the superconducting magnets, the 35.4 W/m/beam synchrotron radiation emitted by the protons will be absorbed by a stainless steel tube, the so called beam-screen chamber, held at a temperature window of 40-60 K. Image currents will be induced into the steel walls of the beam-screen endangering the beam stability. To counteract this effect, the interior of a beam-screen chamber has to be coated with a highly conductive material. Our consortium explores the possibility to replace the conventional beam-screen coating Cu with $REBa_2Cu_3O_{7-x}$ (RE = rare earth) Coated Conductors (CCs) in order to increase the beam stability margin.
In this contribution, we demonstrate why commercially available REBCO CCs are promising candidates for the FCC-hh beam screen coating. Critical current densities measured up to 9 T at 50 K, which is the operating reference temperature of the beam screen chamber, point towards a superconducting performance that can sustain the induced peak image currents of 25 A at FCC conditions. We present the surface resistance R_s of CCs and Cu colaminated on stainless steel at 8 GHz and in a wide range of cryogenic temperatures and magnetic fields. We find that CCs outperform Cu under operating conditions close to those to be found in the FCC-hh. In

addition, high frequency vortex parameters like the depinning frequency are extracted from the data by fits with the Gittleman-Rosenblum model. This allows a discussion on the limits of the mean-field model and the correlation between surface resistance and microstructure of different REBCO CCs. The next steps towards an aspect ratio study of Cu and CCs in order to minimize trapped fields in the beam screen chamber, their assembly in the beam screen and the expansion of measurement conditions to the more realistic 16 T and 1 GHz will be discussed.

1:15 PM NM02.08.02
Late News: Direct Visualization of Current-Stimulated Oxygen Migration in YBa2Cu3O7-δ Thin Films Alejandro Silhanek[1], Stefan Marinković[1], Alejandro Fernández-Rodríguez[2], Simon Collienne[1], Sylvain Blanco Alvarez[1], Sorin Melinte[3], Boris Maiorov[4], Gemma Rius[5], Xavier Granados[2], Narcis Mestres[2] and Anna Palau[2]; [1]Université de Liège, Belgium; [2]Institut de Ciencia de Materials de Barcelona, ICMAB-CSIC, Spain; [3]Université Catholique de Louvain, Belgium; [4]Los Alamos National Laboratory, United States; [5]Institute of Microelectronics of Barcelona, Spain

The past years have witnessed major advancements in all-electrical doping control on cuprates. In the vast majority of cases, the tuning of charge carrier density has been achieved via electric field effect by means of either a ferroelectric polarization or using a dielectric or electrolyte gating. Unfortunately, these approaches are constrained to rather thin superconducting layers and require large electric fields in order to ensure sizable carrier modulations. In this work, we focus on the investigation of oxygen doping in an extended region through current-stimulated oxygen migration in $YBa_2Cu_3O_{7-\delta}$ superconducting bridges. The underlying methodology is rather simple and avoids sophisticated nanofabrication process steps and complex electronics. A patterned multiterminal transport bridge configuration allows us to electrically assess the directional counterflow of oxygen atoms and vacancies. Importantly, the emerging propagating front of current-dependent doping δ is probed in situ by optical microscopy and scanning electron microscopy. The resulting imaging techniques, together with photoinduced conductivity and Raman scattering investigations, reveal an inhomogeneous oxygen vacancy distribution with a controllable propagation speed permitting us to estimate the oxygen diffusivity. These findings provide direct evidence that the microscopic mechanism at play in electrical doping of cuprates involves diffusion of oxygen atoms with the applied current. The resulting fine control of the oxygen content would permit a systematic study of complex phase diagrams and the design of electrically addressable devices.

1:30 PM NM02.08.03
Late News: Analytical Modelling of the Functional Properties of Superconductors—A Useful Tool Complementary to Numerical Simulation Pierre Bernstein, Yiteng Xing and Jacques Noudem; Normandy University, France

Most investigations on the functional properties of bulk superconductors, such as the trapped field and the levitation force, are done nowadays by numerical simulations combining the finite element method and the A, H or T-Ω formulations of the differential Maxwell equations. By comparison, analytical models require generally a regular distribution of the applied field and are practical with simple superconductor shapes with a high level of symmetry only. They have however the advantages to require much less computation time than numerical simulations and to show physical laws that are not always obvious in the results of the simulations. In this contribution we'll present analytical mean field models of superconducting magnetic levitation (SML) reproducing the levitation force on the one hand and the guidance force on the other hand. We'll show that these models give very useful information for the design of the applications of SML concerning: i) the localization of the shielding currents in the superconductors and ii) the condition for stability of axisymmetric levitating systems.

1:45 PM NM02.08.04
Late News: Reducing Cross-Field Demagnetization in Stacks of REBCO Tapes by Soldering Enric Pardo[1], Mykola Solovyov[1], Anang Dadhich[1], Shuo Li[2], Marek Mosat[1] and Jan Souc[1]; [1]Slovak Academy of Sciences, Slovakia; [2]Northeastern University, China

The most powerful remnant-magnetic-field magnets are stacks of REBCO high-temperature superconducting tapes, which can trap up to 17.7 T. However, relatively low alternating magnetic fields perpendicular to the trapped magnetic field can demagnetize, or even fully demagnetize, the stacks [1]. This is a problem for many power devices, such as rotating machines with stacks of tapes in the rotor. Promising applications are aircraft propulsion motors for hybrid or electric airplanes [2], where ripple fields are of the order of 1 kHz or higher. At this frequency, a flight of only 1 hour corresponds to more than 3 million ripple-field cycles, which can fully demagnetize the stack, if the ripple field amplitude is high enough [1]. In this contribution, we present a solution to reduce cross-field demagnetization for many cycles, based on soldering the tapes. We base our study in both measurements and modeling. For modeling, we use the Minimum Electro-Magnetic Entropy Production (MEMEP) [3] to find the screening currents, taking into account the effect of soldering the tapes with a finite resistivity [4]. For the measurements, we magnetize the stack in liquid nitrogen with a superconducting magnet and later apply a transverse alternating field by means of a copper coil for frequencies of up to 500 Hz. Modeling shows that soldering the tapes with low enough resistance can drastically reduce the cross-field demagnetization. In order to achieve sufficiently small tape-to-tape resistance, we solder the tapes face-to-face in the experiments, confirming the findings from modeling. With this contribution, we show that soldered stacks with low resistance between tapes are very interesting for applications, and hence it is worth to dedicate efforts in this direction.

2:00 PM NM02.08.06
Late News: Controlling the Doping of YBCO Nanowire Through Electromigration Edoardo Trabaldo, Riccardo Arpaia, Eric Wahlberg, Floriana Lombardi and Thilo Bauch; Chalmers University of Technology, Sweden

The understanding of copper oxide superconductors, and in particular $YBa_2Cu_3O_{7-\delta}$, is inextricably tied to the complex electronic phases of those materials in their normal state. Here various nanoscale ordering phenomena occur as a function of doping and temperature and thus two key factors need to be addressed: 1) study the material at the nanoscale and thus the characteristic length scales of the phenomena under study, 2) precise control of the charge doping, which determines its properties.
Nanowires with different oxygen content are the ideal platform to study the electronic properties of YBCO as a function of doping. Alas, their fabrication is challenging, and each doping level requires a separate fabrication process. Moreover, the nanowire properties at different doping levels might vary due to different fabrication conditions. As an alternative solution, we use electromigration (EM) to control ex-situ the doping level of YBCO nanowires.
This process involves the displacement of the dopant oxygen atoms by applying a strong electric current. Pulsed EM can be used to gradually reduce the doping of a YBCO nanowire, while DC biased EM can be conversely used to restore the oxygen content of the same nanowire. These EM processes result in high-quality YBCO nanowires and can be used to fine tune their doping level. Indeed, with a single nanowire we were able to recover most of the YBCO phase diagram, with critical temperatures ranging from 90 K to 45 K.
The ex-situ control of the doping level in YBCO nanowires is a milestone towards an in-depth study of the phase diagram of cuprates. The EM bypasses the challenges of different fabrication techniques and opens the way for using the same nanowire to study the entire phase diagram. Moreover, this technique is interesting for the technological applications of YBCO weak links, where the tuning of the nanowire properties, such as

critical current and kinetic inductance, is required.

2:15 PM NM02.08.07
Late News: Development of Hot Spot in Coated Conductor Tape Due to Local Reduction of Critical Current Fedor Gomory and Jan Souc; Slovak Academy of Sciences, Slovakia

Coated conductor (CC) tapes with functional layer of high-temperature superconductor REBCO (RE = Y, Gd, Er,…) exhibit impressive capability of transporting large amounts of electricity when the critical current, I_c, could commonly reach 1000 A in a tape 12 mm wide when cooled down to 77 K. However, when checking this property along the tape length, it quite often reveals the existence of locations with suddenly reduced I_c value. It is then not obvious which value of current should be taken as the limitation for a steady DC transport. We expect that a current slightly surpassing the local critical value could be sustained, but at its further increase the temperature will rise quickly creating the "hot spot" with enormous local dissipation causing an irreparable damage.
We present the model allowing to investigate the evolution of temperature in the location with reduced critical current analytically. It was found, that at surpassing the local I_c this temperature could stabilize at an elevated value, provided the dissipation is balanced by the cooling capability of surrounding environment. However, for a given tape architecture and cooling conditions, there is always the value of transported current that triggers the development of a hot spot. Advantage of our approach is that it allows in rather simple way to predict the result of DC transport at currents larger than the local minimum of critical current. Experiments with the tapes optimized for use in a resistive fault current limiter confirmed the validity of our theoretical formulas.

SESSION NM02.09: Vortex Pinning and Critical Current
Session Chairs: Qiang Li and Mike Sumption
Thursday Afternoon, April 22, 2021
NM02

4:00 PM NM02.09.01
Late News: Strong Increases in Transport Current, Grain Refinement and Point Pining with Internal Oxidation of Ti, Zr, and Hf Solutes in APC Nb3Sn Superconductors Mike D. Sumption[1], Xingchen Xu[2], Jacob Rochester[1], Xuan Peng[3], Gabriel Ortiz[1] and Jinwoo Hwang[1]; [1]The Ohio State University, United States; [2]Fermilab, United States; [3]Hyper Tech Research, United States

Over the last few years, it has been shown that an internal oxidation process can be used to more than double the layer Jc of state-of-the-art Nb3Sn conductors, with ternary level Bc2 values and practical conductor layouts. Part of the reason for this large increase is that the grain size is reduced, and since conventional Nb3Sn pins flux exclusively at the grain boundaries, this leads to large transport increases. This grain boundary refinement is cause by Zener pinning associated with oxide nanoparticles generated by the oxygen which has diffused in during the internal oxidation process. However, the oxide nanoparticles themselves pin flux directly. As the size of the nanoparticles decreases and their density increases, we can shift the character of the pinning from grain boundary to point pinning, as quantified by the shape of the pinning curve. In this work we compare various members of the group-IVB elements (Ti, Zr, Hf) as internal oxidants, showing that the size decreases while density increases as we move from Ti to Zr to Hf. We also confirm that internal oxidation is required to obtain the largest grain reductions and required for any level of peak shift. We use TEM to show the size and distribution of the precipitates, as well as map their distribution across the growth layer. We see that the TiO particles are typically 100 nm, while those of the ZrO are 5-10 nm, and those of the HfO are below 5 nm. We discuss the role of classic nucleation and growth in determining these factors. We find that the Fp curve shifts from 0.2 Birr for unoxidized Hf and control samples to 0.25 Birr for ZrO precipitates to 0.27 Birr for HfO. Further consideration of the underlying mechanisms should allow yet further improvements in conductor

performance. Our results, in particular the influence of the precipitates on peak shift, suggests that internal oxidation is presently the most promising route for high field performance increases in Nb3Sn.

4:15 PM NM02.09.02
Late News: Optimizing Supercurrent Transmission in NiFe Ferromagnetic Josephson Junctions Using Ni "Dusting" Swapna Sindhu Mishra, Robert M. Klaes, Reza Loloee and Norman O. Birge; Michigan State University, United States

Josephson junctions with ferromagnetic layers where the ground-state phase difference can be reliably controlled are a potential candidate for applications in cryogenic memory devices, which can greatly reduce the ever-growing energy requirements for large-scale computing. Phase control has been successfully demonstrated with junctions containing a Ni fixed layer and a NiFe free layer [1,2]. However, there are still several improvements that can be made to increase the efficiency and reliability of these junctions. We present work on improving the transmission efficiency of single layer NiFe junctions by “dusting” the NiFe with thin layers of Ni on both sides. We also present a study of the 0-Pi transitions in these Ni “dusted” NiFe junctions.

This work is supported by Northrop Grumman Corporation.

4:30 PM NM02.09.03
Late News: Understanding the Role of Interfilament Bonding on the Critical Current Density of bi-2212 Round Wires and Optimization of Wire Architecture Imam Hossain, Jianyi Jiang, Peter J. Lee, Temidayo Abiola Oloye, Fumitake Kametani, David Larbalestier and Eric Hellstrom; Florida State University, United States

Currently, the record J_c achieved in Bi-2212 short samples is around 9600 ampere per mm^2 at 5 T in 4.2 K. However, this performance has not yet been reproduced in long length coils and to date, the maximum J_c achieved in a coil is much lower compared to short samples. One possible reason for this lower J_c in coils is because the Bi-2212 wire in the coils has more interfilamentary bonding than in short Bi-2212 wires. This difference in amount of bonding can be explained by the amount of time the Bi-2212 spends in the melt state (t_{melt}) during the heat treatment. Short samples are heat treated in small overpressure (OP) furnaces and the heat treatment parameters can be controlled precisely. Large coils, which have large thermal masses, have to be heat treated in large OP furnaces where precise temperature control is not straight forward and small variations can cause significant changes in t_{melt}. We find that J_c depends on t_{melt} and this dependence is more prominent in wires with shorter distance between the Bi-2212 filaments compared to wires with larger filament separation. For a given t_{melt}, wires with smaller filament separation have more filament bonding than wires with larger filament separation. We believe the amount of filament bonding impacts the degree of Bi-2212 alignment, with longer t_{melt} resulting in less aligned Bi-2212 and therefore lower J_c. We are studying the underlying mechanism of how interfilament bonding impacts the electromagnetic properties of Bi-2212 wires. In our studies, we have found that interfilament bonding causes fluctuations in Bi-2212 filament cross-sections along the length of the wire, which possibly reduces the critical current. We have begun studying the kinetics of interfilament bond formation so we can quantitatively describe the amount of bonding that occurs in different wires as a function of time during the OP heat treatment. Our goal is to use this kinetic data to optimize the distance between Bi-2212 filaments to minimize the impact t_{melt} has on J_c, which should make it easier to OP heat treat coils in large OP furnaces, and will improve coil performance.

4:45 PM NM02.09.04
Late News: High Speed MgO Buffer Layer Deposition System for Commercial HTS Tape Production

James A. Greer[1], Larry Scipioni[1], Alexey Mankevich[2], Anton Markelov[2] and Alexander Molodyk[2]; [1]PVD Products, United States; [2]S-Innovations, Russian Federation

The rapidly growing field of compact nuclear fusion technology is driving the need for HTS-equipped electromagnets. The amount of tape needed just to build a single demonstrator reactor outstrips – by an order of magnitude – the present worldwide capacity to produce tape. Thus, higher speed tape manufacturing is a critical need. One of the bottlenecks in the production of buffered tape is the epitaxial MgO layer deposited on amorphous oxide. In the Stanford process, ion beam assisted deposition (IBAD) produces the biaxially textured template for subsequent addition of epitaxial MgO (EPI) by electron beam evaporation on heated substrates. The IBAD growth rate is limited by the available ion beam flux, which must match the arriving flux of MgO molecules at the tape substrate.
PVD Products has developed and commercialized a dual-chamber system for high speed production of IBAD/EPI layers. The system can process 1 kilometer of 100 µm thick tape at a speed of 200 meters/hour. Longer lengths of thinner tape are possible due the high capacity electron beam sources. The system features extended length deposition zones with multiple tape passes and, most importantly, a unique IBAD geometry pairing one evaporator with two large rectangular RF ion sources. The EPI layer chamber is likewise equipped with dual evaporation sources to support growth of thick EPI MgO at high processing speed. Multi-pass deposition handles 12 mm wide tape, and the tool is also designed to handle a single lane of 10 cm wide tape, albeit at a lower tape speed of ~50 m/hour. Two dedicated, differentially pumped RHEED chambers provide real-time feedback on film quality of both the IBAD and EPI processes without exposing the RHEED system to evaporant or high gas pressure. The tool has demonstrated processing 1 km of tape in a continuous 5-hour run. Due to the robust design, initial testing has also been extended to web speed up to 350 m/hr while still producing good RHEED patterns from both chambers. We will give an overview of the technology and present results from initial characterization the films deposited on metal tapes, including post-processing of LMO and ReBCO to complete the HTS stack.

SESSION NM02.10: Superconducting Files and Coated Conductors Applications
Session Chairs: Noriko Chikumoto and Kaname Matsumoto
Thursday Afternoon, April 22, 2021

8:15 PM *NM02.10.01
Recent Progress of HTS R&D and Production at Shanghai Superconductor Technology Yutaka Yamada[1,2], Yue Zhao[2,3], Jiamin Zhu[2,3], Guangyu Jiang[2], Chunsheng Cheng[2], Zhiyong Hong[2,3] and Zhijian Jin[3]; [1]Chubu university, Japan; [2]Shanghai Superconductor Technology Co., Ltd, China; [3]Shanghai Jiao Tong University, China

Recent efforts to develop REBCO wire at Shanghai Superconductor Technology will be presented. Mainly two kinds of wire, GdBCO and EuBCO with/without pinning center are constantly produced at a high-speed deposition rate of 50nm/sec. Monthly production of the wire achieved in 2020 achieved about 50 to100km/month. Not only mass-production but also R&D for high-field application are also being developed. For example, we achieved high critical current, I_c, and pinning force at 4K, 18T of 430 A/4 mm-width and 806.2 GN/m^3, respectively. In addition to these main R&D, efforts to improve production system are being done for wire precise size control, Hastelloy substrate thickness, and so on.

8:40 PM *NM02.10.02
SuperOx Research and Development Strategy for Customization of Commercial REBCO Coated Conductors for Various Applications Sergey Lee; SuperOx Japan, Japan

During 10 years since it foundation SuperOx Japan has been successfully developing IBAD/PLD approach for manufacturing of 2G HTS wires and in collaboration with SuperOx and S-Innovations (Russia) delivered hundreds of kilometers of REBCO based coated conductors for R&D and commercial projects worldwide. SuperOx strategy based on customization of 2G HTS superconducting wires for application in particular temperature and field ranges. Based on the operating conditions in terms of magnetic field strength and temperature the company outlined five target areas for the development of new 2G HTS wires including:
1) Superconducting fault current limiters (SFCL, operating in self-field at 77K);
2) Rotating machines, particularly motors for aircrafts (1-3T and 65-70K);
3) Magnets for induction heaters, flywheels and MagLev (3-5T, 30-40K);
4) Coils for fusion reactors (12-20T, 20K);
5) Inserts for high-field NMR (>25T, 4.2K).
The R&D strategy for new line of SuperOx 2G HTS products relied on the combination of following approaches:
Variation of composition by chemical substitutions;
Optimizing the overall superconducting material stoichiometry;
Controlling of hole doping level (oxygen content);
Introduction of pinning centers including fabrication of multilayers;
Heavy ion irradiation of the HTS wires.
By the end of 2020 SuperOx companies reached production capacity of 300 km of 2G HTS wires per year and in 2021 we are planning to approach the level of 1000 km/year. In the course of production, it was revealed that new tapes demonstrate extremely attractive properties, for instance critical current (Ic) up to 1000A/12mm (s.f, 77K) record high engineering current (Je) exceeding 1000A/mm2 at 20K-20T and over 2000A/mm2 at 4.2K and 20T was demonstrated.
In this work we carried out systematic analysis of large number of industrially produced tapes studied by XRD, SEM-EDX, TEM, micro Raman techniques and their connection with final Ic-B-theta characteristics. Several important features responsible for superior Ic-B characteristics were identify which was very helpful to stabilize the production of tapes with improved Ic-B characteristics and to increase the production yield.

Strong Vortex Pinning in (Ba,K)Fe_2As_2 Epitaxial Thin Films by Grain Boundary Engineering Kazumasa Iida[1,2], Dongyi Qin[3], Chiara Tarantini[4,5], Takafumi Hatano[1,2], Hikaru Saito[6,2], Yiming Ma[6], Chao Wang[6], Satoshi Hata[6,6,2], Michio Naito[3,2] and Akiyasu Yamamoto[3,2]; [1]Nagoya University, Japan; [2]JST CREST, Japan; [3]Tokyo University of Agriculture and Technology, Japan; [4]National High Magnetic Field Laboratory, United States; [5]Florida State University, United States; [6]Kyushu University, Japan

Significant progress on the thin film growth of iron-based superconductors (FBS) has been achieved over the last decade. As a result, high quality, epitaxial thin films of the technological important FBS [e.g., Fe(Se,Te), doped *Ln*FeAsO (*Ln*: lathanoide) and doped *Ae*Fe_2As_2 (*Ae*: alkari earth elements)] are realised on different kinds of single crystalline substrates and technical substrates except for (Ba,K)Fe_2As_2.
Recently, we have successfully fabricated (Ba,K)Fe_2As_2 epitaxial thin films on fluoride substrates[1], which gives a great opportunity to investigate electrical transport properties. Here, we report on a high critical current density J_c of 14.6 MA/cm^2 at self-field and 4 K, corresponding to the pinning efficiency $\eta=J_c/J_d$ of 8.8% (J_d: depairing current density). This value is much higher than the single crystal with artificial isotropic defects (η=3.5%) [2]. The angular-dependent J_c always shows a large *c*-axis peak below 25 K, which is the opposite behaviour to the expected one from the upper critical field anisotropy. Microstructural analysis by transmission electron microscope revealed the presence of many grain boundaries located almost parallel to the crystallographic *c*-axis. These results suggest that low-angle grain boundaries work as strong correlated pinning centres.

Late News: Critical Current Density in Ca and Ce Counter-Doped YBCO Jamil Tahir-Kheli and Carver Mead; California Institute of Technology, United States

A recent paper (https://arxiv.org/abs/1702.05001) suggests that the D-wave gap symmetry of cuprate YBCO may be changed to S-wave gap symmetry by simultaneous doping of an electron doping atom and a hole doping atom into the parent compound. An S-wave gap symmetry creates better Josephson junctions across grain boundaries in poly-crystalline YBCO and would lead to an increase of its critical current density, Jc. A low Jc in poly-crystalline cuprates has been a major technological roadblock to fabricating high-Jc cuprate wires. We synthesized Y(1-x-y)Ca(x)Ce(y)Ba2Cu3O(7-d), where the Ca and Ce atoms substitute onto Y sites as hole and electron donors, respectively. We find that over a broad range of Ca and Ce dopings (x and y each varying from 0.0 to 0.32), the Tc of the cuprates is in the range of 72-77 K. This Tc stability to a large quantity of impurities is incompatible with a D-wave superconducting gap and suggests the appearance of S-wave gap symmetry. In order to study the Jc of our samples, we have designed a non-contact radiofrequency (RF) resonator that measures changes in the AC resistance and inductance in order to extract the Jc. In this talk, we will present our results for Jc as a function of temperature and Caand Ce doping.

SESSION NM02.11: On-demand

8:00 AM NM02.11.01
Late News: Critical Current Distributions of Bi-2212 Compared to Benchmark Nb-Ti Superconductors Shaon Barua[1,2], Daniel Davis[2], Yavuz Oz[2], Jianyi Jiang[2], Eric Hellstrom[2], Chiara Tarantini[2], Ulf Trociewitz[2] and David Larbalestier[2]; [1]Florida State University, United States; [2]National High Magnetic Field Laboratory, United States

In composite superconductors, the local critical current can vary along the length due to variable vortex pinning interactions, as well as variations in filament connectivity due to filament shape variation and, especially in HTS conductors, variations in grain-to-grain connectivity. This critical current (I_c) distribution can be extracted from a d^2V/dI^2 treatment of the V-I curves, as originally proposed by Baixeras and Fournet [1] and used by Warnes [2] to study filament-sausaging degradation of critical current density (J_c) in Nb-Ti. High J_c is now available in Bi-2212 round wires and there is intense interest in farther optimization of these wires. Brown [3] recently studied wires with almost 6 times variation in J_c made over almost a decade and found that their normalized $J_c(H)$ characteristics were almost identical, from which we concluded that their vortex pinning was identical and that J_c was determined by their grossly varying connectivity. In Nb-Ti there is concern about filament connectivity only when filaments are overdrawn and they start to sausage, unlike Bi-2212 where cross-sectional non-uniformity is built into the filament shape due to the large shape anisotropy of Bi-2212 grains and many poor grain-to-grain connections further degrade filament connectivity. Attainable J_c values in Nb-Ti reach ~ 0.2 of the depairing current density (J_d), while reaching only ~ 0.01 J_d in Bi-2212, suggesting significant room for raising J_c if better connectivity can be obtained (Bi-2212 does however have higher J_c than Nb-Ti now). Our measurements show that J_c in Bi-2212 depends significantly on both powder source and the heat treatment used

to densify and grain-align the 2212. We find that the standard deviation to mean ratio s/m of various Bi-2212 wires range from ~ 0.1 - 0.2, while our benchmark Nb-Ti conductor is about 0.05 at ~ 0.5H_{irr}. We find it interesting that (i) there are clear trends that J_c rises as s/m declines and (ii) that the s/m values are only about twice as high as our fully optimized Nb-Ti wire, which unlike Bi-2212 is isotropic and has one single value of H_{irr}. We conclude that this technique is valuable for comparison of various Bi-2212 conductors and for comparison to more traditional Nb-Ti and Nb_3Sn conductors.

Late News: Probing Materials Losses with Planar Superconducting Resonators Corey Rae H. McRae[1,2]; [1]University of Colorado Boulder, United States; [2]National Institute of Standards and Technology, United States

Materials losses from native oxides on superconducting metal surfaces, interfaces between materials, and bulk dielectrics are the dominant source of decoherence in superconducting quantum processors. Superconducting microwave resonators can act as a convenient qubit proxy for assessing loss performance and characterizing loss mechanisms such as two-level system loss, non-equilibrium quasiparticles, and magnetic flux vortices. This talk will provide an overview of accurate resonator loss measurement, summarizing techniques that have been evolving for over two decades, and will conclude with recommendations for future measurements in this field.

8:20 AM NM02.11.04

Late News: Effect of Varying the Cooling Rate (RF) on Over Pressure Heat Treated (OPHT) Bi-2212 Round Wires Temidayo Abiola Oloye, Jianyi Jiang, Imam Hossain, Eric Hellstrom, David Larbalestier and Fumitake Kametani; Florida State University, United States

Advances in precursor powder and processing technology has increased the potential of $Bi_2Sr_2CaCu_2O_x$ (Bi-2212) as a capable material for application in high field high temperature superconducting (HTS) magnets. The record high critical current densities (J_c [4.2K, 30T] = 4670A/mm^2) was achieved by improved precursor powder, in particular the recent Engi-Mat powder. Further understanding and optimization of the processing stage will provide another avenue for further increases in the J_c of Bi-2212 round wires (RW). The use of Over Pressure Heat Treatment (OPHT) has greatly simplified the processing of Bi-2212 RW with less time and resources spent in the processing stage. Notwithstanding these advantages of OPHT, the exact influence of the key OPHT parameters, most especially the rate of cooling (R_F) and the time in the melt (t_{melt}) on the micro- and nano- structure of fully heat treated Bi-2212 RW is still not fully understood. In this study, we systematically vary R_F and t_{melt} for 2 wire diameters (1mm and 1.2mm) and investigate how this affects the microstructure, grain texture, and overall J_c of the recent Bi-2212 RWs made with the new Engi-Mat powder. We found that the 1mm diameter wire showed minimal variation in J_c (about 5%) and microstructure, while at 1.2mm, the wires showed significant variation microstructure and J_c (about 20%). Overall, our results showed the possibility of achieving minimal variation in J_c with a wide OPHT processing window. This study is particularly important for scaling up Bi-2212 processing from short sample OPHT to large coil processing while maximizing the J_c of Bi-2212 RW. Further details will be given in the presentation.

8:30 AM NM02.11.05

Late News: Experimental and 3D Modelling Investigation of DC Magnetic Shielding by Machinable MgB2 Bulks Michela Fracasso[1,2], Samuele Ferracin[1], Roberto Gerbaldo[1,2], Gianluca Ghigo[1,2], Francesco Laviano[1,2], Andrea Napolitano[1,2], Daniele Torsello[1,2], Mykola Solovyov[3], Fedor Gomory[3], Marco Truccato[2,4],

Mihai A. Grigoroscuta[5], Mihail Burdusel[5], Aldica Gheorghe[5], Petre Badica[5] and Laura Gozzelino[1,2];

Bulk superconductors (SC) have recently found a mighty application in magnetic shielding [1], with MgB_2 bulks as a very promising option [2]. For this purpose, a combination of modelling procedure and growth technique able to manufacture properly shaped products with high and homogeneous critical current density, can be a successful approach guiding the whole optimization process.
This work focuses on the shielding properties of tube- and cup-shaped MgB_2 bulks with small height/outer radius aspect ratio. Moreover, the effect of adding a ferromagnetic (FM) sheet around the superconductor is addressed. All the SC samples were produced by processing the starting commercial MgB_2 powders added with hexagonal BN into high-density bulks via spark plasma sintering, obtaining fully machinable samples [3]. Starting from the experimental analysis, a 3D modelling evaluation was then carried out.
In more details, first, the properties of both SC and hybrid SC/FM shields were measured in both axial- (AF) and transverse-field (TF) configurations using cryogenic Hall probes [4,5]. In a second step, the experimental results were reproduced by finite element calculations with COMSOL Multiphysics® [4], exploiting a 3D magnetic vector-potential (**A**) formulation [6]. The good agreement obtained by comparing the computed induction fields with those measured experimentally allowed us to validate this modelling approach for our application.
Finally, this numerical procedure was applied to explore new shield design with similar aspect ratio but optimized performance. In particular, the shielding efficiency of three different cup-shaped arrangements were compared both in AF and TF configurations, studying the effect of superimposing ferromagnetic vessels of different sizes around the superconductor.

8:40 AM NM02.11.06
Late News: Investigating the Use of 2G REBCO Coated Conductors in Magnetic Confinement Fusion Devices William Iliffe, Chris Grovenor and Susannah Speller; University of Oxford, United Kingdom

The toroidal field (TF) magnets of magnetic confinement fusion (MCF) power plants need to operate at high current density for extended periods to be cost effective. This requires these TF magnets to use superconducting current carriers. To aid in their design, this work aims to better understand how ReBCO coated conductors will perform when subjected to the exotic particle environment present in electricity producing MCF devices. This has been achieved using a combination of irradiation damage simulation and ion bombardment experiments.

Simulation based investigations have been used to determine the predominant changes to ReBCO during neutron irradiation in several settings (fusion and fission). Ion bombardment experiments included 2 irradiation campaigns performed with room temperature samples. These used 2MeV He+ and 3.1MeV O2+ ions to mimic the effects of neutron irradiation. The results using each ion species, were compared with those of published neutron irradiation experiments. The 3rd ion bombardment campaign involved the in-situ irradiation and superconducting property measurement of ReBCO samples whilst at their operating temperature. This required a new, dedicated experiment to be designed and built, in collaboration with Surrey University's Ion Beam Centre.

A summary of the findings of the irradiation damage simulations, results from the 3 irradiation campaigns and a summary of the in-situ irradiation and testing experiment will be presented, along with proposed next steps.

8:43 AM NM02.11.07
Late News: Optimization of Milling Energy Density and Heat Treatment Temperature for Enhancing Intergrain Critical Current Density in K Doped Ba-122 Bulks Shah Alam Limon, Chongin Pak, Chiara Tarantini, Eric Hellstrom, David Larbalestier and Fumitake Kametani; Florida State University, United States

Iron based superconductors (FBS) are interesting materials that have high intragranular J_c of ~$6x10^5$ Acm^{-2} as thin film single crystal at 4.2 K and 15 T, high irreversibility field of > 90 T, T_c of >35 K, and very low critical field anisotropy. An increase of intergranular J_c is needed to make these materials suitable for high field magnet applications. Intergrain connectivity issues must be overcome for achieving high J_c. Extrinsic factors, such as impurity phases and grain boundary porosity, are the present cause of poor intergrain connectivity in FBS polycrystalline bulks and wires. Combining high-pressure heat treatment and clean synthesis protocol, we studied how the milling energy density and heat treatment (HT) temperature affect the superconducting properties of $Ba_{0.6}K_{0.4}Fe_2As_2$ (K-Ba-122). By changing RPM and milling time of planetary ball mill, we precisely evaluated milling energy density E_{BM}, ranging from 65 MJ/kg to 1 GJ/kg in different bulks. A novel two-stage heat treatment was used for each bulk. In 1st stage, different HT temperature and ambient pressure was applied in different bulks. We fixed the 2nd stage HT temperature and pressure consistent (600 °C and 193 MPa). We obtained after the 1st HT a T_c of ~38 K, which is close to the highest T_c reported for optimally doped K-Ba-122 single crystals. However, in all cases, T_c drops by 3-4 K after the high pressure 2nd HT. Optimization of 1st stage HT for any E_{BM} was achieved at 750ºC, where magnetization J_c after the complete two-stage HT was highest compared with other 1st HT temperatures. Maximum J_c of 1.1×10^5 Acm^{-2} at 1T is achieved by synthesizing bulk at 100 MJ/kg and 750 ºC 1st HT, followed by the high-pressure 600 ºC 2nd HT. In this specific case, T_c after 1st HT was 37.6 K and after 2nd HT 34.6 K. The milling energy of 100 MJ/kg at 1st milling appeared to contribute reducing the formation of current-blocking FeAs phase. In this presentation, we will discuss about the correlation between milling energy, heat treatment temperature, connectivity and improved superconducting properties in polycrystalline K doped Ba-122.

Late News: The Influence of the Pre-Magnetization Value on the Levitation Force of HTS Tape Stacks Aleksandr Starikovskii, Maxim Osipov, Irina Anishchenko and Igor Rudnev; National Research Nuclear University MEPhI, Russian Federation

This study presents new results on investigation of the levitation force between a permanent magnet and pre-magnetized GdBCO superconducting tape stacks containing from 20 to 100 tapes of 12 mm × 12 mm. The stacks were cooled with liquid nitrogen in the field of a superconducting magnet with a magnetic induction of 3 T and then they were placed in a cryostat of the levitation force measuring system. Stacks of 100 tapes were cooled in different applied fields with magnetic induction in the range of 0.1-1 T. The field captured by the tapes was measured with a Hall sensor 5 minutes after magnetization. Experimental data on levitation force value and the effect of lateral displacement on it for stacks of tapes with different thicknesses and trapped flux have been obtained. Levitation force decay during the lateral displacements above a permanent magnet was observed for different stacks. Based on the obtained results, it was concluded that pre-magnetized stacks show greater repulsive forces than non-magnetic ones, and the difference increases with the number of tapes in the stack. Capture of the magnetic flux not only provides a greater levitation force, but also leads to a greater attenuation of the levitation force at lateral displacements which increases with increasing magnetization. The captured flux depends on the external field as follows: it increases with an increase in the applied field up to 0.4 T, after which it reaches saturation. The observed physical processes were simulated, and obtained results are in good agreement with the experimental data.
This work was supported by a grant from the Russian Science Foundation (Project 17-19-01527).

Late News: Dissipation Caused by Phase Slip Center in NbTi Superconducting Bridge Khalil Harrabi, Abdelkarim Mekki and Hocine Bahlouli; KFUPM, Saudi Arabia

We report on the dissipation caused by step current pulse in NbTi superconducting filament on fuzed silica. The non-equibroum state is induced by a current exceeding the the critical current Ic. A voltage appears after a certain delya time td, and close to Tc the dissipation is governed by the phase slip center phenomena. It bears similarity to single photon detection using a superconducting nanowire biased with a current skower than the critical current Ic. The film cooling time is deduced from fitting the data with the Time Time-Dependent Ginzburg-Landau (TDGL) theory due to M. Tinkham. We find taht the film cooling time is longer close to Tc than at lower temperature and this attributed the number of phonon population that increased.

Late News: Simplified Colloidal Route for Preparation of Nanostructured Au-Ag Films with Superconductivity in the Ambient Navyashree Vasudeva, Pritha Mondal, Subham K. Saha, Rekha Mahadevu, Anand Sharma and Anshu Pandey; Indian Institute of Science, India

Au-Ag nanostructures have been posited as potential room temperature, ambient pressure superconductors in past studies. This presentation will summarize recent progress made towards the growth of films of these materials. Au-Ag nanostructures comprise discrete ~1 nm Ag nanocrystals embedded at specific loading densities into an Au matrix. This motif is nontrivial to produce through standard colloidal techniques that rely upon spherically or axially symmetric growth around a central nucleus. I will present methods developed by us that enable a simplified route for the preparation of these materials. The structural properties of Au-Ag materials produced through this method will be described. This presentation will further provide an overview of their unconventional optical and electrical properties. In particular, we will describe the suppression of plasmon resonances within these materials along with the emergence of a broad non-dissipative resonance over the visible. We will further describe the observation of zero resistance in films of these materials. In certain samples, these states with resistivity below 10^{-10} ohm-m are also observed at temperatures as large as 400 K. Other aspects including stability, and sensitivity of these materials towards air exposure, will be discussed.

9:16 AM NM02.11.11
Late News: Theoritical Insights into the Unconventional Electronic Structure and Optics of Engineered Au-Ag Nanostructures Pritha Mondal, Subham K. Saha, Awadhesh Narayan and Anshu Pandey; Indian Institute of Science, India

Recently it was shown that bimetallic nanostructured films composed of gold and silver exhibit certain unconventional electrical and optical properties which are not expected from any conventional metallic films. To account for these observations, we have developed a coarse grained theoretical model to explain the experimental findings. We adopt a jellium model for the gold silver material. A metal-insulator transition mediated by correlation enhancement is described. I will show that the system is associated with two temperature scales with a potential superconducting transition occurring below the electron localization temperature.

9:26 AM NM02.11.12
Late News: Unconventional Optical, Structural and Magnetic Properties of Au-Ag Nanostructures with Superconductivity in the Ambient Subham K. Saha[1], Rekha M[1], Pritha Mondal[1], Navyashree Vasudeva[1], Samartha Channagiri[1], Pavithra Bellare[1], Arpita Mukherjee[2], Nihit Saigal[1], Guru P. Rajasekar[1], Dev K. Thapa[1], Biswajit Bhattacharyya[1], Narayanan Ravishankar[1] and Anshu Pandey[1]; [1]Indian Institute of Science, India; [2]University of Gothenburg, Sweden

Recent studies on engineered Au-Ag nanostructure assemblies have attracted tremendous interest due to their unconventional electrical and magnetic properties. Briefly, these nanostructures have been shown to exhibit an

immeasurably low resistive state, typically with resistivity below 10^{-10} ohm-m and also a highly diamagnetic state at temperatures approaching and greater than the ambient. Along with these observations, they also exhibit an unusual optical response which is not anticipated from their constituent material. Generally, Au or Ag nanostructures show their definitive plasmon resonances under optical excitation. This corresponds to the collective oscillations of free electrons which leads to an excitation of dipolar modes. Contrary to conventional Au and Ag materials, Au-Ag nanostructures do not show any definitive plasmon resonance at a particular frequency but rather show a broad extinction over the entire UV-VIS optical window even extending up to NIR. We de-convolve the extinction into constituent scattering and absorption components. It is found that extinction entirely comprises of scattering with negligible absorption. Further, these nanostructures do not show any dissipative dynamics in pump-probe spectroscopy. We shed further insights into the unconventional properties of these materials through EELS and structure correlated single particle microscopy. Our findings indicate significant electronic reconfiguration in these nanostructures that gives rise to deviations from the usual dielectric response of Au and Ag.

Canfield[1,2]; [1]Ames Laboratory, United States; [2]Iowa State University, United States; [3]Lawrence Berkeley National Laboratory (current affiliation), United States; [4]McGill University, Canada; [5]University of Waterloo, Canada

With the steady rise of topological materials, attention of the community is now shifting to magnetic

incarnations that host a largely unexplored territory from both a theoretical and experimental perspective. Magnetic topological materials allow for the formation of new
structures (as the spin can introduce new periodicities) and are yet to be mapped out in generality and resultantly harbor a lot of potential for novel effects. Hence, having a stable material platform is of tremendous interest to underpin both theory and experimental progress in this direction. So far, several materials are reported as magnetic Weyl semimetal though a material with a single pair of Weyl points that readily offers tuning of its topological states is yet to be found. EuCd2As2 is a magnetic semimetal that has the potential of manifesting nontrivial electronic states, depending on its low temperature magnetic ordering. By discovering and taking advantage of the chemical tunability of EuCd2As2, we report the successful growths of single crystals of EuCd2As2 with the ferromagnetic and antiferromagnetic ground state. In addition, we will discuss a detailed temperature-dependent Angle-resolved photoemission spectroscopy (ARPES) study on the ferromagnetic EuCd2As2.
This work was supported by the Center for Advancement of Topological semimetals, an Energy Frontier Research Center funded by the U.S.DOE, Office of Basic Energy Sciences. Work at the Ames Laboratory was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division. The Ames Laboratory is operated for the U.S. DOE by Iowa State University under Contract No. DEAC0207CH11358.

8:25 AM *NM03.01.03
Exotic Quantum Magnets and Competing States—New Yb Kondo Systems Emilia Morosan; Rice University, United States

Novel physics discoveries heavily rely on the design and synthesis of new materials, which, in turn, depends a lot on the growth method. I will use the backdrop of my group's discoveries of several Kondo systems, to emphasize the importance of the interplay between chemistry, materials science and physics in unveiling new materials' properties. In particular, I will focus on YbT3M7 where the transition metal T is either Rh or Ir, and the metal M is Si or Ge. These are rhombohedral compounds, chemically and structurally very similar, with some similar physical properties and substantive differences. They all show evidence for strong electronic correlations and Kondo physics; one orders ferromagnetically (YbIr3Ge7) while the other two have antiferromagnetic ground states. Most remarkable, YbIr3Si7 shows long range antiferromagnetic order and non-Fermi liquid behavior even within the ordered state, while the electrical resistivity indicates bulk insulating behavior with ARPES and DFT calculations pointing to a conductive surface. We reconcile the observed Kondo physics, long range magnetic order and the insulating-to-metal crossover from bulk to surface with a proposal of Kondo exhaustion and evience for a Yb valence transition from magnetic (3+ in the bulk) to non-magnetic (2+ on the surface).

8:50 AM NM03.01.04
Late News: Tunable Chiral Symmetry Breaking in Symmetric Weyl Materials Sahal Kaushik[1], Evan Philip[2] and Jennifer Cano[1]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Asymmetric Weyl semimetals, which possess an inherently chiral structure, have different energies and dispersion relations for left- and right-handed fermions. They exhibit certain effects not found in symmetric Weyl semimetals, such as the quantized circular photogalvanic effect and the helical magnetic effect. In this work, we derive the conditions required for breaking chiral symmetry by applying an external field in symmetric Weyl semimetals. We explicitly demonstrate that in certain materials with the T_d point group, magnetic fields along low symmetry directions break the symmetry between left- and right-handed fermions; the symmetry breaking can be tuned by changing the direction and magnitude of the magnetic field. In some cases, we find an imbalance between the number of type I left- and right-handed Weyl cones (which is compensated by the number of type II cones of each chirality.)

9:05 AM NM03.01.05
Late News: A New Cubic Hall Viscosity in Three-Dimensional Topological Semimetals Iñigo Robredo[1,2], Pranav Rao[3], Fernando de Juan[1,4], Aitor Bergara[1,2], Juan Luis Mañes[2], Alberto Cortijo[5], Maia Vergniory[1,4] and Barry Bradlyn[3]; [1]Donostia International Physics Center, Spain; [2]University of the Basque Country, Spain; [3]University of Illinois at Urbana-Champaign, United States; [4]Basque Foundation for Science, Spain; [5]Universidad Autónoma de Madrid, Spain

In this work, we study the non-dissipative viscoelastic response of three dimensional crystals. We show that for systems with tetrahedral symmetries, there exist new, intrinsically three-dimensional Hall viscosity coefficients that cannot be obtained via a reduction to a quasi-two-dimensional system. To study these coefficients, we specialize to a tight binding model for a chiral magentic metal inspace group $P2_13$ (198), which features a threefold degenerate "spin-1" fermion at the Fermi level. Using the Kubo formula for viscosity, we compute the non-dissipative Hall viscosity for the spin-1 fermion in two ways. First we use an electron-phonon coupling ansatz to derive the "phonon" strain coupling and associated phonon Hall viscosity. Second we use a momentum continuity equation to derive the viscosity corresponding to the conserved momentum density. We conclude by discussing the implication of our results for hydrodynamic transport in three-dimensional magnetic metals,and discuss some candidate materials in which these effects may be observed.

Atomic-Scale Studies and Design of Topological Spin Textures and Majorana States in Magnet-Superconductor Hybrid Systems Roland M. Wiesendanger; University of Hamburg, Germany

Since the discovery of the existence and manipulation possibilities of individual nanoscale skyrmions in ultrathin transition metal films on heavy-element substrates [1] by spin-polarized scanning tunneling microscopy (SP-STM) [2], the field of magnetic skyrmions [3,4] has gained significant interest due to their great potential for future magnetic memory and logic devices [5,6]. In particular, the small size, enhanced stability and unidirectional current-driven movement of chiral magnetic skyrmions make them interesting for novel types of magnetic device concepts. These unique properties of skyrmions are intimately linked to interfacial Dzyaloshinskii-Moriya (DM) interactions [7,8] which recently have been studied directly at the level of individual magnetic atoms on surfaces of heavy-element substrates [9]. Based on these fundamental investigations of the distance- and material dependencies of interfacial DM interactions, it has become possible to design non-collinear spin textures in low-dimensional systems based on the powerful combination of SP-STM and single-atom manipulation techniques [10,11]. Proximity-coupling of such well-defined low-dimensional non-collinear spin-states with elemental superconductors allows the design of yet another type of interesting topological states, i.e. Majorana zero modes, which offer great potential for topological quantum computation [11,12]. Besides the emergence of Majorana states in quasi-1D hybrid systems consisting of spin-spirals interacting with elemental superconductors, we will also discuss most recent progress towards the observation of Majorana states in quasi-2D skyrmion-superconductor hybrid systems [13].

Skyrmions and Chiral Spin Textures in Non-Centrosymmetric Magnetic Materials Roland Kawakami; The Ohio State University, United States

Magnetic domain structures are fundamentally altered by the presence of the Dzyaloshinskii-Moriya interaction (DMI), which introduces a preference for the twisting of neighboring spins. This produces various chiral spin textures including topological skyrmion bubbles, helical phases, and chiral domain walls. Two important directions for the field are to (1) explore and visualize the complex magnetic phases down to the atomic scale and (2) develop small skyrmions at room temperature for potential high-density memory applications. For this, we are investigating skyrmions and chiral spin textures in thin films of FeGe, MnGe, and Fe-rich FeGe grown by molecular beam epitaxy. These materials have a B20 structure with broken inversion symmetry to generate a bulk-like DMI, which yields skyrmions that are often studied by the topological Hall effect or other macroscopic probes. In our work, we visualize the spin textures from the submicron-scale down to the atomic-scale using spin-polarized scanning tunneling microscopy, magnetic force microscopy, and Lorentz transmission electron microscopy. I will discuss our team's advances in atomic-layer engineering for FeGe to boost the Curie temperature above room temperature while shrinking the skyrmion size down to < 20 nm, the atomic-scale visualization of helical spin textures with topological defects in MnGe, and initial work toward skyrmions in epitaxial 2D magnets.

The work was done in collaboration with Tao Liu, Camelia Selcu, Jake Repicky, Jay Gupta, David McComb, Mohit Randeria, Prasanna Balachandran, Nuria Bagues Salguero, Binbin Wang, Po-Kuan Wu, Shuyu Cheng, Tim Hartnett, Denis Pelekhov, Perry Corbett, Brendan McCullian, Adam Ahmed, Chris Hammel.

Skyrmions and Topology in Magnetic Materials Claudia Felser; Max Planck Institute Chemical Phyics of Solids, Germany

Topology a mathematical concept became recently a hot topic in condensed matter physics and materials science, a complete classification of all non-magnetic inorganic materials are availbale [1,2]. Recently the focus have shifted to magnetic materials, first antiferromagnetic materials are classified, too [3]. In magnetic materials the Berry curvature in real and reciprocal space lead to new topological properties such as Skyrmions [4] and Antiskyrmions [5] and in magnetic Weyl semimetals to giant responses in antiferromagnetic [6] and ferromagnetic compounds [7]. Heusler compounds as tunable materials are interesting for both categories, they might even allow for the investigation the relation between Berry curvatures in real and reciprocal space. In materials hosting Antikyrmions the Dzyaloshinskii Moriya-Exchange and the dipol-dipol interaction is important. The dipol-dipol interactions allows for interesting mesoscopic effects. New materials can be designed by changing the symmetry, magnetic moments (ferro, ferri, antiferro, compensated ferri) and magnetic crystalline anisotropy [8].

Anti-Skyrmions and Skyrmions in Heusler Compounds Stuart Parkin; Max Planck Institute of Microstructure Physics, Germany

Heusler compounds are a large family of compounds which exhibit a wide range of properties. The inverse tetragonal Heusler compounds exhibit unidirectional magnetic anisotropy. Some of these compounds, in particular those containing heavy elements, exhibit non-collinear spin structures, that are derived from a Dzyaloshinskii-Moriya (DMI) vector exchange interaction. We show that such materials can exhibit a range of spin textures including both anti-skyrmions and elliptical Bloch skyrmions in the same compound, as well as helical spin textures that propagate along particular crystal directions. Another fascinating aspect of these structures is that the size of the anti-skyrmion and the wavelength of the helices can be varied from sub 100 nm to more than a micron by varying the thickness of the lamella in which the structures are observed. This is due to the important role of long-range magneto-dipole interactions that are more much important in these Heusler compounds than, for example, in the widely studied cubic B20 compounds in which skyrmions have been extensively explored. Chiral spin textures in ferro-, ferri- and anti-ferrimagnetic materials and thin film heterostructures are of fundamental interest with great potential for spintronic applications especially Racetrack Memory.

Modulation Doping via the 2D Crystalline Acceptor $RuCl_3$ Kenneth Burch; Boston College, United States

Two-dimensional (2d) nano-electronics, plasmonics, and emergent phases require clean and local charge control, calling for layered, crystalline acceptors or donors. Here I will describe how the Relativistic Mott Insulating state of RuCl3 provides a new opportunity to introduce modulation doping into 2D materials. Specifically, we demonstrate and optimize this charge transfer with extensive Raman, photovoltage, and electrical conductance measurements combined with ab initio calculations. Also, we find the doping is exceptionally local, can occur through hBN, works with various exfoliated, CVD, and MBE materials. Time permitting, I will discuss new opportunities this opens for nanoplasmonic, optoelectronics, and correlated phases.

Exploring and Expanding the Compositional and Microstructural Space of Transition Metal-Based 3D and 2D Carbides and Nitrides Jan Paul Siebert[1], Niels Kubitza[2], Minh Hai Tran[2], Andreas Reitz[1], Robert Brilmayer[2], Annette Andrieu-Brunsen[2] and Christina Birkel[1,2]; [1]Arizona State University, United States; [2]Technische Universität Darmstadt, Germany

Transition metal-based carbides that belong to the family of MAX phases are an intriguing class of materials –

particularly in terms of their mechanical properties – as they combine characteristics of metals and ceramics. More recently, some of their members have also been discussed in terms of their magnetic behavior, whereas most studies are conducted on thin film samples and the synthesis of bulk materials with later transition metals (e.g. Mn) is still a real challenge. Besides, MAX phases are used as precursors for a relatively new class of 2D materials, the so-called MXenes that are investigated in the context of a plethora of potential applications, for example in catalysis, battery and biomedical research.
Our group utilizes a diverse set of synthesis techniques to prepare new MAX phases as well as known ones with unique morphologies. In this talk, I will focus on the following two examples: (i) The synthesis of MAX phase Cr_2GaC by an initially wet chemical approach that allows a new type of processability of the soluble precursors. (ii) Design of a "smart" hybrid MXene with switchable conductivity and temperature as an external stimulus. We employ X-ray powder diffraction and electron microscopy techniques to study the structure and microstructure of the products, respectively. In the case of the wet chemical-based synthesis of Cr_2GaC, we conducted detailed thermal analysis and ex-situ Neutron diffraction to propose a formation mechanism of the MAX phase particles.

1:50 PM *NM03.03.03
Near-Fermi-Level Electronic States in Hexagonal ABC Intermetallic Compounds from First Principles
Karin M. Rabe; Rutgers, The State University of New Jersey, United States

Ternary ABC intermetallic compounds exhibit a rich variety of crystal structures and electronic properties. In this work, we study the structural energetics and band structures of real and hypothetical ABC intermetallic phases with structures obtained by stacking binary honeycomb layers with single layers of interstitial atoms in various ways, using first principles calculations to determine the structural parameters and the bands in each phase. We use this dataset to analyze and model the bands near the Fermi level to classify the systems considered and to extract a set of rules that allows us to to predict and design hexagonal ABC intermetallic materials with targeted transport and optical properties, connecting to experimental measurements on known hexagonal ABC phases. in particular, we investigate the rich physics of polar metals in this family of materials, which offer the promise of functional properties switchable by appropriate applied fields and stresses.

2:15 PM NM03.03.04
Berry Curvature and Topological Nernst Effect in Biased Bilayer WSe_2
Vassilios Vargiamidis[1], Panagiotis Vasilopoulos[2] and Neophytos Neophytou[1]; [1]University of Warwick, United Kingdom; [2]Concordia University, Canada

We investigate the anomalous thermoelectric transport in bilayer WSe_2 with broken inversion symmetry, due to a gate electric field, regardless of time-reversal symmetry. We compare the cases in which the spin-orbit coupling (SOC) is absent or present. In the presence of SOC and of a valley-contrasting Berry curvature, anomalous spin and valley Nernst responses are generated. The Nernst signals exhibit peaks and dips, as the chemical potential is varied, that have the signs of the Berry curvatures of the bands and are proportional to their magnitudes. In the absence of SOC but with an electric field present, the Nernst responses are the same in the conduction and valence bands due to particle-hole symmetry. The anomalous valley Nernst coefficient is enhanced by increasing the electric field strength. When time-reversal symmetry is violated, e.g., upon using an insulating magnetic substrate, the total Nernst coefficient is finite and exhibits a dip-peak feature. We also analyze the orbital magnetization and the orbital magnetic moment. In the absence of a gate electric field the magnetization vanishes due to the spin degeneracy of the bands. In the presence of electric field, the magnetization and its two contributions, one due to the magnetic moment and one due to the Berry curvature, are calculated and interpreted in terms of opposite circulating currents of the bands in the two layers. The results are pertinent to other transition metal dichalcogenides and future caloritronic applications.

2:30 PM NM03.03.05
Late News: Structural Defects and Low Temperature Twisting of Kagomé Layers in Intermetallics
Mekhola Sinha[1], Hector K. Vivanco[1], Cheng Wan[1], Maxime Siegler[1], Veronica J. Stewart[1], Lucas A. Pressley[1],

Tanya Berry[1], Ziqian Wang[1], Isaac Johnson[1], Mingwei Chen[1,2], Thao T. Tran[1,3], W. Adam Phelan[1,4] and Tyrel M. McQueen[1]; [1]The Johns Hopkins University, United States; [2]Tohoku University, Japan; [3]Clemson University, United States; [4]Los Alamos National Laboratory, United States

Kagomé intermetallics with 2D lattices have served as an ideal platform to study the exotic quantum phenomenon associated with flat bands and Dirac-type dispersions. It is essential to explore the electronic properties of these structures for the experimental realization of 2D kagomé lattice in bulk materials. We explore a specific family of kagomé intermetallics with the formula MT_6X_6 compound where M = Mg, Lu, Y; T = Co, Fe, Cr; and X = Ge. Single crystals of $MgCo_6Ge_6$ were grown by laser Bridgman technique. X-ray precession images and electron diffraction measurements collected at T = 293(2) K show that the compound crystallizes in space group *P*6/*mmm*, with a = 5.06094(15) Å, c = 7.7271(2) Å. Residual electron maps provide evidence of columnar disorder along c axis while no defects were found in the electronic structures of flux-grown $LuFe_6Ge_6$ and YCr_6Ge_6 crystals. Further investigation of the crystal structure reveals spontaneous twisting of the Co kagomé layers in $MgCo_6Ge_6$. We look into crystal orbital hamiltonian population analysis to understand the cooperative twisting between layers within the Co-kagomé network and the interlayer tetragonal bonding. Despite the appearance of static tilting, no evidence of a phase transition was found in magnetization, resistivity, or specific heat measurements, implying that the twisting exists at all temperatures, but is thermally fluctuating at room temperature. This behavior is further supported by looking into related materials to understand the pairwise twisting and bonding in layered structures.

2:45 PM NM03.03.06
Late News: Temperature and Composition Evolution of Charge Density Wave and Superconducting Orders in Ta-Based Dichalcogenides by Total X-Ray Scattering Valeri Petkov; Central Michigan University, United States

A characteristic feature of quantum materials is the presence of various lattice degrees of freedom manifesting themselves as local structural distortions leading to competing ground state phases of the electronic system and exotic behavior. More often than not, the distortions are not well expressed and/or perfectly periodic, making it difficult to identify and quantify them using traditional crystallographic techniques. We will demonstrate the advantages of total x-ray scattering and large-scale structure modeling in studying lattice instabilities in archetypal quantum materials such as Ta-based dichalcogenides. In particular, we will show that the low-temperature charge density wave state in trigonal prismatic 2H-TaSe2 emerges via a gradual buildup of locally correlated clusters of Ta atoms, and not via a spontaneous emerging of Ta superstructure at the transition temperature [1]. We will also show the presence of a hierarchical relationship among the crystal lattice, charge density wave and superconducting orders in ternary Ta-Te-Se solid solutions, where different degrees of crystal lattice order-disorder appear to promote and maintain the different orders to a different extent. The relationship may well explain the observed irregular evolution of the superconducting transition temperature with the relative Te to Se ratio [2].

4:00 PM *NM03.04.02
Frontiers of Crystal Growth and Characterization of Topological and Quantum Intermetallics Tyrel M. McQueen; Johns Hopkins University, United States

Materials by design is the rational prediction and creation of functional materials with defined properties. Its goal is to meet current and future societal needs for better or more complex materials, from biocompatible materials in medicine to lightweight alloys for space applications and energy generation, storage, and transport. Unfortunately the chemistry underlying modern materials science and engineering has lagged other sub-fields in an extremely critical area: the ability to selectively make and break bonds in the solid state. This is due to limited synthetic methodology and method development. True materials by design cannot be achieved until reliable synthetic capabilities are developed that can actually produce the specified materials. In this talk, I will highlight the progress being made in such synthesis by design, with a particular focus on intermetallic quantum materials necessary to realize new electronic and magnetic states of matter including topological superconductivity and axion insulators. Efforts to build and maintain US leadership in the area of new materials discovery and synthesis – particularly via the JHU Institute for Quantum Matter and PARADIM, the Platform for Accelerated Realization, Analysis, and Discovery of Interface Materials (PARADIM), an NSF-MIP National User Facility, and opportunities for use of these capabilities by the community, will also be presented.

4:25 PM *NM03.04.03
Weyl Nodes and Magnetostructural Instability Samuel M. Teicher and Ram Seshadri; University of California, Santa Barbara, United States

The room temperature ferromagnetic phase of the cubic antiperovskite Mn_3ZnC is known from from first-principles calculation to be a nodal line Weyl semimetal. Features in the electronic structure that are the hallmark of a nodal line Weyl state—a large density of linear band crossings near the Fermi level—can also be interpreted as signatures of a structural and/or magnetic instability. We examine this system carefully, and use it as a jumping off point to understand the possible implications of Weyl-like features in the electronic structures, and Peierls-like structural distortions and related structural and magnetic instabilities.

4:50 PM NM03.04.06
Exciting Features of Electronic Band Dispersion of IrGa & RhGa Compounds from First-Principles
Joshua Steier[1,2], David Gordon[3], JeanPierre Alvarez[3], Kalani Hettiarachchilage[1] and Neel Haldolaarachchige[3]; [1]Seton Hall University, United States; [2]Stony Brook University, The State University of New York, United States; [3]Bergen Community College, United States

Dirac materials have recently been one of the most significant attractions of the scientific community. We present an ab initio study of electronics properties of IrGa and RhGa compounds, with the absence and presence of spin-orbit interaction using first-principles calculations. Linearly dispersed band crossings, which are characteristic of topological semimetals, were identified near Fermi energy. These include type I and II Dirac points and nodal lines. Additionally, the sensitivity of Dirac points to physical pressure was studied by applying compressive and tensile stress to the lattice axis. The unusual electronic structure of IrGa will be useful to search for novel Dirac Fermions and it is a good candidate for further research and experimental studies.

Insulator-Metal Transition, Topological Superconductivity and Parity Violation in UTe2 Youichi Yanase[1], Jun Ishizuka[1], Shuntaro Sumita[2] and Akito Daido[1]; [1]Kyoto University, Japan; [2]RIKEN, Japan

We theoretically study magnetism and superconductivity in UTe2, which is a recently discovered strong candidate for an odd-parity spin-triplet superconductor. Theoretical studies for this compound faced difficulty because first-principles calculations predict an insulating electronic state, incompatible with superconducting instability. To overcome this problem, we take into account electron correlation effects by a GGA+U method and show the insulator-metal transition by Coulomb interaction. Using Fermi surfaces obtained as a function of U, we clarify the topological properties of possible superconducting states. Fermi surface formulas for the three-dimensional winding number and three two-dimensional Z2 numbers indicate topological superconductivity at an intermediate U for all the odd-parity pairing symmetry in the Immm space group. Symmetry and topology of superconducting gap nodes are analyzed, and the gap structure of UTe2 is predicted. Topologically protected low-energy excitations are highlighted, and experiments by bulk and surface probes are proposed to link Fermi surfaces and pairing symmetry. We show that a recent ARPES experiment is consistent with the topological superconductivity.

Next, we provide and analyze a periodic Anderson model for UTe2. The 24-band tight-binding model reproduces the band structure obtained from a GGA+U calculation consistent with an ARPES experiment. The Coulomb interaction of *f*-electrons enhances Ising ferromagnetic fluctuation along the *a*-axis and stabilizes the spin-triplet superconductivity of either $B3u$ or Au symmetry. When effects of pressure are taken into account in hopping integrals, the magnetic fluctuation changes to an antiferromagnetic one, and accordingly, the spin-singlet superconductivity of Ag symmetry is stabilized. Based on the results, we propose pressure-temperature and magnetic field-temperature phase diagrams revealing multiple superconducting phases. Interestingly, a mixed-parity superconducting state with spontaneous parity violation is predicted.

8:40 PM *NM03.05.02
Local Magnetic Measurements of Unconventional Superconductors Katja C. Nowack; Cornell University, United States

A fundamental property of a superconductor is its response to an applied magnetic field. In this talk, I will discuss how we use scanning superconducting quantum interferences device (SQUID) microscopy to study the local magnetic response in two different types of superconductors. First, I will discuss measurements on focus ion beam defined microstructures fabricated from single crystals of the heavy-fermion superconductor $CeIrIn_5$. By imaging the local diamagnetic response, we observe that the superconducting transition temperature, T_c, varies throughout the structure in a complex pattern. This pattern arises due to the interplay of a non-trivial strain field from the differential thermal contraction of the substrate and microstructure and the sensitivity of T_c in $CeIrIn_5$ to the strength and direction of strain. Devices with different geometry show that the spatial modulation of T_c can be tailored in agreement with predictions based on finite element simulations. These results offer a new approach to manipulate strain-sensitive electronic order on micrometer length scales in strongly correlated matter. Second, I will show how we use scanning SQUID to perform local magnetic measurements on few-layer van der Waals superconductors. We can directly probe the diamagnetic response as a function of temperature and other tuning parameters despite the extremely small sample volume. I will discuss

how we can extract the superfluid stiffness and other characteristics of the superconducting state from our measurements.

Imaging of $CeIrIn_5$ microstructures was primarily supported by the Department of Energy, Office of Basic Energy Sciences, Division of Materials Sciences and Engineering, under Award DE-SC0015947. Measurements of van der Waals superconductors were supported by the Cornell Center for Materials Research with funding from the NSF MRSEC program (DMR-1719875) and the NSF (DMR-2004864).

Topological and High-Field Reentrant Superconductivity in UTe_2 Nicholas P. Butch[1,2]; [1]NIST Center for Neutron Research, United States; [2]University of Maryland, United States

Spin triplet superconductivity is found in UTe_2 below 1.6 K. Remarkably, it coexists with strong spin fluctuations, has an extremely high upper critical field of 35 T, and breaks time reversal symmetry. I will describe how superconductivity in UTe_2 differs from conventional superconductivity and I will present evidence that this phase is topologically nontrivial. I will also discuss how in UTe_2 large magnetic fields give rise to a new, reentrant, superconducting phase, between 40 T and 65 T, the highest values reported for any material.

9:30 PM NM03.05.04
Scanning SQUID Microscopy of the Quantum Anomalous Hall Effect George M. Ferguson[1], Run Xiao[2], David Low[1], Ling-Jie Zhou[2], Anthony Richardella[2], Cui-Zu Chang[2], Nitin Samarth[2] and Katja C. Nowack[1]; [1]Cornell University, United States; [2]The Pennsylvania State University, United States

We report magnetic imaging of Cr-doped $(Bi,Sb)_2Te_3$ heterostructures in the quantum anomalous hall regime. We used a scanning superconducting quantum interference device (SQUID) microscope with micrometer scale spatial resolution to image the magnetic fields above current biased devices. Using these images we reconstructed the current density, allowing us to visualize where current flows in the devices. We also used top and back gates to study how the magnetization is affected by electrostatic gating. By performing these measurements as a function of current bias, gate voltage and magnetization direction we construct a comprehensive picture of electronic transport in our devices.

Late News: Quantum Magnetism in EuPd3S4 Tanya Berry[1], Vincent Morano[1], Micheal Nickolas[2], Xin (Jason) Zhang[1], Qun Yang[2], Topias Foerster[3], Zhijun Zhu[4], Rafal Wawrzynczak[2], Tom Halloran[1], Walter Schnelle[2], Johannes Gooth[2], Jeffrey Lynn[4], Claudia Felser[2], Collin Broholm[1] and Tyrel M. McQueen[1]; [1]Johns Hopkins University, United States; [2]Max Planck Institute for chemical Physics of Solids, Germany; [3]HZDR – Helmholtz-Zentrum Dresden-Rossendorf, Germany; [4]National Institute of Standards and Technology, United States

Double Dirac materials are a topological phase of matter that have an unprecedented eightfold electronic degeneracy. They display a host of exotic charge transport properties that are strongly impacted by magnetic fields. Quantum magnets are known to exhibit a variety of magnetic phases of matter with emergent quasiparticles. Here we report the discovery of quantum magnetism in the Dirac material $EuPd_3S_4$. The zero-field magnetic structure is found to be a 2-sublattice antiferromagnetic state with no magnetic coupling between sublattices at the mean-field level that results in an emergent degree of freedom corresponding to the relative orientation of the sublattice magnetizations. Application of a magnetic field drives domain ordering before collapsing to a fully ferromagnetic state. These magnetic states are found to dramatically impact the electronic structure of $EuPd_3S_4$, resulting in the destruction of the 8-fold degenerate state and formation of mostly likely Weyl states. Our findings open the door to the experimental and theoretical explanation of the interplay between novel magnetic states and topological phases of matter.

8:00 AM *NM03.06.01
Even and Odd Parity Superconductivity in $CeRh_2As_2$ Javier F. Landaeta[1], Seunghyun Khim[1], Jacintha Landaeta[1], Nyantakyi Bannor[1], Manuel Brando[1], Philip Brydon[2], Daniel Hafner[1], Robert Küchler[1], Raul Cardoso[1], Ukrike Stockert[1], Andrew Mackenzie[1,3], Daniel Agterberg[4], Christoph Geibel[1] and Elena Hassinger[1,5]; [1]Max Planck Institute for Chemical Physics of Solids, Germany; [2]University of Otago, New Zealand; [3]University of St Andrews, United Kingdom; [4]University of Wisconsin–Milwaukee, United States; [5]Technical University Munich, Germany

Multiple new forms of unconventional superconductivity have been discovered over the past four decades. In most cases, the strong electronic correlations and the interplay between superconductivity and other phases (magnetic ones, among others) leads to understanding that the simple frame of electron-phonon superconductivity breaks down. Because this implies that complex phase diagrams with different superconducting states are expected, it is striking that many materials only show a single-component superconducting phase diagram. Here, we report the discovery of two-phase unconventional superconductivity in $CeRh_2As_2$ with a transition temperature of 0.26 K. Using thermodynamic and magnetic probes, we establish that the superconducting critical field is as high as 14 T for magnetic fields along the c-axis. Furthermore, a c-axis field drives a transition between two different superconducting states. In spite of the fact that $CeRh_2As_2$ is globally centrosymmetric, we show that local inversion-symmetry breaking at the Ce sites enables Rashba spin-orbit coupling to play a key role in the underlying physics. More detailed analysis identifies the transition from the low- to high-field states to be associated with one between states of even and odd parity.

8:25 AM NM03.06.02
Late News: Epitaxy, Exfoliation and Strain-Induced Magnetism in Rippled Heusler Membranes Dongxue Du[1], Sebastian Manzo[1], Vivek Saraswat[1], Konrad Genser[2], Karin M. Rabe[2], Paul M. Voyles[1], Michael Arnold[1] and Jason K. Kawasaki[1]; [1]University of Wisconsin, United States; [2]Rutgers, The State University of New Jersey, United States

Single-crystalline membranes of functional materials enable the tuning of properties via extreme strain states; however, conventional routes for producing membranes require the use of sacrificial layers and chemical etchants, which can both damage and limit the ability to make membranes ultrathin. Here we demonstrate the epitaxial growth of the cubic Heusler compound GdPtSb on graphene-terminated Al2O3 substrates. The weak Van der Waals interactions of graphene enable the mechanical exfoliation to yield free-standing GdPtSb membranes. Despite the presence of the graphene interlayer, the Heusler films have epitaxial registry to the underlying sapphire, as revealed by x-ray diffraction, reflection high energy electron diffraction, and transmission electron microscopy. Whereas unstrained GdPtSb is antiferromagnetic, we show that the large strains or strain gradients in rippled membranes induce a spontaneous magnetic moment at room temperature, with a saturation magnetization of 5.2 bohr magneton per Gd atom, approaching the ~ 7 bohr magneton limit expected for ferromagnetic ordering. Our membranes provide a novel platform for tuning the magnetic properties of intermetallic compounds via strain (piezomagnetixm and magnetostriction) and strain gradients (flexomagnetism).

Carrier Conduction and Magnetic Interactions in a Nanostructured Epitaxial

Ferromagnet/Semiconductor Fe: FeVSb Estiaque Haidar Shourov, Chenyu Zhang, Paul M. Voyles and Jason K. Kawasaki; University of Wisconsin–Madison, United States

Magnetic semiconductors are attractive for memory devices and spintronic applications [1]. However, the practical utility of dilute magnetic semiconductors (DMS) such as Mn: GaAs, albeit having all key ingredients for these applications, are hindered due to low Curie temperature. On the other hand, narrow bandgap semiconductors often make excellent thermoelectric candidates. A conventional strategy for improving the thermoelectric figure of merit (ZT) is to decrease the phonon thermal conductivity via nano-structuring [2]. Recently, it has been suggested that magnon drag (spin wave) [3], spin fluctuations [4], and enhanced effective mass [5] are alternative strategies to enhance thermoelectric performance by enhancing the power factor. Here we demonstrate the controllable synthesis of a ferromagnet/semiconductor nanostructured system: Fe nanoparticles embedded epitaxially within a semiconducting FeVSb matrix. Transmission electron microscopy confirms that the nanoparticle formation is mediated by bulk segregation for all composition greater than 10% excess Fe in stoichiometric FeVSb. Our Fe: FeVSb thin films, grown by molecular beam epitaxy, display magnetic moment and anomalous Hall effect that scale with the volume fraction of Fe nanoparticles. The parent stoichiometric FeVSb is predicted to be diamagnetic, but our stoichiometric films also exhibits magnetic signatures in transport and magnetometry at 300K. This suggests that within the solubility limit of Fe, $Fe_{1+\delta}VSb$, where δ is the bound of solubility, is a potential dilute magnetic semiconductor with Curie temperature greater than room temperature. Additionally, the ferromagnetic nanoparticles can induce spin polarized charge carriers in the semiconducting matrix due to proximity effect, making this highly controllable and tunable system appealing for spintronics. Our angle-resolved photoemission spectroscopy (ARPES) measurements on the parent semiconductor FeVSb reveal an enhanced effective mass due to electronic correlations [6]. The combination of nanostructure precipitates, magnetic interaction, and electronic correlation in this highly tunable heterostructure presented here offers a promising route for new thermoelectric application for practical waste heat recovery.

Complex Magnetic Phases in Polar Tetragonal Intermetallic $NdCoGe_3$ Binod K. Rai[1,2], Ganesh Pokharel[3,1], Hasitha Suriya Arachchige[3,1], Seung-Hwan Do[1], Qiang Zhang[1], Masaaki Matsuda[1], Matthias Frontzek[1], Vasile O. Garlea[1], Andrew D. Christianson[1] and Andrew F. May[1]; [1]Oak Ridge National Laboratory, United States; [2]Savannah River National Laboratory, United States; [3]The University of Tennessee, Knoxville, United States

Polar materials can host a variety of topologically significant magnetic phases, which often emerge from a modulated magnetic ground state. Relatively few noncentrosymmetric tetragonal materials have been shown to host topological spin textures and new candidate materials are necessary to expand the current theoretical models. This presentation will discuss the anisotropic magnetism in the polar, tetragonal material $NdCoGe_3$ via thermodynamic and neutron diffraction measurements. The H-T phase diagram shows several magnetic field-induced phases with an applied field in the plane. Neutron diffraction data reveal that $NdCoGe_3$ hosts complicated magnetic order derived from modulated magnetic moments, with the ground state characterized by the propagation vector k = (0.494, 0.0044, 0.385) at 1.8 K.

Topology Enabled Unconventional Superconductivity in a Time-Reversal Symmetry-Breaking Bulk Superconductor Valentin Taufour, Jackson Badger, Yundi Quan, Matthew Staab, Antonio Rossi, Kasey Devlin, Peter Klavins, Susan Kauzlarich, Inna Vishik and Warren Pickett; University of California, Davis, United States

In recent years, much efforts have been made towards the discovery of topological superconductors. Topological superconductivity can be artificially engineered in hybrid structures combining topological materials with conventional superconductors, or it can exist intrinsically in certain unconventional superconductors. Odd-parity superconductors are candidates for intrinsic topological superconductivity because topologically non-trivial gap functions naturally show up in these materials. These superconductors can be discovered in the proximity of magnetic instabilities such as in the superconducting ferromagnets, or in structural families that lack inversion symmetry. In this presentation, I will present our experimental and computational results on a new superconductor that breaks-time reversal symmetry because of its intrinsic topological properties. The normal state band structure includes Dirac lines and a Dirac loop at the Fermi level resulting from non-symmorphic symmetry operations, as well as Dirac points robust against splitting from SOC. The topology of the Fermi surface provides a platform for inter-band pairing and time-reversal symmetry breaking superconductivity. Our results illustrate a new route to realize spin-triplet superconductivity in a centro-symmetric structure without the need for a nearby magnetic instability.

9:35 AM NM03.06.07

Pressure-induced suppression of axionic charge density wave and onset of superconductivity in the chiral Weyl semimetal Ta_2Se_8I Qingge Mu[1], Dennis M. Nenno[2], Yanpeng Qi[3], Fengren Fan[1], Cuiying Pei[3], Moaz ElGhazali[1], Johannes Gooth[1], Claudia Felser[1], Prineha Narang[2] and Sergey Medvediev[1]; [1]Max Planck Institute for Chemical Physics of Solids, Germany; [2]Harvard University, United States; [3]ShanghaiTech University, China

The Weyl points with opposite chiralities can be coupled by charge density wave (CDW) resulting in axion quasiparticle in condensed matter physics [1, 2]. Recently, the Weyl semimetal Ta_2Se_8I was reported to exhibit axions in the collective mode of CDW, the sliding CDW which is detected with nonlinear *V-I* curves [3]. Here we investigate the electrical transport property and crystal structure under pressure. Upon applying pressure, the axionic CDW is suppressed, which is manifested by the decrease of transition temperature and corresponding single particle energy gap. A superconducting transition appears at the vicinity of the complete suppression of the CDW. The superconducting T_c is enhanced monotonically to 4.5 K with pressure up to 47 GPa. No main structural transition is detected from Raman spectra and synchrotron XRD patterns. However, partial amorphization is observed in which the stretching mode of Se-Se survives, and Ta_2Se_8I evolves into superconducting state at low temperature indicating that the $TaSe_4$ chains may play an important role in the pressure-induced superconductivity. Our investigations construct a complete phase diagram depicting the evolution of anionic CDW and superconductivity with respect to pressure, giving further understanding of correlated topological states.

Tunable Quantum Anomalous Hall Effect by the Exchange Coupling Between vdW Magnetic Layers
Huixia Fu[1], Jiewen Xiao[1], Chaoxing Liu[2] and Binghai Yan[1]; [1]Weizmann Institute of Science, Israel; [2]The Pennsylvania State University, United States

The layered antiferromagnetic $MnBi_2Te_4$ films have been proposed to be an intrinsic quantum anomalous Hall (QAH) insulator with a large gap. It is crucial to open a magnetic gap of surface states. However, recent experiments have observed gapless surface states, indicating the absence of out-of-plane surface magnetism, and thus, the quantized Hall resistance can only be achieved at the magnetic field above 6 T. We propose to induce out-of-plane surface magnetism of $MnBi_2Te_4$ films via the magnetic proximity with magnetic insulator CrI_3. A strong exchange bias of ~40 meV originates from the long Cr-e_g orbital tails that hybridize strongly with Te *p* orbitals. By stabilizing surface magnetism, the QAH effect can be realized in the $MnBi_2Te_4/CrI_3$ heterostructure. Moreover, the high–Chern number QAH state can be achieved by controlling external electric gates. In addition, we have derived a simple electron-counting rule to predict the magnetic exchange coupling between general vdW layers for both homo- and hetero-vdW junctions.

Chern Numbers and Nodal Points in Topological Semi Metals Maia Vergniory; Donostia International Physics Center, Spain

Nonmagnetic topological materials have dominated the landscape of topological physics for the past two decades. These breakthroughs in nonmagnetic materials have not yet been matched by similar advances in magnetic compounds. Using magnetic band theory and topological indices obtained from Magnetic Topological Quantum Chemistry (MTQC), I will present a systematic way of identifying magnetic topological materials. I will then, focus on high order magnetic semimetals, and provide a topological classification of different fermions in these phases. Finally I will present new experimental realizations in materials. In particular I will focus on the pyrite compound CoS2, using complementary bulk- and surface-sensitive angleresolved photoelectron spectroscopy and ab-initio calculations we discovered Weyl-cones at the Fermi-level and we directly observed the topological Fermi-arc surface states that link the Weyl-nodes, which will influence the performance of CoS2 as a spin-injector by modifying its spin-polarization at interfaces.

Seeing the Topological Ground States Through Infrared Spectroscopy Ana Akrap; University of Fribourg, Switzerland

Nowadays we know of many gapless electronic phases with conical bands, such as graphene, Dirac semimetals, and Weyl semimetals. Their low-energy excitations resemble truly relativistic particles.
To see those excitations, we have to capture the physics at a milli-electron-volt scale.
In our experiments, we access electronic structures at these low energies by combining Landau level spectroscopy, infrared spectroscopy, and effective Hamiltonian models.

Topological Engineering Through Nonlinear Phononics Dominik M. Juraschek[1], Nesta B. Joseph[2], Prineha Narang[1] and Awadhesh Narayan[2]; [1]Harvard University, United States; [2]Indian Institute of Science, India

Topological properties in quantum materials promise applications in lossless electronics and quantum information processing. Recently, dynamical control of the topological phase of the Weyl semimetal WTe_2 has been demonstrated, in which a terahertz-field induced charge current leads to interlayer shear strain that

dynamically changes the Weyl nodes of the system [1]. Here, we theoretically describe an alternative route for topological phase control that is based on a nonlinear phonon coupling. The interlayer shear and breathing modes of layered topological materials couple to infrared-active phonon modes that can be resonantly excited with ultrashort terahertz pulses. The nonlinear coupling leads a transient distortion along the coordinate of the shear and breathing modes that in turn induce changes in the topological phase of the material. Using a combination of first-principles calculations and phenomenological modeling, we demonstrate that the Dirac and Weyl nodes in WTe_2 and ZrTe5 can be modulated through this excitation. Our results suggest that nonlinear phononic rectification of the crystal lattice is a powerful tool for dynamical control of topology in layered quantum materials.

Late News: Filling Anomaly for General 2D and 3D C_4 Symmetric Lattices Yuan Fang and Jennifer Cano; Stony Brook University, The State University of New York, United States

We derive symmetry indicator formulas for the filling anomaly on 2D square lattices with and without time reversal, inversion symmetry, or their product, in the presence of spin-orbit coupling. We go beyond previous work by considering lattices with atoms occupying multiple Wyckoff positions. We also provide an algorithm using the Smith normal form that systematizes the derivation.
The formulas determine the corner charge in 2D atomic or fragile topological insulators, as well as in 3D insulators and semimetals by studying their 2D slices. We apply our results to a 3D tight-binding model on a body-centered tetragonal lattice, whose projection into the 2D plane has two atoms in the unit cell. We apply these results to several antiperovskites as material examples.

2:30 PM *NM03.08.02
Topological Magnets in 2D and 3D M. Zahid Hasan; Princeton University, United States

Electrons organize in ways to give rise to distinct phases of matter such as insulators, metals, magnets or superconductors. In the last ten years or so, it has become increasingly clear that in addition to the symmetry-based classification of matter, topological consideration of wavefunctions plays a key role in determining distinct or new quantum phases of matter [see, for an introduction, Hasan & Kane, Reviews of Modern Physics 82, 3045 (2010)].
In this talk, I briefly introduce these new topological concepts in the context of their experimental realizations in magnetic materials. As examples, I present how tuning a topological insulator whose surface hosts an unpaired Dirac fermion can give rise to Weyl fermion (massless charged fermion) in nonmagnetic and magnetic semimetals with "fractional" Fermi surfaces, and in strongly correlated magnets such as the Heusler, kagome

and related materials. These exotic topological matter harbor novel and unprecedented properties that may lead to the development of next generation quantum technologies including novel qubits.

2:55 PM *NM03.08.03
New Insights into Topological Semimetals Jennifer Cano[1,2]; [1]Stony Brook University, The State University of New York, United States; [2]Flatiron Institute, United States

The field of topological semimetals continues to reveal new insights. I will discuss recent developments starting with the classification of nodal fermions in both magnetic and non-magnetic space groups. I will then introduce higher order Fermi arcs as a bulk-edge correspondence for Dirac fermions, and discuss a refinement of the symmetry indicators that predict these hinge states. Finally, I will discuss some material predictions.

Topological States of Cadmium Arsenide Films Grown by Molecular Beam Epitaxy Susanne Stemmer; University of California, Santa Barbara, United States

Interfaces and heterostructures with topological semimetals offer new opportunities to control and manipulate their unique electronic states and a wealth of associated phenomena, for example, via electric field effect, strain, or symmetry breaking. In this presentation, we will discuss recent progress in heterostructures of a prototype three-dimensional Dirac semimetal, cadmium arsenide (Cd_3As_2), which are grown by molecular beam epitaxy. We show that high-mobility, epitaxial Cd_3As_2 films can be grown in different crystallographic orientations. We discuss the nature of the quantum Hall effect of thin Cd_3As_2 films grown in different orientations and using different measurement geometries that uniquely identify the quantum Hall effect from single Dirac fermions on the surfaces. We will discuss other remarkable phenomena in the quantum limit of (001) films. We will also discuss pathway towards realizing novel topological systems.

5:40 PM *NM03.09.02
Quantized Transport on Topological Semimetal Fermi Arcs Masaki Uchida; The University of Tokyo, Japan

Cd_3As_2 is an ideal system for investigating quantum transport in topological semimetals. In addition to its high electron mobility and long mean free path, its natural growth orientation is different from the rotational axis connecting the two Dirac nodes. This allows us to detect orbital motions in topological semimetal surfaces. We have successfully developed a growth technique realizing high mobility Cd_3As_2 films with excellent surface flatness, and first observed quantum Hall states induced by quantum confinement [1]. Related film techniques such as electric gating and chemical doping of Zn also enable systematic transport studies of the Dirac semimetal films, with controlling the bulk dimensionality [1, 2], Fermi energy [3, 4], and band topology [3, 4]. By carefully fabricating $(Cd_{1-x}Zn_x)_3As_2$ films with three-dimensional and uniform thickness, we have observed surface quantum oscillations and their evolution into quantized states in films [5, 6]. This is evidenced by distinct differences in oscillation frequency, field angle dependence, and temperature change from the bulk ones. Moreover, we have found intrinsic coupling between two spatially-separated surface states in Weyl orbits by measuring dual-gate devices [7]. Independent scans of top- and back-gate voltages reveal concomitant modulation of doubly-degenerate quantum Hall states, which is not possible in conventional surface orbits as in topological insulators. Our results evidencing the unique spatial distribution of Weyl orbits provide new

opportunities for controlling the novel quantized transport. In particular, fabrication of heterointerfaces for proximitizing the surface Fermi-arcs with ferromagnets [8] and superconductors will be promising, as well as another chemical doping of Sb for increasing band-inversion energy [9].

Investigations of Topological and Quantum Phenomena in Heusler and Rare-Earth Monopnictide Epitaxial Thin Films Chris J. Palmstrom; University of California, Santa Barbara, United States

Controlling electronic properties via bandstructure engineering is at the heart of modern semiconductor devices. We have extended this concept to semimetals utilizing confined thin film geometries and hetero-epitaxial interfaces to engineer electronic structure in rare-earth monopnictide and half-Heusler semimetallic systems. In the case of the rare-earth monopnictide, LuSb, quantum confinement changes the carrier compensation and differentially affects the mobility of the electron and hole-like carriers resulting in a strong modification in its large, non-saturating magnetoresistance behavior. Bonding mismatch at the heteroepitaxial interface of the semi-metal (LuSb) and a semiconductor (GaSb) leads to the emergence of a novel, two-dimensional, interfacial hole gas and is accompanied by a charge transfer across the interface that provides additional avenues to modify the electronic structure and magnetotransport properties in the ultra-thin limit.

The prediction and observation of topological surface states in half-Heusler compounds raises exciting possibilities to realize exotic electronic states and novel devices by exploiting their multifunctional nature. However, their position with respect to the Fermi level and the high density of bulk carriers has made it difficult to detect them through transport measurements. Here, we introduce compensation doping in epitaxial PtLuSb thin films as an effective route to tune the chemical potential and simultaneously reduce the bulk carrier concentration by more than two orders of magnitude compared to the parent compound. Linear magnetoresistance is shown to appear as a precursor phase that transmutes into a quantum Hall phase arising from the topological surface states on further reduction of the coupling between the surface states and the bulk carriers. Our approach paves the way to both reveal and manipulate exotic properties of topological phases in Heusler compounds.

6:30 PM NM03.09.04

Magnetic Properties on Bulk $MnBi_2Te_4$ Samples Grown by MBE Seul-Ki Bac[1], Logan Riney[1], Jiashu Wang[1], Kerrie Koller[2,1], Xinyu Liu[1], Maksym Zhukovskyi[1], Tatyana Orlova[1], Malgorzata Dobrowolska[1], Jacek Furdyna[1] and Badih Assaf[1]; [1]University of Notre Dame, United States; [2]Saint Mary's College, United States

Intrinsic magnetic topological insulator $MnBi_2Te_4$ has been extensively studied due to the theoretical prediction that it will provide a platform for novel topological phases, such as the quantum anomalous Hall effects (QAHEs), the axion insulators (AIs), and the type-II magnetic Weyl semimetals depending on thickness. Recently, the QAHE and AI have been observed on MnBi2Te4 flakes with odd and even number of layers, respectively. However, further progress on this novel material is hindered by the difficulty in preparing its high-quality thin films with well-controlled composition and thickness. Here we report on the magnetic properties of $MnBi_2Te_4$ samples grown by molecular beam epitaxy (MBE) with various thicknesses. We observed two main

results: magnetic phase transitions and the linear dependence between the Hall conductance and the magnetization. Both transport and SQUID measurements clearly show magnetic phase transitions between a ferromagnetic to an antiferromagnetic state and vice versa, which brings the possibility of hosting those new topological phases on MBE grown samples. In addition, we verify that the origin of the anomalous Hall effect of MnBi2Te4 is intrinsic, from its linear dependence of magnetization. Our results enable the realization of quantum anomalous Hall effects in the large area MnBi2Te4 films with thickness precisely controlled by MBE.

6:45 PM NM03.09.05

Characterization of the Sr Impurity in Bi_2Se_3 Thin Films by Molecular Beam Epitaxy Logan Riney[1], Xinyu Liu[1], Christian Bunker[1], Dominic Battaglia[1], Seul-Ki Bac[1], Jiashu Wang[1], Yum Chang Park[2], Malgorzata Dobrowolska[1], Jacek Furdyna[1] and Badih Assaf[1]; [1]University of Notre Dame, United States; [2]National Nanofab Center, Korea (the Republic of)

The Bi-chalcogenides are the most prominent topological materials to be studied to date. Alloying transition and alkali metals into the Bi-chalcogenides has enabled the discovery of topological superconductor candidates Sr-, Nb, and Cu- doped Bi_2Se_3. In this work, we synthesize $Sr_xBi_2Se_3$ thin film by molecular beam epitaxy on GaAs(111) substrates. While we do not succeed in obtaining superconductivity, our results provide insight on the mechanism by which Sr is alloyed into Bi_2Se_3. First, X-ray diffraction measurements indicate an increasing c-axis lattice parameter suggesting the formation of some Sr interstitials. Second, the mobility extracted from transport measurements and phonon linewidths extracted from Raman spectroscopy indicate that Sr likely alloys into the structure. Third, an increasing n-doping is seen with increasing Sr content. And lastly, a reduction of the electron coherence length with increasing Sr suggests that inelastic charged impurity or electron-electron scattering is enhanced. It is thus clear that Sr leads donor type impurities and more n-doping in Bi_2Se_3 despite. The thermodynamics of the MBE codeposition process seem to be generally unfavorable to the formation of Sr interstitials, thus making the synthesis of superconducting films highly challenging.

Late News: Two-Dimensional Quantum Oscillations Observed in Magnetic Topological Semimetal EuSb2 Films Mizuki Ohno[1], Masaki Uchida[1,2,3], Ryosuke Kurihara[4,5], Susumu Minami[6], Yusuke Nakazawa[1], Shin Sato[1], Markus Kriener[5], Motoaki Hirayama[1,5], Atsushi Miyake[4], Yasujiro Taguchi[5], Ryotaro Arita[1,5], Masashi Tokunaga[4,5] and Masashi Kawasaki[1,5]; [1]Dept. of Appl. Phys., the Univ. of Tokyo, Japan; [2]PRESTO, Japan Science and Technology Agency (JST), Japan; [3]Department of Physics, Tokyo Institute of Technology, Japan; [4]ISSP, the Univ. of Tokyo, Japan; [5]RIKEN CEMS, Japan; [6]Dept. of Phys., the Univ. of Tokyo, Japan

Topological nodal-line semimetals (TNLSMs) have attracted burgeoning attention because unprecedented quantum transport and magnetoelectric response originating from the Zak phase have been theoretically expected. Moreover, recent computational exploration has accelerated efforts to find magnetic TNLSM materials for controlling these topological phenomena by magnetic fields. In general, however, time-reversal symmetry breaking by magnetic ordering destroys robustness of the nodal lines, and thus only few magnetic TNLSM materials have been reported so far. In addition, quantum oscillations have never been observed in these magnetic topological nodal-line semimetals. Namely, discovery of a new magnetic TNLSM and fabrication of its high-mobility films have been strongly desired.
In order to introduce magnetic moments into typical nonmagnetic TNLSM $CaSb_2$, we prepare isostructural $EuSb_2$ single-crystalline films by molecular beam epitaxy (MBE). Our first-principles calculations demonstrate that $EuSb_2$ hosts topological nodal lines protected by nonsymmorphic symmetry even under antiferromagnetic ordering of the Eu^{2+} spins. An X-ray diffraction rocking curve is very sharp, ensuring high crystallinity of the obtained film. Observed Shubnikov-de Haas oscillations with multiple frequency components exhibit small effective masses and two-dimensional field-angle dependence even in a 250 nm thick film, suggesting possible contributions of surface states.
Our demonstration of the new magnetic TNLSM and first observation of quantum magnetotransport in its films will stimulate further investigation and control of exotic transport phenomena proposed for magnetic topological semimetals.

Skrymions in Magnetic Multilayers Hongying Jia, Markus Hoffmann, Gustav Bihlmayer and Stefan Bluegel; Forschungszentrum Jülich GmbH, Germany

Spin-orbit interaction in combination with structural inversion asymmetry on magnetic surfaces, interfaces, hetero- and nanostructures is a source for a variety of spin-dependent transport phenomena and novel magnetic textures, with the chiral magnetic skyrmions [1] being the best known. In this presentation, we discuss our efforts to optimize magnetic multilayers for skyrmions [2-7] in potential applications. We elaborate on the issues of skyrmion size [7], stability and lifetime [8], and detection [9, 10]. Furthermore, we discuss multilayers of monolayer-thick films and compare those to results of stacks of thicker films. Motivated to enable efficient material screening, we report on our efforts to replace the Dzyaloshinskii–Moriya interaction (DMI) with a descriptor (e.g. work function, electric dipole moment [11]) that is easier to evaluate or measure.

Our investigations make use of a multiscale approach based on (i) density-functional theory (DFT) (the FLAPW method as implemented in the FLEUR code [12] and the Korringa-Kohn-Rostoker (KKR) method as implemented in juKKR [13]) combined with (ii) the atomistic spin dynamics code SPIRIT [14,15] by which the lifetime of the skyrmions are determined combining the Geodesic Nudged Elastic Band method (GNEB) [16] or the Systematic Saddle Point Search method [8] with the Harmonic Transition State Theory (HTST) and (iii) micromagnetic reasoning.

Stability and Ultrafast Topological Switching of Magnetic Skyrmions Felix Buettner; Helmholtz-Zentrum Berlin, Germany

Magnetic skyrmions are long-lived topological excitations in a small subset of magnetic materials, such as some heavy-metal / ferromagnet multilayers with strong interfacial spin-orbit interactions. These materials can host a high density of skyrmions without any topological counterparts, which defines these states as topological phases with a large net topological charge. A transition from a topological trivial state to a skyrmion state is hence considered a topological phase transitions. Such topological phase transitions, which involve the nucleation or annihilation of magnetic skyrmions, are in principle allowed due to the discrete nature of the lattice. However, they are still suppressed by the same strong energy barriers that also allow skyrmions to exist at room temperature [1]. Topological phase transitions are therefore expected to be of first order, with hysteresis and a transition dynamics characterized by slow and heterogeneous nucleation, as known, e.g., from freezing of water. In fact, we find that heterogeneous nucleation is the underlying principle of electrical skyrmion nucleation, which crucially relies on materials defects to break the translational symmetry [2].

Surprisingly, however, we find that picosecond homogeneous nucleation of an extended topological phase, comprising a dense array of nanometer-scale magnetic skyrmions, can be induced by a single femtosecond laser pulse.

In this talk, after giving an introduction to the stability [1] and the spin-orbit torque nucleation [2] of magnetic skyrmions, I will discuss the nucleation dynamics of this all-optical topological phase transition, which we were able to follow in real time during the early user operation of beamline SCS at the European XFEL [3]. Using time-resolved small angle x-ray scattering, we discovered that rapid, homogeneous nucleation of the skyrmion phase is mediated by a previously undisclosed transient fluctuation state. This state, which is characterized by high spatial frequency magnetic fluctuations, persists for approximately 100 ps after exciting our magnetic multilayer with a femtosecond, infrared laser pulse. The topological phase emerges from these fluctuations by nucleation and coalescence, a mechanism that goes well beyond existing theories of topological phase transitions such as the Kibble–Zurek mechanism and the Berezinskii–Kosterlitz–Thouless transition. The process is completed on a time scale of 300 ps. Using atomistic spin dynamics simulations, we confirm that the fluctuation state is key to the ultrafast increase of the global topological charge, enabled by an almost complete elimination of the topological energy barrier in this transient state of matter.

Kinetically Controlled Skyrmion Flow Christian Pfleiderer; Technische Universität München, Germany

The non-trivial topology of skyrmions in magnetic materials results in a massively enhanced coupling to spin currents and an emergent electrodynamics directly observable in the transport properties. We report an investigation of the conditions and characteristics of the unpinning and subsequent motion of skyrmions in the class of chiral magnets as inferred from the transverse and longitudinal susceptibility as well as kinetic neutron scattering.

Stability of Néel-Type Skyrmion Lattice Against Oblique Magnetic Fields in GaV_4S_8 and GaV_4Se_8
Martino Poggio; Universität Basel, Switzerland

Magnetic skyrmions have mostly been studied in cubic chiral helimagnets, in which they are Bloch-type and their axes align along the applied magnetic field. In contrast, the orientation of Néel-type skyrmions is locked to the polar axis of the host material's underlying crystal structure. In the lacunar spinels GaV4S8 and GaV4Se8, the Néel-type skyrmion lattice phase exists for externally applied magnetic fields parallel to this axis and withstands oblique magnetic fields up to some critical angle. Here, we map out the stability of the skyrmion lattice phase in both crystals as a function of field angle and magnitude using dynamic cantilever magnetometry. The measured phase diagrams reproduce the major features predicted by a recent theoretical model, including a reentrant cycloidal phase in GaV4Se8. Nonetheless, we observe a greater robustness of the skyrmion phase to oblique fields, suggesting possible refinements to the model. Besides identifying transitions between the cycloidal, skyrmion lattice, and ferromagnetic states in the bulk, we measure additional anomalies in GaV4Se8 and assign them to magnetic states confined to polar structural domain walls.

Skyrmions for Unconventional Computing and Revealing Latent Information Karin Everschor-Sitte; Johannes Gutenberg Universität Mainz, Germany

Novel computational paradigms in combination with proper hardware solutions are required to overcome the limitations of our state-of-the-art computer technology, in particular regarding energy consumption. Due to the inherent complex and non-linear nature, spintronics offers the possibility towards energy-efficient, non-volatile hardware solutions for various unconventional computing schemes.[1-3]
In this talk, I will address the potential of magnetic skyrmions for in particular two unconventional computing schemes – reservoir computing and stochastic computing. Reservoir computing is a computational scheme that allows drastically simplifying spatial-temporal recognition tasks. We have shown that random skyrmion fabrics provide a suitable physical implementation of the reservoir [4,5] and allow to classify patterns via their complex resistance responses either by tracing the signal over time or by a single spatially resolved measurement. [6]
Stochastic computing is a computational paradigm that allows speeding up a calculation while trading for numerical precision. Information is encoded in terms of bit-streams as a probability. A key requirement and simultaneously a challenge is that the incoming bitstreams are uncorrelated. The Brownian motion of magnetic skyrmions allows creating a device that reshuffles the bit-streams. [7,8]
In any type of hardware-based computation, finally, some sort of readout of the system is needed. While often a significant effort is made in enhancing the resolution of an experimental technique to obtain further insight into the sample and its physical properties, advantageous data analysis has the potential to provide a deeper insight into a given data set. This is particularly relevant when the signal is close to the resolution limit, i.e. where the noise becomes at least of the same order as the signal. [9]

Local Spectroscopy on Magnon Modes in Skyrmion-Hosting Materials in the Microwave Frequency Regime Dirk Grundler; EPFL, Switzerland

After the discovery of the magnetic skyrmions in the A-phase of a chiral magnet [S. Mühlbauer et al., Science 323, 915 (2009)], the interest in non-collinear spin structures has substantially increased. Such nanoscale spin structures depend crucially on the material, temperature and energy contributions relevant to magnetically ordered states such as symmetric Heisenberg exchange, antisymmetric Dzyaloshinskii–Moriya exchange interactions, Zeeman energy, magnetocrystalline and shape anisotropy. The engineering of materials and energy terms is now decisive to harvest the promised functionalities of skyrmions e.g. as racetrack memory [A. Fert et al., Nat. Nano. 8, 152 (2013)], probabilistic computing approach [D. Pinna et al., Phys. Rev. Applied 9, 064018 (2018)] and microwave oscillator [S. Zhang et al., New J. Phys. 17, 023061 (2015)]. For all these possible applications a detailed understanding of spin dynamics in the technologically relevant GHz frequency regime [Y. Onose et al., Phys. Rev. Lett. 109, 037603 (2012), S.A. Montoya et al., Phys. Rev. B **95**, 224405 (2017)] is of utmost importance. At the same time eigenresonances provide a fundamental insight into the relevant energy terms [T. Schwarze et al., Nat. Mater. 14, 478 (2015)].
In the talk we report on broadband spectroscopy performed on non-collinear spin structures supported by different materials systems such as the chiral bulk magnet Cu_2OSeO_3 and multilayers prepared from FeGd. The low magnetic damping in both systems allowed us to observe rich magnon spectra which depended characteristically on the different magnetic phases. Our experiments range from about 10 K to room temperature. Beyond broadband spin-wave spectroscopy we performed Brillouin light scattering with a focused laser beam (bulk Cu_2OSeO_3) and x-ray magnetic circular dichroism microscopy (FeGd multilayers grown on a

membrane). Specific cooling cycles and magnetic field histories applied to Cu_2OSeO_3 induced metastable phases which displayed eigenmode spectra not known from the earlier publications [Y. Onose et al., Phys. Rev. Lett. 109, 037603 (2012); T. Schwarze et al., Nat. Mater. 14, 478 (2015)]. We report our latest experimental results obtained on the dynamics of non-collinear spin structures in the bulk chiral magnet Cu_2OSeO_3 and FeGd multilayers.

The work was possible due to excellent cooperation with Ping Che, and M. Albrecht, A. Bauer, K. Baumgaertl, M. Bechtel, H. Berger, E. Catapano, M. Garst, J. Gräfe, M. Heigl, A. Kúkol'ová, A. Magrez, A. Mucchietto, C. Pfleiderer, H.M. Rønnow, T. Schönenberger, G. Schütz, J.-R. Soh, I. Stasinopolous, M. Weigand, J. Waizner. The research is funded by SNSF via grant 171003 (sinergia project Nanoskyrmionics) and by DFG via transregio TRR80.

Skyrmion and Tetarton Lattices in Twisted Bilayer Graphene Achim Rosch; University of Cologne, Germany

Recent experiments on twisted bilayer graphene show an anomalous quantum Hall (AQH) effect at filling of 3 electrons per moirè unit cell. The AQH effect arises in an insulating state with both valley- and ferromagnetic order. We argue [1], that weak doping of such a system leads to the formation of a novel topological spin texture, a `double-tetarton lattice'. The building block of this lattice, the `double-tetarton', is a spin configuration which covers 1/4 of the unit-sphere twice. In contrast to skyrmion lattices, the net magnetization of this magnetic texture vanishes. Only at large magnetic fields more conventional skyrmion lattices are recovered. But even for large fields the addition of a single charge to the ferromagnetic AQH state flips hundreds of spins. Our analysis is based on the investigation of an effective non-linear sigma model which includes the effects of long-ranged Coulomb interactions.

Exploring Magnetic Skyrmions in Co-Zn-Mn Compounds—From Far-From-Equilibrium States to Effects of Magnetic Frustration Jonathan White; Paul Scherrer Institute, Switzerland

First discovered in 2009 to form a lattice of whirlpool-like twists in MnSi, magnetic skyrmions have since been explored extensively in other bulk magnetic crystals, and in synthetic systems such as magnetic mono- and multilayers. Regardless of the host system, the topological winding of skyrmions is the common ingredient that leads to unique physical properties attracting significant interest. In particular, it is established that skyrmions when created display a robustness against perturbation and decay that is generally referred to as topological protection. This is a central concept underlying the stability of skyrmions and their suitability for use in applications, either within equilibrium phases or far-from-equilibrium states.

In this talk, we will review our recent experimental studies of Co-Zn-Mn compounds [1-6], a family of high-temperature chiral cubic magnets discovered recently to host Bloch-type chiral skyrmions over an extended temperature range, including room temperature [1]. Amongst the remarkable properties displayed by these materials, we will focus first on how skyrmions phases fall out of thermal equilibrium remarkably easily on supercooling to form robust metastable skyrmion states [2-3]. These metastable skyrmion states extend unprecedentedly across the majority of the phase diagram, and can even display a thermally-reversible structural transformation that surprisingly does not trigger a decay to the thermodynamic ground state.

Second, we focus in on the Co7Zn7Mn6 composition, the phase diagram of which hosts two thermodynamically distinct equilibrium skyrmion phases [5]. One of these skyrmion phases is the so-called A-phase, stable just below the transition temperature and familiar to all chiral cubic magnets. The second skyrmion phase in this system is much more unusual, being stable at much lower temperatures, with this fact alone implicating multiple skyrmion stability mechanisms exist in this single system, and the existence of a new

skyrmion phase stability mechanism at low temperature. From extensive recent experiments [6], we will argue that the stability of the low temperature skyrmion phase is due to a cooperative interplay between chiral magnetism and the magnetic frustration that arises due to a hyper-kagome structural motif in the crystal structure.

Overall, our experiments on Co-Zn-Mn compounds showcase this system as a rich playground for exploring the connection between topological skyrmions, the physics of far-from-equilibrium topological states and magnetic frustration.

Ferromagnetic and Synthetic Antiferromagnetic Skyrmions in Magnetic Multilayers—3D Textures and Investigations of the Dzyaloshinskii-Moriya Interaction Nicolas Reyren[1], Yanis Sassi[1], Matthieu Grelier[1], Cyril Léveillé[2], Fernando Ajejas[1], Erick Burgos-Parra[1,2], Sachin Krishnia[1], Titiksha Srivastava[1,3], William Legrand[1], Davide Maccariello[1], Sophie Collin[1], Aymeric Vecchiola[1], Karim Bouzehouane[1], Nicolas Jaouen[2], Stefania Pizzini[4], André Thiaville[5], Vincent Cros[1] and Albert Fert[1]; [1]Unité Mixte de Physique, CNRS, Thales, Paris-Saclay, France; [2]Synchrotron Soleil, France; [3]SPEC, CEA-Saclay, France; [4]Institut Néel, France; [5]Laboratoire de Physique des Solides, France

Magnetic skyrmions are localized magnetic textures in magnetic films, behaving as particles and topologically different from the uniform ferromagnetic state. In metallic magnetic multilayers (MML) with perpendicular magnetic anisotropy (PMA), non-collinear chiral spin textures are stabilized by interfacial Dzyaloshinskii-Moriya interaction (DMI), which favours a unique sense of magnetization rotation. Magnetic skyrmions in MML were identified to be extremely promising for applications, as well as of fundamental interest. [1] The magnetism community provided a great effort during the last years to control skyrmions properties, notably size, velocity, and stability in field and temperature.

We soon realized that the increase of repetitions of the multilayers serving the thermal stability of the magnetic textures has the *a priori* adverse effect of stabilizing hybrid magnetic textures that is a depth dependence of the chirality (of domain walls or skyrmions) due to the competitions between dipolar fields and DMI. [2] We will describe ferromagnetic skyrmion propagation in different type of structures and discuss the role of their three-dimensional (3D) magnetic textures with hybrid chirality.

The dipolar fields are also responsible for the increase in skyrmion diameter. Both the hybrid chirality and the size increase suggest that reducing the role of dipolar fields is desirable in view of applications. A solution is to use ferromagnetic layers coupled antiferromagnetically through Ruderman-Kittel-Kasuya-Yoshida (RKKY) interaction, namely synthetic antiferromagnetic (SAF) MML. Manipulating the SAF MML is of course difficult using external magnetic fields only, and a solution using a bias layer will be discussed. [3] Studying SAF systems with conventional magnetic force microscopy (MFM) and other techniques is challenging. We will present experimental investigations using MFM in vacuum [3], NV-center microscopy, electrical transport measurement [4] and x-ray scattering techniques [5] to investigate the magnetization textures, and, in particular, the skyrmions in SAF.

Understanding precisely our observations requires a detailed understanding of the DMI. Therefore, we investigate systematically the DMI using Brillouin light scattering, stripe domain period, and domain wall propagation in several types of multilayers to measure its dependence with thickness [6] and materials [6,7]. In

particular, we unravel a strong correlation between the work function and the DMI amplitude [7].

Skyrmions, Hopfions and Related Topological Defects in Chiral Magnets and Liquid Crystals Avadh Saxena; Los Alamos National Laboratory, United States

Nontrivial topological defects such as two- and three-dimensional skyrmions, skyrmion tubes and hopfions have been observed in a variety of materials including chiral magnets, nematic liquid crystals and even in ferroelectrics as well as other materials (e.g. multiferroics) and physical contexts such as condensates. I will present a comparative study of these topological entities in terms of modeling them using the relevant variable, e.g. magnetization, polarization or the director field. I will also focus on their energetics, a variety of topological invariants that characterize them and how to study their properties for potential applications.

2:39 PM *NM04.03.02
Tailoring and Measuring Anisotropy in Skyrmion Hosts Istvan Kezsmarki; Universität Augsburg, Germany

The impact of magnetic anisotropy on the skyrmion lattice (SkL) state in non-centrosymmetric magnets has been overlooked for long, partly because a semi-quantitative description of the equilibrium SkL phase forming near the Curie temperature could often be achieved without invoking anisotropy e
ffects. Recently, anisotropy has been reported to play a crucial role in the formation of low-temperature equilibrium SkLs in cubic helimagnets, the transformation between different metastable SkLs and the deformation of skyrmions in axially symmetric polar magnets. While these findings highlight the importance of magnetic anisotropy with regard to the stability, symmetry and shape of individual skyrmions and SkLs, systematic experimental studies quantifying the strength of anisotropy in skyrmion hosts are virtually non-existing. Here, we determine the type and the strength of magnetic anisotropy in various skyrmion-host families, using multi-frequency electron spin resonance spectroscopy, and report on strong variations of anisotropy driven by composition, temperature or even by magnetic field.

3:03 PM *NM04.03.05
Thermodynamic Phenomena of Skyrmions Wanjun Jiang; Tsinghua University, China

Skyrmions are particle-like topological spin textures stabilized by the Dzyaloshinskii-Moriya interaction, which

have recently stimulated great interests in spintronics community. The dynamics of which have been frequently studied via using magnetic fields and current-induced spin torques. On the other hand, a comprehensive understanding of thermal effects, including random thermal fluctuation and directional thermal currents, on the dynamics of skyrmions are not fully established yet.

In this talk, I will first discuss our recent experimental observation of the thermal fluctuation-induced random walk of a single isolated Néel-type magnetic skyrmion in an interfacially asymmetric Ta/CoFeB/TaO_x multilayer. In particular, an intriguing topology dependent Brownian gyromotion behavior of skyrmions has been identified. The onset of Brownian gyromotion of a single skyrmion induced by the thermal effects, including a nonlinear temperature-dependent diffusion coefficient and topology-dependent gyromotion are further formulated based on the stochastic Thiele equation.

Subsequently, I will discuss the thermal generation, manipulation and detection of nanoscale skyrmions, which were made in microstructured devices made of different multilayers – $[Ta/CoFeB/MgO]_{15}$, $[Pt/CoFeB/MgO/Ta]_{15}$ and $[Pt/Co/Ta]_{15}$ integrated with on-chip heaters, by using a full-field soft X-ray microscopy. In particular, the thermal generation of densely packed skyrmions at the device edge, together with the unidirectional diffusion of skyrmions from the hot region towards the cold region were experimentally observed. These thermally generated skyrmions can be further electrically detected by measuring the accompanied anomalous Nernst voltages. These results could open another exciting avenue for enabling skyrmionics, and promote interdisciplinary studies among spin caloritronics, magnonics and skyrmionics.

Advanced Transmission Electron Microscopy of Magnetic Skyrmions at the Nanoscale Rafal Dunin-Borkowski, Andras Kovacs, Thibaud Denneulin and Fengshan Zheng; Forschungszentrum Jülich GmbH, Germany

Off-axis electron holography is a powerful technique, which can be used to record the phase shift of an electron wave that has passed through an electron-transparent specimen in a transmission electron microscope. According to the Aharanov-Bohm equation, the phase shift is sensitive to local variations in electromagnetic potential, which are in turn dependent on nanoscale properties of a specimen of interest, such as charge density or magnetization. The determination of such properties from a recorded phase image is an ill-posed problem that is difficult to tackle. We have developed a model-based iterative reconstruction technique, which can be used to retrieve the projected in-plane magnetization distribution from the magnetic contribution to a recorded phase image, or alternatively the three-dimensional magnetization distribution from a set of at least two tilt series of magnetic phase images. The technique is based on the optimized implementation of a forward model, which maps a given magnetization distribution onto one or more phase images. The forward model utilizes sparse matrix multiplications for efficient projections and Fourier-transform-based convolutions with pre-calculated convolution kernels based on analytical solutions for the magnetic phase images of simple geometrical objects. The ill-posed problem is tackled by replacing the original problem by a least squares minimization, which is augmented by regularization techniques to find a solution for the reconstructed magnetization distribution. Tikhonov regularization of first order is used to apply smoothness constraints to the magnetization, which is justified by the minimization of exchange energy. *A priori* information about the positions and sizes of magnetic objects in the field of view are utilized in the form of a three-dimensional mask, which reduces the number of unknowns to be retrieved. The model-based approach is flexible and can account for arbitrary linear phase ramps and phase offsets, as well as for untrustworthy (low confidence) regions in input images. We have applied it successfully to reconstruct in-plane (projected) magnetization distributions from

individual experimental magnetic phase images and three-dimensional magnetization distributions from tilt series of phase images. Diagnostic measures, which are based on optimal estimation theory, have been used to analyze the quality of the reconstruction results. The influence of the regularization strength has been assessed, in order to obtain the best solution in the presence of noise and other artefacts.

In order to visualize the magnetization distributions of Bloch-type magnetic skyrmions in three dimensions, we have used model-based iterative recosntruction to study patterned FeGe nanostructures that host individual skyrmions in the absence of applied magnetic fields, allowing tomographic tilt series of off-axis electron holograms to be recorded. We have also identified novel superstructures of skyrmion strings in thin films of chiral magnets that form characteristic patterns in phase images recorded using off-axis electron holography.

In order to visualize the magnetization distributions of Néel-type skyrmions that are stable at room temperature, we have studied perpendicularly-magnetized multilayers of heavy metals and ferromagnets sputtered on SiN membranes by tilting the sample with respect to the incident electron beam direction in the presence of applied magnetic fields and compared experimental phase images with simulated phase images derived from atomistic models. Furthermore, we have studied two-dimensional magnetic materials, which possess strong perpendicular magnetocrystalline anisotropy and show Néel-type skyrmion bubbles after field cooling.

3:51 PM *NM04.03.03
Curvilinear Magnetism—Geometrically Curved Ferro- and Antiferromagnets Denys Makarov;
Helmholtz-Zentrum Dresden-Rossendorf e.V., Germany

The main origin of the chiral symmetry breaking in magnetic materials is associated with the intrinsic Dzaloshinskii-Moriya interaction (DMI). At present, tailoring of DMI is done rather conventionally by optimizing materials, either doping a bulk single crystal or adjusting interface properties of thin films and multilayers. A viable alternative to the conventional material screening approach can be the exploration of the interplay between geometry and topology. The research field in magnetism, which is dealing with the study of the impact of geometrical curvature on magnetic responses of curved 1D wires and 2D shells is known as curvilinear magnetism [1]. The perspective of the development of curvilinear magnetism is outlined in the 2017 and 2020 Magnetism Roadmaps [2,3]. In this presentation, we will discuss on the recent achievements in the field and address the following topics:
A fully 3D approach to treat curvilinear effects in ferromagnetic nanowires and thin shells of arbitrary shape is established by Gaididei et al. back in 2014 [4] and was recently extended by Sheka et al. [5] to properly account for effects of non-locality due to the presence of long-range magnetostatic interaction. Volkov et al. has proven that the exchange-driven chiral effects in curvilinear ferromagnets are experimental observables [6] and can be used to realize nanostructures with tunable magnetochiral properties from standard magnetic materials.
In contrast to the intrinsic DMI, a concept of mesoscale Dzyaloshinskii-Moriya interaction was put forth, which is a result of the interplay between the intrinsic (spin-orbit-driven) and extrinsic (curvature-driven) DMI terms [7]. The mesoscale DMI governs the magnetochiral properties of any curvilinear ferromagnetic nanosystem and depends both on the material and geometrical parameters. Its strength and orientation can be tailored by properly choosing the geometry, which allows stabilizing distinct magnetic chiral textures including skyrmion and skyrmionium states as well as skyrmion lattices [8-10]. Interestingly, skyrmion states can be formed in a material even without an intrinsic DMI [8,10].
Sheka et al. [5] discovered a novel non-local chiral symmetry breaking effect, which does not exist in planar magnets: it is essentially non-local and manifests itself even in static spin textures living in curvilinear magnetic nanoshells. To identify this new interaction, a generalized micromagnetic theory of curvilinear ferromagnets was constructed accounting for local and nonlocal effects. The curvature leads to the emergence of the new magnetostatic charge, the geometrical charge, determined by the local characteristics of the surface. This newcomer is responsible for the appearance of novel fundamental chiral symmetry breaking effect.
The field of curvilinear magnetism was recently extended towards curvilinear antiferromagnets. Pylypovskyi et al. [11] demonstrated that intrinsically achiral one-dimensional curvilinear antiferromagnet behaves as a chiral helimagnet with geometrically tunable DMI, orientation of the Neel vector and the helimagnetic phase

transition. This positions curvilinear antiferromagnets as a novel platform for the realization of geometrically tunable chiral antiferromagnets for antiferromagnetic spinorbitronics.

Imaging Skyrmions in Ferromagnets and Antiferromagnets with Scanning NV-Center Microscopy
Aurore Finco; Laboratoire Charles Coulomb, Université de Montpellier and CNRS, France

NV-center magnetometry emerges as a powerful technique to investigate complex magnetic textures at the nanoscale under ambient conditions. It makes use of the response to magnetic field of the single spin of an NV-center [1], which is a defect in the crystalline structure of diamond consisting of a nitrogen atom and a vacancy. We demonstrate here its imaging capabilities both on ferromagnetic skyrmions stabilized at zero external field and on antiferromagnetic domain walls and skyrmions in a synthetic antiferromagnet.

To observe non-collinear textures in ferromagnets, we operate the NV magnetometer in photoluminescence quenching mode, allowing the detection of stray field producing areas by measuring the spatial variations of the emitted NV center photoluminescence. In addition, the use of a diamond probe ensures that the experiment is carried out in the absence of external magnetic perturbation. To illustrate this, we show that skyrmions with a diameter about 60 nm [2] are stabilized by the exchange bias coming from the interface between the antiferromagnet IrMn and the ferromagnet NiFe in an optimized Pt/Co/NiFe/IrMn stack.

In addition to ferromagnets, antiferromagnets have recently attracted a great interest in spintronics owing to the robustness of their magnetic textures and their fast dynamics. However, since they exhibit no net magnetization, antiferromagnets are challenging to work with. Therefore, we introduce a new imaging mode of the scanning NV-center microscope which does not rely on the measurement of the static magnetic stray field but on the detection of magnetic noise originating from spin waves inside the non-collinear antiferromagnetic textures of interest. The presence of magnetic noise accelerates the NV spin relaxation. As a consequence, the emitted photoluminescence is reduced, allowing a simple detection of the noise sources [3].

We demonstrate this new technique on synthetic antiferromagnets [4] consisting of two ferromagnetic Co layers antiferromagnetically coupled through a Ru/Pt spacer. We first image domain walls and prove that we perform noise-based imaging by measuring a shorter NV spin relaxation time above an antiferromagnetic domain than above a domain wall. Calculations of the spin waves dispersion both in the antiferromagnetic domains and in

the domains walls as well as maps of simulated magnetic noise intensity enable us to conclude that the noise which we probe arises from spin waves channelled in the domain walls.

Going further, we tune the composition of the synthetic antiferromagnet stacks in order to stabilize spin spirals or antiferromagnetic skyrmions. In both cases, our relaxometry-based technique is able to image the non-collinear structures, demonstrating its efficiency and opening new avenues of exploration in the characterization of complex structures in magnetically-compensated materials.

This work was done in collaboration with Spintec in Grenoble, France, the Unité Mixte de Physique CNRS/Thalès in Palaiseau, France and the Center for Nanoscience and Nanotechnology (C2N) in Palaiseau, France. This project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 846597 and from the DARPA TEE Program.

Skyrmion Dynamics in MnSi Tobias Weber[1], David Fobes[2], Johannes Waizner[3], Paul Steffens[1], Greg Tucker[4], Martin Boehm[1], Lukas Beddrich[5], Chris Franz[5], Henrik Gabold[5], Rob Bewley[4], David Voneshen[4], Markos Skoulatos[5], Robert Georgii[5], Georg Ehlers[6], Andreas Bauer[5], Christian Pfleiderer[5], Peter Boeni[5], Marc Janoschek[7] and Markus Garst[8]; [1]Institut Laue-Langevin, France; [2]Los Alamos National Laboratory, United States; [3]University of Cologne, Germany; [4]ISIS Pulsed Neutron and Muon Source, United Kingdom; [5]Technische Universität München, Germany; [6]Oak Ridge National Laboratory, United States; [7]Paul Scherrer Institute, Switzerland; [8]Karlsruhe Institute of Technology, Germany

For temperatures in the range between ca. 28 and 29 K and for magnetic fields of about 0.16 − 0.21 T, the itinerant magnet MnSi features a vortex-like skyrmion order [1] of its electron spins. The study of the structure of magnetic skyrmions has generated much experimental and theoretical interest since its discovery over ten years ago. Here, we present the first comprehensive study of the dynamics of the skyrmion phase.

MnSi's non-centrosymmetric space group has profound consequences for dynamics in all ordered magnetic phases of MnSi. Namely, it introduces a Dzyaloshinskii-Moriya term which leads to magnon creation at energies that are different from those for magnon annihilation, with this phenomenon being restricted to reduced momentum transfers whose vector q has components perpendicular to the skyrmion plane. The dynamical magnetic structure factor $S(q, E, H)$, with $q = Q - G$ and lattice vector G, thus becomes asymmetric ("non-reciprocal") with respect to changing the sign of either q, the energy transfer E, or the magnetic field H, but is symmetric upon interchanging the signs of any two of these variables. Such an asymmetric behavior could so far also be observed for the field-polarized [2, 3], the paramagnetic [4] and the conical [5,6] phase of MnSi.

For our recently completed study [7] we fully mapped out the magnetic dynamics in the skyrmion phase of MnSi. To that end, we employed polarized triple-axis, time-of-flight and spin-echo experiments. Apart from an in-depth analysis of the non-reciprocal dynamics, we succeeded in observing a splitting of the magnon energies into closely-spaced Landau levels for momentum transfer vectors inside the skyrmion plane. Theoretically, we describe our results using a mean-field linear spin-wave model. A correction of the theory for instrumental resolution yields an excellent quantitative agreement between experiment and theory.

Magnetic Ordering and Magnetoresistance of Antiferromagnet $CaFe_2O_4$ Jonathan Valenzuela, Tekiyah Robinson, Kory Wells, Sunil Karna and Doyle Temple; Norfolk State University, United States

The oxide compounds containing iron are widely studied because of many interesting phenomena including charge disproportionation, spin polarization, and the magentoresistive effect. $CaFe_2O_4$ crystallizes in the orthorombic *Pbnm* structure which consists of distorted FeO_6 distorted octahedra through edge- and corner-sharing with intercalated Ca atoms. We have recently grown a large single crystal of $CaFe_2O_4$ by the optical floating-zone method. The two transitions T_1~240 K and T_2~200 K are observed in our magnetic susceptibility measurements. Our neutron powder diffraction reveals two competing magnetic phases, Γ6 and Γ3, at low temperatures which are distinguished by their *c*-axis stacking of ferromagnetic b-axis stripes. Γ6-type magnetic phase develops below 240 K that starts to reduce with the emergence of Γ3-type magnetic phase below 200 K. The detailed magnetoresistance measurements in different crystal orientations will also be discussed in the presentation.

Emergent Topological Structures and Phase Transitions in Ferroelectric Superlattices Lane W. Martin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

In superconductivity, colossal magnetoresistance, and multiferroism, emergent phenomena arise from the interplay of various degrees of freedom and competing phases that drive nanoscale complexity (*i.e.*, chemical, ionic, electronic, etc. variations) that can be readily controlled using external stimuli and can result in colossal changes in physical responses. Leveraging advances in *ab initio* design, atomically precise synthesis, and multi-modal characterization of materials researchers can now induce such competition in an on-demand fashion and probe the resulting order in ways never imagined before. While non-trivial topological magnetic textures such as skyrmions have generated particular interest due to their topological protection and their potential for use in memory applications, similar effects in ferroelectrics were not expected. Such topologically protected structures or concomitant topological-phase transitions in ferroelectric were thought to be unlikely because the primary order parameter is strongly coupled to the lattice distortion and thus continuous evolution of the order parameter would result in a large elastic-energy cost. But advances in materials heterostructuring, superlatticing, nanostructuring, *etc*. are now opening the door to previously unexpected effects – including the observation of novel structures reminiscent of topological structures in magnetic systems in such polar materials.

Here we will summarize and highlight recent advances in the study of ferroelectric/dielectric superlattices such as $(PbTiO_3)_n/(SrTiO_3)_n$, wherein unit-cell-level control enables one to place the Landau, electrical, elastic, and gradient energies into competition which drives the formation of topologically non-trival structures including so-called polar vortices and skyrmions. We will introduce and explore a number of aspects of these systems, including: the fundamental nature of the features that can be produced and the mechanisms behind their formation, routes to tune the morphology of the emergent structures to produce both polar vortices and skyrmions with a skyrmion number of +1, observations of phase coexistence (mediated by a first-order phase

transition) between such emergent, non-trivial phases and trivial ferroelectric phases, the potential for the formation of a novel multi-order-parameter state which belongs to a class of gyrotropic electrotoroidal compounds, the realization of electric-field control of such mixed-phase systems which permits interconversion between the non-trivial emergent states and trivial ferroelectric phases concomitant with order of magnitude changes in piezoelectric and nonlinear optical responses, the potential for a non-classical, BKT-like topological phase transition in these materials, electric-field and light susceptibilities, the potential for exotic dielectric phenomena, and much more. All told, this work will provided a primer on this growing field, highlight similarities and differences with the magnetic community, and show how multi-modal approaches are rapidly rewriting our understanding of this class of materials.

Comprehensive Screening and Alloy Design of Inverse Heusler Antiskyrmion Hosts Daniil A. Kitchaev and Anton Van der Ven; University of California, Santa Barbara, United States

The scarcity of bulk materials capable of hosting (anti)skyrmions over a wide range of ambient temperatures remains one of the most substantial obstacles to moving from proof-of-concept experiments to practical skyrmion-based devices. We have recently demonstrated that achieving a wide temperature range for skyrmion stability requires moving from the cubic symmetry seen in conventional bulk skyrmion hosts, to uniaxial symmetries[1], alongside ensuring a high Curie temperature. Several high-temperature antiskyrmion host materials consistent with these criteria have been experimentally reported within the family of inverse Heusler alloys[2,3]. We report a comprehensive computational exploration of the inverse Heusler family of compounds in search of synthesizable compositions capable of hosting antiskyrmions and other helimagnetic phases over a wide range of temperatures near ambient conditions. We develop a universal model connecting the chemical, structural, and magnetic phase stability of these alloys, building from first-principles calculations of their structure, to finite temperature and mesoscale behavior. While very few ordered ternary inverse Heuslers may host antiskyrmions, we identify an abundance of disordered quaternary inverse Heusler alloys that are likely to support these magnetic phases, in addition to those previously reported. These results establish the first set of rational design criteria for engineering thermally-robust topological magnetism, and identify a number of promising chemical spaces for experimental exploration.

8:15 PM NM04.05.01
Distinct Topological Skyrmion Lattices in Tetragonal Heusler Compounds Jacob Gayles[1,2], Toni Helm[3,1] and Claudia Felser[2]; [1]University of South Florida, United States; [2]Max Planck Institute for Chemical Physics of Solids, Germany; [3]Dresden High Magnetic Field Laboratory, Helmholtz Zentrum Dresden Rossendor, Germany

Tetragonal Heusler compounds that lack inversion symmetry was shown to stabilize an antiskyrmion lattice, even above room temperature. Recently, multiple distinct Skyrmion states have been proposed to emerge in the Heusler ferromagnetic metal $Mn_{1.4}PtSn$. The compound displays a transition from A.S.K. to Bloch-type Skyrmions, as seen from Lorentz transmission electron microscope results, placing $Mn_{1.4}PtSn$ in a select category. This Heusler compound forms in a superstructure with the D_{2d} symmetry, which allows for an

anisotropic Dzyaloshinskii-Moriya interaction (D.M.I.) perpendicular to the tetragonal axis. We use density functional theory calculations of $Mn_{1.5}XY$ and Mn_2XY to extract the relevant exchange interactions that determine the rich phase diagrams in these materials. The exchange interactions are between the comparatively large moments on the Mn atoms ~4 μ_B, which show magnetic states that are ferrimagnetic non-collinear up to the spin reorientation. The D.M.I. and anisotropy's primary source is the X ion, either Rh, Pd, Ir, or Pt, which also influences the exchange interactions. The Fermi level can be tuned by the Y ion, either In, Sn or Sb. The interplay of these microscopic exchange interactions leads to a rich phase diagram that can display distinct skyrmion phases in external fields.
The Topological Hall effect (THE), a direct measurement of the topological magnetic excitations in conductive compounds, has proven a subject in detecting Skyrmion lattice phases. We calculate the anomalous Hall effect and topological Hall effects in these regimes to capture the electronic structure's influence on the Berry curvature. Here we report new insights of the magnetotransport, which is compared to experimental findings in the magneto-optical Kerr effect, magnetic force microscopy studies, ferromagnetic resonance, specifically in the intriguing magnetic properties of $Mn_{1.4}PtSn$. We show how the contribution of Skyrmions can be detected in transport devices. Our results provide evidence for the existence of antiskyrmions and ferrimagnetic in-plane Skyrmions depending on a wide range of temperatures and the orientation of an external magnetic field. These findings lead to a unique possibility to stabilize distinct skyrmions and for detection by all-electrical means.

8:30 PM DISCUSSION

8:45 PM NM04.05.04
Topological Nature of Magnetic and Electronic Structures in Cubic B20 Nanostructures Nitish Mathur[1], Matthew J. Stolt[1], Fehmi Yasin[2], Xiuzhen Yu[2] and Song Jin[1]; [1]University of Wisconsin Madison, United States; [2]RIKEN, Japan

Nanostructured platform for materials with real space (magnetic skyrmion) and momentum space (Weyl fermions) topological features could enable efficient memory and quantum computing devices. We have developed “bottom-up” chemical vapor deposition (CVD) techniques to synthesize single-crystal nanostructures of non-centrosymmetric cubic B20 FeGe (magnetic skyrmion host) and CoSi (Weyl semimetal). Magnetic skyrmions are depicted as two-dimensional spin texture, in reality, they possess a three-dimensional structure of skyrmions that looks like elongated strings extending throughout the thickness of the sample. We report the creation and annihilation of skyrmion strings in FeGe nanostructures under in-plane magnetic field ($H_{||}$) using magnetotransport and defocused Lorentz transmission electron microscopy (LTEM) detection techniques for the first time. Unusual asymmetric and hysteretic magnetoresistance (MR) features are observed during magnetic phase transitions within the skyrmion strings stability regime when $H_{||}$ is along the nanostructure’s long edge, which increase the sensitivity of MR detection. On the other hand, CoSi are found to possess unconventional chiral fermions with higher Chern number and chirality dependent band dispersion. We synthesized novel merohedral twinned nanowires of Weyl semimetal that could possess a topological defect (exhibits spontaneous symmetry breaking) connecting/separating two enantiomeric atomic arrangements inside the crystal itself. We discuss here the notable synthesis results, experimental techniques, and challenges to explore the topological nature of magnetic and electronic structures in nanostructure morphology.

9:00 PM NM04.05.05
Real-Space Observation of Topological Skyrmions/Antiskyrmions and Their Controlled Transformation in Non-Centrosymmetric Magnets Licong Peng[1], Kosuke Karube[1], Rina Takagi[1], Wataru Koshibae[1], Kiyou Shibata[1], Kiyomi Nakajima[1], Taka-hisa Arima[1,2], Naoto Nagaosa[1,2], Shinichiro Seki[1], Yoshinori Tokura[1,2,2], Yasujiro Taguchi[1] and Xiuzhen Yu[1]; [1]RIKEN Center for Emergent Matter Science (CEMS), Japan; [2]University of Tokyo, Japan

Topological skyrmions and antiskyrmions have attracted enormous attention due to their different emergent phenomena and potential applications to spintronics. In this talk, we will present the real-space observations of skyrmions/antiskyrmions and their transformation in two kinds of non-centrosymmetric magnets[1,2] by Lorentz

transmission electron microscopy. We will show the stability and manipulation of the square-shape antiskyrmions in a square lattice and elliptically-deformed skyrmions with opposite helicities as determined by the interplay of magnetic dipole interaction and anisotropic Dzyaloshinskii–Moriya interaction. We then show that their topological nature, such as topological charge, helicity, and lattice form, is highly controllable by manipulating the in-plane and out-of-plane magnetic fields, temperature, and thickness, etc..

9:15 PM *NM04.05.06
Emergent Electromagnetic Induction in Helical-Spin Magnets Yoshinori Tokura[1,2]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan

We report on the inductor function as designed and realized via emergent electromagnetic field (EEMF) in metallic magnets with helical spin orders. An inductor is one of the most fundamental circuit elements for modern electronic device. The magnitude of such a conventional inductance is proportional to the volume of an inductor's coil, which is known as a hardly-solvable hindrance to miniaturization of inductors. Here, we demonstrate an inductance of quantum-mechanical origin, that is originating from the emergent electric field induced by current-driven dynamics of spin helices in a magnet. In microscale rectangular-shaped devices of a magnet with nanoscale spin helices, e.g. $Gd_3Ru_4Al_{12}$, we observed that the inductance is prominently enhanced in spin helically-modulated phases, showing a typical inductance value (L) as large as sub micro-henry for the device whose volume is $\sim 10^{-6}$ times smaller than the inductor available at present. The observed inductance is enhanced by the nonlinearity in current and shows non-monotonous frequency dependence, both of which result from the current-driven dynamics of the spin-helix structures. We discuss the possibility of the highly inductive helimagnets working beyond room temperature as a most distinct outcome of EEMF in quantum materials.

Late News: Magnetic Skyrmions in a Thermal Gradient-Experimental Observation and Critical Speed-Up Jan Masell[1], Xiuzhen Yu[1] and Naoto Nagaosa[1,2]; [1]RIKEN CEMS, Japan; [2]The University of Tokyo, Japan

When a magnetic insulator is subject to a temperature gradient, an effective magnon current flows from the hot to the cold side of the sample. It was theoretically proposed that this magnon current exerts a torque on the magnetization, similar to a spin-transfer torque in a bulk magnet, which can move magnetic skyrmions towards the source of heat [1,2,3].
I will present recent experimental observations which confirm the directed motion of skyrmions in the chiral magnetic insulator Cu_2OSeO_3 when a heat gradient is applied. The experimentally observed skyrmion velocity is in qualitative agreement with our theoretical predictions. Moreover, our theoretical analysis predicts an enhancement of the magnon current at the phase transition from a conical to a field-polarized background. The embedding phase is therefore expected to have a strong impact on the motion of skyrmions in a thermal gradient, including a critical speed-up at the aforementioned phase transition, which I will discuss in this presentation.

9:55 PM *NM04.05.08
Control, Drive and Manipulation of Various Topological Spin Textures Xiuzhen Yu; RIKEN, Japan

Exotic topological spin textures[1)] and their dynamics attract much attention to fundamental physics[2)] and applications to novel electron-devices[3)] owing to their topological nature and emergent electromagnetic properties. Here, I will present how to control, drive and manipulate nanometer-scale topological spin textures and their lattice forms, such as (anti) skyrmion, (anti) meron and their transformations between antiskyrmions and skyrmions, merons and skyrmions, and transformations of their lattice forms between square lattice (sq.-ML) and triangular lattice (hex-SkL), with finely tuning the external magnetic field in several magnets[4-6)] with non-centrosymmetric crystalline structure. On the other hand, the minute (atomic-scale) skyrmions have been successfully manipulated in centrosymmetric magnets with Ruderman–Kittel–Kasuya–Yoshida (RKKY)-type electronic coupling[7-8)]. To manipulate and track individual skyrmions and its lattice form using a relatively low electric current, we make a microdevice composed a thin helimagnet of FeG with a small notch[9)], which allowed the spin current to be localized in a specific area near the corner of the notch. Drift, Hall and torque motions of single 80-nm-size skyrmions and their clusters are tracked with directional current at low current density, a thousand times weaker than those used in that for drives of magnetic domain walls.

Shubnikov de-Haas Oscillation and Quantum Hall Effect in Bulk CaCuSb Single Crystal—Evidence of 2D Charge diffusion Souvik Sasmal[1], Rajib Mondal[2], Arumugam Thamizahvel[1], Bahadur Singh[1] and Vikram Tripathi[1]; [1]Tata Institute of Fundamental Research, India; [2]UGC DAE Consortium For Scientific Research, India

As the charge carriers in 3D materials are not confined and free to move in all spatial dimensions, Quantum Hall Effect (QHE) in 3D is rare and it is relatively unexplored in experiments due to the limited choice of viable candidate materials. Here, we report on the observation of weak antilocalization (WAL) and QHE followed by Shubnikov de-Haas (SdH) oscillations with oscillation frequency 314 T and effective mass in bulk CaCuSb single crystal. It crystallizes in the hexagonal structure ($P6_3/mmc$). One of the unique features of this crystal structure is to possess two Cu-Sb layers in the unit cell that act as the conduction channels. Significant anisotropy in electrical transport measurements along crystallographic *a*- and *c*- direction suggests that magneto-transport effect is due to charge diffusion on Cu-Sb planes but not along *c*- axis. A cusp like behavior in the low field region of magnetoresistance reveals WAL in this compound, as observed in *ABC*- type hexagonal structure CaAgBi [1]. Magnetoconductance (MC) follows 2D scaling law as reflection of merging MC data as a function of normal component of magnetic field for different angles. Quantized Hall plateaus are observed in the $1/\rho_{xy}$ *vs* $1/B$ plot are attributed to the multiple 2D conduction channels in the system. The first-principles calculations show that CaCuSb is a semimetal with dominant hole carriers at the Fermi level. Our study shows that CaCuSb can provide a unique platform to study QHE in high magnetic fields.

Topological Quasiparticles—Magnetic Skyrmions Axel Hoffmann; University of Illinois at Urbana-Champaign, United States

Magnetic skyrmions are topologically distinct spin textures and can be stable with quasi-particle like behavior.[1] This makes them interesting for information technologies,[2] where data is envisioned to be encoded in topological charges, instead of electronic charges as in conventional semiconducting devices. Using magnetic multilayers we demonstrated that inhomogeneous charge currents allow the generation of skyrmions at room temperature in a process that is remarkably similar to the droplet formation in surface-tension driven fluid flows.[3] Micromagnetic simulations reproduce key aspects of this transformation process and suggest a second mechanism at higher currents that does not rely on preexisting magnetic domain structures.[4] Indeed, we demonstrated this second mechanism experimentally using non-magnetic point contacts.[5] Using this approach, we demonstrated that the topological charge gives rise to a transverse motion on the skyrmions, i.e., the skyrmion Hall effect.[6] Finally, I will provide an outlook on dynamic excitations of magnetic skyrmions.[7,8]

SESSION NM04.06: On-demand
Wednesday Morning, April 14, 2021
NM04

8:00 AM NM04.06.02
Late News: Disordered Spin Textures and Emergent Magnetic Transport Properties in Tb5Sb3 Single Crystal Aki Kitaori[1], Naoya Kanazawa[1], Jonathan White[2], Victor Ukleev[2], Yoshichika Onuki[3] and Yoshinori Tokura[1,3]; [1]University of Tokyo, Japan; [2]Paul Scherrer Institute, Switzerland; [3]RIKEN, Japan

Non-collinear magnetic structure induces emergent magnetic field on conduction electrons, resulting in such as a geometrical Hall effect and so on [1]. Especially in helimagnets with short magnetic periods, the geometrical or topological Hall effect can dominate Hall resistivity profile [2]. Such systems have been attracting attention as a material platform where emergent magnetic fields can be utilized.
Some Mn_5Si_3-type rare-earth compounds, such as Dy5Si3 and Ho_5Sb_3, are known for famous material examples to exhibit helimagnetic orderings. Among them, Tb_5Sb_3 has been identified as a helimagnet that hosts various magnetic structures.
We have succeeded in growing single crystals of Tb_5Sb_3 and revealed the magnetic and electric transport properties. We found peculiar magnetic-field dependences of Hall resistivity showing peak structures, which

cannot be explained by anomalous Hall effect proportional to the magnetization and may indicate the emergent field contributions. We have also identified the possible formation of a disordered helimagnetic state by small-angle neutron scattering (SANS). In this poster, we will discuss the relation between the Hall resistivity profile and the disordered helical magnetic structure.

Late News: Solution-Processed Yttrium Iron Garnet Thin Films as Novel Magnetostrictive Materials
Shreya K. Patel and Sarah Tolbert; University of California, Los Angeles, United States

Many spintronic devices require low damping materials that also exhibit high magnetostriction.[1,2] However, the efficiency of such devices is limited by the high conductivity of metallic magnetostrictive materials, causing significant electrical losses from eddy currents and increased damping. Yttrium iron garnet ($Y_3Fe_5O_{12}$, or YIG) is a promising alternative to metallic magnetostrictive materials since it exhibits low Gilbert damping.[3,4]Additionally, YIG exhibits acceptable magnetic properties for spintronic devices including a relatively low coercivity.[4,5] Despite these advantages, YIG intrinsically exhibits near-zero magnetostriction. Theoretical and experimental data has shown that doping YIG with cerium (substituting for yttrium) can significantly increase magnetostriction due to increased spin-orbit couplingin bulk, single crystal materials.[5,6] We utilize solution processing for facile stoichiometry control as well as integrability into a future device. The synthesis and characterization of these novel magnetostrictive YIG materials will be presented.

Remarkable Dependency of the Chirality Transfer Efficiency on the Shape of Nanoscale Chiral Additives
Ahlam Nemati, Sasan Shadpour and Torsten Hegmann; Kent State University, United States

Intelligent nanoscale tuning of chirality in liquid crystal media holds great potential for deciphering the level of homochirality and origin of chirality in the living systems. Notably, we have reported some of the highest ever-reported value of the helical twisting power in achiral N-LCs for chiral ligand-coated GNRs [1-2]. Moreover, we demonstrate how the amplification of chirality facilitated by GNRs decorated with chiral molecules can be used to clearly distinguish the chiral induction strength of a homologous series of binaphthyl derivatives, differing only in the length of a non-tethered aliphatic chain, in the induced chiral N*-LC phase [3-4]. Recent further research shows that we are now able to accurately control the helical pitch and the helical twisting power values in N-LC/nanoparticle composites. These composites include mixtures of N-LCs with diverse chiral ligand-coated nano shapes (spherical, rod, prism, disk, and star) and varying aspect ratios (2-10) of gold nano shapes. Finally, we additionally support our experimentally derived arguments of a more comprehensive understanding of the chirality transfer's dependency on shape by calculations of a suitable pseudoscalar chirality indicator [5].

Late News: Thermodynamically Stable Colloidal Solids—Interfacial Free Energy-Particle Size Distribution Correspondence Andrew Nelson and Lawrence Friedman; National Institute of Standards and Technology, United States

The thermodynamics of solid-solution interfaces is one of the most basic topics of interest in colloid science. The work of interface formation, called in varying contexts the surface or interfacial energy or tension, is the thermodynamic parameter that dictates the stability and evolution of suspensions, gels, emulsions, and many other systems. From the perspective of the synthetic chemistry of solid nanoparticles, the interfacial energy usually is taken to be responsible for a serious obstacle in the preparation and use of these highly dispersed materials: where the free energy of interfaces is positive, systems will inevitably coarsen to minimize this quantity. Establishing a system in which interfaces are actually stable, by the controlled reduction of the interfacial energy, offers a framework for preparing stable, reproducible, and controllable nanoparticle dispersions for both fundamental and engineering applications. Such dispersions of solids, in analogy to the much better-characterized case of microemulsions, have been prepared but not yet systematized. From the statistical thermodynamics of nanoparticle dispersions and using the tools of classical nucleation theory and liquid mixtures, we provide a simple analytical expression giving a one-to-one correspondence between the measurable size distribution of a colloidal suspension at equilibrium and the size-dependent interfacial free energy. The size distribution can be given only in terms of parameters that are relatively easy to control, estimate, or measure, such as the molecular solubility, densities, and cohesive energies. Consideration of older experimental data, in light of this framework, allows us in principle to characterize different modes through which different colloidal solutions are stabilized in equilibrium, such as through preferred curvature or electrostatic charging. Finally, we indicate the parameters that must be optimized in order to solve the problem of preparing monodisperse nanoparticles and discuss whether previous syntheses may have reached the narrowest achievable size distribution allowed at equilibrium.

8:30 AM NM05.01.05
Silver Ion Cluster Formation and Xe Sorption in Silver-Exchanged Zeolites—Insights Toward Accelerated Materials Design Eric Hoar and Lindsay Roy; Savannah River National Laboratory, United States

The trace analysis of xenon is an indicator of nuclear activity and as such the collection of Xe isotopes from the environment is of great importance for environmental monitoring and treaty verification. Silver clusters have been shown to selectively sorb Xe better from the environment when integrated into an aluminosilicate zeolite framework system vs. other systems such as MOFs. Despite the large amount of research on these Ag-zeolites, resolving the role of silver (Ag) in the sorption mechanism remains a complex issue with several contradictory reports in the literature. Prior to the design of novel sorption materials, research must first address the fundamental questions of why Ag-zeolites outperform other porous adsorbents with respect to Xe uptake. To better understand the role of silver ion cluster formation in the sorption of Xe, this talk will focus on using density functional theory (DFT) methods to identify specific structure-property relationships in Ag-exchanged chabazites which contribute to increased sorption uptake. The results show that small, highly charged clusters form high-index facets within the large cavities of the zeolite, which could allow for rapid sorption of Xe onto their surface. Optimization of these features must be considered when designing high-performance, low-cost adsorbents for noble gases. Ultimately, these results will be used to develop strategies for exploring Xe sorption uptake using a machine learning sorption model amenable to straightforward validation by first-principles simulation and experimental data.

8:45 AM NM05.01.06
Material Interdiffusion During Low Temperature Sintering of Nanoporous Metals Natalya Kublik[1], Stanislau Niauzorau[1], Sridhar Niverty[2], Nikhilesh Chawla[2] and Bruno Azeredo[1]; [1]Arizona State University, United States; [2]Purdue University, United States

In the past decade, nanoscale metals have found use in reactive metal inks due to its ability to fuse at lower temperatures and create electrically conductive traces. [1] This study examines a new class of nanoscale metals and their morphology evolution during sintering. Specifically, interdiffusion of atoms in nanostructured metals is investigated during low temperature (e.g. 44% of Tm of AuCu eutectic point) sintering of nanoporous Au thin films and Cu powders. Both powders and thin-films are synthesized by chemical dealloying yielding ligaments that are 46 and 64 nm, respectively, and the former is dispersed over the latter as an initial condition for sintering. Samples are transferred into the tube furnace while wet in dehydrated alcohol to prevent oxide formation [2] and are sintered in a reducing atmosphere (H_2/Ar mixture, 5% of H_2) at 400 °C. After sintering, cross-sections through the neck zone between powders and thin-film are obtained via focused ion beam milling and the concentration profiles across the welded interface are measured via energy dispersive X-ray spectroscopy with large diffusion penetration depths (0.8 μm) across the interface being detected. Before and after sintering SEM images not only show thermal coarsening of the ligaments in both materials, but also evidence of neck formation between ligaments bridged across their original interface. Our results will be presented in the context of existing literature for neck formation and welding between bulk and nanoscale metals. This study might shed a light on the interdiffusion of porous metals during low temperature sintering.

9:00 AM NM05.01.07
Late News: Optimization of NanoCluster Beacons (NCB) Using an NGS Platform and Machine Learning Yu-An Kuo, Oliver S. Zhao, Soonwoo Hong, Trung D. Nguyen, Yuan-I Chen, Chien-Yu Lin and Tim Yeh; The

University of Texas at Austin, United States

The key to future fluorescence sensing lies in the use of new methods for fluorescence modulation, beyond what is currently available. DNA-templated silver nanoclusters (DNA/AgNCs; for instance, Ag_8, Ag_{10} and Ag_{16}) offer such an opportunity as their fluorescence emission color can be tuned by their DNA hosts or activated by nearby DNA strands termed the activators. The resulting complexes, called NanoCluster Beacons (NCB), have found applications in sensing nucleic acids, proteins, small molecules, enzyme activities and cancer cells. Whereas new applications of this unique molecular probe are emerging across a broad range of disciplines, it is unclear what sequence features of the activators ultimately control the fluorescence activation color and brightness of NCB. Further diversification and optimization of NCB will require a large ligand composition space (of the activator) to be scanned, beyond what robotic plates or test tube method can provide.

Here we introduce a high-throughput approach to study the fluorescence activation behavior of silver nanoclusters. By using a next-generation sequencing (NGS) chip (Illumina *MiSeq*), more than 10^4 activators can be screened in a single experiment, which is nearly 100-fold higher than the throughput of current robotic plate method. The activation results reveal that the middle six nucleobases (of the 18nt-long activator) are the most critical in determining the activation intensity of silver nanoclusters, as randomizing these nucleotides leads to many dark NCBs. Interestingly, position 4-6 of the activator are found particularly important in stabilizing yellow NCB, while position 2-4 are hotspots for creating red NCB.

Taking advantage of our high-throughput chip screening platform, we have identified many pairs of NCB which only differ by a single nucleotide in their activator sequences but give drastically distinct activation outcomes (either by color difference or intensity difference). These extreme pairs are termed the polar opposite twins (POT). We have identified red and yellow POTs with intensity difference as high as 8-fold (T to C at position 4) and 29-fold (C to G at position 5), respectively. Moreover, based on the NGS selection results, a workflow to generate new activator designs using random sampling and support vector machine is established. We successfully obtained a new red-emissive NCB having intensity difference as high as 2.9-fold compared to selected red NCB standard.

Late News: Novel Tools for Nanoparticle Characterisation Niamh Mac Fhionnlaoich, Ye Yang and Stefan Guldin; University College London, United Kingdom

Advancing colloid science & engineering requires a detailed understanding of building blocks, their spatial arrangement and interaction with chemical and biological targets. In my group, we have developed a number of novel analytical approaches. I will introduce the measure of information entropy as a powerful statistical method to evaluate the dispersity of colloidal populations and optimise synthetic parameters [1]. We have recently established an alternative route to evaluate 2D colloidal ordering based on the so-called spatial distribution function [2]. In comparison to conventional approaches, such as the radial distribution function or the 2D fast Fourier transform, this method is particular powerful for assemblies displaying limited order. I will further elaborate on how a simple protocol, based on quartz crystal microbalance with dissipation monitoring (QCM-d), for the stepwise in situ quantification of AuNPs immobilisation and subsequent uptake and release of chemical and biological binding partners [3]. Crucially, the frequency shift patterns offered by QCM-d enabled us to model the binding kinetics and calculate binding parameters, such as the association and dissociation rate constants (k_{on} and k_{off}) and apparent binding constant K_a. In combination with a recently developed synthetic protocol for decoupled control of size and surface composition [4], this analytical toolbox provides a powerful platform for systematic studies on colloidal behaviour, ligand-shell mediated nanoparticle-stimuli interactions and rational optimisation of material design for environmental and biomedical applications.

Nanoparticles for Ultrasensitive Biosensing Molly Stevens; Imperial College London, United Kingdom

This talk will provide an overview of our work in the design of functionalised polymer and inorganic nanoparticles for applications in ultrasensitive biosensing [1]. We engineer simple conceptually novel approaches to detect disease biomarkers, such as abnormally regulated enzymes, to extend the detection window for early disease diagnostics. We aim to design biosensing strategies that are simple, cost-effective and easy deploy to the point-of-care to democratise access to advanced diagnostic technology. We will discuss impactful sensing applications for infectious and non-communicable diseases for example innovative smartphone enabled tests for epidemic surveillance in the field [2] and injectable nanoparticle-based sensing probes for in vivo detection of cancer that produce a colorimetric response in urine in under 1 hour [3]. This talk will also provide an overview of our recent advances in Raman spectroscopy characterisation techniques for high-throughput tracking of surface functionalisation in single nanoparticles [4].

10:55 AM NM05.02.02
Late News: Leveraging Critical Phenomenon in Multi-Scale Nanoparticle Networks to Make Large Area Field Effect Transistors for Sensing Applications Abhijeet Prasad[1,2], Michael Stoller[2] and Ravi F. Saraf[1,2]; [1]University of Nebraska–Lincoln, United States; [2]Vajra Instruments Inc, United States

Phenomenon of Coulomb blockade (CB) due to single electron (local) charging in nanogranular metallic system has long been a scientific curiosity due to their exotic electronic properties. The attraction is an insulator-to-metal transition observed at cryogenic temperatures where the electron transport is affected by local charging of the nano-grains by just a single electron. We have observed functionally similar behavior in large nanoparticle array of a quasi-one dimensional (1D) nanoparticle necklace network (N^3) of 10 nm Au particles from 4 K to

room temperature (RT). Here, we demonstrate a new class of field effect transistor (FET) operating at RT where the conductance of N^3 devices is modulated over two orders of magnitude by a gate electrode. The demonstrated gain is ~500x higher, sensing area is ~150x larger, and the current is 10^4x higher than previously published close-packed nanoparticle array FET's. Remarkably, the N^3 FET I-V behavior exhibits universality, where the conduction gap is invariant and the I-V behavior can be superimposed in a master curve at different gate voltages. To understand universality of I-V behavior the network topology is quantitatively mapped by leveraging the local-1D structure of N^3. Simulations using topological maps indicate that conduction pathways morph with "fractal-like" growth of conducting channels as charging barriers are systematically overcome by gate bias. Due to self-similar conduction path morphing, we conclude that at RT electron transport in these disordered systems is primarily driven by critical phenomenon, akin to second order phase transformations. The high gain, large sensing area, and flexibility for functionalization of Au can allow N^3 devices to serve as a platform for a new class of high sensitivity sensors.

11:10 AM NM05.02.03

Late News: Colorful Applications of Fluorescent Silica Nanoparticles—Interactions Between Bio-Organic Molecules and Inorganic Surfaces Aashani D. Tillekaratne, Chamari Hettiarachchi, Sewwandi Kuruppu, Nirojan Lalichchandran, Kasun Ananda and Navindra Keerthisinghe; University of Colombo, Sri Lanka, Sri Lanka

Silica nanoparticles are known as versatile inorganic materials that provide an efficient platform to interact with biological molecules. These interactions are believed to have occurred on prebiotic Earth at the origin of life. Experimentally, the interaction between silica and biomolecules is granted feasible due to the ease of synthesis and the ease of their surface modification. Having rich surface chemistry due to the presence of silanol groups extending out of their surface and available for bonding, these nanoparticles can be conjugated with fluorescent dyes which can further be functionalized to be conjugated with biological and/or organic counterparts leading to a variety of colorful and interesting applications. In the present study, we have synthesized fluorescent silica nanoparticles by the reverse microemulsion method and using three different fluorescent dyes, fluorescein isothiocyanate (FITC), Rhodamine-B, and Tris(2,2'-bipyridyl)dichlororuthenium(II) hexahydrate (commonly known as Rubpy). In the synthesis, the microemulsion is prepared by mixing cyclohexane, n-hexanol, and Triton X-100 (or dioctyl sulfosuccinate sodium salt). To this microemulsion, the fluorescent dye which is conjugated with the linker, 3-aminopropyltriethoxysilane (APTES) is added followed by the silica precursor, tetraethylorthosilicate (TEOS). Hydrolysis and condensation are then initiated by adding ammonia. After stirring for 24 hours, the microemulsion is broken with acetone and the nanoparticles are recovered after centrifugation and washing. Scanning electron microscopy images showed spherical shaped particles with an average diameter of around 150 nm. These fluorescent silica nanoparticles showed excellent photostability and minimal dye leakage over a period of one hour which is a reasonably long duration for the proposed bioconjugation experiments. To facilitate the bioconjugation process, these dye-doped nanoparticles were functionalized, first with amine groups using APTES and then with carboxyl groups using succinic anhydride. Fourier Transform Infrared (FTIR) spectra confirmed the surface functionalization. These fluorescent silica nanoparticles were used to detect latent fingerprints on the surfaces of aluminum foil, stainless steel, glass, plastic, and wood using the powder dusting method and the suspension method. Powder dusting on aluminum foil produced the best results after exposing the surfaces to the nanoparticles for 30 minutes after the fingerprint was placed on the surface. On top of this, the most interesting application of these fluorescent silica nanoparticles was their use in the detection of Escherichia coli, which is considered the best biological indicator for coliform contamination in food and water. The anti-E. coli antibody was immobilized on the fluorescent nanoparticle surface by reacting the carboxyl functionalized nanoparticles with the protein at room temperature. Then the E. coli culture was mixed with the antibody-conjugated nanoparticles in phosphate-buffered saline (PBS). After incubation, a smear was made on a microscopic slide and observed under the fluorescence microscope. For the nanoparticles doped with all three dyes, FITC, Rhodamine-B, and Rubpy, fluorescence microscopic images were obtained with the resolution of observing up to a single bacterial cell. Staining of the moving live cells was also observed. These interesting results demonstrate the effectiveness of the fluorescent silica nanoparticles in the use of chemical and biological sensors. Their excellent photostability and the ability

to retain the dye for longer periods in the nanoparticle matrix compared to the free dye in solution are added advantages when these sensors are developed.

11:25 AM NM05.02.04
Late News: Fluorescence Enhancement and Functionalization of Nanodiamonds for Optically Trackable Drug Delivery Pietro Aprà[1,2], Mirko Sacco[1], Veronica Varzi[1], Valentina Boscaro[1], Margherita Gallicchio[1], Alessandro Barge[1] and Federico Picollo[1,2]; [1]University of Torino, Italy; [2]National Institute for Nuclear Physics, Italy

Currently, a strong interest has been focused on the employment of nanoparticles as promising tools in biomedical research, diagnostics and therapy. In this frame, Nanodiamonds (NDs) earned a solid reputation due to their interesting features, such as inertness, fluorescence, biocompatibility and the possibility of modifying their surface termination [1]. Aim of this work is the realization of diamond-based drug delivery systems which are optically trackable during *in-vitro* experiments, by exploiting the fluorescence properties deriving from the Nitrogen–Vacancy (NV) lattice defects [2], consisting in a substitutional nitrogen atom nearby to a vacancy defect. This system is optically active, with a wide excitation spectrum around 500 – 600 nm and emission at 600 – 800 nm, and provides a photostable label suitable for different types of bio–imaging and bio–sensing applications. By mean of ion–beam induced damaging, more defects can be introduced in the crystal lattice, thus creating new NV centers and enhancing the fluorescence of NDs [3]. To this scope, in the first part of the work the NDs were irradiated with a 2 MeV proton beam, exploring a wide range of fluences (between 10^{14} – 10^{17} protons cm^{-2}). Raman and Photoluminescence (PL) spectroscopy were employed as elective investigation techniques to quantify the ion–implanted NDs fluorescence. As a result, PL spectra showed that the creation of new NV centers by proton–irradiation led up to two orders of magnitude increase in fluorescence with respect to the unirradiated samples.
In the second part of the work, the NDs surface was chemically modified to allow a proper covalent–linking functionalization with cetuximab (NDs–Ctx), a monoclonal antibody specific for EGFRs, which are receptors typically overexpressed on colon–rectal cancer cells membrane. The successful surface grafting procedure was verified by means of Thermogravimetric Analysis. NDs–Ctx were then administrated to cultured DiFi rectal carcinoma cells and their internalization degree (compared to a control sample of unmodified NDs) was evaluated by confocal microscopy. From the analysis of the acquired images, a high uptake level was observed in the platelets of NDs–Ctx treated DiFi cells, while weak or no NDs fluorescence signal was assessable inside the cells in the case of unirradiated NDs administration.
In conclusion, post–synthesis treatments and proton–beam irradiation of NDs were effective in strongly enhancing their fluorescence yield. Moreover, cetuximab was successfully conjugated on NDs surface and the targeting and uptake–inducing properties of the system were observed on DiFi cell line. These results reinforce the suitability of NDs as promising nano–tools for both biolabeling and drug delivery applications, worthy of further investigations to combine these two potentials.

11:40 AM NM05.02.05
Luminescence Properties and Cell Uptake Analysis of Nanophosphors for Bio-Imaging Applications Dalia H. Chavez[1], Karla O. Juárez-Moreno[2,3], Gustavo Hirata[4] and Rosella Reyes[1]; [1]Centro de Enseñanza Tecnica y Superior, Mexico; [2]Centro De Nanociencias y Nanotecnologia-UNAM, Mexico; [3]CONACYT-CNyN-UNAM, Mexico; [4]Centro de Nanociencias y Nanotecnologia-UNAM, Mexico

Nanotechnology is providing new tools for cell imaging and diagnosis through the synthesis and tuning of

nanophosphors with special physicochemical properties. Yttrium oxide (Y2O3) host has gained broad research interest due to its excellent chemical stability, good thermal stability and low cost; this host can be used to synthesized luminescence upconversion nanoparticles (UCNPs) and downconversion nanoparticles (DCNPs) that can be used as biolabels for fluorescence imaging. The UCNPs absorb near infrared photons to upconvert them to emit in the visible spectra; also, the DCNPs absorb UV photons and emit in the visible spectra. In this study we analyzed biocompatible UCNPs and DCNPs co-doped with rare earth ions, they were functionalized with amino groups and folic acid ligands (FA) that bind to folate receptors (FR) overexpressed on certain types of cancer cells, the functionalized nanoparticles (FA-NPs) were internalized into the cancer cells studied via endocytosis by the conjugation FA-FR. We present a nanotoxicological study that includes cytotoxicity, genotoxicity, hemocompatibility and in vitro inflammatory studies. The study demonstrated that bare and functionalized NPs are no cytotoxic and no genotoxic at the tested concentrations (0.01 to 20 mg/ml) in three cell lines (breast, skin cancer and osteoblasts). Also they are hemocompatible and do not exert nitric oxide production in vitro by macrophages. The FA-NPs were clearly localized into the cell cytoplasm with bright red luminescence. We can conclude that these nanoparticles are biocompatible and can be further used for cancer cells bioimaging.

11:55 AM NM05.02.06
Late News: *In Vitro* Evaluation of the Antimicrobial Activity by the Nebulization Method of Hydrogen Peroxide and AgNPs Synthesized by the Green Route Juan Carlos Martinez[1], Hiram D. Gonzalez Martinez[2], José Alejandro López Venzor[2], Christian Gabriel Carranco Torres[1] and Raúl Carrera Cerritos[1]; [1]Instituto Politécnico Nacional, Mexico; [2]Nabicron S.A.P.I. de C.V., Mexico

Since 2019, institutions and governments around the world have faced the challenge of containing the progress of the COVID-19 pandemic caused by the Sars-CoV-2 coronavirus. According to the WHO, one of the main transmission routes for COVID-19 is contact with contaminated surfaces. For this reason, a thorough disinfection is essential to prevent contagion. In this sense, nanotechnology has attracted significant attention due to its cross-cutting properties in different disciplines. Silver nanoparticles (AgNPs) have been one of the most investigated nanomaterials and recently applied by various industries. In this work, the synergistic effect of the *in vitro* antimicrobial activity of hydrogen peroxide with biosynthesized AgNPs from a geranium plant extract was evaluated. AgNPs were characterized by HRTEM, UV-Vis spectroscopy as well as ICP-MS for their analytical determination where an average particle diameter less than 50 nm was obtained with a spherical morphology and a concentration of 1,474.6 mg / L. The air disinfection method (ADM) was used for the evaluation of the antimicrobial effect in vitro against *Escherichia coli* ATCC 25922. This test showed a 99.99% of bacterial growth reduction with a dose of 76.6 mg / L of AgNPs and 0.55% hydrogen peroxide, after eight minutes of nebulized exposure of the solution. These results provide valuable information on the way to explore new bionanotechnological antimicrobial agents to promote the safety, innocuousness and hygiene of products, spaces and surfaces.

12:00 PM NM05.02.07
Late News: *In Vitro* Microbiological Test of Silver Nanoparticles Extracted by Green Method on Pseudomonas aeruginosa Juan Carlos Martinez, Raúl Carrera Cerritos, Karla Paola Sánchez Guerrero and Rocío Alejandra Silva Contreras; Instituto Politécnico Nacional, Mexico

Recently, antibacterial solutions have been investigated in the medical area, since the excessive use of antibiotics has caused microorganisms to express greater resistance to this type of antibiotics. In this research work, the effect of Ag nanoparticles on *Pseudomonas aeruginosa* bacteria (ATCC27853) was verified as a function of time. Different concentrations of colloidal solution were prepared and exposed during the incubation time in order to identify the minimum inhibitory concentration (1:2, 1:4, 1:8 and 1:16). Nanoparticles synthesized by the green route were used using *Pelargonium spp* extract as a reducing agent. Average diameters of nanoparticles <50 nm was obtained, which were characterized with a JEOL JEM1010 transmission electron microscope. The inhibitory effect of nanoparticles in Pseudomonas aeruginosa was verified by counting colony forming units (CFU) for 0, 2 and 4 hours of bacterial incubation. The tests showed that the 1: 2 concentration

ratios exhibited a 100% inhibition since the initial interaction of the colloidal solution with the growing bacteria and during the four hours of monitoring. While in the 1: 4 ratio, 100% inhibition was observed up to 2 hours after the initial time of the nanoparticles-bacteria interaction. For the rest of the dilutions, there were gradual inhibitions as a function of time, however, they were not 100%. Finally, we conclude that the use of nanomaterials generated by green routes are an alternative for their application in biological systems that are currently a health problem in living beings. As a perspective of this work we suggest to perform cytoxicity tests in cellular biological systems for biomedical applications.

Late News: Development of SERS-Active Gelatin Based Hydrogels for Label Free Detection of Bio-Analytes Zahra Khan[1,2]; [1]A*STAR, Singapore; [2]UCL, United Kingdom

— Hydrogels are a macromolecular network of hydrophilic copolymers with physical or chemical cross-linking structure with significant water uptake capabilities. They are a promising substrate for Surface-enhanced Raman Spectroscopy (SERS) as they are both flexible and biocompatible materials. Conventional SERS-active substrates suffer from limitations such as instability and inflexibility which restricts their use in broader applications. Gelatin based hydrogels have been synthesised in a facile and relatively quick method without the use of any toxic cross-linking agents. Composite gel material was formed by combining the gelatin with simple polymers to enhance the functional properties of the gel. Gold nanoparticles, prepared by a reproducible seed-mediated growth method, was combined into the bulk material during gel synthesis. After gel formation, the gel was submerged in the analyte solution overnight. SERS spectra was then collected from the gel using a standard Raman spectrometer. A wide range of analytes were successfully detected on these hydrogels showing potential for further optimization and use as SERS substrates for biomedical applications.

Heavy Metal Extraction from Water by the Filtration with Iron-Tannic Acid Complex Sujoy Saha and Hemali Rathnayake; University of North Carolina at Greensboro, United States

Water purification by the removal of heavy metals is one of the most challenging fields of scientific research. In natural waters, heavy metals are generally present in trace amounts but most of them have a wide range of hazardous and detrimental effects to the human body even at very low concentrations. Heavy metals especially lead, and cadmium can cause severe health effects including cancer, nervous system damage, organ damage, and in extreme cases, death. Thus, it is very important to extract heavy metal from industrial wastewater along with drinking water. In this research, we used the Iron-Tannic Acid complex for the filtration of water and could successfully extract Pb^{2+}, $Cd^{2+,}$ and Ag^{+} cations from different water samples containing those heavy metal. The amount of heavy metal in the water was detected by Inductively Coupled Plasma - Optical Emission Spectrometry (ICP-OES). The presence of large numbers of carboxylic acid groups in the Iron-Tannic Acid complex is therefore responsible for the strong binding of the heavy metal cations. Among all of the heavy metal filtration materials, the Iron-Tannic Acid complex has the greatest potential in heavy-metal extraction processes for future applications.
Keywords: Heavy metal extraction, Metal-organic complex, water purification

12:25 PM NM05.02.10
Late News: Surface Charge-Dependent Toxicity of Hematite Nanoparticles Svetlana Vihodceva[1], Andris Šutka[1], Mariliis Sihtmae[2], Merilin Rosenberg[2,3,4], Maarja Otsus[2], Krišjanis Šmits[5], Liga Bikše[5], Kaja Kasemets[2] and Anne Kahru[2]; [1]Riga Technical University, Latvia; [2]National Institute of Chemical Physics and Biophysics, Estonia; [3]University of Tartu, Estonia; [4]Tallinn University of Technology, Estonia; [5]University of Latvia, Latvia

In the current study, the antibacterial activity and ecotoxicity of positively and negatively charged hematite (α-Fe_2O_3) nanoparticles were studied. α-Fe_2O_3 nanoparticles were obtained by simple green hydrothermal synthesis, while surface charge was controlled by a surface functionalization with citrate coating. The antibacterial activity was evaluated to Gram-negative bacterium *Escherichia coli* and Gram-positive bacterium

Staphylococcus aureus. Microbes were exposed to different concentrations of α-Fe_2O_3 nanoparticles in deionized water for 30 minutes and 24 h at room temperature and evaluated for the post-exposure colony forming ability. The positively charged α-Fe_2O_3 showed *E. coli* bactericidal activity already after 30 minutes. Extending the exposure to 24 h increased the antibacterial effect with minimal bactericidal concentration values between 100-1000 mg/L. Bactericidal activity against *S. aureus* was not observed. Negatively charged α-Fe_2O_3 did not exhibit any activity against both tested bacteria. Our results confirmed that deionized water could be a model medium for the antibacterial testing. Additionally, ecotoxicity studies with *Vibrio fischeri* showed no ecotoxicity of α-Fe_2O_3 - EC_{50} > 1000 mg/L. No reactive oxygen species production in abiotic or biotic conditions in the dark was observed. Confocal laser microscopy images analysis by MicrobeJ confirmed that more positively charged nanoparticles were associated with generally negatively charged bacterial cells than negatively charged nanoparticles and this effect was larger for *E. coli* which is also in concordance with positive charged α-Fe_2O_3 nanoparticles being more toxic to *E. coli* than *S. aureus*.

Late News: Elucidating Alloying Strategies for Ni-Based Bimetals Using Geo-Inspired Perovskite Oxides
Kandis L. Abdul-Aziz[1], Soham Shah[1], Mingjie Xu[2] and Xiaoqing Pan[2]; [1]University of California, Riverside, United States; [2]University of California, Irvine, United States

In-situ exsolution of reducible transition metals from geo-inspired perovskite precursors allows for the synthesis of strongly-adhered nanoparticles that are thermally-stable and homogeneous in size and shape. The perovskite oxides are materials that can reversibly exsolve transition-metal cations as nanoparticles under fluctuating reducing and oxidizing reaction conditions. The exsolution process occurs when the cation dopant diffuses from the bulk of the perovskite and form nanoparticles on the surface under reducing conditions. Earlier work on perovskite oxide precursors has determined that bulk defects can modulate the ionic diffusion of dopant metal monomers. This presentation extends the notion of exploring the rich defect chemistry of geo-inspired perovskite oxides to control the formation and growth of regenerable Ni-Fe nanoparticles from Ni-doped $LaFeO_3$ perovskite oxide precursors [1]. The Ni-doped lanthanum ferrite perovskite precursors were prepared with varying ratios of the La and Fe in the parent perovskite of either 0.9:1, 1:0.9, and 1:1. The exsolved Ni-Fe nanoparticles exhibited notable ranges in composition, size, and dispersion. The systems were characterized using High-angle annular dark-field imaging scanning transmission electron microcopy (HAADF – STEM), X-ray diffraction(XRD) and in situ X-ray Absorption Spectroscopy (XAS). This presentation will discuss recent work to address the existing materials chemistry challenges for Ni-based bimetallic nanoparticles' controlled formation.

1:15 PM NM05.03.03

$Cu_{2-x}S$/PbS Core/Shell Nanocrystals with Improved Solubility and Chemical Stability Patrick Yee[1], Sarah Brittman[2], Nadeemullah Mahadik[2], Joseph Tischler[2], Rhonda Stroud[2], Alexander Efros[2], Peter Sercel[3] and Janice Boercker[2]; [1]National Research Council, United States; [2]U.S. Naval Research Laboratory, United States; [3]California Institute of Technology, United States

Excitonic PbS nanoparticles have shown excellent photosensitivity in the IR region, but limited device efficiencies because short diffusion lengths restrict film thicknesses to less than the absorption length. They also have slow radiative recombination rates, which limit the performance of light-emitting diodes. To address these limitations, we work to couple PbS excitons with plasmons on the nanoscale in order to increase the radiative rates and absorption cross sections. For the plasmonic component, we use the doped plasmonic semiconductor, $Cu_{2-x}S$, which has a tunable plasmon resonance that can be designed to overlap with the excitonic absorption of PbS in the short-wave infrared regime.

We demonstrate a synthetic method to add a thin PbS shell layer, with a controlled thickness, to $Cu_{2-x}S$ cores using Pb oleate and bis(trimethylsilyl)sulfide as the Pb and S precursors. Energy-dispersive X-ray maps and high angle annular dark field images collected with scanning transmission electron microscopy confirm the $Cu_{2-x}S$/PbS core/shell architecture. Absorbance spectroscopy shows a blueshift in the plasmon resonance of the $Cu_{2-x}S$/PbS core/shell nanoparticles relative to the parent $Cu_{2-x}S$ nanoparticles. Using X-ray diffraction, we show that this blueshift is due to the oxidation of the $Cu_{2-x}S$ cores (an increase in x) upon PbS shell deposition. The shell thickness is controlled by tuning the amount of Pb and S precursors. Transmission electron microscopy indicates progressive growth in the core/shell nanoparticle diameter with increasing Pb:Cu ratios and a monodisperse distribution of nanoparticles.

While no photoluminescence is observed from the PbS shell, these core/shell nanocrystals are highly promising for studying exciton-plasmon coupling in binary superlattices with PbS nanocrystals for three reasons: 1) the Pb shell increases the $Cu_{2-x}S$ core solubility, aiding in assembly, 2) the PbS shell blueshifts and enhances the plasmon resonance of the $Cu_{2-x}S$ core such that it overlaps better with the PbS exciton energy range, and 3) the PbS shell hinders the $Cu_{2-x}S$ cores from chemically quenching the photoluminescence of neighboring PbS nanocrystals in solution. The ability to hinder quenching is dependent on the PbS shell thickness in the $Cu_{2-x}S$/PbS core/shell nanoparticles, with the thicker PbS shells better preserving the excitonic PbS photoluminescence. Thus, the $Cu_{2-x}S$/PbS core/shell nanoparticles provide an opportunity to controllably investigate plasmon-exciton coupling in a variety of binary superlattice symmetries and stoichiometries.

1:30 PM NM05.03.06

Late News: Ultralow-Platinum Pt@Ni@Pt Core-Bishell Nanorods Bifunctional Oxygen Evolution and Reduction Electrocatalyst in Alkaline Medium Melina Zysler, Victor Shokhen, Samuel S. Hardisty, Anya Muzikansky and David Zitoun; Bar Ilan University, Israel

Pt-Ni nanoparticles were vastly explored because of the synthetic tunability and the high electrochemical performance toward oxygen reduction reaction (ORR), the application and high-efficiency catalytic activity are commonly confined for acidic medium due to the Pt corrosion in alkaline medium. The alternative Ni-rich nanoparticles investigated as oxygen evolution reaction (OER) catalyst have shown insufficient efficiency in the acidic medium because of the known transition metal leaching process. The novelty in our work is the ability to produce an active bifunctional catalyst that accomplishes both ORR and OER in alkaline medium. Our advance was accomplished by a comprehensive investigation of the synthesis parameters and by a rational material design.

The ultralow-platinum Pt@Ni@Pt core-bishell nanorods achieve an unprecedented (for a Pt-based catalyst) overpotential of 0.29 V at 10 mA cm^{-2} and current density of 162 mA μg^{-1}_{Pt} at 1.6 V (vs. RHE) for the OER, while still maintaining a very decent value of 0.32 A mg^{-1}_{Pt} at 0.85 V for the ORR. These values outperform the standard Pt catalyst for the ORR and the Ni catalyst for the OER, using less than 1%wt. Pt. This work advances the field of ultra-low platinum content, which in our point of view will be one of the critical issues that will allow the green energy technology to be implemented.

Also, this research revealed a unique methodology that allows morphology and size tunability of Pt@Ni core-

shell nanoparticles. The kinetic control of the core and the shell was achieved by combining two commonly used solvents as reducing agents while keeping the (111) plane electrochemically active. We highlight that the understanding of the relationships between the composition of a material and its structure and properties is a fundamental objective and a key challenge in nanoscience research.

Enhanced Combustion Performance of Functional Metal Nanoparticle Materials Sungwook Hong and Roxanne Esparza; California State University, Bakersfield, United States

Aluminum nanoparticles (ANPs) have been considered attractive additives for solid-fuel rockets due to a high energy density with an increased burning rate. Unfortunately, the use of the ANPs is limited by the following reasons: ANPs can be readily sintered and oxidized, prior to the combustion process, degrading the combustion performance. In order to resolve these problems, a surface coating of the ANPs by hydrocarbons has been proposed. while previous studies reported that the hydrocarbon coating is essential for the ANPs to be used combustible materials, atomic-scale understanding of thermal behaviors of the hydrocarbon-coated ANPs has yet to be achieved. Here we perform reactive molecular dynamics (RMD) simulations to investigate effects of hydrocarbon coating on the combustion performance of the ANPs. Our RMD simulations reveal detailed reaction steps for the sintering process of the bare/hydrocarbon coated ANPs. As such, our RMD simulations provides a valuable input for experimental synthesis of functional metal nanoparticle materials for energy conversion applications.

S.H. and R.E. acknowledge the new tenure-track faculty start-up fund from School of Natural Science, Mathematics and Engineering at California State University, Bakersfield (CSUB).

1:40 PM NM05.03.08
Late News: Citrus Limon as Reducing Agent for the Synthesis of Gold Nanoparticles by Multiwave Ultrasonic Technique Juan Carlos Martinez, Julio Cesar Ramos Dominguez, César Fernando López Sánchez and Raúl Carrera Cerritos; Instituto Politécnico Nacional, Mexico

Nanotechnology has studied applications in biomedical areas, for which several nanomaterials have been synthesized that present limitations such as toxicity and instability in organisms, so green methodologies have been developed that help reduce this problem. In this work we report the green synthesis of AuNPs using as a reducing agent lemon extract (Citrus limon), and the multiwave ultrasonic technique as an excitation element. As the precursor reagent, trihydrated chlorouric acid (HAuCl4.3H2O, Sigma Aldrich SKU 520918) was used, and as a reducing agent the lemon juice extract. The reaction was carried out in an ultrasonic bath at a frequency of 40kHz, at 55 ° C for one hour (Branson 2800 series). The final solution obtained showed a purple coloration, and was characterized by UV-VIS spectrophotometry and transmission electron microscopy (JEOL JEM 1010). Peak absorbance peak at 530 nm was observed and particle diameters between 12 and 16 nm were obtained.

The reported results could be of interest to carry out fusion of nanometric inorganic materials by the ultrasonic technique, and by controlling the temperature and frequency, metal structures with different morphology and properties could be generated.

1:45 PM NM05.03.09
Late News: Nanoporous Ni Produced from the Reduction of NiO Nanoparticle Dispersions and Implications for Low-Cost Functional Applications Mark Atwater and Beck Boan; Liberty University, United States

Porous Ni has many potential applications, such as energy storage, fuel cells, and catalysis, which account for its rapid rise in publication frequency in recent years. Nanoporous Ni is less commonly reported, but it is expected to have enhanced properties due its higher surface area. Dealloying is the most developed method for creating nanoporous metals, with Ni precursors including Ni-Mn, Ni-Mn-Cu, or the classic Ni-Al alloys, first developed and patented by Murray Raney in 1927, and therefore referred to as “Raney” nickel. The general strategy of dealloying is well-developed and provides a valuable method for achieving nanoscale porosity. The commonality among dealloying methods is the preferential removal of a sacrificial phase. That phase must be carefully removed in its entirety, as any residue will alter the final properties. Here we present the removal of a second phase to create nanoscale porosity in a scheme broadly similar to dealloying; however, the sacrificial phase is an oxide, not another metal. This oxide reduction provides a single-metal strategy for nanoporosity (e.g., Ni+NiO), thereby eliminating any source of metallic contamination. Furthermore, the opportunity exists to intentionally alloy with greater accuracy by alloying before or during oxide reduction. For example, Ni and Cu can be alloyed during milling in metallic phase or, as a simple extension, CuO would be added with NiO so that the desired metallic composition is obtained after reduction. Any number of permutations to this approach can be employed for completely unique control of the final structure and composition. This technique is remarkably simple and scalable. The precursors are created through standard powder metal processes (milling, compaction, etc.), and the required temperatures are quite modest. Additionally, this provides an environmentally friendly alternative to chemical etching by acids, which are commonly employed in dealloying. The processing, properties, and applications will be reviewed.

2:00 PM NM05.03.10
Late News: Facile Synthesis of Ru-ZrP Catalysts with Nano-Anadem Structure and Its Application in Hydrogenation of Acetophenone Xiaoyu Li and Qiang Zhang; Washington State University, United States

As a reaction generally used in industrial processes, the catalytic hydrogenation of organic compounds containing carbonyl groups using nanomaterials is extensively studied. Herein, we describe the preparation of an unusual nanomaterial, ruthenium nano-anadem decorated zirconium phosphate nanoplatelets, which can be used to realize the selective hydrogenation reaction of ketone. We choose acetophenone (AP) for main study as it is the simplest ketone and can lead to important hydrogenation products, such as ethylcyclohexane (EC) for bio-oils and 1-cyclohexylethanol (CE) for many polymers production and biofuel purpose.
α-zirconium phosphate (α-ZrP) serving as a solid support has been widely studied. We obtained α-ZrP nanoplatelets with high yield and good quality by using a modified refluxing method. Through an ion-exchange and reduction reaction pathway, Ru nanoparticles can be loaded on ZrP nanoplatelets to yield Ru-ZrP nano-anadem structures. The obtained Ru-ZrP composites with different loading amount were characterized *via* powder X-ray diffraction (PXRD), nitrogen adsorption and de-adsorption, transmission electron microscopy (TEM), Scanning electron microscopy (SEM), and X-ray photoelectron Spectroscopy (XPS). We also explained the detailed growth mechanism. The successful synthesis of Ru-ZrP nanoplatelets were also supported by its excellent catalytic performance in the hydrogenation reaction of acetophenone. To obtain an optimized reaction condition, many factors such as reaction time, reaction temperature and pressure of hydrogen gas were investigated. Conversion and yield were determined by gas chromatography mass spectrometry (GCMS). Conversion rates of AP could be achieved 100% at room temperature. The resulting products include at least 93% yield rate of CE and EC as the rest. The stability and possible mechanism for Ru-ZrP catalyzed AP were discussed. It shows very good stability after 5 runs of recycle. The kinetics of this reaction were discussed as

well as some rare intermediates in details. The results suggest that there is a great potential for this novel Ru-ZrP nanostructures in catalytic applications.

4:00 PM *NM05.04.01
Synthesis and Machine Learning of Patchy Nanoparticles Qian Chen; University of Illinois at Urbana-Champaign, United States

I will discuss my group's two recent progresses on constructing a library of hybrid patchy nanoparticles. Synthetically, we applied the concept of "island formation" established for planar substrates, where ligands cluster as they adsorb, to preparing gold nanoparticles of diverse shapes with precisely sized polymer patches. These polymer patches adapt their configuration in response to external stimulus and modulate the self-assembly behaviors of the nanoparticles. Meanwhile, we applied machine learning based data-mining method to relate synthesis conditions with the patterns of the patchy nanoparticles, to allow for predictive synthesis and design. Such fundamental understanding of the synthesis, interaction and assembly of patchy nanoparticles can bear relevance to their increasing ramifications in addressing staggering national needs in environment, energy, and health.

4:25 PM NM05.04.02
Late News: Spatially Resolved Fourier Transform Impedance Spectroscopy—A Technique to Rapidly Characterize Composite Materials, Interfaces and Devices Mathew Kelley, Grigory Simin, Kamal Hussain, Asif Khan, Andrew Greytak and MVS Chandrashekhar; University of South Carolina, United States

We demonstrate a technique to quickly build and spatially map the frequency response of optoelectronic devices. The transfer function of a linear system is the Fourier transform of its impulse response. Such an impulse response is obtained from transient photocurrent measurements of devices such as photodetectors and solar cells. We introduce and apply Fourier Transform Impedance Spectroscopy (FTIS) to a PbS colloidal quantum dot (QD)/SiC heterojunction photodiode and validate the results using intensity-modulated photocurrent spectroscopy. Cutoff frequencies in the devices were as high as ~10kHz, showing their utility in advanced thin film and flexible electronics. The practical frequencies for FTIS lie in the mHz-kHz range, ideal for composite materials such as QD films that are dominated by interfacial trap states. These can lead to characteristic lengths for charge collection ~20-500 μm dominated by transmission line effects, rather than intrinsic diffusion and drift length scales, enabling extraction of interfacial capacitances and series/parallel resistances.

4:40 PM NM05.04.03
Late News: Understanding Intermediates in Cluster Synthesis Using Mass Spectrometry Grant E. Johnson[1], Michael Hewitt[2], Marshall Ligare[1], Ulises Reveles[3], Niranjan Govind[1] and Heriberto Hernandez[2]; [1]Pacific Northwest National Laboratory, United States; [2]Grinnell College, United States; [3]Advanced Career Education Center, United States

Rational synthesis of size- and composition-selected clusters with predetermined properties for applications in catalysis, energy conversion and storage, and chemical separations will be facilitated by a mechanistic understanding of cluster nucleation, growth, and etching in solution. We have characterized the formation of triphenylphosphine (PPh_3) ligated gold clusters in the $Au_{1\text{-}22}$ size range using online reaction monitoring

combined with high-mass-resolution electrospray ionization mass spectrometry. To improve the sensitivity and mass resolution of larger clusters for unambiguous identification, we increased the number of scan averages and reduced the width of mass collection windows, thereby mitigating mass and abundance bias resulting from small gold-ligand species present in high abundance. We have identified new clusters including $Au_5(PPh_3)_5^+$, $Au_{12}(PPh_3)_9HCl^{2+}$, $Au_{15}(PPh_3)_9Cl^{2+}$, $Au_{16}(PPh_3)_{10}Cl_2^{2+}$, $Au_{17}(PPh_3)_{11}^{3+}$, $Au_{18}(PPh_3)_{10}^{2+}$, $Au_{19}(PPh_3)_{10}Cl^{2+}$, $Au_{20}(PPh_3)_{12}H_3^{3+}$, $Au_{21}(PPh_3)_{10}Cl^{2+}$, and $Au_{22}(PPh_3)_{10}Cl_2^{2+}$, indicating that a full range of clusters between $Au_{1–22}$ is present in solution. We present evidence that the $Au_{12–14}$ size range is a transition point in cluster nucleation where smaller clusters exhibit a one-to-one gold-to-ligand ratio while larger clusters feature additional gold atoms without an equal number of accompanying ligands. Our results show that differently functionalized phosphines may be used to direct the size and abundance of gold clusters in solution. While for PPh_3-ligated clusters the most abundant species are $Au_{6–9}$, for methyldiphenylphosphine (PPh_2Me) and dimethylphenylphosphine ($PPhMe_2$)-ligated clusters the most abundant species are $Au_{10–11}$ and $Au_{12–14}$, respectively. We also present evidence that small hydrogen-containing intermediates ($Au_2(PPh_3)_2H^+$ and $Au_4(PPh_3)_4H^+$) are responsible for the growth of larger clusters. Degradation of these intermediates and growth of larger clusters are shown to be dependent on irradiation of the solution with light. Together, our findings advance the mechanistic understanding of the size-selective synthesis of clusters in the subnanometer size regime where “each atom counts” toward tuning the properties of clusters for eventual applications.

4:54 PM NM05.04.05
Dielectrophoretic Control of Particle Suspensions with Topographical Features Albanie Hendrickson-Stives and Christine Keating; The Pennsylvania State University, United States

Alternating current (AC) electric fields can be used for the reconfigurable, directed self-assembly of particles as a result of forces such as dielectrophoresis. Electrodes patterned via photolithography and 3D microprinting create a gradient in the AC electric field to control particle assemblies. Since these systems are spatially controllable and reconfigurable, they are of interest for realizing tunable metamaterials and optical responses. Here we focus on assemblies with topographical electrodes and particles with materials properties for desired interactions with electromagnetic radiation. Current work is focused on single and multicomponent assemblies with particles of varying composition (e.g. SiO2, TiO2, PMMA). Because of their different properties, each of the particle types has distinct assembly structures and orientations that can be obtained based on the electric field conditions. The various assembly structures can then have their own distinct interactions with light based on the particles present and their orientation.

4:59 PM NM05.04.07
Monte Carlo Simulations Reveal the Properties of Magnetic Tunnel Junction-Based Molecular Spintronic Devices Due to Exchange Coupling Between Paramagnetic Molecules and Two Ferromagnetic Electrodes Marzieh Savadkoohi, Bishnu R. Dahal, Andrew Grizzle, Christopher D’Angelo and Pawan Tyagi; University of the District of Columbia, United States

Magnetic Tunnel Junction (MTJ)-based Molecular Spintronic Devices (MTJMSDs) can lead to new forms of metamaterials and devices for the futuristic computers. MTJMSD is produced by chemically bonding a paramagnetic molecule between two ferromagnetic layers of a MTJ. Variation in coupling strength and nature of molecule -FM layer can produce an unprecedented testbed to observe novel phenomenon. Fundamental understanding of MTJ-based devices and their characteristics needs investigation of various factors such as molecular coupling strength and nature with the two FM electrodes. It is extremely challenging to study the impact of wide range of molecule-FM coupling strengths on MTJMSD via experiments. This paper focuses on Monte Carlo Simulations (MCS) to investigate the impact of molecular coupling with two FM electrodes. We utilized continuous MCS process and Metropolis algorithm[1] to study molecular coupling effect. Our model is a cross junction form MTJMSD where molecules are placed between two elongated FM electrodes representing FM-molecule-FM configuration. In this paper we focused on Heisenberg type exchange coupling. We studied various permutations when molecule formed ferromagnetic or antiferromagnetic coupling with the two FM electrodes. The MTJMSD device used in this study was defined with H×W×L (=11×50×50) dimension where H

is the height, W is the width and L is the length of device. Molecular plane is along the H side of the device structure and located between equal number of atomic FM layers (5×5). We changed the Heisenberg exchange coupling strengths and nature between the paramagnetic molecule and left FM electrode (JmL) and right FM electrode (JmR). To achieve the equilibrium energy state, we conducted 200 million iterations and studied the spatial and temporal evolution of the FM electrodes and MTJMSD as a function of JmL and JmR. The magnitude and nature of JmL and JmR affected the MTJMSD's magnetization, heat capacity, and magnetic susceptibility. For positive JmL and JmR the MTJMSD attained the highest magnetization due to the molecule induced parallel configurations of the two FM electrodes. However, when JmL and JmR were opposite in nature, molecule induced antiparallel magnetizations on the two FM electrodes. With opposite JmL and JmR MTJMSD magnetic moment settled closed to zero. Our MCS study also showed that molecular coupling effect spreads over a long range with respect to the molecular junction sites. According to our MCS results, molecular coupling impacted the whole junction when the critical magnitude of JmL and JmR was ~20% of the Curie temperature of two FM electrodes. These MCS studies also explain the experimentally observed strong molecule induced exchange coupling. Our group observed long range effect of antiferromagnetic coupling between the FM electrodes of an MTJ via organometallic molecular clusters (OMCs) [1-3]. Studying the effect of different thermal energies on MTJMSD's magnetization properties is the next milestone of this ongoing project and will be studied in parallel to experimental works.

A Computational Approach to Fundamentally Understand Blending Thermodynamics Between Polymers and Single-Wall Carbon Nanotubes Yichen Deng, Ying Mu and Kenneth Benson; Northeastern University, United States

Motivated by the idea that 1D nanomaterials can be used as templates for polymer chain alignment and orientation, carbon nanotubes (CNTs), a typical 1D nanomaterial, have been widely used as nano-fillers for reinforcing the polymer matrix in order to improve mechanical/structural properties of composite materials. Dispersing CNTs in the polymeric matrix remains a major challenge to address in order to increase the efficiency of enhancement. Experimental work of our lab has shown that the use of a non-solvent induced phase separation process can lead to regions of complete CNT-polyacrylonitrile (PAN) interaction within the matrix. To systematically explore the mechanism behind this phenomenon, full atomistic simulation is used to study the energy profile within the CNT/PAN/DMF system. To connect the simulation with the experimental work, a coarse-grained model using dissipative particle dynamic (DPD) method has been built to scale-up the simulated system. In this study, small angle X-ray scattering and thermal gravimetric analysis (TGA) techniques are employed as a tool to validate the interaction parameter setting of our DPD model. This parameter will provide important information/feedback needed to estimate a 'chi' parameter for PAN-CNT interaction. More broadly this coarse-graining approach can also be applied to other 1D-polymer systems to determine whether selective interaction is possible.

9:00 PM NM05.05.01
Nonthermal Plasma Synthesis of Nitrogen-Doped Titanium Dioxide Nanoparticles with Visible Light Photocatalytic Activity Qiaomiao Tu, Chad Beaudette and Uwe Kortshagen; University of Minnesota Twin Cities, United States

Titanium dioxide (TiO_2) has been extensively studied for water splitting,[1] dye-sensitized solar cells,[2] and photocatalysis[3] due to its chemical stability and efficient photon-electron transfer. However, the wide bandgap (3.0-3.2 eV) and rapid recombination rate limit its utilization of visible solar radiation when used as a photocatalyst. Nitrogen doping has proven to be an effective way to alter the band structure and extend the photoactive region to visible light.[4] Despite these advantages, a single-step synthesis route with wide tunability of nitrogen doping is still desirable.
Here, we demonstrate the synthesis of nitrogen-doped titanium dioxide nanoparticles with enhanced visible light absorption and photocatalytic activity via a one-step nonthermal plasma route. We investigated the plasma power influence on the particle growth and nitrogen incorporation under various reactor geometries, which allows for tuning of the substitutional and interstitial nitrogen doping level, bandgap and thus light absorption behaviors. By adjusting the locations of the electrode and the oxygen injection into the plasma, the particles transitioned from entirely interstitial nitrogen-doped to substitutional nitrogen-doped. The reactor design also allowed for phase tuning from amorphous, to crystalline anatase, rutile, and mixed anatase/rutile.
Photocatalytic performances of the as-synthesized nanoparticles were evaluated through the degradation efficiency of organic dyes methyl orange (MO) and methylene blue (MB) under natural sunlight irradiation. The low concentration of TiO_2 required in this work for degradation of both MO and MB dyes without external facilitation of metal ion doping or hydrogen peroxide addition indicates that the nitrogen-doped TiO_2 nanoparticles are efficient visible-light photocatalyst.
This work expands the scope of nonthermal plasmas for functional oxide nanocrystal fabrication, demonstrating its versatility in tuning material composition and structure. The discussion on the relationship between plasma conditions and nanoparticle properties provides fundamental insights into engineering nanoparticle growth and functionalization.
This work was supported by the National Science Foundation under MRSEC grants DMR-1420013 and DMR-201140.

Full Daytime Sub-Ambient Radiative Cooling in Commercial-Like Paints with High Figure of Merit Xiangyu Li[1,2], Joseph Peoples[1], Zhifeng Huang[3], Zixuan Zhao[1], Jun Qiu[4] and Xiulin Ruan[1]; [1]Purdue University, United States; [2]Massachusetts Institute of Technology, United States; [3]Wuhan University, China; [4]Harbin Institute of Technology, China

Radiative cooling is a passive cooling technology that acts by reflecting sunlight and emitting radiation in the sky window. Although highly desirable, full daytime sub-ambient radiative cooling in commercial-like single-layer particle-matrix paints has not been achieved. Here, we demonstrate full daytime sub-ambient radiative cooling in $CaCO_3$-acrylic paint by using large band gap $CaCO_3$ fillers, a high particle concentration of 60%, and

a broad size distribution. Our paint shows a high solar reflectance of 95.5% and a high normal emissivity of 0.94 in the sky window. Field tests show cooling power exceeding 37 W/m^2 and a surface temperature of >1.7°C below ambient at noon. A figure of merit RC is proposed to compare the cooling performance independent of weather conditions. The standard RC of our paint is 0.49, among the best radiative cooling performances, while offering the benefits of convenient paint form, low cost, and compatibility with commercial paint fabrication processes.

Ligand Identity Determines Carrier Dynamics in $CuInSe_2$ Nanocrystals Samantha Harvey; Northwestern University, United States

Semiconductor nanocrystals (NCs) continue to garner interest for their unique optoelectronic properties that are controllable through size, shape, and composition. $CuInSe_2$ NCs have been hailed as a less-toxic alternative to Cd and Pb based materials and exhibit bandgaps similar to Si making them ideal for photovoltaic application. Synthesis of these materials has allowed them to be prepared using a variety of ligands. Broadly it is well known that ligands play a key role in stabilitizing these colloids and passivating surfaces, but they can also be crucial to intraband and interband relaxation as well as electronic and thermal conductivity. Very little research has focused on the effects of ligands on photophysics in $CuInSe_2$. Here we demonstrate through a variety of optical techniques the strong impact that ligands have on carrier dynamics in $CuInSe_2$ NCs.

Enhanced Infrared Photodiodes Based on PbS/$PbCl_x$ Core/Shell Nanocrystals Adam Colbert[1], Diogenes Placencia[1], Erin Ratcliff[2], Janice Boercker[1], Paul Lee[2], Edward Aifer[1] and Joseph Tischler[1]; [1]U.S. Naval Research Laboratory, United States; [2]The University of Arizona, United States

The performance of short-wave infrared (SWIR) photodetectors based on colloidal lead sulfide (PbS) depends critically on advances in passivation strategies to address the more complex surface structure of large-diameter particles. Nanocrystals prepared using $PbCl_2$ precursors result in formation of a thin $PbCl_x$ shell, providing improved air stability and photoluminescence quantum yields compared to those derived from other lead sources. We directly compare the performance of SWIR photodiodes fabricated with PbS/$PbCl_x$ (core/shell) nanocrystals versus their PbS-only (core) counterparts. Despite their inherently similar bulk properties, the core/shell-based devices exhibit greater external quantum efficiencies and reduced dark current densities, while the core-based devices suffer from shunting and inefficient charge extraction. To elucidate the implications of the shell chemistry on device performance, we evaluate the thickness-dependent energy level offsets and interfacial chemistry of the nanocrystal films with the zinc oxide electron-transport layer. Our results suggest the disparate device performance between the two synthetic routes is associated with unfavorable interface dipole formation and a high prevalence of surface defect states in the core-only system, due to incomplete removal of the native organic ligands using conventional thin-film halide exchange. The $PbCl_x$ shell offers a promising route to passivate the additional surface facets of large nanocrystals, that previously established ligand treatments fail to adequately to address.

Resistance Variations for Different Pattern Designs of Printed Conductors Due to Non-Uniform Ink Drying Milad Ghalamboran and Gerd Grau; York University, Canada

Printed electronics is a promising low-cost and high-throughput technology for electronic device fabrication. Printed electronics can create flexible electronics on flexible, large-area, thin, and lightweight substrates such as plastic or paper. Wearable electronics, flexible displays, and sensor tags are promising applications of flexible-printed electronics. Conductive, dielectric, and semiconductor patterns can be printed by adding different nanoparticles to a solvent with specific agents to improve printability and prevent particle agglomeration. Printed materials require drying to evaporate the solvent and solidify the material. Electrical conductivity is one of the most important properties of printed metal nanoparticle conductors. Conductivity should be the same

irrespective of pattern design: size, location, or density of adjacent patterns. However, we demonstrate here that inconsistencies in the drying process for printed patterns with close proximity cause resistivity variations. We studied these resistivity variations experimentally in arrays of printed square electrodes. Silver nanoparticle ink is used to inkjet print 9, 25, and 49 square shape electrodes in 3x3, 5x5, and 7x7 arrays to study the resistivity variation between squares at different positions in the array. Electrical resistivity measurement shows higher resistivity for printed squares at the center of each array, while printed squares at the corners exhibit lower resistivity after drying on a hot plate. This variation depends not only on the location of each electrode in an array but also on the number of electrodes. This means, for the same drying temperature and duration, the array with a larger number of electrodes shows higher resistivity variation due to the higher evaporation rate of the corner electrodes than the center. As an example, the resistivity variation for 3x3 and 7x7 arrays is 40% and 69%, respectively. Compared to a single isolated electrode, the resistivity at the center of a 7x7 array is 81.7% higher. We studied this phenomenon also for printed squares with three times larger area (9 mm^2), and the results show the same trend but with an overall larger resistivity. Different types of patterns, such as lines and square spirals, show the same trend when features are printed in close proximity, which is inevitable for a spiral. After drying, nanoparticles are sintered in a second post-treatment process to improve the electrical conductivity of the printed metal nanoparticle film. In the sintering process, metal nanoparticles melt and merge to form larger grains with fewer grain boundaries, so the modified morphology of the printed structure can improve the electrical conductivity. Conventionally, sintering is performed at an elevated temperature. Here, we find that sintering on a hotplate at 120 °C results in a reduction in the resistivity variation between different electrodes in a 7x7 array to 9.6%. Compared with conventional thermal sintering, intense pulsed light (IPL) sintering is preferable for high-throughput manufacturing. IPL, as a fast sintering method, applies short, high-intensity light pulses from a Xenon lamp to the printed patterns to improve their electrical conductivity while the substrate temperature stays low. Using IPL can also reduce the resistivity variations of the printed square patterns in an array. There are three parameters for controlling the total energy from the light pulses in IPL. Optimization is necessary to find an optimum number of pulses, on-time, and voltage to achieve the highest electrical conductivity of printed silver nanoparticle ink as well as the lowest resistivity variation. With optimum IPL parameters, the resistivity variation changed to 20% and 22% for 3x3 and 7x7 arrays, respectively. This understanding of printed metal conductor post-processing is important for circuit designers who need to consider resistivity variations and proximity effects in complex circuit patterns.

Defect Mediated Site-Specific Nucleation of Aligned Carbon Nanotubes Supriti Sen, Mula Raju and Chacko Jacob; Indian Institute of Technology Kharagpur, India

Oxygen vacancy defects in silicon dioxide substrates act as defect-mediated nucleating sites for metal nano-particles. Site-specific nucleation of metal catalyst particle and the subsequent growth of nanostructures could thus be accomplished by modulating the number density of these oxygen vacancies on specific substrate sites. This study demonstrates surface passivation dictated site-selective growth of vertically aligned multiwall carbon nanotubes (MW-CNTs), on a SiO_2/ Si patterned substrate. Contrasting choice of growth site of MWCNTs is observed for substrates pre-treated in a reducing atmosphere versus that pre-treated in a mildly oxidizing atmosphere. The different substrate pre-treatments alter the number density of oxygen vacancies on the SiO_2 and Si terraces of the substrate which in turn alters the preferred nucleation site for the metal catalyst particle, resulting in the observed switching of site-selectivity. Scanning electron microscopy of the as-synthesized CNT architectures revealed a high degree of site-selectivity in the growth pattern. Hermans orientation factor revealed a reasonably high degree of alignment of the MWCNTs for both the growth patterns. Transmission electron microscopy and Raman spectroscopy have been employed to study the structure and quality of the synthesized tubes and the catalyst particles. Auger electron spectroscopy was used to study the chemical state of the substrate surfaces and the nucleated catalyst particles. The results demonstrate the significance of surface defects in the nucleation and the subsequent growth of nanostructure.

Plasmon-Mediated Synthesis of Periodic Arrays of Gold Nanoplates Using Substrate-Immobilized Seeds Lined with Planar Defects Svetlana Neretina, Robert A. Hughes and Spencer D. Golze; University of Notre Dame, United States

The architectural diversity realized by plasmonic nanostructures is in large part due to seed-mediated colloidal growth modes that are seeded, not only by single-crystal seeds, but by seeds with a well-defined internal defect structure. Multi-twinned seeds have, for example, been used to generate colloids with icosahedral and decahedral structures while seeds with planar defects realize nanoplate geometries. Recently, we demonstrated a nanofabrication route that synergistically combines nanoimprint lithography, directed assembly, and liquid-phase epitaxy to obtain periodic arrays of complex noble metal nanostructures over a square centimeter area. This benchtop process leverages a synthetic strategy in which seed-mediated liquid-phase growth modes are carried out on substrate-immobilized seeds. While the strategy has led to the generation of substrate-based structures with considerable architectural diversity, it is fundamentally limited by the inability to fabricate seeds with the same internal defect structure as those routinely used in colloidal chemistry. Here, we demonstrate a large-area processing route for generating substrate-based Au seeds lined with stacking faults and use them to synthesize arrays of epitaxially aligned Au nanoplates using a plasmon-mediated growth mode. The work advances the possibility of bringing an exciting nanoplate chemistry to the substrate surface and, in doing so, provides the building blocks needed to enable on-chip plasmonic devices.

***In Vivo* Clustering of Gold Nanoparticles and Quantum Dots via Copper-Free Click Reaction for Real-Time Imaging and Tumor Sensing** Vu O. Pham-Nguyen, Ji Un Shin, Mao Wei, Ju Won Lee, Jae Keun Park, Miso Lee, Wan Ho Cho and Hyuk Sang Yoo; Kangwon National University, Korea (the Republic of)

Nowadays, fabrication of biosensors for cancer detection, monitoring of angiogenesis or cancer metastasis and cancer imaging holds vast potential. We herein proposed a biosensor based on clustering of matrix metallopeptidase (MMP)-responsive gold nanoparticles (AuNP) and quantum dots (QD) by azide-alkyne copper-free click reaction. Briefly, AuNP were surface-decorated with two types of poly(ethylene glycol) (PEG); 1) short chain of azide-terminated PEG, 2) long chain composed of double PEG chains with a connecting peptide (MMP CP) vulnerable for MMP digestion. We precisely controlled the immobilized PEG ratios so that the azide moieties can be exposed only when MMP externally digests the long chain of PEG. De-shielded AuNPs will be subsequently clicked to alkyne-functionalized QD. Due to the high concentration of MMP at tumor site, the fluorescence resonance energy transfer (FRET) between QD and AuNP during clusters formation is speculated that can be used for tumor sensing. To characterize the surface decoration of AuNP, UV-Vis spectrum and Raman spectroscopy of decorated AuNP were analyzed. A red shift in UV-Vis spectrum according to the size change of AuNP during decoration and 2 distinct peaks for PEG in Raman spectrum were clearly observed confirmed the successful decoration of carboxylate-PEG and mPEG-MMP CP on AuNP surface. The size changes of decorated AuNP was further confirmed by DLS and TEM, where a huge increase in hydrodynamic diameter of the AuNP was confirmed in the order of AuNP (~40nm), AuNP/PEG (~60nm) and AuNP/PEG/MMP CP (~90nm). In consistence with the DLS results, shell thickness of AuNP obtained by analyzing TEM images showed the same trend according to stepwise decoration of AuNP. Moreover, when AuNP/PEG-azide was labeled with alkyne fluorescence dye, a significant increase of the fluorescence intensity was recorded by spectrofluorophotometer and IVIS in comparison to AuNP-dye suspension confirmed the click-functionality of AuNP/PEG-azide. Thus, AuNP/PEG-azide was speculated that can be used for click reaction toward alkyne-QD. The enzyme responsive clustering process was investigated by incubating with

different concentration of MMP-2. There was a dramatic increase of AuNP diameter up to about 400nm and the FRET efficiency also increased up to ~58% after 2h of incubation confirmed the cluster formation of AuNP and QD. This results suggesting that AuNP and QD can be employed for tumor sensing due to the elevated MMP-2 concentration at tumor site. To stimulate *in vivo* clustering behaviors, AuNP and QD were incubated with the supernatants of cell cultured medium. The diameter of the clusters and FRET efficiency also increase after 2h of incubation. Furthermore, we monitored the fluorescence intensities of QD by IVIS when co-injected with AuNP to tumor bearing mice. Consequently, after 6h post injection, the fluorescence intensity of QD was clearly reduced confirmed the feasibility of our platform for real-time imaging and tumor sensor *in vivo*.

Sintering of Silver Nanoparticle Patterns Using Formic Acid Vapors Justin Courville, Muhibbur Rahman and Seonhee Jang; University of Louisiana at Lafayette, United States

The use of metal nanoparticles (NPs) for printed conductive patterns are gaining a lot of attention because of the low cost and shorter manufacturing time in the fabrication of flexible electronic devices. Flexible electronics include organic thin film transistor (OTFT), organic light-emitting diode (OLED), sensors, and wearable devices. Metallic NP inks mainly comprised of metal NPs such as gold (Au), silver (Ag), and copper (Cu) are commonly used for printing of conductive patterns on flexible substrates. After printing of NP inks, sintering process is required to achieve high conductance of the patterns. Metallic NP inks also contain the organic capping molecules and additives which are barrier to high conductance. Through sintering process, these organic compounds should be removed. Ag NPs are the most widely used in many applications due to their high electrical conductivity and chemical stability. In this study, the effect of sintering atmosphere on the conductivity of printed patterns is investigated. Sintering atmosphere is chosen among air, nitrogen (N_2), and N_2-bubbled through formic acid. The sintering temperature is maintained below 200ºC to avoid the deformation and degradation of flexible substrate. The formic acid atmosphere shows a better removal of the organic compounds than air or N_2. At the beginning of thermal sintering, the organic capping molecules surrounding the NPs decompose and necking between the adjoining NPs occurs, followed by grain growth and densification. The electrical conductivity of Ag film is dependent on sintering conditions. It is observed that the resistances of Ag films decrease as the sintering temperatures increase when sintering atmosphere is chosen between air and N_2. Ag films sintered under N_2-bubbled through formic acid shows low resistances below 0.14 Ω even at temperatures below 100ºC. In comparison, the resistances of Ag films sintered under air or N_2 drastically decreases from 1.59-2.57 and 0.20-0.22 Ω when the sintering temperatures increase from 80 to 140ºC. The microstructure and chemical composition of the printed conductive patterns under different sintering conditions such as temperature, time, and type of atmospheres are analyzed. The grain growth, pore distribution, and level of organic residues determine the conductivity of the printed patterns. Formic acid vapors play an important role in decomposition of organic molecules, neck formation of NPs, and densification of the film, compared to the patterns sintered under air or N_2. The average hardness and elastic modulus of the films sintered under formic acid vapors and N_2 are higher than that sintered under air at sintering temperature of 140ºC.

Late News: Label Free Detection of Small Molecules Using Surface-Enhanced Raman Spectroscopy (SERS) with Gold Nanoparticles Synthesised with Various Capping Agents Zahra Khan[1,2]; [1]A*STAR, Singapore; [2]UCL, United Kingdom

SERS has received increased attention in recent years focusing toward biological and medical applications due to its great sensitivity as well as molecular specificity. In the context of biological samples there are generally two methodologies for SERS based applications: label free detection and the use of SERS tags. Necessity of tagging can make the process slower and limits the use for real life. Label-free detection offers the advantage that it reports direct spectroscopic evidence associated with the target molecule rather than the label. Reproducible, highly monodisperse gold nanoparticles (Au NPs) were synthesised using a relatively facile seed mediated growth method. Different capping agents (TRIS, citrate and CTAB) were used during synthesis and characterization was performed. They were then mixed with different analyte solutions before drop-casting onto

a glass slide prior to Raman measurements to see which NPs displayed the highest SERS activity as well as their stability. A host of different analytes were tested, both non-biomolecules and biomolecules which were all successfully detected using this method at concentrations as low as 10^{-3}M with salicylic acid reaching a detection limit in the nanomolar range. SERS was also performed on samples with a mixture of analytes present whereby peaks from both target molecules were distinctly observed. This is a rapid and effective way of testing samples and offers potential applications in the biomedical field as a tool for diagnostic and treatment purposes.

9:10 AM NM05.06.06
Probing Charge Transport Kinetics in Plasmonic Environment with Cyclic Voltammetry Mohammad Shahabuddin, Ashleigh K. Wilson, Natalia Noginova, Md A. Rab and Joyce Fields; Norfolk State University, United States

Modification of physical and chemical phenomena is observed in vicinity of metamaterials may involve different mechanisms specific for nanostructured and plasmonic media. In order to better understand the factors responsible for modification of electrochemical reactions in plasmonic environment, we employ the cyclic voltammetry method and investigate how the vicinity to nanostructured metallic surfaces affects the electron-transfer process and charge transport kinetics. In addition, we explore effects of laser light illumination and discuss the results taking into account photoinduced electric potentials and plasmon-related heating.

9:15 AM NM05.06.07
Late News: Carbon Fibers for Energy Storage Devices—Electrochemical Double Layer Supercapacitors, Pseudocapacitors and Zn-Air Batteries Zahra Abedi, Desiree Leistenschneider, Weixing Chen and Douglas G Ivey; University of Alberta, Canada

Development of inexpensive energy storage devices is crucial due to the ever increasing demand for sustainable energy. The material used as the electrode material in energy storage devices is one of the most important factors affecting the device's performance, price and sustainability. Asphaltene, as a high carbon content by-product of the oil sands industry, can be used as the base material for the electrodes in electrochemical double layer supercapacitors (EDLC), pseudocapacitors and the air electrode in Zn-air batteries (ZAB). Asphaltene is the most polar fraction and heaviest part of oil sands bitumen. Approximately 20 wt% of bitumen produced from the oil sands consists of asphaltene.
Carbon fibers (CF) derived from asphaltene were chemically activated to prepare activated carbon fibers (ACF). ACF were used to prepare stable and high performance flexible EDLC and pseudocapacitor electrodes as well as air electrodes for ZAB.
ACF used as the active electrode material in EDLC showed a specific surface area (SSA) as high as 2290 $m^2\ g^{-1}$ and total porosity of 1.27 $cm^3\ g^{-1}$ that included 0.88 $cm^3\ g^{-1}$ of micropores (pore width < 2 nm) and 0.29 $cm^3\ g^{-1}$ of mesopores (2 nm < pore width < 50 nm). The maximum specific capacitance (C_s) reached was 311 F g^{-1} at a specific current (I_s) of 0.04 A g^{-1} that dropped to 248 F g^{-1} at 1 A g^{-1} (in 6 M KOH); capacitance retention was 91% after 10,000 cycles. This material was later used in an EDLC device with an ionic liquid electrolyte ($EMIMBF_4$, 1-ethyl-3-methylimidazolium tetrafluoroborate); specific energy (E_s) and power (P_s) values of 35.7 Wh kg^{-1} at a P_s of 525.4 W kg^{-1}, respectively, were achieved. These were comparable to energy and power values delivered by some batteries. [1]
Because of the high performance and high conductivity of ACF used in the EDLC devices, this material was chosen to be used in ACF/MnO_2 composite electrodes to aid the pseudocapacitive performance of MnO_2. Birnessite-type MnO_2 (δ-MnO_2) was prepared through a hydrothermal process; its microstructure was subsequently thermally modified to reduce its crystallinity by introducing defects. These defects acted as active sites to enhance electrolyte ion adsorption/desorption, which can increase C_s, E_s and P_s. The maximum C_s reached by the composite electrode was 395 F g^{-1} at a specific current of 0.04 A g^{-1}, with 282 F g^{-1} at 1 A g^{-1}. Capacitance retention was 74% after 5,000 cycles. The maximum P_s in 6 M KOH for the composite electrode was 2.57 kW kg^{-1} at E_s of 6 Wh kg^{-1}.
Asphaltene based carbon fibers were chosen to prepare homemade gas diffusion layers (GDL) for use in air electrodes in ZAB. Air electrodes were prepared with CF carbonized at three different temperatures, i.e., 500

ºC, 800 ºC and 1500 ºC. The oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) activity of the electrodes, as well as commercially purchased electrodes, were tested in 1 M KOH. All homemade electrodes showed much better OER activity than the purchased ones. ORR activity was similar for both commercial electrodes and homemade electrodes prepared with CF at 1500 ºC (CF-1500). CF-1500 will be tested in full ZAB cells to determine their performance and cycling behavior and compared with purchased electrodes. Finally, electrodes, prepared with CF-1500 and electrocatalysts consisting of Mn-mixed metal oxides, will be tested in ZAB half cells and full cells.

9:30 AM NM05.06.08
Elucidating the Plasmonic Modes in Metal Nanojunctions with Nanoparticle Libraries Jingshan S. Du, Charles Cherqui, George Schatz, Vinayak P. Dravid and Chad A. Mirkin; Northwestern University, United States

Plasmonic resonances in metal nanostructures have enabled the creation of a new class of chemical sensors, photocatalysts, and therapeutics. In particular, coupling plasmonic metals to other functional nanostructures provides an effective way to generate multi-functional materials, tailored to respond to controlled light inputs in specific ways. Remarkably, these advances have occurred despite a lack of understanding of how energy transfer occurs between metallic domains and the geometric and dielectric effects on the plasmonic properties in hetero-nanostructures. Here, we present a nanoparticle library approach designed to explore the plasmonic modes of metal nanojunctions with various geometries, metal types, and composition ratios. Polymer nanoreactors generated by scanning probe lithography were used to prepare location-encoded particle libraries on electron-transparent substrates where the individual nanoparticles have precisely defined size and composition. Single-particle level far-field light scattering and near-field energy-loss maps were sequentially collected from the same nanojunctions, allowing for mode identification of the entire plasmonic spectrum and correlation between the near-and-far-field properties of the system. Notably, a dipole injection from a plasmonically active metal to a lossy metal is revealed in the nanojunctions, suggesting that field enhancement on the surface of the lossy metal is responsible for photocatalytic “energy transfer” in reactions on the lossy metal. We report on a new group of hetero-nanoprisms containing both active and lossy metals in a planar configuration. The unique plasmonic mode distribution uncovered by our methods yields a design paradigm for creating the next generation of low-cost (due to elemental composition), multi-functional nanomaterials.

Integrated Synthesis and Process Design Enabling Kinetic and Structural Control in Self-Assembled Polymer-Grafted Nanocrystal Superstructures Xingchen Ye; Indiana University Bloomington, United States

Polymer-inorganic nanocomposites based on polymer-grafted nanocrystals (PGNCs) are enabling technologically relevant applications owing to their unique physical and chemical properties. While diverse PGNC superstructures have been realized through evaporation-driven self-assembly, this approach presents multifaceted challenges in understanding and ultimately controlling the assembly kinetics and superstructure selection. In this presentation, I will first discuss our work on the rapid assembly of multicomponent superstructures from a homogeneous disordered PGNC mixture. We find that controlling the nature of assembly environment allows for exquisite control of the rate and extent of PGNC assembly. Characterization of kinetically arrested intermediates reveals a multistep crystallization pathway defying classical nucleation theory. Next, I will discuss examples on polymer-grafted anisotropic nanocrystals. It is found that the interplay between

nanocrystal shape and interaction softness give rise to tunable assembly phase behavior.

10:55 AM NM05.07.02
Shape-Driven, DNA-Mediated Engineering of Colloidal Superlattices Wenjie Zhou[1,2], Haixin Lin[1,2], Yuanwei Li[1,2], Zizhuo Liu[1], Ziyin Huang[1,2], Devleena Samanta[1,2], Koray Aydin[1] and Chad Mirkin[1,1,2]; [1]Northwestern University, United States; [2]International Institute for Nanotechnology, United States

The emergence of order from disorder has fascinated, puzzled, and inspired generations of scientists. Colloidal assembly of nanoscale objects is of particular interest as a wide range of hierarchical structures can be obtained simply by changing the size, shape, and surface chemistry of the nanomaterials. Over the past decade, advances in colloidal nanocrystal (NC) synthesis have provided access to a library of well-defined nanoscale building blocks. The organization of isotropic NCs, i.e. uniformly functionalized nanoscale spheres or pseudo-spheres, has been extensively studied and design rules have been empirically set or theoretically explained. In contrast, very few design rules exist for anisotropic NCs, such as asymmetrically functionalized spheres, rods, plates, and polyhedral NCs, and the rules that do exist are often challenged by unusual cases. Therefore, our current understanding of the self-organization process of anisotropic NCs has yet to achieve the leap from “discovery by chance” to “synthesis by design”. In this presentation, we present synthetic methodologies towards the assembly of designer 2D and 3D NC superlattices using DNA-functionalized polyhedral NCs and a series of geometry-inspited strategies.

For 2D structures, we have developed a shallow template-assisted DNA-mediated assembly strategy to precisely arrange colloidal NCs onto surfaces with single-particle orientational control across millimeter areas. In addition to our precise control over the in-plane arrangement, the oligonucleotide bonds between the NCs and substrate can be reversibly expanded and contracted, enabling post-synthetic tunability. As an example, we have synthesized a tunable NC-based metasurface that rapidly responds to changing solution polarity and, therefore, is promising for the fabrication of reconfigurable 2D optical devices. To achieve 3D structures, we have developed a series of PEG-DNA ligands that enabled the assembly of polyhedral NCs into ordered and dense-packed superlattices, which is challenging due to the rigiditiy of pure DNA. Taking advantage of the highly customizable nature of oligonucleotides and geometry inspired designs, polyhedral NCs of different sizes and shapes were densely assembled/co-assembled. This resulted in the introduction of eleven new structures to the DNA-engineered colloidal crystal family, including the first colloidal quasicrystal engineered with DNA. Moreover, we have shown the ability to inversely design and experimentally produce ordered superlattices based on polyhedral complementarity. Importantly, these colloidal organization platforms may enable systematic exploration of structure-functional relationships, as well as on-demand design and fabrication of highly ordered nanoscale architectures which will be of interest to the metamaterial communities.

11:10 AM NM05.07.03
Assembly of Covalently-Linked Quantum Dot Heterostructures: Characterization of Excited-State Charge-Transfer Dynamics in Dispersed and Multilayered Systems Caitlin R. McGranahan, Guy Wolfe II and David Watson; University at Buffalo, The State University of New York, United States

Semiconductor quantum dots (QDs) are prime candidates as harvesters of light and donors of excited charge carriers for solar energy conversion. The unique properties of QDs can be exploited to generate desirable energetic offsets to promote interfacial charge transfer between QDs. Our group’s recent efforts have established the validity of utilizing carbodiimide-mediated coupling chemistry to selectively tether two QDs through the formation of an amide bond between the terminal functional groups of capping ligands [1]. We previously reported on excited-state hole transfer in colloidal CdS/CdSe QD heterostructures, which exhibit quasi-type-I interfacial energetic offsets [1]. Type-I energetics rely on the excitation of one QD component, which results in unidirectional charge transfer and hindered charge separation.
This presentation reports on our efforts to improve and expand upon our previous work in two ways. First, we synthesized and characterized covalently tethered colloidal CdSe/CdTe QD heterostructures via formation of amide bonds. These heterostructures exhibit type-II energetics that promote interfacial charge separation,

irrespective of which constituent QD is initially excited, and afford enhanced control over the thermodynamic driving forces for charge transfer. Within these heterostructures, photogenerated electrons are transferred from CdTe to CdSe, and photogenerated holes are transferred from CdSe to CdTe, on timescales of 10^{-8} s. Second, we prepared ternary CdSe/CdTe heterostructures by immobilizing a covalently-linked bilayer of these QDs on a metal oxide substrate. When compared to colloidal heterostructures, thin films consisting of QDs adsorbed to a metal oxide substrate introduce the possibility of an additional stepwise excited-state charge transfer process. We hypothesized that a stepwise process such as this should facilitate extended spatial separation of charge carriers and longer charge-separated state lifetimes, such that energy is harvested more efficiently and desirable processes can more effectively compete with recombination. Dynamic quenching of emission was observed in heterostructure-modified thin films, consistent with excited-state charge transfer. Rate constants for photoinduced electron and hole transfer between QDs are on the order of 10^8 s^{-1} and 10^7 s^{-1}, respectively. The bidirectional interfacial charge transfer within these type-II QD heterostructures, both in dispersion and within films, further reveals the potential of this system for use in light harvesting and solar energy conversion. This presentation will highlight these recent results as well as our ongoing time-resolved spectroscopic characterization of photoinduced charge transfer in CdSe/CdTe QD heterostructures.

Late News: Gas-Phase Nitrogen Doping of Monolithic TiO2 Nanoparticle-Based Aerogels for Efficient Visible-Light-Driven Photocatalytic H2 Production Junggou Kwon, Kyoungjun Choi, Murielle Schreck, Tian Liu, Elena Tervoort and Markus Niederberger; ETH Zürich, Switzerland

Hydrogen production using abundant solar energy and semiconductor photocatalysts holds significant potential as a clean and sustainable energy system. Macroscopically sized aerogel monoliths synthesized from preformed anatase nanoparticles are promising three-dimensional photocatalysts due to their immense surface area, high porosity, translucency, and the nanoscale characteristics of the semiconducting crystalline building blocks. Recent studies showed that such titania aerogels decorated with metals are effective for gas-phase photocatalytic CO_2 reduction and H_2 production [1, 2]. However, TiO_2 nanoparticle-based aerogels remain limited to UV-driven photocatalysis due to the intrinsic wide bandgap (3.2 eV). To increase conversion efficiency from solar energy to H_2 production, visible-light sensitization is necessary. Here, we present a facile method for the doping of the aerogel monoliths postsynthetically to make them visible-light active for H_2 production. A CVD gas-phase reaction and plasma utilization at low temperature provided efficient nitrogen incorporation into preformed TiO_2 aerogels without affecting their initial properties. The nitridation improves the optical absorption and charge separation efficiency through an appropriate balance between doping amount and coexistent defects. In comparison to the non-doped sample, the nitrogen-doped aerogels show a significant enhancement in visible-light-driven photocatalytic H_2 production (3.1 mmol h^{-1} g^{-1}) with excellent stability over 5 days. Our approach of gas-phase nitridation of preformed aerogel monoliths offers a powerful tool to improve their properties as visible-light active photocatalysts.

Alignment Frustration in Block Copolymer Films with Polymer Grafted Nanoparticles under Soft-Shear Cold Zone Annealing Saumil Samant[1], Shimelis Hailu[2], Maninderjeet Singh[3], Nihar Pradhan[4], Kevin Yager[5], Alamgir Karim[3] and Dharmaraj Raghavan[2]; [1]Intel Corporation, United States; [2]Howard University, United States; [3]University of Houston, United States; [4]Jackson State University, United States; [5]Brookhaven National Laboratory, United States

Block copolymers (BCPs) provides a platform to sequester nanoparticles in a specific polymeric domain of a BCP system and fabricate aligned nanostructures that can be of significant importance in design of electrostatic capacitors. To aid in the dispersion of nanoparticles in the BCP system, polymer grafted nanoparticles were synthesized using grafting to and grafting from methods. Here, we report the influence of loading of polymer grafted nanoparticles (homopolymer and BCP grafted) on the dispersion and assembly of nanoparticles within cylinder forming BCP (c-BCP) of PS-*b*-PMMA films under static and sharp dynamic thermal gradient soft shear. The application of static thermal field via oven annealing on BCP-g-NP filled as-cast c-BCP films induced a morphology transition from poorly ordered cylinders to mixed morphology, while under dynamic thermal field via cold-zone annealing with soft-shear (CZA-SS), a morphology transition from poorly ordered cylinders to long range ordered parallel morphology was observed. However, at high nanoparticle loading (~10%), there is frustration in the unidirectional alignment of the BCP matrix due to aggregation of functionalized nanoparticles. These findings will be compared and contrasted with homopolymer grafted nanoparticles loaded BCP to establish the significance of graft ligand chemistry in entropic contribution to the frustration in the unidirectional alignment of BCP matrix.

Colloidal Crystal Engineering with Metal–Organic Framework Nanoparticles and DNA Shunzhi Wang[1,2], Sarah S. Park[1,3], Cassandra Buru[1], Omar Farha[1] and Chad Mirkin[1]; [1]Northwestern University, United States; [2]University of Washington, United States; [3]Pohang University of Science and Technology, Korea (the Republic of)

Colloidal crystal engineering with nucleic acid-modified nanoparticles is a powerful way for preparing 3D superlattices, which may be useful in many areas, including catalysis, sensing, and photonics. To date, the building blocks studied have been primarily based upon metals, metal oxides, chalcogenide semiconductors, and proteins. Here, we show that metal–organic framework nanoparticles (MOF NPs) densely functionalized with oligonucleotides can be programmed to crystallize into a diverse set of superlattices with well-defined crystal symmetries and compositions. Electron microscopy and small-angle X-ray scattering characterization confirm the formation of single-component MOF superlattices, binary MOF–Au single crystals, and two-dimensional MOF nanorod assemblies. Importantly, DNA-modified porphyrinic MOF nanorods (PCN-222) were assembled into 2D superlattices and found to be catalytically active for the photooxidation of 2-chloroethyl ethyl sulfide (CEES, a chemical warfare simulant of mustard gas). Taken together, these new materials and methods provide access to colloidal crystals that incorporate particles with the well-established designer properties of MOFs and, therefore, increase the scope of possibilities for colloidal crystal engineering with DNA.

Room Temperature Thermoelectric Behavior of GO-TiO_2@PEDOT: PSS Hybrid Composite Shivani Shisodia[1,2], Djamila B. Hourlier[2], Dharmendra P. Singh[3], Benoit Escorne[4], Abdelhak Hadj Sahraoui[1] and Michael Depriester[1]; [1]Université du Littoral Côté d'Opale, France; [2]Centre National de la Recherche Scientifique, France; [3]Université du Littoral Côte d'Opale, France; [4]Pôle de Recherche "Environnement, Milieux Littoraux et Marins" (EMLM), France

The ability of thermoelectric (TE) materials to convert waste heat, produced from fossil fuels, into electricity is an interesting approach to harvest thermal energy. Till now, inorganic TE materials are best known for their high ZT values but they suffer from high toxicity, high cost, and hideous processing. On the other hand, the low TE efficiency of organic materials is lagging behind their inorganic counterparts. Therefore, we propose a hybrid material as an alternative to obtain a high dimensionless figure of merit.

We utilize the hybrid organic-inorganic approach by taking advantage of the low thermal conductivity of organic polymers, and large Seebeck coefficient of inorganic materials, which is essential for obtaining an improved TE efficiency. Nevertheless, accomplishing a high electrical conductivity whilst keeping a low

thermal conductivity is difficult; and optimization of both parameters is of utmost importance.

To surmount the aforementioned difficulties, we propose a p-type hybrid composite made of an organic polymer poly (3,4-ethylene dioxythiophene): polystyrene sulfonate (PEDOT: PSS) filled with inorganic graphene oxide-titanium dioxide (GO-TiO_2), as a cost-effective and scalable outcome for future TE applications. A facile two steps synthesis route has been opted to synthesize GO-TiO_2@PEDOT: PSS hybrid nanocomposite. The oxo (C=O) and hydroxyl groups (-O-H) of GO have been firstly attached to TiO_2 nanoparticles and then used as a template for the oxidative polymerization of EDOT.

As-synthesized hybrid nanocomposites were analyzed by XRD, SEM, FTIR, UV-Vis spectroscopy, and TG-DSC. The thermal conductivity of the materials was done by the photothermal radiometry (PTR) technique and obtained results were in good agreement with the theoretical predictions proposed in Nan's model. Seebeck coefficient measurements were done by a home-made setup based on two probe method.

The influence of filler on the thermoelectric properties of PEDOT: PSS has been studied. It was observed that the thermal conductivity of PEDOT: PSS has been decreased by half; whereas, the Seebeck coefficient was increased by 2.5 times with the addition of 5wt% GO-TiO_2 into the PEDOT: PSS polymer matrix. The obtained hybrid material can be utilized in various applications such as power generation, cooling, and refrigeration, printing applications, etc. up to 300°C as suggested by the thermogravimetric analysis results.

Late News: PbSe Nanorod Degree of Organization Dictated by the Ligand Structure Tugba Haciefendioğlu and Demet Asil; Middle East Technical University, Turkey

PbSe nanorods have been considered as one of the most promising nanoparticles for solar energy field owing to their high multiple exciton generation yield. As a design rule in solar cell applications, strongly coupled nanoparticles with low exciton binding energy are necessary. In this respect, successful integration of nanorods into solar cells, where an efficient exciton dissociation is demanded, requires fundamental understanding of nanorod ligand interactions. This study discloses the effect of ligand type on the nanorod ordering and on the photovoltaic performance. We found that the ligands which are flexible and have free rotation about the axis of the ligand molecules lead to ordered nanorods whereas completely disordered nanorods are obtained when rigid ligand molecules with torsional degrees of freedom are used for the ligand exchange process. We utilized high-resolution transmission electron microscopy imaging technique to study the effect of ligand structure on nanorod ordering. Steady state photoluminescence measurements were performed to investigate the effect of degree of order on the photo-physical properties. Finally, photovoltaic characteristics of the solar cells based on different ligands were investigated.

Late News: Scalable Synthesis of Nanoporous Atomically Thin Graphene Membranes for Dialysis and MolecularSeparations via Facile Iso-Propanol-Assisted Hot Lamination Piran Ravichandran Kidambi; Vanderbilt University, United States

Scalable graphene synthesis and facile large-area membrane fabrication are imperative to advancenanoporous atomically thin membranes (NATMs) for molecular separations. Although chemical vapordeposition (CVD)

allows for roll-to-roll high-quality monolayer graphene synthesis, facile transfer withatomically clean interfaces to porous supports for large-area NATM fabrication remains extremely challenging.Sacrificial polymer scaffolds commonly used for graphene transfer typically leave polymer residues detrimentalto membrane performance and transfers without polymer scaffolds suffer from low yield resulting in high non-selective leakage through NATMs. Here, we systematically study the factors influencing graphene NATMfabrication and report on a novel roll-to-roll manufacturing compatible isopropanol-assisted hot lamination (IHL)process that enables scalable, facile and clean transfer of CVD graphene on to polycarbonate track etched(PCTE) supports with coverage ≥99.2%, without compromising support integrity/porosity. We demonstrate fullyfunctional centimeter-scale graphene NATMs that show ~2-3 orders of magnitude higher permeance andbetter selectivity than commercially available state-of-the-art polymeric dialysis membranes, specifically in the0-1000 Da range. Our work highlights a scalable approach to fabricate graphene NATMs for practicalapplications and is fully compatible with roll-to-roll manufacturing processes.

Late News: Polymer-Ligated Monodisperse Metal Chalcogenide Nanoparticles with Markedly Improved Stabilities Shuang Liang and Zhiqun Lin; Georgia Institute of Technology, United States

Metal chalcogenide semiconducting nanoparticles (NPs) possess appealing optoelectronic properties that render a wide range of applications, including photovoltaics, photodetectors, and light-emitting diodes (LEDs). Yet, the instability of this class of low-bandgap NPs in ambient conditions remains a key challenge for their practical use. Herein, we demonstrate an unconventional strategy by employing star-like diblock copolymers as nanoreactors to in-situ craft monodisperse metal chalcogenide (e.g., PbSe) NPs with precisely tailorable size, surface chemistry, near-IR optical properties, and significantly improved stabilities in air. The surface of PbSe NPs is intimately and permanently ligated with polymer hairs (i.e., the outer blocks of star-like block copolymers), imparting the protection of PbSe NPs against oxidation and preventing them from aggregation. Intriguingly, alternating the composition and chain lengths of the outer blocks affords a remarkable control over the enhancement of stability of PbSe NPs in ambient conditions.

Photocatalytic Activity of Semiconductors Zn-Based Quantum Dots Josian Luciano-Velázquez[1], Carla I. Quiles-Vélez[1], Sebastián A. Cruz-Romero[1], Gabriel E. Torres-Mejías[2] and Sonia J. Bailón- Ruíz[2]; [1]University of Puerto Rico, Mayagüez, Puerto Rico; [2]University of Puerto Rico, Ponce, Puerto Rico

Semiconductor quantum dots like zinc sulfide have interesting potential applications, consequent to their size-dependent optical properties. These nanostructures can be used on agriculture, environmental chemistry, and fluorescence microscopy, among others. The great rise in nanotechnology has sparked interest in the scientific community in nanomaterials for the use of photodegradation in aquatic bodies. Quantum Dots (QDs) like ZnS nanoparticles (NPs) can absorb electromagnetic radiation and generate photo-excited nanostructures which would be generating reactive oxygen species directly in aqueous phase. The presence of ROS in aquatic environments can be used to destroy organic contaminants by photocatalysis processes. Previous studies had evidenced that the presence of impurities (i.e. copper) into the crystalline structures of QDs can enhance their optical properties and consequently their catalytic capacity. Because of this, the present investigation was focused on generating water-stable ZnS nanoparticles with catalytic properties. This work had three objectives:

1) synthesis of pure and doped ZnS nanoparticles following a reflux method; 2) characterize nanostructures; and 3) study the photocatalytic properties of these nanostructures. A redshift was observed in the photoluminescence peak of pure ZnS nanoparticles when they were doped with heavy metals. Pure ZnS NPs and Cu-doped ZnS NPs evidenced luminescent peaks at 446 nm and, 541 nm, respectively. Nanoparticles (pure and doped) evidenced sizes less than 5 nm and morphologies mainly spherical. Photodegradation studies were evaluated in presence of organic dyes like methylene blue and different concentrations of pure and doped quantum dots (250 and 500 ppm). The destruction of organic dyes in the presence of photo-excited ZnS nanoparticles is envisioned as a fast and clean technology.

2:00 PM NM05.08.05
Sulfur-Infusion Hole Transport Layers for Improved Charge Collection in Colloidal Quantum Dot Solar Cells Arlene Chiu, Eric Rong, Christianna Bambini, Yida Lin, ChengChangfeng Lu and Susanna Thon; Johns Hopkins University, United States

Colloidal quantum dot (CQD) materials have many optoelectronic applications such as in photodetection, light emitting diodes and solar energy harvesting. However, CQD devices are limited in their efficiency in comparison to bulk semiconductor materials, particularly in the field of PbS CQD solar cells. We have identified the hole transport layer (HTL) as a critical component limiting the performance of these devices. Here, we introduce a new method of sulfur infusion via electron beam evaporation to the current ethanedithiol-passivated PbS CQD-based HTL (PbS-EDT), used in the highest-performing PbS CQD solar cell architectures, to increase the carrier mobilities and doping densities.

We used 1D optoelectronic simulations to identify specific factors associated with the HTL that limit the performance of PbS CQD solar cells, including low electron mobility, low doping density, and non-optimal energy band levels. Because the function of the HTL is to block electrons and transport holes, the discovery of low electron mobility in the HTL as a limiting factor in solar cell efficiency was an unexpected result. We hypothesized that this could indicate that significant photogeneration occurs in the HTL and that low electron mobility in this layer is therefore limiting the ability to extract those photogenerated charges. To further test this hypothesis, we increased the thickness of the PbS-PbX_2 (X = Br, I) CQD absorbing layer in simulations and found that there was a point at which an increase in electron mobility in the HTL no longer impacted the performance of the solar cell. This, along with optical simulations of the electric field distribution in the layered solar cell structure, confirmed our hypothesis.

Based on the results of the simulations, we aimed to develop a new HTL with high electron mobility and doping density. We performed stoichiometric control of the HTL by introduction of elemental sulfur to increase carrier mobilities and doping densities, testing effective sulfur thicknesses of 1-15 Å. To characterize our new HTL, we obtain doping densities using capacitance–voltage (Cap-V) measurements, carrier mobilities using space-charge-limited current (SCLC) measurements, and performed current density–voltage (J-V) measurements under simulated solar illumination to measure solar cell device performance parameters. We verified that our new HTL materials had increases in both doping density and electron mobility of an order of magnitude compared to the standard HTL materials, while the hole mobility remained relatively unchanged. We were also able to achieve a clear improvement in device performance of 1% absolute power conversion efficiency (PCE). The primary effects of our sulfur infusion method were an increase in electron mobility through reduction of the surface trap state density and an increase in p-type doping density by shifting the film stoichiometry. The improvement in these two properties correlated with an increase in the solar cell PCE through increases in the short circuit current and fill factor, as expected.

We demonstrated new HTL materials for CQD solar cells based on sulfur infusion of PbS-EDT CQDs that enable high electron mobility and doping density. Our new HTL increased device performance, from a maximum of 9.3% to 10.4% PCE. Elemental sulfur infusion is a facile and effective method to boost performance in PbS CQD solar cells and could provide a means for improved efficiencies in other PbS CQD-based optoelectronics.

2:15 PM NM05.08.07
Processability of a Thermally Stiffening Polymer Nanocomposite with Diffuse Interface Chen Gong[1], Donovan Weiblen[1], Deniz Rende[1], Pinar Akcora[2] and Rahmi Ozisik[1,1]; [1]Rensselaer Polytechnic Institute, United States; [2]Stevens Institute of Technology, United States

Thermally stiffening polymer nanocomposites were synthesized by chemically grafting or physically adsorbing a high-glass-transition-temperature polymer onto a nanofiller and then embedding this into a polymer matrix that has a glass transition temperature that is less than that of the grafted/adsorbed polymer. In the current study, we investigate the effect of extrusion at three different shear rates on the structure and properties of two different thermally stiffening polymer nanocomposites: poly(bisphenol A carbonate), PC or poly(2–vinyl pyridine), P2VP-adsorbed silica nanofillers embedded in a poly(ethylene oxide), PEO, matrix. Results were compared to bare silica containing PEO nanocomposites and neat PEO. Results indicate that extrusion at 80 °C led to some degree of agglomeration of the silica nanofillers and formation of structures at different length scales as characterized by small engle X-ray scattering (SAXS). Crystallinity of PEO was found to decrease upon extrusion in all nanocomposite samples but those PC and P2VP-adsorbed systems had higher crystallinity compared to bare-silica containing nanocomposites, and the crystallinity of P2VP-adsorbed system was the highest among all nanocomposite samples. This was attributed to the formation of nanofiller agglomerates and to the greater isolation of the matrix PEO chains from the silica nanoparticles due to the presence of adsorbed polymer layer; which were also supported with attenuated total reflectance–Fourier transform infrared spectroscopy (ATR-FTIR) results. Viscoelastic properties of the PC-adsorbed systems were found to recover their pre-extruded properties whereas all other nanocomposites showed large degree of decreases in their viscoelastic responses upon extrusion.

4:00 PM *NM05.09.01
Probing Crystallization Pathways of Aluminum Hydroxide Nanoparticles Xin Zhang[1], Ying Chen[1], Suyun Wang[1], Mehran Amiri[2], May Nyman[2], Sebastian Mergelsberg[1], Carolyn Pearce[1], Lili Liu[1], Mowei Zhou[1], Duo Song[1], Eric Bylaska[1], Jian Zhi Hu[1], Nancy Washton[1], Karl Mueller[1], Zheming Wang[1], James J. De Yoreo[1], Sue Clark[1] and Kevin Rosso[1]; [1]Pacific Northwest National Laboratory, United States; [2]Oregon State University, United States

Aluminum is the third-most abundant element in Earth's crust. As a result, aluminum hydroxide polymorphs, such as gibbsite, bayerite and nordstrandite are abundant minerals in soils and dominate aluminum ores. Because of their various properties such phases have been deployed widely as adsorbents, fire retardants, coatings, catalysts, and luminescence powders, as well as comprising important precursors to various alumina products. Understanding the crystallization pathways of the aluminum hydroxide polymorphs is thus important to geochemistry, environmental science, energy storage, catalysis, biomedicine, industrial processing, and even nuclear waste treatment. Here we use *in situ* magic angle spinning nuclear magnetic resonance (MAS-NMR), scanning electron microscopy (SEM), scanning/transmission electron microscopy (S/TEM), atomic force microscopy (AFM), small angle X-ray scattering (SAXS), X-ray absorption spectroscopy (XAS), electrospray ionization (ESI)-mass spectrometry, high resolution powder X-ray diffraction (XRD), and X-ray pair distribution function (PDF) techniques to probe the nucleation and crystal growth mechanisms of various aluminum hydroxide nanoparticles in details. By focusing on understanding the role of aluminum coordination change dynamics from tetrahedral in solution to octahedral in solids and vice versa, and by quantifying

intermediate polyoxoaluminate cluster formation, some unifying principles governing these transformations emerge. Furthermore, various advanced techniques reveal the transformation and aggregation of aluminum-oxo clusters during the hydrothermal process, which indicate cluster assembly pathways to aluminum hydroxide nanoparticle nucleation and crystal growth. These findings are important for developing new methods to morphology and size-controlled synthesis of aluminum hydroxide nanoparticles, and may aid in the design of chemical processes for managing the aluminum inventory in nuclear waste.

4:25 PM NM05.09.02

Laser Photothermal Nano-Assembly of Palladium Nanoparticles and 3D Porous Graphene Pilgyu Kang[1,1,1], Byoung Gak Kim[2], Seung Min Lee[1], Minsu Kim[2], Farbod Moghaddam[1], Daniel Mitchell[1] and Heeyoung Jeong[2]; [1]George Mason University, United States; [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

A facile, rapid, and scable manufacturing method for nano-assembly of palladium nanoparticles (PdNPs) and graphene is desired for broad applications in energy storage and harvesting, sensing and detection, and catalysis. However, existing approaches to obtain the organic-inorganic hybrid nanostructuress involve multi-step processes for synthesis of constituent elements. Graphene nanomaterials are synthesized by chemical vapor deposition and reduction of graphene oxides and metal nanoparticles are combined by electrodeposition, solution-based chemical processing, and thermal annealing. Laser-based method recently demonstrated rapid, cost-effective production of 3D porous graphene called laser-induced graphene (LIG) by pulsed laser irradiation of various polymers as a carbon/graphene precursor such as polyimide, and the laser method and LIG showed a promise to facile, scalable, rapid manufacturing of nanostructured graphene and functional devices for broad applications including sensing and detection, energy storage and harversting and nanocatalysts. However, the laser photothermal generation of inorganic-organic nanostructured composite materials has not been explored. Here, we present a one-step, rapid, scalable laser photothermal nano-assembly method to synchronously generate Pd NPs and porous graphene by using polymer films that contains Pd and carbon precursors. We use the polymers of intrinsic microporosity (PIM-1) as a graphene precursor, which has high solubility in volatile solvent and miscibility with inorganic materials. The outstanding compatibility with inorganic materials and solubility in volatile organic solvents of PIM-1 allow for homogeneous films without phase separation, and formation of the films only by removing volatile solvents at ambient condition. A pulsed CO_2 laser irradiation on the homogeneous films of PIM-1 and Pd-ligands induces localized graphitization (carbon atoms in the polymer chains become sp^2 hybridized) yielding nano- to microscopic 3D porous graphene while the organic functional groups of Pd-ligands are vaporized and Pd atoms nucleate and crystallize in nanoparticles. Thus, our laser-induced photothermal local heating yields synchronous nano-assembly of highly dense and monodispersed PdNPs in porous nanostructured graphene. Based on low energy requirements of PdNPs to form palladium hydrides (PdHx) and exceptional electrical properties of the porous graphene including high conductivity and electron mobility we used the laser nanomanufactured hybrid nanostructures for highly sensitivity hydrogen gas sensing with the limit of detection down to 1 ppm. We also demonstrated fast and reversible hydrogen gas detection in the range of 1-50 ppm H_2, which is attributed to chemical reversibility of the hybrid nanostructues. We showed mechanically flexible, wearable H_2 sensor with outstanding mechanical flexiblity and reliability of the hybrid nanostructues under cyclic bending strain of 0.22% as well as cyclic twisting angles of ±90° up to 10,000 cycles. Furthermore based on our hybrid nanostructures we developed a wireless H_2 gas sensor platform enabling monitoring with a smartphone. Our approach combining the laser photothermal method and the versatile polymer of the PIM-1 has potential to manufacture hybrid nanostructred materials of various metal nanoparticles and porous graphene for broad fields in energy storage and harvesting, sensing and detection, and catalysis as well as diverse applications including electrochemical sensors, gas storage systems, and supercapacitors.

4:40 PM NM05.09.03

Late News: How 3D Printed Polymeric Scaffolds Optimize Geometry, Mechanical Stability and Photocatalytic Performance of Nanoparticle-Based Aerogels Murielle Schreck, Nicole Kleger and Markus Niederberger; ETH Zürich, Switzerland

Photocatalytic hydrogen production is one of the most important techniques, which have to be part of a sustainable energy system to ensure the survival of our polluted planet. The search for the most efficient photocatalyst for this technique includes not only finding the right material, but as importantly, finding the right structure. We suggest 3D, translucent, nanoparticle-based aerogel monoliths as promising candidates for the photocatalytic hydrogen production in the gas phase. To achieve the best photocatalytic performance, the right fit between the geometries of especially 3D photocatalysts and reactors measuring their performance is crucial. Here, we report how we take control of the geometry of the photocatalyst by introducing 3D printed polymeric scaffolds into the aerogels. Thanks to these scaffolds, we can investigate the gas flow through the aerogel, the UV light penetration into the aerogel and the optimal fit with our custom-made continuous gas flow reactor to maximize the hydrogen production rate. We manage to raise the hydrogen production rate from originally 433 $\mu mol\ g^{-1}\ h^{-1}$ by a factor of almost 4 to 1578 $\mu mol\ g^{-1}\ h^{-1}$ just by modifying the geometry of the aerogels. Additionally, the rigid scaffolds enhance the mechanical stability of the fragile aerogels, increasing the fabrication yield and, therefore, saving material, money and time. With the possibility to engineer these 3D printed polymeric scaffolds, we can match the geometry of any 3D, template-free, self-supporting photocatalyst to the geometry of reactors built for any photocatalytic gas phase reaction and maximize the photocatalytic performance.

4:55 PM NM05.09.04

Late News: Printable Dielectric Thin Films of Metal-Polymer Core-Shell Nanoparticles Roman Buchheit[1], Björn Kuttich[1], Lola González-García[1] and Tobias Kraus[1,2]; [1]INM – Leibniz Institute for New Materials, Germany; [2]Saarland University, Germany

Printable dielectrics are important materials for flexible and inkjet-structured electronics. Many of them are composites with a polymer and a nanoparticle component. Non-conductive nanoparticles, for example oxides with high dielectric constant, form dielectric composites that can be described by effective-medium theory and often contain a large volume fraction of particles [1]. Conductive metal nanoparticles at low concentrations form dielectric polymer composites with properties that are usually discussed using percolation theory [2]. The volume fraction of the metal has to be kept low in order to avoid short circuits.

Here, we present a dielectric material with a microstructure and properties that range in between the two cases introduced above. We electrically insulate conductive gold nanoparticles with a covalently bound polystyrene shell. These hybrid core-shell nanoparticles are then dispersed and deposited in thin dielectric films. The distribution of the gold in the polystyrene matrix is controlled by the structure of the covalently bound polymer shell and its interactions. We tune the amount of the organic phase in the final dielectric layer by different conditions during ligand exchange, which leads to different polymer ligand densities on the gold core.

We will discuss the dielectric constants and the microstructure of dielectric layers prepared from ink of core-shell hybrid nanoparticles with 5 nm diameter gold cores and thiol-terminated polystyrene shells (PS) of different molecular weights (M_n=5000 Da or M_n=11000 Da) with different densities. Thermal Gravimetric Analysis (TGA) data of the dry films indicated gold volume content between 4.9 vol% and 21.1 vol% depending on the polymer shell density. Small-Angle X-ray Scattering (SAXS) and Transmission Electron Microscopy (TEM) revealed different microstructures of the dielectric films that ranged from crystalline bcc packings to fully disordered, but homogeneous packing as visible in TEM. Impedance measurements in the frequency range from 100 Hz up to 1 MHz indicated a dielectric constant of 3.5 for the highest grafting density of polystyrene at a dielectric loss of below 2% at 1 kHz, while the lowest grafting density of polystyrene led to a dielectric constant of up to 40 with a dielectric loss of below 5% at 1 kHz.

We believe that the covalent attachment of polymer ligands to metal cores is a promising approach to "molecular hybrid" films that can be deposited by wet processing without agglomeration. Our approach solves the problems of particle agglomeration in earlier nanocomposites of metal nanoparticles in polymers at high particle loading [3,4]. The strong attachment of the insulating polymer ligands prevents dielectric failure that otherwise besets nanocomposites at increased metal contents.

Light Activated Gas Sensing Application of Assembly of Sol-Gel Synthesized CuO Bundles Rutuja Bhusari, Jean-Sébatien Thomann and Renaud Leturcq; Luxembourg Institute of Science and Technology, Luxembourg

Chemiresistive gas sensors based on sol-gel synthesised colloidal materials with controlled size, shape and composition have demonstrated notable sensing properties [1]. In our earlier work we showed that ordered assemblies of ZnO nanorods produced in solution via wet chemical synthesis lead to formation of network like structures on electrodes, with sensing capabilities at room temperature [2]. Current passing through such a network between one electrode to another, is modulated based on the surface chemistry taking place between surrounding environment and material deposited [2].
In this work, we extend our previous work to assembly of CuO bundles forming a network between gold electrodes. Copper oxide (CuO) is a well-known p-type material used for variety of applications including chemiresistive gas sensors. CuO is known to have excellent optical and chemical properties which can be tuned for variety of applications. For example, Hou et al. have studied study the effect of morphology and surface structure of CuO nanostructures on the CO sensing properties [1]. In addition to this, CuO nanostructures have been found to be sensitive to a variety of reducing and oxidising gasses [2, 3, 4]. In this work, synthesis and characterisation of CuO bundles network is presented, followed by sensing response towards oxygen. The properties are tuned by annealing of the network, which acts on the junctions between the bundles. Moreover, we investigate the optical properties of such an assembly of structures to improve its electrical characteristics and enhance its gas sensing response using light activation.

Resolving the Atomic Structure of Sequential Infiltration Synthesis Derived Indium Oxyhydroxide Clusters Alex Martinson, Xiang He and David Tiede; Argonne National Laboratory, United States

Sequential infiltration synthesis (SIS) is a route to the precision deposition of inorganic solids in analogy to atomic layer deposition (ALD), but occurs within (vs upon) a soft material template. We reveal a possible pathway for the sequential infiltration synthesis of InO_xH_y clusters in a PMMA host matrix and the inorganic films (after annealing) composed of sub-6 nm In_2O_3 nanocrystals. Interestingly, small InO_xH_y clusters with only

1 to 3 In atoms were found to form after a single SIS cycle. These small InO_xH_y clusters serve as sites for reaction in subsequent cycles and/or subsequent condensation with other small nuclei that first proceeds linearly and, later, more three-dimensionally. Although the structures of as-grown InO_xH_y clusters lack long-range crystallographic order, they exhibit local coordination environments similar to cubic In_2O_3 and $In(OH)_3$. Crystallization of the InO_xH_y clusters is easily achieved by annealing the hybrid InO_xH_y/PMMA thin films in air, which leads to the formation of denser, but still microporous, In_2O_3 thin films. The size and subtleties of the In_2O_3 structure depend on the number of SIS cycle used to deposit the inorganic phase before annealing. Lattice expansion, longer In-O bond lengths, and larger atomic displacement were observed in samples with greater SIS cycles. These methods and findings may provide fundamental insights into other SIS processes as well as map a route to the precision synthesis of discrete-atom-number clusters.

5:40 PM NM05.09.07
Investigation of Optical Properties of TiO_2, WO_3, and Y_2O_3 Nanoparticles Sergey Mamedov; HORIBA Scientific, United States

Metal oxide nanoparticles are attractive materials for many applications but have recently become an essential part of dye-sensitized solar cells and highly efficient catalysis materials. The material's efficiency depends on size, shape, and surface chemistry, which critically determine their properties and interaction.
Raman spectroscopy is a powerful method to investigate nanoparticles' vibrational properties, as the Raman band's peak and width are very sensitive to the local structure. Besides, phonons' behavior at the nanoparticles boundary strongly depends on the particle size and is a critical factor in creating a highly efficient material. It was shown that the Raman peak of TiO_2 at 142.9 cm^{-1} shifted to a high-frequency region with a decrease in the nanoparticles' size. However, Raman spectroscopy of nanopowders of WO_3 and Y_2O_3 were not investigated yet. Nanopowders of TiO_2, WO_3, and Y_2O_3 with the mean size ranged from 5 to 40 nm were investigated by Raman spectroscopy in the broad spectral range. The phonon confinement model was applied to calculate the Raman spectra of these materials. The correlation length of the phonons calculated from the spectra of nanoparticles shows a significant difference between large (> 40 nm) and small (<10 nm) nanoparticles. Grain size can be extracted from the Raman spectra of nanomaterials by applying a model of confined phonons. Results showed a good correlation between grain sizes obtained from Raman spectra and XRD. Raman spectra are more sensitive to nanoparticles' structural motive compared to XRD. The Raman spectra may be different even if X-ray diffraction shows that the particle size is the same. It reflects the differences in the surface structure of nanoparticles.

Late News: Direct White Light Emission (WLE) via Controlling the N Doping Centres in Carbon Dots (CDs) Barun K. Barman and Tadaaki Nagao; National Institute for Materials Science, Japan

Direct white light emission (WLE) from single-component emitters, free from rare-earth and toxic metals have been strongly required in industry, but it is still a grand challenge. Recently, fluorescent carbon dots (CDs) has emerged as a new class of metal-free luminescent materials that are composed mainly of C, O, H. Their fluorescence properties are tuned by the doping centre and surface functional groups leading to multiple emission in the entire visible spectra. The systematic investigation of the N-doping centres and surface functional groups has provided a vital understanding of the emission property. For example, the optimized synthetic strategy enabled us to dope graphitic N centres and lead to the broadband WLE extended in the entire

visible spectra (400 to 750 nm). The decrease or increase of the graphitic N centres into the CDs led to the green and orange emission, respectively. Because the graphitic N creates mid-gap states within the HOMO−LUMO gap of the pristine CDs, as a result, the light absorption is red-shifted which gives rise to the low energy fluorescence in the visible spectrum. These as synthesized CDs show direct and ideal WLE both in solution and in solid forms with CIE value of (0.33, 0.34) and high colour rendering index (CRI 92). These CDs can form transparent and efficient WLE film with long term stability, when they are mixed in the polymer matrix and excited via UV light. This study provides an important guiding principle for CDs syntheses for realizing spectrally tuned emission and direct WLE.

8:00 PM NM05.10.02
Late News: Ammonia Uptake of a Metal Organic Framework Adsorbent from Ultralow to Ambient Pressure Dae Won Kim[1], Dong Won Kang[1], MInjung Kang[1], Jung-Hoon Lee[2], Jong Hyeak Choe[1], Yun Seok Chae[1], Doo San Choi[1], Hongryeol Yun[1] and Chang Seop Hong[1]; [1]Korea University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Even though various porous adsorbents have been examined as NH_3 capture applications, these materials generally displayed insufficient NH_3 uptake, low affinity at the ppm level, and poor chemical stability against humid NH_3. Herein, we report the NH_3 capture properties of iso-reticular series metal-organic frameworks M_2(dobpdc) (M= Mg, Mn, Co, Ni, and Zn) that contain open metal sites. Among the series, the Mg analogue recorded highest ammonia uptake, outperforming any other existing benchmark materials with 23.9 mmol g^{-1} at 1 bar and 8.25 mmol g^{-1} at 570 ppm in ambient temperature. From the NH_3-temperature programmed desorption curves we could compare the strength of the interaction between NH_3 and Lewis acidic open metal sites and activation energy of desorption of NH_3, which was further supported with van der Waals-corrected density functional theory calculations. The structural stability of Mg_2(dobpdc) upon exposure to wet NH_3 was superior to that of the other M_2(dobpdc) and the frameworks tested, displaying intact structural integrity over 3 days. The NH_3 breakthrough experiments in humid conditions revealed that Mg_2(dobpdc) could selectively capture NH_3 in wet conditions without structural degradation or capacity loss for multiple cycles. The NH_3 adsorption mechanism of Mg_2(dobpdc) in dry and wet conditions was elucidated with in-situ FT-IR spectroscopy, showing that ammonium ion was accompanied in wet condition. To summarize, these results demonstrated that Mg_2(dobpdc) is a recyclable compound that selectively capture NH_3 with significant NH_3 affinity and capacity. We envision that Mg_2(dobpdc) is promising candidate for real-word NH_3-capture applications.

8:05 PM NM05.10.05
Late News: Fundamental Study of the Dispersion of Carbon Nano-Onions Armando J. Nieves-Carrasquillo, Angelica Del Valle-Perez and Lisandro Cunci; Universidad Ana G. Méndez, Puerto Rico

Multi-shell fullerenes, known as carbon nano-onions (CNOs) discovered by Ugarte in 1992, are structured by concentric shells of carbon atoms. Different methods for their synthesis have been developed and their properties have been widely studied. The chemical functionalization of CNOs has been investigated and several synthetic pathways were found to be applicable for the introduction of a variety of functional groups. CNOs exhibit poor solubility in both aqueous and organic solvents due to aggregation. This is promoted by strong intermolecular interactions such as van-der-Waals forces. To overcome this tendency to aggregate, functionalization of the surface of the carbon materials is the method of choice. The purpose of this project is to make the oxidized CNOs bear a relative centrifugal force at different time durations. Analyzing between two functionalizing methods, furnace and via synthesis. How well the material disperses, provides a fundamental concept for the synthesis efficiency. According to preliminary results, there is a tendency on which the concentrated CNOs (obtained via synthesis) difference in weight gets narrow, as duration of the centrifugal force increases. Because of their structure, high conductivities, and dispersion properties, CNOs acquired by synthesis are often used as conductive additives in electrochemical energy storage devices, such as battery and supercapacitor electrodes, where an increase in the rate performance (power) of the device is necessary. Chemically modified CNOs were probed in different fields of application and have revealed to be a promising nanomaterial that attracts a growing interest among researchers and opens new avenues for investigation. CNOs

can be implemented as a catalytic support. In addition, this material can be used as a metal-free catalyst that can increase its catalytic performance by doping with polymers providing nitrogen or phosphorus atoms to the surface. Both methods start using nano-diamonds; a carbon nanomaterial of strong structure which undergo a temperature of approximately 1650°C inside a furnace to obtain the CNOs structure. The CNOs oxidized through synthesis requires a constant temperature and stirring to attain oxygen based functional groups. The preliminary elemental detection of oxygen atoms was gathered by Energy-Dispersive Spectroscopy. To detect states in the CNO's molecular system, Raman Spectroscopy was utilized to confirm the carbon structure of CNOs by the identification of the peaks D and G characteristic of this carbon material. An in-depth characterization analysis was done using X-Ray Diffraction, providing detailed information about chemical composition, and crystalline structure. The morphology and microstructure of CNOs were studied using a Transmission Electron Microscope and Scanning Electron Microscopy.

8:10 PM NM05.10.06
Late News: The Rates of Unlayered Graphene Formation in a Supercooled Carbon Melt at Low Pressure
Philip Chrostoski, Chathuri Silva and Philip Fraundorf; University of Missouri, United States

Elemental carbon has important structural diversity, ranging from nanotubes through graphite to diamond. Previous studies of micron-size core\rim carbon spheres extracted from primitive meteorites; whose isotopic signatures indicate an origin in red-giant star nucleosynthesis [ApJLett **578** L152 (2002), Elements **10** 441 (2014)], suggest they formed around such stars via the solidification of condensed carbon-vapor droplets, followed by gas-to-solid carbon coating to form the graphite rims. Similar core\rim particles result from the slow cooling of carbon vapor in the lab [Hundley LPSC 2018 HAL-02238804]. Although experimental indications from particle slicing suggest that this core material may not have special strength, it's properties as a diffusion barrier may be quite interesting if one can synthesize material with graphene sheets as large (e.g. 600 atoms or 4 nm widths) and abundant (e.g. 6x1019/cc) as we find in the presolar cores [M&M **26** 2838 (2020)]. Although we've not yet done any percolation theory modeling, the small size of pores in a single graphene sheet [Nature **579** 229 (2020)] suggest that this material may be able to stop diffusion of even small atoms like helium over astrophysical (not just geologic) time scales. Before working on oven design, we first want to model nucleation and growth as a function of time at temperature to see what laboratory conditions are likely to be required. This is also relevant, of course, for astrophysicists in understanding conditions of carbon condensation around the types of stars that created the carbon atoms of which we are made [COSPAR 2021]. Our preliminary results suggest that the presolar cores solidified over longer times (say tens of seconds) at lower temperatures (say 2400K) compared to the laboratory cores (say tenths of seconds) at higher temperatures (say 3050K). The analytical models so far follow the "few parameter" approach of Turnbull and Fischer [JChemPhys **17** 71 (1949)] for reaction (not diffusion) limited nucleation & growth. Using this model, with preliminary energy values extracted from atomistic data and/or experimental constraints in the lab-grown case, we generated an analytical growth model to compare with pre-solar and lab-grown data, which gave us the above-quoted preliminary numbers. We looked at our "liquid model" systems for set temperature molecular dynamics anneals at experimentally-estimated densities of 1.8 g/cc. Our system had a 42-atom graphene sheet with the rest of the liquid atoms randomly placed with a nearest neighbor > 1.9 Å. Looking at 2D growth, we see when at temperatures ranging from 1700 – 4200 K the growth rate increases as temperatures increase. Future work to refine these models will hopefully generate better-constrained energy values from our atomistic simulations, to use with such analytical models. Along with this, downward temperature ramps will be examined instead of fixed temperature anneals as rates of cooling are likely the key parameter in both laboratory and astrophysical settings. We will also be looking at models for supercooling thresholds with containerless liquid metals – [*Nucleation in Condensed Matter* (2010)] and the uses of dynamical atomistic models of both nucleation and growth [JPetrology **54** 913 (2013), *Handbook of Continuous Crystallization* (2020)].

8:15 PM NM05.10.07
Magnetoactive Multi-Walled Carbon Nanotube for 3D Motion Tracking Electroluminescence Display
Seung Won Lee, Chanho Park, Hyeokjung Lee, Kyuho Lee and Cheolmin Park; Yonsei University, Korea (the Republic of)

Development of human-interactive display enabling the simultaneous sensing, visualisation, and memorisation of a magnetic field remains a challenge. Here we report a skin-patchable magneto-interactive electroluminescent display, which is capable of sensing, visualising, and storing magnetic field information, thereby enabling 3D motion tracking. An alternating current (AC) EL display is developed with a magnetoactive conductive fluid of multi-walled carbon nanotubes (MWNTs), decorated with superparamagnetic iron oxide (Fe3O4) nanoparticles, in n-hexadecane on which an AC-field responsive emissive layer is placed with two parallel electrodes. By constructing mechanically flexible arrays of magneto-interactive displays, a spin-patchable and pixelated platform is realised. The magnetic field varying along the z-axis enables the 3D motion tracking (monitoring and memorisation) on 2D pixelated display. This 3D motion tracking display is successfully used as a non-destructive surgery-path guiding, wherein a pathway for a surgical robotic arm with a magnetic probe is visualised and recorded on a display patched on the abdominal skin of a rat, thereby helping the robotic arm to find an optimal pathway.

8:30 PM NM05.10.10
Efficient Radiative Cooling of Low-Cost $BaSO_4$ Nanoparticle-Paper Dual-Layer Thin Films Andrea L. Felicelli, Joseph Peoples, Jie Wang, George Chiu and Xiulin Ruan; Purdue University, United States

Radiative cooling allows for effective dissipation of heat into deep space, making it an environmentally clean as well as passive cooling technology. It has been shown to be effective at reducing energy consumption from the cooling requirements of many widespread systems including commercial and residential buildings and outdoor electronic equipment. The development of versatile and cost-effective materials with good radiative cooling performance is critical to furthering the range of applications of this technology as well as improving the potential for the technology within existing applications. The $BaSO_4$ nanoparticle-embedded coatings we have developed have consistently shown strong radiative cooling performance with a solar reflectance of greater than 95% and an emissivity of greater than 0.90 in the "sky window", which is the region of the atmosphere that is transparent (corresponding to 8-13 μm wavelengths). These performance parameters demonstrate these coatings to be a potentially promising material to continue to study for radiative cooling applications. Specifically, it is also highly desirable to reduce the coating thickness and preserve the high performance. Doing so promotes cost-effectiveness and maintains energy savings that the material can provide. The work presented demonstrates a thin and cost effective dual-layer $BaSO_4$-paper structure with a high radiative cooling performance. We have coated $BaSO_4$-nanoparticle–embedded layers with varying thickness on transparency films or commercial cotton-based paper, which allowed us to form a series of dual-layer thin films. Their spectral and total optical reflectance, transmittance and absorptance (or emissivity) are characterized across the ultraviolet, visible, near-infrared and mid-infrared wavelength range. The results allow for the decoupling of the effects of the developed $BaSO_4$ nanoparticle-embedded coatings from the effects of moderately-to-highly reflective substrates they may be applied over, demonstrating the effectiveness of the coatings themselves for radiative cooling applications versus other surfaces that appear visually similar. Furthermore, the transparency film substrates alone show high emissivity in the sky window but low reflectance in the solar spectrum, while the inexpensive and widely-available commercial cotton-based paper shows high emissivity in the sky window and moderately high reflectance in the solar spectrum. We have been able to demonstrate that by coating the paper with just a thin layer of our $BaSO_4$-based nanocomposites, we can significantly increase its radiative cooling performance to be comparable with other state-of-the-art approaches. This is demonstrative that the developed $BaSO_4$ nanoparticle-paper dual-layer film could be a cost effective and high performance radiative cooling material at small thicknesses.

8:45 PM NM05.10.12
Brown TiO_2 Incorporated Novel 3D MXene as Efficient ORR/OER Electrocatalysts for Lithium-Air Batteries Nur Aqlili Riana Che Mohamad, Haeji Hong, Filipe Marques Mota and Dong Ha Kim; Ewha Womans University, Korea (the Republic of)

A key step to assure the practical application of Li-air batteries involves replacing O_2 with air due to their

expected high practical specific energy densities from 1000 to 2000 Wh kg^{-1} which could even match with 1700 Wh kg^{-1} of the gasoline energy system. The Lithium-air batteries involve the oxygen reduction reaction (ORR) during the discharge and the oxygen evolution reaction (OER) in the charging process thus structured ORR/OER electrocatalyst greatly governs the performance of the battery. The promising 2D materials like MXene gained much attention over recent years due to the displayed properties of both ceramics and metals, such as high electrical and thermal conductivity, certain softness, unusual damage tolerance, as well as excellent oxidation resistance, and withstand the volumetric expansion during lithiation. In order to maximize the benefits of MXene, the utilization of 3D MXene could further provide a larger surface area with high exposed specific active sites, high robustness, and 3D conductive network. In this study, we accessed the promise of incorporating the active and stable oxygen vacancies in Brown TiO_2 into the novel 3D network of MXene which is believed to accelerate the Li_2O_2 formation and decomposition by lowering the reaction energy barrier of the reversibly decomposing discharge products. Coupled electrochemical and spectroscopic analyses in the present study disclose the systematic discharge formation and decomposition through the controlled tailoring of active vacancy sites as well as manipulating the morphology of novel 3D MXene network.

8:50 PM NM05.10.15
Late News: Design and Engineering of Cu2O-CuO Nanostructured Heterojunctions Subish John and Somnath C. Roy; IIT Madras, India

Heterojunction design is an effective strategy for seperation of photogenerated charges and reduce recombination in a semiconductor. In the nanostructured form, such heterojunctions have the added advantage of higher specific surface area that serves as efficient catalyst , chemical sensors etc. CuO and Cu_2O , both *p* type materials with the band gap values of 1.6 and 2.1 eV respectively, form type II heterostructure , wherein electrons and holes are favorably seperated and migrate in opposite directions. The heterojunctions between these materials have been studied in planer or thin film configuration. Here we present fabrication of Cu_2O nanowire- CuO nanoflake heterojunctions fabricated by a combination of electrochemical anodization followed by hydrothermal porcessing techniques. The Cu_2O nanowires formed by electrochemical anodization of Copper foil are treated in hydrothermal conditions at 150 ºC to grow CuO nanoflakes in a perpendicular direction on the nanowire surface. Such nanoscale 3D morphologies result in a photocurrent an order of magnitide higher than bare Cu_2O nanowires. The heterojunction system is characterised by x-ray diffraction, scanning and transmission electron microscope, optical absorption spectrocopy and photoelectrochemical impedance spectroscopy. Our investigations indicate that, in addtion to solar energy harvesting, the Cu_2O-CuO nanostructured heterojunctions can also be potentially effective in rechargable batteries and supercapacitpr applications.

Assembling Magnetic Nanoparticles into Superparamagnetic Nanocomposites Dale L. Huber; Sandia National Laboratories, United States

Magnetic nanoparticles can exhibit a property known as superparamagnetism where they have extremely high susceptibility and a complete absence of magnetic hysteresis. This would represent an ideal inductor or transformer material if it could be maintained in a bulk material. To do this, magnetic nanoparticles must be densely packed without touching, as contact would lead to the formation of ferromagnetic domains and loss of superparamagnetism. The formation of bulk superparamagnetic materials can be discussed in terms of two

fundamental steps. The first is the large-scale synthesis of precisely size controlled magnetic nanoparticles, and the second is the densification of these particles into a highly magnetic material. The properties of magnetic nanoparticles vary dramatically with size, with an abrupt transition from superaparmagnetic to ferromagnetic behavior. The highest magnetic susceptibility, however, is typically found just before this transition to ferromagnetism. Therefore, careful control of particle size and reproducibly of particle size are critical for real world application. The chose approach here is high temperature decomposition reactions with precise control over reaction kinetics. The second required step is densification while maintaining a critical separation. As particles move closer together, they undergo an abrupt transition where they begin forming multi-particle ferromagnetic domains. An ideal nanocomposite would be close to this critical distance to maximize magnetic particle loading without showing deleterious interparticle magnetic interactions. Careful control of the particles' surface chemistry and appropriate chemical crosslinking can generate strong nanocomposites with excellent magnetic properties that extend to the MHz frequency regime with low losses and little to no decrease in susceptibility. We have designed and synthesized a number of these composites and are currently investigating their application in high frequency switching circuits for power electronics. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

2:40 PM NM05.11.02

Functional $Sr_{0.5}Ba_{0.5}Sm_{0.02}Fe_{11.98}O_4/x(Ni_{0.8}Zn_{0.2}Fe_2O_4)$ Hard-Soft Ferrite Nanocomposite Material—Structural, Magnetic and Microwave Analyses Sadik Güner[1], Yassine Slimani[2], Munirah A. Almessiere[2], Alex V. Thrukhanov[3] and Abdulhadi Baykal[4]; [1]RWTH Aachen University, Germany; [2]Imam Abdulrahman Bin Faisal University, Saudi Arabia; [3]National University of Science and Technology MISiS, Russian Federation; [4]Institute for Research and Medical Consultations (IRMC), Imam Abdulrahman Bin Faisal University, Saudi Arabia

The structural, magnetic and microwave characteristics of $Sr_{0.5}Ba_{0.5}Sm_{0.02}Fe_{11.98}O_4$ (SrBaSmFe) and $x(Ni_{0.8}Zn_{0.2}Fe_2O_4)$ (NiZnFe) 1:x ($0.0 \leq x \leq 3.0$) hard/soft ferrites nanocomposites (NCs) are presented in this study. SrBaSmFe/*x*(NiZnFe) hard/soft ferrite NCs were synthesized applying one-pot citrate combustion approach. The structural analyses of all NCs were performed via XRD, SEM, TEM and HR-TEM. Room temperature (RT) 300 K and 10 K magnetization curves were investigated by VSM measurements. Both RT and 10 K magnetization and coercivity data have maximum values for SrBaSmFe/1.0(NiZnFe) NCs (i.e. $x = 1.0$) and continuously reduce with the increasing weight fraction of NiZnFe soft ferrite. Some magnetic hysteresis loops are seen with a kink shape. Magnetic analyses revealed the ongoing hard ferrimagnetic nature of NCs at both temperatures. Squareness ratios (SQRs) were specified to be inferior to the theoretical limit value of 0.50, assigning the multi-magnetic domain nature for NCs. The plots of switching field distribution (SDF) showed the presence of two distinct peaks. This means that the exchange coupling was not accomplished in these NCs by one-pot approach. Frequency dependence of microwave characteristics were discussed utilizing co-axial method in frequency range 0.7-18 GHz. Non-linear dependences of the main microwave properties with varying composition rate might originate from the soft magnetic phase influence. Behavior of the microwave properties are correlated well with the composite theory.

2:55 PM NM05.11.03

Late News: Single Nanoparticle and Virion Mass Spectrometry in Air by Self-Focusing Nanomechanical Sensors Selim Hanay[1], Ramazan Tufan Erdogan[1], Hadi Pisheh[1], Mohammed Alkhaled[1], Mehmet Kelleci[1], Hashim Alhmoud[1], Ilbey Karakurt[1], Batuhan E. Kaynak[1], Cenk Yanik[2] and Aykut Özkul[3]; [1]Bilkent University, Turkey; [2]Sabanci University, Turkey; [3]Ankara University, Turkey

The COVID-19 pandemic highlighted the necessity to develop rapid *in situ* viral detection techniques to isolate infection breakouts. Current biochemical detection techniques, such as polymerase chain reaction (PCR), remain inadequate for initial response due to the delay associated with sequencing the viral genome and reagent development. Alternatively, physical properties of the virus such as mass and size can be quickly profiled and utilized for rapid detection using mass spectrometry (MS). The recent developments in Nanoelectromechanical Systems (NEMS) have made it possible to measure the mass of single particulates with high accuracy; however,

significant challenges still exist in adapting NEMS-MS for real-life samples. Sample delivery to the sensing element generally requires the use of delicate vacuum systems and the sensing element suffers from low capture efficiency due to its miniscule size. Here, we develop a NEMS-MS device with an integrated polymeric electrostatic lens to enhance the capture efficiency by several orders-of-magnitude compared to the state-of-the-art, while allowing for operation under atmospheric conditions. After benchmarking and validating device performance with polystyrene and gold nanoparticles, we successfully detected the mass of single inactivated SARS-CoV-2 virions from cell lysates with minimum sample preparation. The results establish NEMS technology as an effective approach for the label-free detection of nanoparticles and emerging viruses.

3:10 PM NM05.11.04

Liquid Porous Nanomaterials for Liquid-Liquid Extraction Justine Ben Ghozi-Bouvrande, Sandrine Dourdain and Stéphane Pellet-Rostaing; Institut de Chimie Séparative de Marcoule, CEA, CNRS, ENSCM, Univ.Montpellier, France

Nowadays, separation of chemical elements is an important stake for applications as broad as ore mining, metal recycling or pharmaceutical industry. Although liquid-liquid extraction represents the most applied method at industrial scale, it involves many economic and environmental constraints related to the use of large quantities of solvents. There is therefore a growing interest for alternatives as solid-liquid separation and flotation processes, which however, would require re-designing the actual industrial installations. These alternatives present moreover limited performances, in terms of extraction and selectivity capacities. This project proposes to evaluate a new approach by replacing the organic phases of liquid-liquid extraction processes, with a porous liquid. The Oak Ridge Corporation proposed in 2014 [1], a new class of porous liquid, based on hollow silica nanospheres (HS) obtained by a surfactant templated silica sol gel. To form the “liquid material”, the HS are grafted with an organosilane and a PEG. This ionic bond between the functions gives the interesting property to render the HS liquid and to provide solid empty cavities in a liquid state, without any solvent. In this work, we evaluate the application of such liquid empty cavities to extract metals from an aqueous phase. This extraction approach would be at the exact junction between the conventional liquid-liquid and solid-liquid extraction processes, taking the advantages of the two processes.

To form the porous liquid, HS were prepared thanks to the self-assembly of a surfactant in presence of oil and silica precursors. After the synthesis, the surfactant is removed by calcination and monodisperse HS are made. Various synthesis parameters were investigated to control and understand the morphology of the HS. Indeed, the size of the core, the shape and the homogeneity of the particles could be changed and controlled.

TEM micrograph and SAXS data showed that we obtain highly monodisperse HS with a core radius of 6nm and silica shell of 7nm.

The HS are further grafted with an organosilane and a PEG interacting thanks to an ionic bond. This ionic corona has the property to turn the solid nanospheres into a liquid material.

For extraction application, it appears essential to characterize in details the structure and the permeability of these HS, not only to metallic species but in the first place, to aqueous solutions and gaz.

In order to optimize the synthesis route for enhanced permeability, adsorption of argon and nitrogen were carried out with the solid and the liquid to highlight the accessibility to gas of the porosity throughout all the steps of grafting. Gaz sorption reveals that the porosity is becoming less accessible after the grafting step, which means when the solid becomes liquid. This first result showed that the synthesis procedure has to be optimized to limit this loss of opened porosity (which may be due to a closure of the microporous network present in the silica shell of the HS).

An adsorption study was also conducted with liquid solutions by matching the contrast of various solvent and silica by SAXS and SANS to rely the permeability and the pores structure. The SANS signal of the non-grafted HS was completely extinguished with a H_2O/D_2O ratio matching the scattering length density of nanosphere’s silica. It allowed us understanding the permeability of reference HS to solvent, specifically if and how the grafting influences the solvent permeability.

Finally, some preliminary extraction tests performed on the solid non-grafted HS, showed that significant amounts of metallic cations can be extracted.

This study confirm that all the synthesis process has to be optimized and understood to maintain the extraction

efficiency of the material when it is in the liquid state.

Synthesis and the Magnetocaloric Behavior of La0.7Sr0.3MnO3/$SrFe_{12}O_{19}$ Nanocomposites Surendra Dhungana, Sanjay R. Mishra and Dipesh Neupane; The University of Memphis, United States

Recently there has been a renewed interest in exploring novel materials with a large magnetocaloric effect (MCE), due to the fact that solid magnetic refrigeration potentially could replace gas refrigerants. The ferromagnetic perovskite manganites have drawn attention due to its outstanding physical properties as this system displays a rich phase diagram in the magnetotransport, structural properties, and magnetocaloric. The typical way to enhance the MCE is to introduce an insulating phase to the grain boundaries and at the surfaces of manganites as a second phase. Therefore, the composite of the high resistive second phase compound and manganite could be an effective route to improve the MCE properties. In this view, the study is being conducted to understand the impact of the second phase ($SrFe_{12}O_{19}$) on the magnetization and magnetocaloric effect of the $La_{0.7}Sr_{0.3}MnO_3$ manganites. With the possibility of the exchange interaction between soft $LaSrMnO_3$ and hard-$SrFe_{12}O_{19}$, a modulation in MCE in the composite is expected.

One-pot auto-combustion technique followed by calcination at 1100 C was used to prepare magnetically hard-soft $x SrFe_{12}O_{19}$-x (100-x) wt % $La_{0.7}Sr_{0.3}MnO_3$ (x=0, 10, 20, 30, 40, 100) nanocomposites using nitrite salts. X-ray diffraction (XRD) and scanning electron microscopy (SEM) were used to characterize the structural properties of the samples. The XRD plots showed no trace of secondary phases in the composite. The hexagonal structure (spacegroup-P63) of $SrFe_{12}O_{19}$, as well as the perovskite cubic structure (spacegroup-Pm-3m) of $La_{0.7}Sr_{0.3}MnO_3$, were confirmed. Furthermore, magnetic and magnetocaloric properties were studied using SQUID analysis. An exchange coupling behavior was obtained between the soft $LaSrMnO_3$ and the hard $SrFe_{12}O_{19}$ phase. Magnetic isotherms are being collected using PPMS to study the magnetocaloric effect in the as-synthesized composites.

Single Molecular Magnet(SMM) Induced Strong Antiferromagnetic Exchange Coupling on a Magnetic Tunnel Junction Based Molecular Spintronics Device Pawan Tyagi, Edward Friebe and Christopher D'Angelo; University of the District of Columbia, United States

Monte Carlo simulations were performed to study the effect of magnetic molecule induced exchange coupling on the magnetic properties of the magnetic tunnel junction based molecular spintronics devices (MTJMSD). We considered all the possible permutations and combinations and nature of interactions between a paramagnetic molecule and the two ferromagnetic (FM) electrodes of an MTJMSD to understand the experimental results. Experimentally observed molecule induced strong antiferromagnetic coupling was only possible when a molecule, with a net spin state, established ferromagnetic coupling with one FM electrode and antiferromagnetic coupling with the other FM electrode. Our MC simulations effectively explain the origin of the experimental data obtained from SQUID magnetometer, ferromagnetic resonance, and MFM studies on MTJMSD. The experimentally estimated molecular coupling strength was in agreement with our results of MC simulations. Increasing MTJMSD size was found to weaken the molecular coupling effect. However, it is quite possible that we underestimated the impact of molecular coupling on the MTJMSD size. In this study, we mainly focused on the Heisenberg type magnetic interaction among nearest neighbors. In reality, molecules are expected to have other modes of couplings such as biquadratic coupling, dipolar coupling, and most importantly paramagnetic molecules are also capable of invoking spin fluctuation assisted coupling between two FM electrodes

3:35 PM NM05.11.09

Impact of Anisotropy of Ferromagnetic Electrodes on Magnetic Tunnel Junction Based Molecular

Spintronics Device (MTJMSD) Properties Bishnu R. Dahal, Marzieh Savadkoohi, Andrew Grizzle, Uzma Amir, Pius Suh, Christopher D'Angelo and Pawan Tyagi; University of the District of Columbia, United States

Covalently bonded Paramagnetic molecular bridges between two ferromagnets (FM) electrodes of a magnetic tunnel junction (MTJ) may enable highly efficient spin transport properties for futuristic computers. The MTJ based molecular spintronics device (MTJMSD) approach can solve the decades' long problems of fabricating robust and mass-producible molecular spintronics device[1]. MTJMSD provides opportunities to connect FM electrodes of a vast range of anisotropy properties to a variety of molecules of length scale. Our prior studies showed that the paramagnetic molecules can produce strong antiferromagnetic coupling with FM electrodes when the molecule establishes a ferromagnetic coupling with one FM electrode and antiferromagnetic coupling with another FM electrode of an MTJ[2]. The device properties of MTJMSD depends upon various factors such as the anisotropy of the FM electrodes, thermal energy (kT), ferromagnet-molecular coupling strengths, spin states of molecules, etc. In this paper, we report a theoretical Monte Carlo Simulation (MCS) study to explain the impact of anisotropy on the MTJMSD equilibrium properties and related experimental observations[3]. Our MCS also studied the impact of thermal energy (kT). The MTJMSD used in this study was represented by an 11x 50 x 50 Ising model, with 11 being the thickness of the MTJMSD and 5x10x50 being the size of each electrode. We ran Markov process for 200 to 500 Million iterations to reach the equilibrium state and record MTJMSD properties such as magnetization of each electrode and complete device. We also studied the energy variation of the MTJMSD system with time as a function of FM electrode anisotropy. We found that increasing anisotropy strength starts exhibiting diverse domain structures within an FM electrode. Increasing anisotropy was found to create stripe-shaped domains with opposite spins. These phases are impacting the overall magnetic properties of the FM electrode where anisotropy was varied. At kT = 0.1 we observed that for the high anisotropy magnitude the magnetic moment of the FM electrode settled close to zero. Our MCS study agreed with the experimentally observed stiped domain on MTJMSD and Magnetic force microscopy data[4]. MCS study showed that the anisotropy was the most influential parameter in defining the properties of MTJMSD. The effect of anisotropy enabled MTJMSDs to compete with the increasing thermal energy. High anisotropy enabled MTJMSD to conserve a high magnetization state close to Curie temperature. Anisotropy factor was instrumental even when all the coupling effects get nullified due to thermal energy induced disorders in the MTJMSD. These MCS studies are expected to inform the designing of the MTJMSD for the logic and memory operation.

Designing Magnetic Metal Oxide Colloidal Nanoparticles for Spatially Resolved Thermometry Adam Biacchi, Thinh Bui, Eduardo De Lima Correa, Cindi Dennis, Solomon Woods and Angela Hight Walker; National Institute of Standards and Technology, United States

Colloidal magnetic nanoparticles (MNPs) of metal oxides are becoming increasingly important for applications such as biomedical imaging, sensing, drug delivery, and hyperthermia. These exploit the very soft magnetism

found in nanoscale ferrimagnets, often ferrites, which yield a strong collective response to applied alternating (AC) magnetic fields while simultaneously remaining dispersed in media. Their synthesis relies on reproducible, scalable, colloidal solution chemistry routes. Further, the size, shape, structure, and composition are tunable, which serve as levers to design and manipulate the magnetic behavior of these functional nanoparticle materials.

Remote 3D magnetic thermometry is an emerging application of MNPs. The technique employs colloidal nanoparticles to measure and image temperature remotely with high spatial resolution throughout a three-dimensional volume. This metrology is based on the temperature-dependent nature of the particles' magnetization, their dispersibility throughout a liquid or solid of interest, and the ability of applied AC magnetic fields to penetrate through many materials. Although progress has been made in the development of magnetic nanothermometry, commercially available MNPs often lack several properties necessary for widespread application, including particle-to-particle consistency, thermosensitivity response, and a non-exothermic response to applied AC magnetic fields.

Here, we report colloidal MNPs specifically designed for remote 3D thermometry. A series of shape- and size-controlled colloidal MNPs based on ferrites were synthesized *via* the thermal decomposition of organometallic precursors. Further, we exploited compositional doping of transition metal elements and exchange coupling between core-shell magnetic heterostructures as means of generating improved temperature-dependent magnetization (200-400 K at <0.001 T applied AC field) from designed spin interaction within the nanoparticles. Extensive structural characterization was performed to better understand the underlying factors influencing the magnetic response. Results collected from X-ray photoelectron spectroscopy, Raman spectroscopy, and high-resolution electron microscopies, including spatially resolved electron energy loss and energy-dispersive X-ray spectroscopies, revealed correlations between the nanoscale atomic structure of these particles with their magnetic performance. Finally, we used a home-built AC magnetic particle spectrometer to determine the magnetization-dependence of these nanothermometers as a function of temperature, frequency, and field amplitude. These studies allow us to interrogate the fundamental response dynamics of dispersed and deposited magnetic nanoparticles under AC driving fields. Collectively, we show that carefully designed complex metal oxide MNPs display tunable thermosensitivity and AC field signal response, which represents a potential pathway to the implementation of a practical 3D thermal imaging platform based on magnetometry.

SESSION NM05.12: Functional Nanoparticle Materials—Synthesis, Property and Applications XII
Session Chairs: Mei Cai and Ou Chen
Tuesday Afternoon, April 20, 2021

9:00 PM NM05.12.01
Impact of Heisenberg Exchange Coupling Strength of Ferromagnetic Electrodes on Magnetic Tunnel Junction Based Molecular Spintronics Devices (MTJMSD) Eva Mutunga[1], Bishnu R. Dahal[1], Marzieh Savadkoohi[1], Andrew Grizzle[1], Christopher D'Angelo[1], Vincent Lamberti[2] and Pawan Tyagi[1]; [1]University of the District of Columbia, United States; [2]Y-12 National Security Complex, United States

Molecules are highly tunable nanostructures because synthetic chemistry can customize their optical, electrical, and magnetic properties. Thus, molecules used as active device elements open a new pathway towards the miniaturization of advanced logic and memory devices, as well as a new class of metamaterials altogether [1]. The anticipation is that molecular electronic devices will function at significantly low power and reach the ultimate device size limits [2]. Prior research [3] shows that when molecules are bridged between two ferromagnetic electrodes they can serve as novel molecular spintronics-based magnetoresistance devices. Moreover, when the molecule itself possesses a net magnetic spin and interacts with the electrodes' spin state,

more dramatic results are observed. With the magnetic tunnel junction based molecular spintronics device (MTJMSD) we observed paramagnetic molecules produced strong exchange coupling between ferromagnetic electrodes. MTJMSD is fabricated by chemically bonding the molecular channels to the ferromagnetic electrodes of a prefabricated magnetic tunnel junction [4]. We observed that molecule impact was dependent on the type of MTJMSD's ferromagnetic electrodes [5]. However, it is challenging to experimentally study the effect of a wide range of ferromagnetic electrodes on MTJMSD properties. This paper discusses our Monte Carlo simulation study focusing on understanding the effect of ferromagnetic electrodes on magnetic and physical properties of MTJMSD. This paper utilized the 3D Ising model to realistically simulate the experimentally studied MTJMSD design. We varied the Heisenberg exchange coupling parameter for the MTJMSD's two ferromagnetic electrodes. This variation simulated the ferromagnetic electrodes with low to high Curie temperature. We recorded the evolution of MTJMSD magnetization with time and observed the impact of ferromagnet type on the nature of evolution of equilibrium state. We varied thermal energy to understand the role of ferromagnetic electrode type on MTJMSD. We also studied the effect of molecular coupling strength in conjunction with the ferromagnetic electrode's Heisenberg exchange coupling. We have recorded spatial distribution of the magnetic moment of the ferromagnetic electrodes to elucidate the impact range of molecules as a function of ferromagnetic electrode type.

Multicomponent CoCrFeMnNi Nanoalloy Particle Formation in Hydrogel Nanofibers Yuen Yee Li Sip, David Fox and Lei Zhai; University of Central Florida, United States

Multicomponent and high entropy alloys (HEAs) are a novel class of metallic material systems in the field of materials science and engineering. Such alloys are comprised multiple principal elements with various multicomponent compositions. HEAs are typically formed at elevated temperatures and require high-energy systems to promote high entropy of mixing and ensure equimolar concentration and distribution. However, our study investigated the idea of distributing metal ions inside a hydrogel nanofiber (NF) at ambient temperatures, with random probability and high entropy via absorption and strong interactions in the NF. The subsequent reduction of the metal ions and the formation of nanoparticles (NPs) in the NF will be influenced by this distribution, leading to the potential for kinetic control of HEA NPs. In this study, we have produced the quinary CoCrFeMnNi nanoalloy particles in stable flexible electrospun hydrogel fibers composed of poly(acrylic acid) (PAA) and poly(allylamine hydrochloride) (PAH). The metal ions were loaded into the NFs by immersion into a solution mix containing the required metal salts, followed by chemical reduction to form the metal NPs. The composition of the metal in the alloy could be tuned by varying the metal salt ratio. The proposed method resulted in random capturing by the carboxyl groups of PAA where the metal ions were kinetically trapped and in minimizing the coalescence of the reduced metals. The hydrogel fiber matrix also allowed for aqueous absorption and provided a viscous environment to promote particle formation in the small diameter range. The fabrication process is beneficial in terms of controllability, simplicity and versatility. The

HEA NP loaded fiber composite was characterized for alloy morphology and distribution, electronic states and overall composition. The structural and functional capabilities of the multicomponent nanoalloys create high-performance materials applicable in the aerospace, catalysis and energy industries. Catalysis is one field of interest to incorporate multicomponent nanoalloy composite because the various constituting metals enable an enhanced and more selective catalytic property when compared to monometallic NPs**.**

Late News: Fog Sensor Cameras Using Upconverting Nanoparticles Udit Kumar[1], Scott Hoos[2], Tamil Selvan Sakthivel[1], Christina Drake[2] and Sudipta Seal[1,1]; [1]University of Central Florida, United States; [2]Kismet Technologies, United States

Fog formation is often unforeseen and rather hard to predict due to the thermodynamics and kinetics of fog formation overland type and surrounding air conditions Reduced visibility is one of the substantial causes of vehicular crashes. Despite having multiple meteorological equipment types for measuring and studying fog characteristics, many are suitable only for marine environments and ports. The current state-of-the-art real-time scattering of the light-based roadside fog detection system is riddled with false-negative and false-positive identifications. Considering this situation, we report a novel Upconverting nanoparticles (UCNPs) cameras-based fog sensor concept that is easy and cost-effective for roadside deployment. For the upconverting application, we have fabricated $NaYF_4$ (Yb, Er) nanoparticles using a facile hydrothermal based route. It has a primarily β- $NaYF_4$ (hexagonal) phase with an average particle size of around 15 nm and 5 nm and fluorescence spectroscopy showing multiple emission in blue-green-red spectrum with an excitation from NIR light (980 nm).
To eliminate false negatives/positives results, our sensor methodology utilizes two fog detection methods. First, based on Koschmieder's law, it involves estimating visibility conditions and scattering light due to fog, and the second one based on contrast change of an engineered object in the field of view of a traffic camera. NIR light within a black background with UCNPs (in front of the camera utilized in a thin film outside of the front of the camera lens) acts as both a scattering source and an object for contrast measurement. UCNPs also take care of the automatic NIR light filters, common in roadside cameras during daytime use. We have observed fog detection at levels 1-6 (Thick fog to light haze) of the International visibility code at both day and nighttime conditions using the synergic complementary scattering-contrast measurement approach.

Late News: Diamine Functionalized Mg2(dobpdc) Micro-Beads with Hydrophobicity for CO2 Capture Jong Hyeak Choe, Yun Seok Chae, Dae Won Kim, Doo San Choi, Hyojin Kim, MInjung Kang and Chang Seop Hong; Korea University, Korea (the Republic of)

Metal-organic frameworks (MOFs) is a new type of adsorbents for removing CO_2. In particular, M_2(dobpdc) shows high performance in CO_2 capture. Shaping of M_2(dobpdc) is important for practical applications. Here, we present a scalable synthesis method for Mg_2(dobpdc) MOF and its shaped beads, which are obtained by using a spray dry method after mixing Mg_2(dobpdc) powders with alumina sol. The synthesized Mg_2(dobpdc)/Al beads have micron-sized diameters. In addition, *N*-ethylethylenediamine (een) functionalization and coating with long alkyl chain silanes results in **een-MOF/Al-Si**, which shows high CO_2 uptake and hydrophobicity. The **een-MOF/Al-Si** microbeads maintain their crystallinity and enhanced CO_2 uptake upon exposure to humid conditions for three days at a high temperature. More details can be found on the poster.

Bimetal-Organic Framework as a Wearable Electrochemical Glucose Sensors for Real-Time Sweat Analysis Maowen Xie, Guang Yao and Yuan Lin; University of Electronic Science and Technology of China, China

Flexible wearable sensor are widely reported as emerging tools for target diagnosis and healthcare management,

mainly for detect biomarkers in various body fluids.[1] Place the sensing element on the skin and engineering a detector that can sense glucose without piercing the skin in real time. The rational design of sensing element is the key for the sensing performance of wearable electrochemical sensors.[2] Carbon materials (graphene, carbon nanotubes, carbon nanofibers, etc.), macromolecule polymers, metallic materials, and biological enzyme-based materials are used as highly efficient functional materials for biosensor with high sensitivity and low detection limit, but poor stability, inferior electrical conductivity, limited flexibility still hinder their practical application. [3-5]
Metal–organic frameworks (MOFs) have attracted considerable attention because their uniform-structured cavities and open channels pave the way for entering and escaping molecules. In particular, MOFs and transition metal-MOFs have been used as various sensors, such as gas sensors, DNA sensors, and glucose sensors.[6] In recent years, Co and Fe are an interesting transition metal that has catalytic activity for glucose oxidation due to the excellent catalytic performance and electronic properties.[7,8] Herein, we describe the development of cobalt-foil MOF nanowire array on ultrathin copper foam (Co-Fe MOF/CF) via hydrothermal method possesses high catalytic activity towards glucose electro-oxidation. Benefits from synergies between bimetals, this electrode shows a short response time of less than 3 s, a wide linear range of 0.04–7 mM, a low detection limit of 0.1 μM (S/N = 3), and a higher sensitivity of 4424.9 μA mM^{-1} cm^{-2}, as well as satisfactory reproducibility,stability and selectivity. In general, our work provided an effective and stable flexible biosensor for the detection of small biological molecules which overcomes the disadvantages of traditional enzyme-based materials. This non-invasive electrochemical biosensor is expected to have considerable applications in personal health monitoring applications,sport and military applications.

A Soft Mechanotransducer Based on Ionic Polymer-Metal Composite for High-Performance Haptic Feedback
Hanbin Choi[1], Youngchan Kim[2], Joo Sung Kim[1], Changhyeon Cho[2], Hyukmin Kweon[1], Seonho Kim[3], U Hyeok Choi[3], Hojin Lee[2,2] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of); [3]Inha University, Korea (the Republic of)

With the development of soft electronics, an ionic electroactive polymer (i-EAP) actuator has dominated research in various fields because, they provide a lot of advantages such as lightweight, flexibility, simple process, and low operating power. However, many i-EAP studies have demonstrated some drawbacks including low blocking force, displacement and so on, in the utilization of various applications. In order to apply these i-EAP actuators to various fields, it is important to provide the optimum characteristics of the i-EAP actuator suitable for the target application. Among the various applications, for soft haptic feedback, it is required to

achieve high blocking force as well as wide bandwidth. Thus, in order to enhance the blocking force of the i-EAP actuator, highly-performance actuators take advantage of inorganic materials having a high mechanical modulus. Although the inorganic material embedded EAP actuator possesses high blocking force, it's application in soft haptic feedback is questionable due to the narrow bandwidth.
In this work, we described an ionic polymer-metal composite based mechanotransducer (IPMCM), with high blocking force and wide bandwidth consisting of ionic conducting polymer electrodes and a IPMCM material. The composite material based on hydrogen bond increases the actuation performance of blocking force and wide bandwidth through the high modulus of inorganic materials. Also, our actuator could control an interface between ionic polymer and electrodes using conducting polymer (PEDOT:PSS) with ionic liquids and DMSO as additives. As a result, the developed IPMCM with ionic conducting polymer was operated with a wide bandwidth of up to 100 Hz as well as a high blocking force of 1.0 mN. In addition, our ionic polymer-metal composite exhibited the different ion transport mechanism containing inorganic particles with similar activation energy of ionic polymers. We believe that our proposed actuator can serve as an ideal guide to human-machine soft haptic interface.

8:00 AM NM05.07.04
Late News: A Biophilic Composite Multi-Functionalized on the Nanoscale Alexandra Rempe[1], Joseph Plumitallo[1], Jin Ho Kim[1], Haelin Jang[2] and Jimmy Xu[1,1,2]; [1]Brown University, United States; [2]Harvard University, United States

This work is a continuation of a growing interest and effort to incorporate into nanocomposites functionalities beyond load-bearing. We report on the concepts and findings of engineering nanocomposites to acquire surface self-disinfection, self-enhanced cell adhesion and growth, on top of internal self-transport of nutrient and growth factors, self-healing and self-lubrication.

Biocomposites have been engineered to repair or replace human mechanics, damaged due to age or injury or deceases, and are of increasing clinical importance. In particular, many surgical procedures require implanting bone-like biomaterials to perform necessary operations. Oftentimes these operations lead to dangerous surgical site infections, as foreign surfaces are an attractive site for bacterial adherence, thus, biocompatibility studies on implantable device require a series of in-depth experiments analyzing both in vitro and in vivo applications.[1] Bone implant biomaterials are generally made of calcium phosphate ceramics, of which hydroxyapatite (HAp) and Whitlockite (WH) have shown notable biocompatibility and bioactivity. Previous research on HAp and WH biomaterials, has created novel advancements seen in dental work, bone implants, and biocoatings.

In an effort to advance such composites beyond the load-bearing function, we have succeeded in engineering a 3D network of nanochannels inside the composite that enables nutrient absorption and transport along with growth factors and enabled self-sustained bone cell growth for selfhealing[2] . With such a built-in network and its Laplace (capillary) force within, lubricants and coolants could also be delivered to the interface of a joint[3 , 4] . We show a further advance of this effort – surface engineering to enable on-command self-infection and enhanced celladhesion/growth, via incorporation of TaN and/or TiO2 nanocomposites and photocatalytic and heterointerface field-induce reactions as representative approaches.

We plan to leverage the visible-light photocatalytic activity and electrical conductivity of copper oxide nanoparticles (CUO NPs) to further contribute to self-disinfection, self-enhanced cell adherence and growth material. Likely because of the electrical conductivity, CuO-Hap nanobiocomposites present high cell viability[5],

thus, we expect this to further the functionality of the TIO2-Hap composite, creating a strong application for the future of biocomposites. We hope by the end of this process we will have pioneered a technique that will help minimize the invasive and inflammatory effects of implant debris and microphage reactivity, setting a new ground for the future and reduction of osteogenesis infections.

Tutorial NM06: Manipulation and Detection of Physical Properties of Two Dimensional Quantum Materials
Session Chairs: Sergey Budko, Judy Cha, Archana Raja and Srinivasa Rao Singamaneni
Saturday Afternoon, April 17, 2021
NM06

5:00 PM *
Optical Spectroscopy—2D Materials Archana Raja; Lawrence Berkeley National Laboratory, United States

Optical spectroscopy is a powerful tool to study nanoscale materials, and in particular atomically thin 2D materials that exhibit extraordinarily strong light matter coupling in 2D materials. In this tutorial I will introduce the optical spectroscopy of 2D transition metal dichalcogenides that are layered semiconductors, and the concept of excitonic Rydberg states to non-invasively understand electronic processes in these materials. In particular I will discuss how excitonic states can be a probe of local strain, doping, dielectric screening and interfacial magnetic exchange. Technical aspects of micro-spectroscopy will be covered along with an overview of advanced capabilities available at national labs that can enable unique insights through correlated, multimodal measurements.

6:00 PM BREAK

6:15 PM *
Quantum Materials—Under Pressure Sergey Budko; Ames Laboratory of US DOE, United States

Pressure is known to control the physical properties of quantum materials. This tutorial will focus on the hydrostatic and uniaxial pressure spanning from general principles to pressure cells design. This includes hydrostaticity, pressure media, experimental techniques under pressure/strain. In particular, this tutorial covers the properties of quantum materials such as superconductors, fragile magnets, novel semimetals under pressure.

7:15 PM BREAK

7:30 PM *
Electrochemical Properties—*In Situ* Characterization Judy Cha; Yale University, United States

Many layered materials have been explored as electrocatalysts for various energy-relevant reactions, most notably for hydrogen evolution reaction (HER). This tutorial will provide basic information on electrochemically driven HER, such as the reaction pathways, mechanisms, and standard experimental set-ups, and present our current understanding of the active sites of layered materials, mostly focusing on transition metal dichalcogenides. The tutorial will discuss the effects of hydrogen adsorption energy, density of catalytically active sites, and catalyst-support interface on the overall activity of HER. Moreover, the tutorial will highlight *in situ* characterization techniques and HER studies based on nanoscale devices, which can provide detailed information on the effects of microstructure and transport properties on HER during reaction.

SESSION NM06.01: Topological/Graphene/Thin Film Magnetism/Anisotropy

8:00 AM NM06.01.01
Tuning Fermi Levels in Intrinsic Antiferromagnetic Topological Insulators $MnBi_2Te_4$ and $MnBi_4Te_7$ by Defect Engineering and Chemical Doping Mao-hua Du, Jiaqiang Yan, Valentino R. Cooper and Markus Eisenbach; Oak Ridge National Laboratory, United States

$MnBi_2Te_4$ and $MnBi_4Te_7$ are intrinsic antiferromagnetic topological insulators, offering a promising materials

platform for realizing exotic topological quantum states. However, high densities of intrinsic defects in these materials not only cause bulk metallic conductivity, preventing the measurement of quantum transport in surface states, but may also affect magnetism and topological properties. In this paper, systematic density functional theory calculations reveal specific material chemistry and growth conditions that determine the defect formation and dopant incorporation in $MnBi_2Te_4$ and $MnBi_4Te_7$. The large strain induced by the internal heterostructure promotes the formation of large-size-mismatched antisite defects and substitutional dopants. Our results show that the abundance of antisite defects is responsible for the observed n-type metallic conductivity. We predict that a Te-rich growth condition should reduce the bulk free electron density, which is confirmed by experimental synthesis and transport measurements in $MnBi_2Te_4$. Furthermore, Na doping is proposed to be an effective acceptor dopant to pin the Fermi level within the bulk band gap to enable the observation of surface quantum transport.

Visualization of Topological States of Matter Using Microwave Impedance Microscopy Monica Allen; University of California, San Diego, United States

A main thrust of condensed matter physics concerns the discovery of new electronic states in emerging quantum materials. One example is the rapidly expanding class of topological materials, which are posited to enable realization of non-abelian particles and topological quantum computing. In this talk, I will discuss how exotic electronic phenomena can arise from the interplay of topology and magnetism in epitaxially-grown topological insulator thin films. Our experiments employ low-temperature microwave impedance microscopy (MIM), which characterizes the local complex conductivity of a material, to directly image chiral edge modes and phase transitions in a magnetic topological insulator. Finally, I will outline how MIM could be used in the future to visualize and manipulate Majorana modes, an emerging platform for topological quantum information processing.

Spectro-Microscopy of 30˚ Twisted Bilayer Graphene Jerzy Sadowski; Brookhaven National Laboratory, United States

A discovery of unconventional superconductivity in a twisted bilayer graphene (tBLG) system has spurred intensive discussions about the importance of interlayer coupling in the tBLG. Even though the electronic valence band structure of this system has been thoroughly studied, much of its macroscale properties, such as conducting electron behavior and light-matter interactions remain uncertain. A 30° twisted bilayer graphene (30°-tBLG) is another material system of interest that was recently enabled experimentally. Here, I present the results of the investigations of the interlayer coupling effects in the twisted 30° bilayer graphene system using surface sensitive low energy electron microscopy (LEEM), micro-spot low energy electron diffraction (μLEED), x-ray photoemission electron microscopy (XPEEM), Raman scattering spectroscopy and scattering-type scanning near-field optical microscopy (sSNOM). Two types of samples were studied in detail – as-grown graphene structures on a copper foil and the graphene transferred to a $TiO_x/SiO_2/Si$ substrate. Strong interlayer coupling between two individual graphene sheets rotated by 30º was revealed by a sharp 12-fold symmetrical LEED pattern acquired in the LEEM microscope. Distinct electron reflectivity contrasts in the LEEM experiment observed between 30°-tBLG and AB-stacked bilayer graphene yielded differences in the conduction band electronic structure between these two systems. Enhancement of interlayer light scattering was observed by the Raman scattering spectroscopy. Most surprisingly, the plasmonic interaction was observed to be sharply quenched on 30°-tBLG, in contrast to enhanced plasmonic interaction observed on chemically similar, AB-stacked bilayer graphene. The plasmonic interactions and sharp contrast in the 30°-tBLG on $TiO_x/SiO_2/Si$ was directly captured in real-space in the sSNOM measurements. We conclude that the 30°-tBLG interface features a unique interlayer resonant interaction in which the interlayer scattering is greatly enhanced. This enhanced interlayer scattering promotes nearly energy-free charge carrier exchange in between two twisted atomic planes.

Probing Magnetic Anisotropy and Interfacial Exchange Interactions at Complex Oxide Interfaces Sanaz Koohfar, Yasemin Ozbek, Hayden Bland and Divine Kumah; North Carolina State University, United States

The control of magnetic ordering and magnetic anisotropy in ultrathin complex oxide films plays a critical role in advancing the development of novel spin-based sensors, storage devices and magnetic tunnel junctions. Perovskite complex oxide interfaces provide an indeal platform for manipulating magnetic ground states due to the stronge coupling of spin, electronic, orbital and structural degrees of freedom at these interfaces. Using a combination temperature-dependent magnetometry and element-specific X-ray magnetic circular dichroism, we investigate the competition between epitaxial strain in interfacial magnetic exchange interactions on the magnetic anisotropy in ferromagnetic LaSrCrO3(LSCO)/LaSrMnO3(LSMO) heterostructures grown by molecular beam epitaxy. Here, we observe an in-plane easy axis for 2 unit cell LSCO/2 unit cell LSMO heterostructures independent of the substrate-induced epitaxial strain and an antiferromagnetic Mn-Cr exchange across the LSMO/LSCO interface. These results highlight the critical role of interfacial magnetic exchange interactions in tuning magnetic anisotropy at complex oxide interfaces.

Room-Temperature Ferromagnetism, Perpendicular Anisotropy, and Reverse Magnetostriction in 2-D MnGaN Yingqiao Ma[1], Diego Hunt[2], Kengyuan Meng[3], Tyler Erickson[1], Fengyuan Yang[3], Maria Andrea Barral[2], Valeria Ferrari[2] and Arthur R. Smith[1]; [1]Ohio University, United States; [2]Departamento de Fisica de la Materia Condensada, GIyA, CAC, Comision Nacional de Energia Atomica, Argentina; [3]The Ohio State University, United States

Two-dimensional (2-D) magnetic materials are of great interest for fundamental science and advanced applications while dilute magnetic semiconductors (DMS) have captured worldwide interest in the hope of combining magnetism with electronic properties. At the intersection of these fields, MnGaN-2D is discovered as an ultimately-thin, 2D-DMS material, consisting of a densely concentrated, hexagonal-like arrangement of Mn, Ga, and N, but with a crystal structure unique from its wurtzite GaN substrate. MnGaN-2D shows room-temperature ferromagnetism as demonstrated using spin-polarized scanning tunneling microscopy and as a function of applied magnetic field. This is also predicted by first-principles theoretical calculations which reveal the origins of the ferromagnetism through its highly spin-split and spin-polarized manganese states.[1]

The SP-STM results have been furthermore confirmed by SQUID magnetometry which reveals a high spin-polarization of ~79% at room temperature and perpendicular magnetic anisotropy.[2] New results for this novel system also suggest the possibility of switching the magnetic anisotropy using strain. Theoretical calculations reveal sensitivity of the filled states magnetic Mn peak to compressive versus tensile strain. Spin-orbit coupling is included in the calculations, which indicate either *out-of-plane* or *in-plane* anisotropy, dependent on the type of strain.

Clear evidence for both compressive and tensile local lattice strains is found by detailed analysis of atomic resolution STM images which reveal a wide, non-Gaussian range of lattice spacings (-18% to + 18% variations), unlike normal materials. Furthermore, scanning tunneling spectroscopy measurements, showing the clear spin-polarized, filled states manganese peak, find fluctuations in the electronic position of this peak. The filled-states Mn peak energy is also found to fluctuate depending on lattice strain in the theoretical calculations, thus indicating a connection between electronic states and magnetic anisotropy in this RT ferromagnetic 2D

layer.

9:35 AM *NM06.01.06
2D Magnetic Materials Alberto Morpurgo; University of Geneva, Switzerland

In this presentation I will review our work on different 2D magnetic materials. I will mainly focus on tunnelling magnetoresistance measurements, in which thin layers of different semiconducting 2D magnetic materials are used as tunnel barrier, whose magnetoresistance exhibit new and interesting effects. I will concentrate on three different systems and of the evolution of their magnetic properties with thickness. The first is CrI3, a ferromagnet in bulk form that exhibit layered antiferromagnetism when exfoliated in thin multilayer form. When used as tunnel barriers, these multilayers exhibit a 10'000% magnetoresistance that originates from a spin-valvbe effect in the transmission probability of the barrier. The second is CrCl3, also a layered antiferromagnet in multilayer form, that contrary to CrI3 (which is an easy axis material), has an easy plane with only weak anisotropy. I will discuss in detail how the evolution of the tunneling magnetoresistance as a function of magnetic field, number of layers and temperature allows the full magnetic phase diagram of these atomically thin crystals to be determined experimentally, and reproduced theoretically in terms of a simple "linear antiferromagnetic chain" model. Finally, I will address the case of MnPS3, which contrary to the other two materials exhibit antiferromagnetic ordering within the individual layers of the the material. I will show that the tunneling magnetoresistance of sufficiently thick multilayers (i.e., 6-layer) allows the bulk magnetic phase boundaries to be traced. As the thickness is reduced to mono or bilayer, a large magnetoresistance persists, indicating the persistence of magnetism, event though its functional dependence differs from that observed in thicker multilayers. Overall, these examples show how tunneling magnetoresistance is a powerful technique to extract information about the magnetic state of 2D magnetic materials, which would not be easy to obtain otherwise.

Dynamic Control of Localized Exciton Emission and Plasmon-Exciton Coupling in Monolayer WSe_2 using a Novel Nanobubble-Nano Gap Architecture Thomas P. Darlington; Columbia University, United States

Applied strain has proven to be one of the most powerful tools in the study of semiconductors, enabling control of fundamental material properties such as the bandgap and electron-phonon coupling. In the context of the 2D semiconductors such as WSe2, inhomogeneous strain in particular has received significant scientific attention with the discovery of localized excitons (LXs) associated with structural features such as nanobubbles, wrinkles, and nanotents. Such LX states have been shown to become single photon sources at cryogenic temperatures, potentially allowing for deterministic placement of single photon sources in-plane by depositing

single 2D layers over designer structures, e.g. nano-pillars, nano-pits, and nano-antennas. While deposition over fabricated structures allows for high spatial precision in LX location, important parameters such as the strain distribution and resulting emitter emission energy are fixed, and can only approximately controlled during deposition of the 2D layer.
In this presentation, I will show a novel approach that allows for the dynamic tuning of the LX emission energy and coupling to a plasmonic cavity. Using a metallized nano-optical probe as an indentor and, we show that nanobubbles in monolayer WSe2 can be controllably deformed, tuning the local strain profile, and leading to controllable redshift in the emission energy. High resolution nano-Raman spectroscopy shows that high strains of order 1 - 2 % can be induced, consistent with naturally formed wrinkles that have been shown to host strongly LXs. Finally dramatic line splitting of the LX luminescence is seen, indicating possible strong-coupling with the gap mode plasmon formed between the metallized nano-optical probe and the gold substrate. Our results show the power of the combined plasmonic cavity-nanobubble approach to control the optical coupling and emission localized excitons in WSe2, and provide greater insight for developing excitonic light sources in 2D materials.

10:45 AM NM06.02.02
WSe_2 as a 2D Quantum Material Integrated into non-Pb Based Bulk Perovskite for Critical Optoelectronics Tunability in an Effort to Enhance Signal-to-Noise Ratio for Non-Invasive Biomedical Device Sensing Saquib Ahmed[1], Sankha Banerjee[2] and Diedra Hodges[3]; [1]Buffalo State College, United States; [2]California State University, Fresno, United States; [3]The University of Texas at El Paso, United States

Integration of 3D bulk materials with 2D quantum materials for physical coupling and applications has been a relatively new area of research. Interfacing of these materials, excitingly, leads to drastic modulations in optoelectronic properties beyond those of the individual materials, thereby leading to an entire genre of innovation and technologies. In this research, DFT studies of 2D WSe_2 coupled with $Cs_2AgBiBr_6$, a non-Pb based perovskite structure, provide a suite of exciting modulations in electronic properties including higher density of states, and conversion of bandgap from indirect to direct type. Additionally, the charge contribution to the HOMO level of the coupled heterostructure is shown to be predominantly by the p orbital of Br atoms, whereas the LUMO level is seen to receive electrons from the d orbital of W, showcasing the critical transition of the excited electron from the bulk $Cs_2AgBiBr_6$ to WSe_2 monolayer upon irradiation. Moreover, the energy levels of the surface states are located just above the top of the valence bands in the bulk $AgBiBr_2$, indicating that the energy loss through charge transfer via surface states is expected to be considerably small. Lastly no mid-gap surface states are seen from density of states plots, indicating that electron-hole recombination hardly occurs even at the surfaces, and thus, long lifetimes of the photoexcited carriers can be realized. Optical properties show enhanced absorption and reflectivity of the 2D-3D heterostructure over each system by itself, together with critically modulated refractive index, dielectric constant (both real and imaginary) and loss term, and extinction index. Thermal and transport properties show similar modulations in the Seeback coefficient and thermal conductivity. These results provide motivation for the application of such a 2D-3D heterostructure for a novel non-invasive glucose monitoring device.Such a device depends on a highly accurate detection of a signal (from an LED light source) that has undergone a change in intensity after passing through the sugar solution. The enhanced electronic, optical, thermal and transport modulations that the 2D-3D heterostructure showcases upon irradation across a range of frequenceis offers multiple modalities for amplifying and detecting such a signal. Importantly, these modalities can be utilized to detect not only changes in blood sugar level, but other markers in the blood (all non-invasively) that indicate changing health conditions.

11:00 AM NM06.02.04
Fast Bayesian Force Fields from Active Learning—Study of Inter-Dimensional Transformation of Stanene Yu Xie[1], Jonathan Vandermause[1], Lixin Sun[1], Andrea Cepellotti[1] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch LLC, Research and Technology Center, United States

Machine learning force field has attracted more and more attentions because those powerful function-fitting schemes are capable to reach first principle accuracy and simulate large scale systems that are prohibited for

quantum molecular dynamics (QMD). Gaussian process (GP) regression is one promising technique among them, whose remarkable competitive advantage over empirical interatomic force fields is the built-in uncertainty quantification based on Bayesian posterior inference, which can be used to monitor the quality of GP predictions. A current limitation of existing GP force fields is that accurate predictions are only enabled by large training data set. However, the prediction cost grows linearly with the size of the training data set, making accurate GP predictions slow and defying the competitive advantage over more accurate ab-initio techniques.

In this work, we present a way to dramatically accelerate Gaussian process models for interatomic force fields based on many-body kernels by mapping both forces and uncertainties onto functions of low-dimensional features. This allows for automated active learning of models combining near-quantum accuracy, built-in uncertainty, and constant cost of evaluation that is comparable to classical analytical models, capable of simulating millions of atoms.

Using this approach, we train force fields and perform large scale molecular dynamics simulations of stanene monolayer. The monolayer dynamics reveals an unusual phase transformation mechanism of 2D stanene, where ripples lead to nucleation of bilayer defects, densification into a disordered multilayer structure, followed by formation of bulk liquid at high temperature or nucleation and growth of the 3D bcc crystal at low temperature.

The presented method opens possibilities for rapid development of fast accurate uncertainty-aware models for simulating long-time large-scale dynamics of complex materials.

The Synthesis and Engineering of Two-Dimensional Janus Quantum Layers Sefaattin Tongay; Arizona State University, United States

Named after the two faced Roman God Janus, 2D Janus layers contain two different atomic types on its top and bottom faces. Previous theoretical studies have shown that broken mirror symmetry together with large change transfer across the top and bottom face opens up completely new quantum properties including Rashba effect, colossal Janus field, dipolar excitons, and Skyrmion formation. Despite the theoretical advances in the field, experimental results are still limited due to limitations in high quality 2D Janus layer synthesis. In this talk, I will introduce recent discoveries made at Arizona State University towards different types of Janus layers. The growth process relies on Plasma enhanced low pressure chemical vapor deposition (PE-LPCVD). With this all room temperature technique, our team can synthesize different Janus layers as well as their vertical / lateral heterojunctions, and Janus nanoscrolls. Further studies from our team will introduce on-demand fabrication of 2D Janus layers with unique in-situ growth capabilities that allows us to collect spectroscopy data during the course of Janus material growth. Results are presented along with microscopy, spectroscopy, high -pressure studies, and electronic transport datasets for complete understanding of these systems.

11:40 AM *NM06.10.06
Intertwined Topological and Magnetic Orders in Atomically Thin Chern Insulator MnBi2Te4 Xiaodong Xu; University of Washington, United States

The interplay between topology and broken time reversal symmetry in a solid-state system can create a Chern insulator. The non-trivial property of its band structure enables quantized Hall transport with dissipation-free chiral edge states. The recently-discovered topological magnet, $MnBi_2Te_4$, provides a desirable platform to study tunable Chern insulator phase. In this talk, I will describe our recent progress in understanding this new material system by the combination of transport, magneto-optical Kerr effect, and microwave impedance microscopy measurement. These probes reveal the formation of the Chern insulator gap, image the associated chiral edge states, and visualize the band-crossing in atomically thin $MnBi_2Te_4$ devices. Our results offer insights into the topological character of the band structure in this new Chern insulator.

Structure of Twisted Transition Metal Dichalcogenide Bilayers Madeleine Phillips and C. Stephen Hellberg; U.S. Naval Research Laboratory, United States

We present density functional theory (DFT) calculations of the reconstruction in $MoSe_2/WSe_2$ hetero-bilayers twisted a small angle away from 180-degree stacking. The bilayer reconstructs to increase the area of the domains with the lowest energy stacking. The overall twist is concentrated in the domain walls and vertices, where the energetic cost of twisting away from 180 degrees is reduced. We consider the local stacking, order parameter, and strain in the relaxed twisted bilayer.

1:15 PM *NM06.03.03
Magnetic Order and Spin Excitations in Two-Dimensional Honeycomb Lattice van der Waals Ferromagnets Pengcheng Dai; Rice University, United States

We use neutron scattering to study magnetic order and spin excitations in honeycomb lattice van der Waals ferromagnet CrI$_3$ and CrGeTe$_3$. In the case of CrI$_3$, we show that ferromagnetic phase transition is first order in nature, and controlled by spin-orbit coupling (SOC) induced magnetic anisotropy, instead of magnetic exchange coupling as in a conventional ferromagnet. We discuss the role of the next-nearest-neighbor Dzyaloshinskii-Moriya interaction and Kitaev's interaction plays on the spin-wave spectra of CrI$_3$. For CrGeTe$_3$, we show evidence of a novel spin-lattice coupling that induce a very large spin-wave broadening over a wide energy and momentum space. We discuss the possible presence of topological spin excitations in CrI$_3$ and CrGeTe$_3$.

1:40 PM *NM06.03.04
Spin-Phonon Dynamics in Layered van der Waals Magnets Arun Paramekanti; University of Toronto, Canada

Layered van der Waals magnets, such as CrI3, show enormous potential for using light to drive phonons and to control magnetic exchange interactions. We present a numerical investigation of such coupled spin-phonon dynamics in model Hamiltonians which incorporate Heisenberg exchange as well as bond-anisotropic Kitaev couplings or Dzyaloshinskii-Moriya interactions. We discuss our results in the context of recent optical pump-probe experiments which observe an oscillatory time-resolved polarization rotation below Tc which may stem from coherent oscillations in the Kerr angle.

2:05 PM NM06.03.05
Flat Bands in Twisted Transition Metal Dichalcogenide Bilayers C. Stephen Hellberg and Madeleine Phillips; U.S. Naval Research Laboratory, United States

The electronic properties of transition metal dichalcogenide (TMD) bilayers vary according to the local atomic structure [1]. In minimally twisted bilayers, there is significant atomic reconstruction away from the rigid moiré pattern [2]. We present the results of density functional theory (DFT) calculations that model the electronic properties of $MoSe_2/WSe_2$ bilayers with a small twist away from commensurate 180-degree stacking. We present band structures and local densities of states that exhibit flat bands in the gap near the band edges.

2:20 PM *NM06.03.06
Manipulation of Dimensionality, Edge State and Strain in Transition Metal Dichalcogenide Nanocrystals
Tomojit Chowdhury[1], Erick Sadler[1], Kiyoung Jo[2], Surendra B. Anantharaman[2], Todd Brintlinger[3], Deep M. Jariwala[2] and Thomas J. Kempa[1,1]; [1]Johns Hopkins University, United States; [2]University of Pennsylvania, United States; [3]U.S. Naval Research Laboratory, United States

Two-dimensional (2D) transition metal dichalcogenide (TMD) crystals exhibit electronic, magnetic, and optical properties which can be manipulated through control of crystal dimensionality, edge character, and strain state. We recently introduced a rational chemical synthesis strategy, based on gas-phase growth of TMD crystals on designer surfaces, that substantially improves control over the dimensions, morphology, and crystalline edges of 2D TMDs without top-down fabrication. TMD nanoribbons prepared in this manner exhibit atomically sharp edges, readily controllable dimensions, and anomalous photoluminescence features. This talk will focus on our recent efforts to better understand some of these optical anomalies. A mixed-dimensional architecture comprised of a 2D TMD crystal carefully interfaced with a Si nanowire enables the introduction of localized strain fields. Detailed structural and optical characterization of these architectures reveals unique edge- and strain-mediated photoluminescence that is localized and significantly red-shifted in energy. Our results highlight how rational design of low-dimensional materials can enable future optoelectronic and quantum device goals.

4:00 PM *NM06.04.01
Late News: Controlled Spin Dynamics in Layered Antiferromagnet MnPS3 via Sub-Gap Optical Excitation of Orbitals and Lattice Mattias Matthiesen[1], Jorrit Hortensius[1], Dmytro Afanasiev[1], Andrea Caviglia[1], Eugenio Coronado[2], Peter Steeneken[1], Makars Šiškins[1], Martin Lee[1], Samuel Mañas-Valero[2] and Herre van der Zant[1]; [1]Kavli Institute of Nanoscience, Netherlands; [2]Universitat de Valencia, Spain

It has in recent years become clear that optical pumping of specific solid state modes using ultrashort pulses of light can provide highly targeted access to magnetic order. Resonant excitation of phonons or of electronic orbitals in magnetic ions has been shown to drive non-equilibrium magnetic dynamics, modify magnetic interactions and induce magnetic phase transitions. Such demonstrations have been mainly focused on three-dimensional crystals, and it is of interest to expand this approach to two-dimensional magnets where the magnetic order is intrinsically fragile and is expected to be more sensitive to perturbation. Here, using time-resolved optical second harmonic generation, we study picosecond dynamics of the antiferromagnetic order in the layered van der Waals antiferromagnet manganese thiosulfate (MnPS3) in response to excitation of various sub-gap transitions. We demonstrate that resonant pumping of an orbital *d-d* transition within the Mn^{2+} electronic multiplet launches coherent antiferromagnetic spin precession, while excitation of high-energy phonons leads to quasithermal incoherent magnetic melting.

4:25 PM NM06.04.02
Ultrafast Optical Control of Magnetism in a Topological Insulator Hari Padmanabhan[1], Nathan Koocher[2], Vladimir Stoica[1], Peter Kim[3], Maxwell Poore[3], Danilo Puggioni[2], Seng Huat Lee[1], Richard Schaller[2], Zhiqiang Mao[1], Richard Averitt[3], James Rondinelli[2] and Venkatraman Gopalan[1]; [1]The Pennsylvania State University, United States; [2]Northwestern University, United States; [3]University of California, San Diego, United States

Magnetic order in topologically non-trivial materials gives rise to new, unconventional topological phases.

These phases exhibit unique properties such as quantized electronic transport and magnetoelectric coupling, which can result in potentially groundbreaking applications in error-tolerant quantum computing and spintronics. The key to harnessing these properties lies in being able to control magnetism in these materials. In this work, we demonstrate that ultrafast optical pulses can be used to coherently control magnetism in the topological insulator $MnBi_2Te_4$, through coupling to optical phonons. First, we find using Raman spectroscopy that optical phonons strongly modulate the exchange interaction, resulting in large changes in phonon energies and linewidths across the magnetic transition in $MnBi_2Te_4$. The spin-induced phonon renormalization observed here is the largest reported in any two-dimensional magnet to date. We exploit this strong spin-phonon coupling to optically engineer the spin Hamiltonian through ultrafast modulation of the exchange interaction through displacively excited coherent phonons. Using a time-resolved Kerr effect probe, we find that this results in a coherent modulation of the magnetization at femtosecond timescales. Our work thus unlocks a new mode of control of magnetism in topological materials.

4:40 PM *NM06.04.03
Using Ultrafast Electron Diffraction to Visualize Lattice Dynamics at Two-Dimensional van der Waals Interfaces Archana Raja; Lawrence Berkeley National Laboratory, United States

Two-dimensional (2D), van der Waals crystals allow the creation of arbitrary, atomically precise heterostructures simply by stacking disparate monolayers without the constraints of covalent bonding or epitaxy. Charge and energy transfer processes at these novel junctions is an area of burgeoning interest both from the fundamental and application points of view. At a type II heterojunction between two 2D semiconductors, ultrafast charge transfer has been previously determined to occur on the order of 10's of femtoseconds after photoexcitation. However, the coupling between the lattice degrees of freedom of the photoexcited monolayers remains less understood. We use ultrafast electron diffraction to directly visualize lattice dynamics in the individual monolayers of the van der Waals heterojunction. We are able to track the transfer of energy from one layer to another by following the change in intensity of the Bragg peaks after photoexcitation. With the aid of first principles calculations, we are able to shed light on the role of lattice dynamics during ultrafast electronic processes at 2D van der Waals heterojunctions.

5:05 PM NM06.04.04
Exploring Nonlinear Light-Matter Interaction and Electrostatic Doping in 2D Quantum Materials Xiaofeng Qian; Texas A&M University, United States

The ability to achieve noninvasive detection and efficient control of electric and magnetic orders in 2D quantum materials is of great importance to the development of ultrathin quantum electronics, optics, spintronics. Here we present our recent theoretical predictions of nonlinear response and sensing of 2D topological materials [1, 2, 3] and electrostatic doping induced switching of magnetic orders in 2D high Curie temperature ferromagnetic semiconductors CrSBr and CrSeBr [4]. First, we will show that time-reversal invariant few-layer WTe_2 holds out-of-plane polarization which can be switched via slight interlayer sliding under vertical electric field. Moreover, ferroicity-driven switching of nonreciprocal nonlinear photocurrent [5] such as ferroelectric nonlinear anomalous Hall effect can be achieved in few-layer WTe_2 by utilizing the intrinsic coupling among nonlinear susceptibility, crystalline symmetry, and quantum geometry of electronic states [1], paving theoretical foundation for nonlinear quantum memory such as Berry curvature memory. We will discuss the very recent experimental demonstration of ferroelectric nonlinear anomalous Hall effect in tri-layer WTe_2 [2]. We will also introduce our recent work on nonlinear photocurrent in PT-symmetry magnetic topological quantum materials [3], where magnetic shift photocurrent can be magnetically switched between two antiferromagnetic states in bilayer antiferromagnetic $MnBi_2Te_4$. Moreover, external electric field can break PT-symmetry and enable normal shift photocurrent that are electrically switchable and tunable down to a few THz regime, suggesting bilayer antiferromagnetic $MnBi_2Te_4$ as a tunable platform with rich THz and magneto-optoelectronic applications. Finally, we will briefly present our recent theoretical prediction of long-range two-dimensional ferromagnetism in monolayer semiconductors CrSBr and CrSeBr with high Curie temperature of ~150K [4] which was also experimentally demonstrated recently, offering potential alternatives to dilute magnetic

semiconductors. We show that electrostatic doping can switch magnetization easy axis, providing unprecedented opportunities for 2D spintronics such as spin valves and spin FETs [4].

Coupling Monolayer WS_2 with a Photonic Polymer Waveguide Through Mode-Center Placement
Angelina Frank, Justin Zhou Yong, James Grieve, Ivan Verzhbitskiy, Alexander Ling and Goki Eda; National University of Singapore, Singapore

The core requirement and challenge for integrated hybrid photonic platforms is effective coupling between the guided mode of a photon-routing structure and a photo-active material. In traditional (e.g. silicon nitride) platforms, the mode center is inaccessible which significantly limits the interaction between material and platform. Here, we overcome this limitation through integration of an atomically thin 2D material (WS_2) on hBN into the mode center of a novel elastomeric single-mode rib waveguide. This is achieved through transfer of the emitter onto a precured polymer layer and its subsequent bonding to the supporting polymer matrix by oxygen-plasma activation. We verify waveguide-emitter coupling by various means: observing polarization-dependent excitation of the integrated emitter when excited through the waveguide, collection of emission from the guide's output face, as well as polarization-dependent extinction in transmission measurements. Representative for room-temperature curing polymers, this work opens up new ways for the integration of (single-photon) emitters into polymer-based optical circuits.

5:35 PM *NM06.04.06
Optical Spectroscopy of Twisted Heterostructures of Transition Metal Dichalcogenides Hyeonsik Cheong; Sogang University, Korea (the Republic of)

Heterostructures of transition metal dichalcogenides (TMDs) have been extensively studied as the alignment of the bands in the constituent materials allow for manipulation of optoelectronic and transport properties. The band offset between the bands is usually the most important parameter in determining the physical properties of these structures. However, as evidenced in the so-called 'magic-angle graphene' [1], the twist angle between the crystallographic directions of the two layers is an important parameter that affect the physical properties. As the twist angle between two layers of a given set of materials is varied, the phonon spectrum as well as the electronic band structure and optoelectronic properties change systematically. Furthermore, at very small twist angles, atomic-scale lattice reconstruction [2] is observed and should be accounted for in describing the physical properties of heterostructures. In this talk, I will present some of the latest experimental data on the phonon spectra and the band structures from twisted heterostructures of TMDs.

***Ab Initio* Spin-Phonon Relaxation in Graphene in Presence of External Electric Field and hBN** Adela

Habib[1], Junqing Xu[2], Yuan Ping[2] and Ravishankar Sundararaman[1]; [1]Rensselaer Polytechnic Institute, United States; [2]University of California, Santa Cruz, United States

For the last two decades, graphene's impressive prospect as a material to revolutionize technologies from electronics to spintronics and quantum computing has prompted numerous studies of its spin dynamics. One of the puzzling phenomena in these studies has been a large discrepancy, at best by two orders of magnitude, between the observed and the predicted spin relaxation lifetimes. Several theoretical studies based on various models have proposed that external factors including but not limited to the substrate and externally applied electric field can influence relaxation reducing spin lifetimes from the predicted microseconds to nanoseconds in measurements. In particular, both these factors are expected to break space-inversion symmetry enhancing spin-orbit coupling strength significantly and consequently increasing spin relaxation rates in graphene. However, past theoretical models do not capture the effects of real substrates and hence do not explain the spin lifetime anisotropy at a graphene/hBN interface with an applied electric field. Consequently, a first-principles approach to explain these relaxation channels is necessary.

Here, we present our investigations of spin dynamics and in particular spin-phonon relaxation fully from first-principles in single layer graphene in the presence of an external electric field and/or hBN substrate. Using our *ab initio* computational method based on density matrices[1], we evolve electron(hole) spins for microseconds after an initial perturbation by a small magnetic field all the while fully accounting for their scattering against phonons. From our results, we predict that room-temperature spin lifetimes in graphene range from hundreds of picoseconds to a few nanoseconds in the presence of an external electric field or hBN. We find that the out-of-plane vs. in-plane spin lifetime anisotropy is greater than 0.5 in graphene on hBN, in a remarkable agreement with experimental observations but deviates from the general consensus in model-based theoretical studies. We report spin anisotropy of 0.5 only as a result of external applied electric field on free-standing graphene confirming its origin to the Bychkov-Rashba type spin-orbit field as widely accepted in theoretical studies. Our findings suggest that both substrate-induced spin-orbit fields and substrate phonons influence spin relaxation substantially and reduce lifetimes to the orders observed in experiments. [1] J. Xu et al, Nat. Commun. 11, 2780 (2020)

Chiral and Helical Edge Transport in High Mobility 2D Materials Chun Ning (Jeanie) Lau; The Ohio State University, United States

Two-dimensional (2D) materials and heterostructures provide excellent platforms for exploring and understanding chiral and helical edge transport. Here we present our works on magnetotransport in high mobility 2D heterostructures. In few-layer black phosphorus devices, we use p-p'-p junctions to study the equilibration and transmission of edge states at the interfaces of regions with different charge densities. We observe both full equilibration, where all edge channels equilibrate and are equally partitioned at the interfaces, and partial equilibration, where only equilibration only takes place among modes of the same spin polarization. Furthermore, the inner p'-region with low-doping level in the junction can function as a filter for highly doped p-regions which demonstrates gate-tunable transmission of edge channels. In Bernal-stacked tetralayer graphene, we observe two topologically distinct phases supporting helical edge states at the charge neutrality point. As the magnetic field and out-of-plane displacement field *D* are varied, we observe a phase diagram consisting of an insulating phase and two metallic phases, with 0, 1 and 2 helical edge states, respectively. These phases are accounted for by a theoretical model that relates their conductance to spin-polarization plateaus. Transitions between them arise from a competition among inter-layer hopping, electrostatic and exchange interaction energies.

Stacking Dependent 2D Magnetism Shiwei Wu; Fudan University, China

In van der Waals layered materials, the symmetries and functionalities could be controlled by modifying the stacking order through rotation and translation between the layers. Whereas most previous work has focused on the electronic and optical properties associated with the van der Waals stacking, the recent discovery of magnetism in 2D materials, achieved through both mechanical exfoliation and molecular beam epitaxy (MBE), provides an exciting opportunity to explore the effects of stacking order on a material's magnetic properties. In this talk, I will present two of our recent studies in this direction. 1) By discovering a giant nonreciprocal second harmonic generation from layered antiferromagnetism in mechanically exfoliated bilayer CrI3, we revealed the underlying C2h symmetry, and thus monoclinic stacking order in bilayer CrI3, providing crucial structural information for the microscopic origin of layered antiferromagnetism. 2) By using the molecular beam epitaxy to grow monolayer and bilayer CrBr3 and in situ characterization with a spin-polarized scanning tunneling microscopy and spectroscopy, we observed that while individual CrBr3 monolayer is ferromagnetic, the interlayer coupling in bilayer depends strongly on the stacking structure and can be either ferromagnetic or antiferromagnetic. Thus, the direct correlation between stacking order and interlayer magnetism pave the way for manipulating 2D magnetism.

2D Correlations in the van der Waals Ferromagnet $CrBr_3$ Using High Frequency Electron Spin Resonance Spectroscopy Christian Saiz[1], Jose A. Delgado[1], Johan van Tol[2], Fazel Fallah Tafti[3] and Srinivasa Rao Singamaneni[1]; [1]The University of Texas at El Paso, United States; [2]Florida State University, United States; [3]Boston College, United States

Broadening the knowledge and understanding on the magnetic correlations in van der Waals layered magnets is critical in realizing their potential next-generation applications. In this study, we employ high frequency (240 GHz) electron spin resonance (ESR) spectroscopy on plate-like $CrBr_3$ to gain insight into the magnetic interactions as a function of temperature (200 – 4 K) and the angle of rotation θ. We find that the temperature dependence of ESR linewidth is well described by the Ginzberg-Landau critical model as well as Berezinskii-Kosterlitz-Thouless (BKT) transition model, indicative of the presence of two-dimensional (2D) correlations. Furthermore, our findings show that the resonance field follows a $(3cos^2\theta - 1)$-like angular dependence, while the linewidth follows a $(3cos^2\theta - 1)^2$-like angular dependence. This observed angular dependence of the resonance field and linewidth further confirm an unanticipated 2D magnetic behavior in $CrBr_3$. This behavior is likely due to the interaction of the external magnetic field applied during the ESR experiment that allows for the mediation of long-range vortex-like correlations between the spin clusters that possibly formed due to magnetic phase separation. This study demonstrates the significance of employing spin sensitive techniques such as ESR to better understand the magnetic correlations in similar van der Waals magnets and suggests the need to study the magnetic correlations in $CrBr_3$ more closely.

7:50 PM NM06.05.05
Creating Half-Metallicity in Two-Dimensional Magnetoelectric Materials Cheng Gong[1], Shi-Jing Gong[2], Geunsik Lee[3], Andrew Rappe[4] and Xiang Zhang[5]; [1]University of Maryland, United States; [2]East China Normal University, China; [3]Ulsan National Institute of Science and Technology, Korea (the Republic of); [4]University of Pennsylvania, United States; [5]University of California, Berkeley, United States

Magnetic two-dimensional (2D) materials [1, 2] opened up unprecedented opportunities for nanoscale spintronic devices in the miniaturized form factor. With the aggressive pursuit for dimensional downscaling is the other paramount endeavor for high energy efficiency [3]. Under the umbrella of the pursuit for the low energy consumption, the realization of high spin polarization via minimal amount of electrical input is a critical prerequisite. In this talk, I will introduce two schemes [4, 5] to create half-metallicity in 2D layered material systems. In scheme I [4], electric field will be applied across the bilayer A-type antiferromagnetic 2D materials. In scheme II [5], a multiferroic superlattice consisting of alternative ferroelectrics and A-type antiferromagnets is constructed for the ferroelectric control of half-metallicity. Both schemes are experimentally relevant, and

will provide valuable contributions to the developments of miniaturized high-efficiency spintronic devices.

Gigantic Current Control of Coercive Field and Intrinsic Spin-Orbit-Torque in Topological van-der-Waals Ferromagnetic Metal Fe_3GeTe_2 Kaixuan Zhang; Seoul National University, Korea (the Republic of)

Controlling magnetic states by a small current is essential for the next-generation of energy-efficient spintronic devices. The emerging spin-orbit-torque-Magnetic-Random-Access-Memory (SOT-MRAM) is the most promising commercial magnetic-RAM in the near future[1]. Unfortunately, the switching current density and power dissipation are still too high for conventional magnet/heavy-metal based SOT-MRAM[1], prompting the development of new large-SOT systems. On the other hand, very recently, van-der-Waals (vdW) magnetic materials have rapidly emerged as key members of the field of two-dimensional materials and device physics [2-7]. Among all the magnetic vdW materials, Fe3GeTe2 received special attention because it is the only topological ferromagnetic vdW metal[8].
Here we report that surprisingly an in-plane current can tune the magnetic state of nm-thin vdW ferromagnet Fe3GeTe2 from a hard magnetic state to a soft magnetic state, through substantial reduction of the coercive field. This surprising finding is possible because the in-plane current produces a highly unusual type of gigantic spin-orbit torque for Fe3GeTe2, which is directly related to the large Berry curvature and so its band topology. And we further demonstrate a working model of a new nonvolatile magnetic memory based on the principle of our discovery in Fe3GeTe2, controlled by a tiny current. Our findings open up a new window of exciting opportunities for magnetic vdW materials with potentially huge impacts on the future development of spintronic.

8:00 AM *NM06.06.01
Giant c-axis Nonlinear Anomalous Hall Effect in T_d-$MoTe_2$ Adam W. Tsen[1], Archana Tiwari[1], Fangchu Chen[1], Shazhou Zhong[1], Elizabeth Drueke[2], Jahyun Koo[3], Austin Kaczmarek[2], Cong Xiao[4], Jingjing Gao[5], Xuan Luo[5], Qian Niu[4], Yuping Sun[5], Binghai Yan[3] and Liuyan Zhao[2]; [1]University of Waterloo, Canada; [2]University of Michigan–Ann Arbor, United States; [3]Weizmann Institute of Science, Israel; [4]The University of Texas at Austin, United States; [5]Chinese Academy of Sciences, China

We report the observation of a giant c-axis nonlinear anomalous Hall effect in the non-centrosymmetric T_d phase of $MoTe_2$, where application of an in-plane current generates a Hall field perpendicular to the layers. By measuring samples across different thicknesses and temperatures, we find that the nonlinear susceptibility obeys a universal scaling with sample conductivity. Application of higher bias yields an extremely large anomalous Hall ratio and conductivity.

Spin-Dependent Transport Through Colloidal Quantum Dots—The Role of the Exchange Interaction John P. Philbin[1], Amikam Levy[2], Prineha Narang[1] and Wenjie Dou[3]; [1]Harvard University, United States; [2]Bar-Ilan University, Israel; [3]University of California, Berkeley, United States

The study of spin transport through semiconductor quantum dots is experiencing a renaissance due to recent advances in nano-fabrication and the realization of quantum dots as candidates for quantum computing. In this work, we combine atomistic electronic structure calculations with quantum master equation methods to study the transport of electrons and holes through quantum dots coupled to two leads with a voltage bias. We find that a competition between the energy spacing between the two lowest quasiparticle energy levels and the strength of the exchange interaction determines if a spin singlet or triplet is the lowest energy two quasiparticle state. Specifically, the low density of electron states results in a spin singlet being the lowest energy two electron state whereas, in contrast, a spin triplet is the lowest energy two hole state due to the high density of states and significant exchange interaction. The exchange interaction is also responsible for spin blockades that our transport calculations suggest persist up to temperatures as high as 77 K for colloidal quantum dots with small core diameters. Lastly, we relate the findings of this study to both optical experiments and the preparation and manipulation of singlet and triplet spin states in quantum dots using voltage biases.

This work is partially supported by the Army Research Office MURI (Ab-Initio Solid-State Quantum Materials) under Grant No. W911NF-18-1-0431. JP is a Ziff Fellow at the Harvard University Center for the Environment.

Observing Quantum-Confinement Effects on the In-Plane Translational Motion of Excitons in CdSe Nanoplatelets Laurens Siebbeles; Delft University of Technology, Netherlands

Colloidal CdSe nanoplatelets (NPLs) can be made with a thickness of atomic precision in the range of about one to a few nanometers only. The lateral sizes are of the order of several to tens of nanometers. The thickness is less than the bulk exciton bohr radius and consequently leads to strong effects of spatial confinement on the internal energy of an exciton. Variation of the thickness of a NPL thus allows one to tune the photoluminescence (PL) and optical absorption spectra.
Interestingly, however, the experimental shape of PL and absorption spectra also depends on the lateral sizes of a NPL. To date, the latter has not received much attention, with the exception of a few (mainly theoretical) studies and the origin of this effect has been inconclusive.

We measured the PL and absorption spectra for a series of NPLs with different lateral sizes and find that the dependence of the optical spectra on the lateral size is fully explained by taking into account the quantum-confinement effects on the translational motion of excitons in the plane of the NPLs. The spectra of all samples considered can be reproduced very accurately by a theoretical description of exciton energies and oscillator strengths based on the quantum mechanical particle-in-a-box model and the known size-distribution of the NPLs.

Magnetic van der Waals Materials Under Pressure Sergey Budko; Ames Laboratory, Iowa State University, United States

Magnetic van der Waals (vdW) materials are considered as promising candidates for low-dimensional magnetism since their vdW nature suggests the possibility of exfoliation down to the monolayer level and their low crystalline symmetry implies an intrinsic magnetic anisotropy. An understanding of the details of their bulk magnetic structure and the tunability of their properties is an important step towards potential applications. In this talk, a brief overview of the effects of hydrostatic pressure magnetic vdW materials will be presented with a particular emphasis on the recent magnetization and heat capacity results under pressure for VI_3 and $CrPS_4$, where a complex interplay between different phases is observed at moderate pressure values.
Work at the Ames Laboratory was supported by the US Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division. Ames Laboratory is operated for the US Department of Energy by Iowa State University under Contract No. DE-AC02-07CH11358.

Long and Short-Range Ordered Magnetism in Honeycomb Na2Ni2TeO6 Nathan Episcopo[1], Po-Hao Chang[1], Thomas W. Heitmann[2], Kinley Wangmo[1], James M. Guthrie[2], Magdalena Fitta[3], Ryan Klein[4], Narayan Poudel[5], Krzysztof Gofryk[5], Rajendra R. Zope[1], Craig Brown[6] and Harikrishnan S. Nair[1]; [1]The University of Texas at El Paso, United States; [2]University of Missouri–Columbia, United States; [3]Polish Academy of Sciences, Poland; [4]National Renewable Energy Laboratory, United States; [5]Idaho National Laboratory, United States; [6]National Institute of Standards and Technology (NIST), United States

Low dimensional magnetic lattices are being studied recently owing to the possibility of realizing flatbands in the magnon spectrum which can then lead to dissipation-less spin transport and associated magnon Hall effect. One could expect to find a magnon insulator, similar to a topological insulator. In the present work we present a rather less-studied honeycomb material $Na_2Ni_2TeO_6$. Our samples of $Na_2Ni_2TeO_6$ conform to hexagonal *P6₃/mcm* space group with refined lattice parameters, a = 5.2023(1) Å and c = 11.1552(8) Å. The physical properties of the present sample are characterized using magnetic susceptibility and specific heat, both of which confirm a phase transition at 28 K. Application of 8 T magnetic field only slightly polarizes the moment at the transition. We obtain a Curie-Weiss temperature of -9.7(2) K and effective paramagnetic moment of 2.24(4) m_B/Ni. This matches well with the spin-only moment of Ni^{2+}. Neutron diffraction experiments are used to determine the static magnetic structure and inelastic neutron scattering reveals a rather flat spin wave excitation at 5 meV. Combining neutron diffraction with density functional theory computations, we obtain a handle on the magnetism of honeycomb layers of Ni in $Na_2Ni_2TeO_6$.

***In Situ* Electron Spin Resonance Studies of MoS_2 During the Hydrogen Evolution** Jose A. Delgado[1], Yulu Ge[1], Dawn Blazer[1], Chinnathambi Karthik[2], Russell Chianelli[1], Dino Villagran[1] and Srinivasa Rao Singamaneni[1]; [1]The University of Texas at El Paso, United States; [2]Boise State University, United States

Finding energy efficient, earth-abundant catalysts to aid in the production of hydrogen has been the subject of intense research for several decades. Characterizing new catalysts is an important step in replacing rare-earth Pt-based catalysts for the hydrogen evolution reaction (HER). To the best of our knowledge, the earth-abundant catalyst MoS_2 has not been studied under HER reaction conditions using spin sensitive techniques. Therefore, our objective is to study the relationship between crystal defects and reactivity on the surface and edge sites of hydrothermally grown nanocrystalline MoS_2 using *in situ* Electron Spin Resonance (ESR). For this purpose, we have developed an *in situ* ESR cell to characterize MoS_2 during HER. This technique is useful for tracing the dynamics of conduction electrons and ferromagnetic/paramagnetic species, which can be used to understand reaction mechanisms and charge transfer processes. The charge transfer mechanisms and defect – reactivity relationships in MoS_2 during HER will be discussed in terms of this highly sensitive *in situ* technique.

NM06.07.03

Proton Fluence-Dependent Magnetic Properties of Irradiated van der Waals $CrSiTe_3$ Hector Iturriaga[1], Rubyann Olmos[1], Dawn Blazer[1], Luis M. Martinez[1], Kinjal Gandha[2], Cajetan I. Nlebedim[2], Yu Liu[3], Cedomir Petrovic[3], Lin Shao[4], Qiang Wang[5], Ju Chen[6], Martin L. Kirk[6] and Srinivasa Rao Singamaneni[1]; [1]The University of Texas at El Paso, United States; [2]Ames Laboratory, United States; [3]Brookhaven National Laboratory, United States; [4]Texas A&M University, United States; [5]West Virginia University, United States; [6]The University of New Mexico, United States

The emergence of novel properties in layered van der Waals magnets subject to external stimuli, such as exfoliation or doping, creates opportunites to favorably adjust their characteristics for the production of functional devices [Nat Rev Phys **1**, 646–661 (2019)]. In particular, $Mn_3Si_2Te_6$, a vdW ferrimagnet, has shown enhanced magnetization after irradiation [Appl. Phys. Lett. **116**, 172404 (2020)]. Therefore, we present the effects of proton irradiation on the magnetic properties of $CrSiTe_3$ (CST), a similar compound that has garnered attention for its potential use in atomically thin devices. Bulk CST is a layered van der Waals semiconducting ferromagnet with a previously reported Curie temperature (T_C) of 32 K [Phys. Rev. Materials **3**, 014001]. In this study, bulk CST crystals were irradiated at several fluences ranging from 10^{15} – 10^{18} protons/cm^2. Low-temperature SQUID magnetometry measurements reveal changes in the reported behavior of the magnetic phases of CST; for example, we find a T_C of up to 37 K in the sample irradiated with 10^{18} protons/cm^2. The evolution of the temperature and magnetic field dependence of the magnetization provides further insight into the differences between pristine and irradiated CST. Furthermore, the magnetic properties of CST will be described by our experimental findings on saturation magnetization, coercivity, T_C, and magnetocrystalline anisotropy.

NM06.07.04

Stability, Electronic States and Magnetization of WTe_2 Edges with Cu Adsorbates Zexi Lu, Micah P. Prange and Peter V. Sushko; Pacific Northwest National Laboratory, United States

Understanding the intrinsic stability, electronic and magnetic properties of functional materials, and their response to external chemical environments is crucial for their application in devices. Two-dimensional (2D) transition metal dichalcogenides (TMDCs) draw great attention due to their unusual electronic properties promising for applications in quantum information sciences (QIS). In particular, edges in some TMDCs exhibit non-trivial topologic states that enable spin-momentum locking critical for realization of topological qubits. Utilization of these states in practical devices depends on our ability to control the details of their properties upon integrating them into larger materials systems. It is therefore critical to understand how the structure,

stability, and electronic properties of these edges are affected by their interfaces with other materials and by intrinsic and extrinsic defects.

In this study, we use first-principles simulations to quantify the stability of several types of edges in pristine and functionalized 1T'-phase WTe_2 and describe their electronic properties. We consider one-dimensional (1D) edges along {010}, {100}, {110} and {310} lattice directions and investigate the effects of the interactions with Cu atoms and clusters depending on the distribution and concentration of the adsorbed Cu species. We find that Cu atoms prefer to either cluster or form a quasi-1D chain along (010) edge, depending on the details of its atomic termination. Our simulations also predict that Cu clusters introduce magnetization and break the non-trivial topological order of WTe_2 protected by time-reversal symmetry. In contrast, the quasi-1D chain of the Cu atoms introduces a deformation that shifts the energy levels of the edge states, most of which remain intrinsic to WTe_2 and support quantum spin Hall effect. Our study suggests avenues for a controlled modification of the critical properties of WTe_2 through the control of its external chemical environments, which can be potentially generalized to a broader class of TMDCs and provide guidance for the design of new devices and manufacturing process.

NM06.07.05

Fluence -Dependent Magnetic Properties of Proton Irradiated Antiferromagnets MPS3 (M= Mn, Fe, and Ni) Samir A. Muniz[1], Hector Iturriaga[1], Luis M. Martinez[1], Lin Shao[2], Suhan Son[3], Je-Geun Park[3] and Srinivasa Rao Singamaneni[1]; [1]The University of Texas at El Paso, United States; [2]Texas A&M University, United States; [3]Institute for Basic Science, Korea (the Republic of)

Magnetic ordering in the two-dimensional (2D) limit has been one of the most important research topics in condensed matter physics for the past couple of years. Layered quasi 2D materials such as $MnPS_3$, $FePS_3$ and $NiPS_3$ form a unique class of compounds. All three compounds are isostructural with the magnetic lattice being the two-dimensional honeycomb, the spin dimensionalities for the three compounds are different. While $MnPS_3$ is best described by the isotropic Heisenberg Hamiltonian, $FePS_3$ is most effectively described by the Ising model and $NiPS_3$ by the anisotropic Heisenberg Hamiltonian. The materials order antiferromagnetically at low temperatures, the Neel temperatures being 78,123 and 155K, respectively. Our main objective of this study is to investigate the magnetic properties of the above compounds upon proton irradiation, which is the versatile strategy in tuning the magnetic properties[1]. These crystals were subjected to proton irradiation at fluences ranging from unirradiated, $1x10^{15}$, $5x10^{15}$, $1x10^{16}$ and $5x10^{16}$ protons/cm^2. We performed Raman, electron spin resonance, and magnetization measurements on all the proton irradiated samples, including the pristine crystals. We will present and discuss the comprehensive experimental findings, and offer the possible explanation for the observed trends.

NM06.07.06

Magnetic Properties of Bulk $CrBr_3$ Crystals Under Hydrostatic Pressure Rubyann Olmos[1], Shamsul Alam[1], Hector Iturriaga[1], Kinjal Gandha[2], Ikenna Nlebedim[2], Fazel Fallah Tafti[3], Rajendra R. Zope[1] and Srinivasa Rao Singamaneni[1]; [1]The University of Texas at El Paso, United States; [2]Ames Laboratory, United States; [3]Boston College, United States

The van der Waals class of materials offer a new approach for two-dimensional magnetism allowing spin fluctuations to be tuned upon exfoliation of layers. Moreover, it has recently been shown that spin lattice coupling and long-range magnetic order can be modified with pressure in van der Waals materials. In this study we look to understand the magnetic structure and properties of $CrBr_3$, a member of the highly anisotropic MX_3 (M = Cr, V; X = Cl, Br, I) compounds. As research on pressure induced magnetic properties of CrX_3 is at its nascent stage, we seek to gain further insight into whether pressure increases or decreases the long-range magnetic ordering on bulk $CrBr_3$ crystals. The application of pressure (0 - 0.8 GPa) shows a decrease in saturation magnetization with small decrease in the Curie temperature from 32.8 K to 29.2 K at 0.8 GPa. Density functional theory calculations with pressure from 0 - 1 GPa show a reduction in volume and interplanar distance as pressure increases. To further understand magnetic properties with applied pressure we calculate the

magnetocrystalline anisotropy energy (MAE) and exchange coupling parameter (J). There is minimal decrease in MAE and the first nearest neighbor interaction (J_1) with a Hubbard U parameter, $U = 0$ eV, shows a reduction in J_1 with respect to pressure. Overall, $CrBr_3$ displays ferromagnetic interlayer coupling and the calculated parameters match well with experiment. We also explore the magnetocaloric effect as a function of pressure for this compound and in the future, further insight will be collected on the local electronic and magnetic structure of this material by employing x-ray magnetic circular dichroism (XMCD) (Cr L2,3 edge) measurements at high pressure (0-10 GPa).

NM06.07.07

Probing the Stability of Shastry Sutherland Lattice in Er_2Pd_2Sn and Er_2Pd_2In Gicela G. Saucedo Salas[1], Baidyanath Sahu[2], C. M. Naveen Kumar[3], Andre Strydom[2], Stuart Calder[4], Qiang Zhang[4] and Harikrishnan S. Nair[1]; [1]The University of Texas at El Paso, United States; [2]University of Johannesburg, South Africa; [3]Institut für Festkörperphysik, Austria; [4]Oak Ridge National Laboratory, United States

The Shastry-Sutherland lattice-based compounds have perennial interest in the condensed matter physics community owing to the quantum phases that it realizes due to frustration. The R_2T_2X intermetallic compounds (R = rare earth, T = transition metal, X =main group), have been reinvestigated recently owing to the spin liquid state in the underlying Shastry-Sutherland lattice (SSL) formed by the *rare earth* [1, 2]. These compounds crystallizing in the Mo_2FeB_2 structure type display an interplay of frustration and quantum criticality. For the current study, we have selected the less-investigated Er_2Pd_2In and Er_2Pd_2Sn. X-ray powder diffraction and subsequent Rietveld refinements confirmed that the compounds were phase-pure and crystallize with tetragonal Mo_2FeB_2 structure. Both the compounds obeyed Curie-Weiss law in the paramagnetic regime, as judged from magnetic susceptibility data, which indicated anti-ferromagnetism. Specific heat data on both the compounds revealed a double peak indicating complex magnetic structure and phase transitions close to 6 K. We will present a detailed analysis of the magnetization and specific heat on both $Er_2Pd_2(Sn/In)$ and the microscopic magnetic structure determined from neutron powder diffraction which indicates an incommensurate wave vector, k (0.09 0.09 0.5).

Late News: Controlling the Anisotropy of a van der Waals Antiferromagnet with Light Dmytro Afanasiev[1,2], Jorrit Hortensius[1], Mattias Matthiesen[1], Samuel Mañas-Valero[3], Makars Šiškins[1], Martin Lee[1], Edouard Lesne[1], Herre van der Zant[1], Peter Steeneken[1], Boris A. Ivanov[4], Eugenio Coronado[3] and Andrea Caviglia[1]; [1]Delft University of Technology, Netherlands; [2]Universität Regensburg, Germany; [3]Universitat de València, Spain; [4]National Academy of Sciences and Ministry of Education and Science, Ukraine

Magnetic van der Waals materials provide an ideal playground for exploring the fundamentals of low-dimensional magnetism and open new opportunities for ultrathin spin-processing devices. The Mermin-Wagner theorem dictates that as in reduced dimensions isotropic spin interactions cannot retain long-range correlations; the order is stabilized by magnetic anisotropy. Here, using ultrashort pulses of light, we demonstrate all-optical control of magnetic anisotropy in the two-dimensional van der Waals antiferromagnet $NiPS_3$. Tuning the photon energy in resonance with an orbital transition between crystal-field split levels of the nickel ions, we

demonstrate the selective activation of a sub-THz magnon mode with markedly two-dimensional behaviour. The pump polarization control of the magnon amplitude confirms that the activation is governed by the instantaneous magnetic anisotropy axis emergent in response to photoexcitation of electronic orbitals with a lowered symmetry. Our results establish pumping of orbital resonances as a universal route for manipulating magnetic order in low-dimensional (anti)ferromagnets.

Nanoscale Quantum Sensing of Two-Dimensional Spin Systems Patrick Maletinsky; University of Basel, Switzerland

The recent discovery of long-range magnetic order in atomically thin ``van der Waals'' (vdW) crystals [1] has attracted significant attention due to their fundamental and technological interest, including predictions of exotic magnetic phases and unique opportunities to control magnetism at the atomic scale.

I will present recent experiments, where we employ single-spin-based quantum sensors for quantitative, nanoscale probing of atomically thin vdW magnets [2]. Specifically, I will describe experiments, where we employ this technology to address magnetism in the prototypical vdW magnet CrI_3 [3], down to the level of atomic monolayers. Our approach enabled nanoscale imaging of magnetic domains, quantitative determination of CrI_3's layer-dependent magnetization, and revealed a delicate interplay between magnetic and crystalline order in CrI_3.

Further, I will present recent results where we employ our quantum sensors to study two-dimensional systems of uncompensated magnetic moments that arise on surfaces of specific antiferromagnets [4]. On the use-case of a single-crystal of the prototypical, magnetoelectric antiferromagnet of Cr_2O_3, we establish how these spin systems can act as reports for the underlying antiferromagnetic order parameter and use this principle to gain new insight into the behavior of domain-walls in this antiferromagnet. Our results show remarkably pristine domain wall behavior in this material, and offer new routes to engineered domain-wall behavior and its application in the field of antiferromagnetic spintronics [5].

I will conclude with an outlook of future engineering challenges [6][7] for nanoscale quantum sensors and our ongoing developments of single spin magnetometers for extreme conditions, such as high magnetic fields, millikelvin temperatures or for high-frequency sensors to probe the dynamics of nanomagnetic systems.

1:40 PM *NM06.08.03
Spontaneous Valley Polarization of Interacting Carriers in a Monolayer Semiconductor Scott Crooker; Los Alamos National Laboratory, United States

This talk will discuss recent magneto-absorption optical spectroscopy studies of dual-gated WSe2 monolayers in high magnetic fields up to 60 T. When doped with a 2D Fermi sea of mobile holes, well-resolved sequences of optical transitions are observed in both left- and right- circular polarization, which unambiguously and separately indicate the number of filled Landau levels (LLs) in both K and K' valleys. This reveals the interaction-enhanced valley Zeeman energy, which is found to be highly tunable with hole density. We exploit this tunability to align the LLs in K and K', and find that the 2D hole gas becomes unstable against small changes in LL filling and can spontaneously valley polarize [1]. These results cannot be understood within a

single-particle picture, highlighting the importance of exchange interactions in determining the ground state of 2D carriers in monolayer semiconductors. [1] Jing Li, Mateusz Goryca, Nathan Wilson, Andreas Stier, Xiaodong Xu, & Scott A. Crooker, Phys. Rev. Lett. 125, 147602 (2020).

2:05 PM NM06.08.04
Late News: Towards Scalable High-Resolution Characterization of 2D van der Waals Heterostructures
Hesham El-Sherif[1], Natalie Briggs[2], Joshua Robinson[2] and Nabil Bassim[1]; [1]McMaster University, Canada; [2]The Pennsylvania State University, United States

Scalable synthesis of heterostructures is recently realized through the *confinement heteroepitaxy* (CHet) technique. In this technique, atoms intercalate the epitaxial graphene (EG) interface and silicon carbide (SiC) substrates, which facilitates large-area environmentally stable 2D Nitrides, 2D Oxides, and 2D metals. One of the recently advanced 2D metals is gallium (2D Ga or Gallenene), which is characterized as a half-van der Waal 2D metal heterostructure due to the bonding variation across the interface. Interestingly, 2D Ga exhibits exotic optical and electronic properties, such as enormous non-linear optical response, superconductivity, and near-zero index. In prior work, the spectroscopic ellipsometry technique reports that 2D Ga is mainly grown with bilayer thickness. However, the heterostructure's thickness, uniformity, and area coverage are not quantitatively understood with high spatial resolution techniques.

Here, we unlock the contrast from scanning electron microscope (SEM) images as a function of the 2D Ga position and the EG thicknesses. The SEM contrast is directly related to the local surface potential. We applied multiple correlative electron microscopy techniques, including the SEM and surface chemical maps in plan view for understanding the secondary electron (SE) emission contrast in SEM images. We also verified the 2D Ga location and the number of layers by correlating SEM with Scanning-Transmission electron microscopy (STEM) imaging and spectroscopy obtained from multiple site-specific cross-sections. Furthermore, we stitched hundreds of atomic-resolution STEM images over 7 µm FIB lamella to confirm that the 2D Ga grows with uniform bilayer Ga covered by EG with thicknesses that vary from 2-layers and up.

Besides, locating the uniform 2D Ga heterostructure positions enables us to segment SEM images that cover few millimeters in area. This segmentation process can be done manually from the image histogram or un-supervised by machine learning techniques. We form a montage view of ~ 2 mm x 1.5 mm area by stitching low-magnification and pixel-dense SEM images. This panorama retains lateral resolution controlled by the SEM resolution (few nm) but preserves atomic-resolution as resolved by correlative microscopy of the heterostructure's thicknesses.

Unlike spectroscopic techniques (ellipsometry or XPS), the *spectroscopic imaging* in SEM allows high-spatial-resolution for tracking intercalants, identify relative surface potentials, or determining the number of 2D layers. This could be further employed to characterize wafers' scalability and uniformity of 2D materials and 2D Van der Waals heterostructures.

2:20 PM *NM06.08.05
MXenes—2D Plasmonic Materials with Metallic Conductivity Yury Gogotsi; Drexel University, United States

MXenes (carbides and/or nitrides of early transition metals) are a very large family of 2D materials. They have a chemical formula of $M_{n+1}X_nT_x$, where M represents a transition metal (Ti, Mo, Nb, V, Cr, etc.), X is either carbon and/or nitrogen (n=1, 2, 3 or 4), and T_x represents surface terminations. The diversity in compositions (>30 stoichiometric MXenes have already been reported, >100 predicted), availability of solid solutions on M and X sites, and control of surface terminations, such as O, OH, F, Cl, S, etc., offers a plethora of structures and chemistries to investigate.[1]
Combining the plasmonic properties with ease in processing, high electronic conductivity (up to 20 S/cm) and mechanical properties exceeding other solution-processable 2D materials, MXenes have the characteristics

necessary to develop as optical and electronic materials. Optical, electronic and transport properties of MXenes can be manipulated by tuning of their chemical composition. This presentation will provide insight into control of the optoelectronic properties (plasmon resonance frequency, electrical conductivity, carrier concentration, mobility and work function) and describe potential applications of MXenes as well as spectroscopic information, which can be applied to designing photonic and optoelectronic devices, such as electron transport layers for solar cells, optical sensors, electrochromic devices, metamaterials, EMI shields, antennas, etc.

2:45 PM NM06.08.06

Low Dimensional Bi_2Te_3-Sb_2Te_3 In-Plane Heterostructures—A Tunable Plasmonic Platform Beyond Noble Metals Parivash Moradifar[1], Austin G. Nixon[2], Tiva Sharifi[3,4], Pulickel Ajayan[3], David Masiello[2] and Nasim Alem[1]; [1]The Pennsylvania State University, United States; [2]University of Washington, United States; [3]Rice University, United States; [4]Umea University, Sweden

Surface plasmons enable routing and manipulating of light on sub-diffraction limit length scales. Surface plasmons are commonly excited by coupling to an electromagnetic field leading to confined local field enhancements effect that be used for strengthening the sub-diffraction light-matter interaction and potentially offer a transformative solution for a wide range of high impact applications such as ultra-efficient nanostructured solar cells, high speed nano-devices, and photothermal biomedical therapeutic applications. Various conventional noble metals (gold and silver) based nanostructures have been extensively studied for their well-known plasmonic responses in the visible spectral range due to their long relaxation time. However, there are strong motivations in exploring alternative plasmonic structures that exhibit lower resistive losses at optical frequencies and more functionally diverse properties. Novel plasmonic building blocks such as topological insulators are considered to be a promising path for exploring low-loss plasmonic alternatives with exotic physical properties at optical frequencies in compare to conventional noble metals-based nanostructures.

Recently, two dimensional materials and group V-VI chalcogenides, known for their excellent thermoelectric and topological insulator (TI) properties, attracted a lot of attention for their exotic plasmonic phenomena. From the group of V-VI chalcogenides, this study will focus on low-dimensional Bi_2Te_3-Sb_2Te_3 in-plane heterostructures as low-band gap semiconductors and topological insulators providing gapless metallic surface states. Bi_2Te_3-Sb_2Te_3 in-plane heterostructure flakes contain a heterointerface between Bi_2Te_3 and Sb_2Te_3 that is formed under multi-step solvothermal synthesis process Bi_2Te_3 and Sb_2Te_3 have a rhombohedral crystal structure with space group of Rm. The bulk structure consists of alternating hexagonal monatomic crystal planes of Bi and Te arranging in ABC order along c-axis.

Monochromated electron energy loss spectroscopy (Mono-EELS) in conjunction with aberration corrected scanning transmission electron microscopy (STEM), in-situ transmission electron microscopy (TEM) and x-ray energy dispersive (XEDS) combined with singular value decomposition (SVD) analysis was used to identify and spatially resolve various surface plasmon excitation modes in these nanostructures. Furthermore, the effect of edge, heterointerface and defects (intrinsic and extrinsic) as potential paths to tailor the plasmonic response in low-dimensional Bi_2Te_3-Sb_2Te_3 in-plane heterostructures was explored. This work is also combined e-DDA calculations to further elaborate the experimental EELS measurements. These findings open a new path to design tunable plasmonic nanostructures with unique functionalities beyond noble metals.

A 2D Crystalline Acceptor for Modulation Doping in van der Waals Heterostructures Erik Henriksen; Washington University in St. Louis, United States

a-RuCl3 is a layered antiferromagnetic Mott insulator exhibiting phenomena related to the Kitaev quantum spin liquid. It can be readily exfoliated down to monolayer thicknesses and incorporated into van der Waals heterostructures along with graphene and myriad other atomically thin materials. In such devices, proximity of a-RuCl3 to graphene leads to a significant charge transfer between the two that, surprisingly, persists even when a thin insulating layer is inserted between them, a phenomenon analogous to modulation doping in epitaxially-grown semiconductors. The effect can be observed in other materials including WSe2, bilayer graphene, and EuS. This enables a new method of control over the charge distribution in van der Waals stacks, for instance by patterning RuCl to create local charge variations. As but one application, we describe the potential to create sharp pn junctions in graphene.

4:25 PM NM06.09.02
Late News: Highly Effective Gating of Graphene on GaN—Bias-Switchable Raman G Band Splitting
Jakub A. Kierdaszuk[1], Ewelina Rozbiegala[2,3], Karolina Pietak[2,3], Sebastian Zlotnik[2,4], Aleksandra Przewloka[2,5,4], Wawrzyniec Kaszub[2], Andrzej Wysmolek[1], Johannes Binder[1] and Aneta Drabinska[1]; [1]University of Warsaw, Poland; [2]Lukasiewicz Research Network - Institute of Microelectronics and Photonics, Centre for Electronic Materials Technology, Poland; [3]Warsaw University of Technology, Poland; [4]Military University of Technology, Poland; [5]Center for Terahertz Research and Applications (CENTERA), Poland

In this communication we present results of highly effective gating of multilayer graphene in structure containing GaN epilayer with undoped GaN spacer. Bias switchable G band splitting showed great perspectives in characterization of devices based on graphene/GaN heterostructures and gives new opportunities in construction of nanosensors.

A 100 nm thick layer of undoped GaN preceded by a 1.3 μm thick layer of highly conductive GaN (n-doped) was grown on a sapphire substrate by MOCVD technique. Four-layer graphene (4-LGr) was used as a top contact to the GaN structures and was prepared in three steps. Firstly, a graphene monolayer grown on a copper substrate was transferred onto another graphene monolayer on a copper substrate by high-speed electrochemical delamination method. Then, a third graphene monolayer was transferred on the two layers of graphene obtained in the previous step. Finally, a fourth graphene monolayer was transferred on the graphene trilayer obtained in the previous step. 4-LGr was transferred on GaN heterostructure by polymer frame method [1]. So fabricated multi-layer graphene has an inhomogeneous and uncontrolled layer stacking.

A detailed analysis of Raman spectra showed three different types of spectra with G-band splitting into one, two or three subbands. No splitting of 2D band was identified. The presence of G band splitting is related to the turbostratic order and suggest different carrier concentrations of subsequent graphene layers in the 4-LGr structure. Therefore, high potential gradient near graphene/GaN junction is present even without bias. Additionally a strong shift of the G bands as a function of gate bias was observed. G band energy shift trends suggest n-doping of graphene. Interestingly, the most significant G band energy shift up to 8.5 cm^{-1} occurs for the lowest bias, in the range between 1 V and -1 V. Further G band energy shift up to 1.4 cm^{-1} in the range between -1 V and -5 V was observed. Raman micromapping showed that strong gating effect as well as band splitting is present over large surface area. Electroreflectance as well as band alignment analysis showed that undoped GaN spacer at reverse bias behaves like capacitor. Current-voltage characteristics exhibit Schottky-like behaviour. Graphene Fermi level shift calculated from current-voltage characteristic and electroreflectance measurements agree with Raman results. Fermi level shifts from 88 meV at 0 V to 200 mV at -5 V. For forward bias, a rapid decrease of electron concentration in graphene occurs (by $9x10^{12}$ cm^{-2}), the carrier concentration in across subsequent layers becomes more uniform so band splitting is less significant.

A substantial Raman position shifts occurs in our Schottky diode structures at one order of magnitude smaller voltages than for graphene deposited on SiO_2 substrates in capacitator type devices [2]. Obtained gating

efficiency is comparable to the results for solution-gated graphene. This strongly suggest that the diode junction is located directly near the graphene layers [3]. Thus, graphene gating is effective at very low voltages which is highly promising for further electron-phonon studies. Moreover, bias switchable G band splitting in turbostratic graphene enable to construct sensors based not on precise fitting of G band position shift but on tracing more significant band splitting.

Light-Induced Electron Spin Resonance Properties of van der Waals CrX_3 (X = Cl, I) Crystals Srinivasa Rao Singamaneni[1], Luis M. Martinez[1], Jens Niklas[2], Oleg Poluektov[2], Ravi Yadav[3,4], Michele Pizzochero[3,4], Oleg Yazyev[3,4] and Michael McGuire[5]; [1]The University of Texas at El Paso, United States; [2]Argonne National Laboratory, United States; [3]Ecole Polytechnique Federale de Lausanne, Switzerland; [4]Ecole PolyTechnique Federale de Lausanne, Switzerland; [5]Oak Ridge National Laboratory, United States

The research on layered van der Waals (vdW) magnets is rapidly progressing owing to exciting fundamental science and potential applications. In bulk crystal form, $CrCl_3$ is a vdW antiferromagnet with in-plane ferromagnetic ordering below 17 K, and CrI_3 is a vdW ferromagnet below 61 K. Here, we report on the electron spin resonance (ESR) properties of $CrCl_3$ and CrI_3 single crystals upon photo-excitation in the visible range. We noticed remarkable changes in the ESR spectra upon illumination. In the case of $CrCl_3$, at 10 K, the ESR signal is shifted from g = 1.492 (dark) to 1.661 (light), line width increased from 376 to 506 Oe, and the signal intensity is reduced by 1.5 times. Most interestingly, the observed change in the signal intensity is reversible when the light is cycled on/off. We observed almost no change in the ESR spectral parameters in the paramagnetic phase (>20 K) upon illumination. Upon photo-excitation of CrI_3, the ESR signal intensity is reduced by 1.9 times; the g-value increased from 1.956 to 1.990; the linewidth increased from 1170 to 1260 Oe at 60 K. These findings are discussed by taking into account the skin depth, the slow relaxation mechanism and the appearance of low-symmetry fields at the photo-generated Cr^{2+} Jahn-Teller centers. Such an increase in the g-value as a result of photo-generated Cr^{2+} ions is further supported by our many-body wavefunction calculations. This work has the potential to extend to monolayer vdWs magnets by combining ESR spectroscopy with optical excitation and detection.

4:55 PM NM06.09.04

Local Magnetic Measurements of a Few-Layer van der Waals Superconductor Alexander Jarjour, Brian Schaefer, George M. Ferguson, Menyoung Lee, Debanjan Chowdhury and Katja C. Nowack; Cornell University, United States

Measurements of thermodynamic properties of few-layer van der Waals superconductors are scarce due to the inherently small volume of mechanically exfoliated samples. Here we measure the magnetic susceptibility of a van der Waals superconductor by using local magnetic measurements enabled by scanning SQUID microscopy. Specifically, we study transition metal dichalcogenide MoS2 which exhibits a superconducting dome with a maximum critical temperature of nearly 10 K in ionic-gated few-layer devices. We combine the magnetic measurements with simultaneous electrical transport and map out changes in superfluid stiffness as a function of temperature and carrier density across the dome. We observe magnetic signatures consistent with a Kosterlitz-Thouless transition, and report our progress towards extracting absolute values of the superfluid stiffness and density from these measurements.

5:10 PM NM06.09.06

Determination of the In-Plane Exciton Radius in Two-Dimensional, Colloidal Semiconductor Nanoplatelets via Magneto-Optical Spectroscopy Alexandra Brumberg[1], Samantha Harvey[1], John Philbin[2], Benjamin Diroll[3], Scott Crooker[4], Eran Rabani[2] and Richard Schaller[1,3]; [1]Northwestern University, United

States; [2]University of California, Berkeley, United States; [3]Argonne National Laboratory, United States; [4]Los Alamos National Laboratory, United States

Nanoplatelets (NPLs), the colloidal analogues of more conventional two-dimensional materials such as transition metal dichalcogenide (TMD) layers and graphene, likewise exhibit modified electronic structure that arises from quantum confinement in only one dimension. It is often assumed that the lack of quantum confinement in the lateral plane yields a spatially extended exciton; however, studies in monolayer TMDs have shown that this is not the case. For colloidal NPLs, smaller exciton binding energies potentially challenge this picture, and reduced dielectric screening at the nanoparticle surface imposed by organic ligands provides additional considerations.

In this work, we implement absorption spectroscopy of CdSe NPLs in pulsed magnetic fields up to 60 T at the National High Magnetic Field Laboratory. The shift of the exciton energy as a function of magnetic field is probed for three different thicknesses and three different lateral areas of CdSe NPLs. Application of magnetic fields up to 60 T allows for the determination of the diamagnetic shift, the (small) second-order modification of the exciton energy. The diamagnetic shift provides insight into exciton lateral extent, as larger spatially extended excitons experience greater perturbations in a magnetic field. We calculate exciton lateral extents based on diamagnetic shift coefficients and find that exciton lateral extent is comparable to NPL thickness, indicating that the quantum confinement and reduced dielectric screening concomitant with few-monolayer thickness strongly reduces the exciton lateral extent. Atomistic electronic structure calculations of the exciton size for varying lengths, widths, and thicknesses support the substantially smaller in-plane exciton extent. This work follows similar studies of exciton spatial extent in monolayer TMDs and provides clear insight into the spatial extent of excitons in these promising, highly processable and scalable, two-dimensional materials.

5:25 PM NM06.09.07
Anisotropic Critical Behavior in $Fe_{2.7}GeTe_2$ Jose A. Delgado, Rubyann Olmos and Srinivasa Rao Singamaneni; The University of Texas at El Paso, United States

The presence of magnetocrystalline anisotropy in $Fe_{2.7}GeTe_2$ has previously been predicted by DFT calculations and confirmed through bulk magnetization measurements. This feature of $Fe_{2.7}GeTe_2$ makes it potentially useful for magnetic storage applications. For this material to be utilized in next-generation spintronic applications, the critical behavior, dimensionality of interaction, and magnetic exchange distance of $Fe_{2.7}GeTe_2$ must be fully understood. Here the hard-axis critical behavior was studied using a modified asymptotic analysis from bulk magnetization measurements for the first time. While much work has been previously done to study the critical behavior of $Fe_{2.7}GeTe_2$, we have found that the critical exponents and exchange distance vary between H//ab and H//c. We have characterized the orientation-dependent critical phenomena of $Fe_{2.7}GeTe_2$, thus establishing a basis for the magnetocrystalline anisotropy from the perspective of competing universality classes.

5:40 PM NM06.07.09
Late News: Using Optical Pulses to Characterize Epitaxial Semiconductor Wafers Sam Mil'shtein and Brandon Keating; University of Massachusetts Lowell, United States

Abstract. In any commercial production of semiconductor wafers the required final step is characterization, producing the information about density of carriers (density of doping), and electron /holes mobilities. These characterization parameters are vital for design of any type of semiconductor electronics. The common, widely used characterization method consists of conductivity measurements combined with Hall effect testing. This common characterization technology requires to produce repeatedly the Van-der-Paw pattern with 6 contacts at testing pattern. The hetero-structured devices and thus hetero-structured wafers are common nowadays in mass production. Some of these layers are intentionally two-dimensional. For these wafers, the photolithography of Van-der-Paw pattern repeated for each epitaxial layer grown one above the other is complicated and costly by itself. Additional equipment, i.e., DC magnet positioned below the tested wafer is needed to finish Hall effect measurements. We developed a new characterization method to be used for testing of one after the other layers,

or selected test of only given layer by optical pulses of controlled wavelength. The optical pulses of selected wavelengths (colors) are produced by wide spectrum source of light and controlled by monochromator. Two ohmic probes are positioned on tested epilayer with distance of few millimeters between them. Focused light spot generates optical pulses with controllable amplitude and frequency near one contact. The second ohmic contact collects pulses of the photocurrent. At the end of this photocurrent stripe the amplitude and shape of moving pulses of carriers are analyzed by oscilloscope. The high amplitude of box-like pulse is registered at first contact. As the pulse proceeds, its amplitude decays and the pulse widens. Changes of pulse width, recorded by the scope, help to calculate diffusivity coefficient of generated photo carriers (D_n or D_p). Voltage bias at probes and direction of current defines the type (electrons or holes) of carriers. Einstein ratio ($D/\mu=kT/q$) is used to calculate the mobility of photo carriers. Simple measurement of current and voltage drop between two ohmic contacts, when the light is switched off, generates information about density of free carriers (density of doping). We discuss experimental setup of the new wafer characterization method [1] and how selection of light wavelengths defines selection of the tested layer.

Interfacial Magnetic Anisotropy in $Y_3Fe_5O_{12}$ Induced by Low Crystalline Symmetry of Transition Metal Dichalcogenide WTe_2 Guanzhong Wu[1], Dongying Wang[1], Nish Verma[1], Yang Cheng[1], Side Guo[1], Guixin Cao[1], Kenji Watanabe[2], Takashi Taniguchi[2], Chun Ning (Jeanie) Lau[1], Fengyuan Yang[1], Mohit Randeria[1], Marc Bockrath[1] and P. Chris Hammel[1]; [1]The Ohio State University, United States; [2]National Institute for Materials Science (NIMS), Japan

The breaking of inversion symmetry at the surface of a magnet significantly alters its properties and can induce a uniaxial anisotropy with its symmetry axis along the surface normal. In a complex oxide, such as ferrimagnetic garnet, this surface anisotropy is easy-plane in nature and can be enhanced by deposition of a non-magnetic material such as a heavy metal or a topological insulator, a phenomenon attributed to the enhanced Rashba spin orbit coupling. In striking contrast, we show here that if low symmetry, semi-metallic WTe_2 is placed in contact with $Y_3Fe_5O_{12}$ (YIG), an additional interfacial perpendicular magnetic anisotropy (iPMA) results. We probe the magnetism of the micron-sized YIG/WTe_2/hBN heterostructure using a high sensitivity ferromagnetic resonance force microscope, that can measure local ferromagnetic resonance with spatial resolution of 100nm and spectral resolution of 1 Oe. The magnitude of iPMA remains constant down to monolayer WTe_2, indicating its interfacial origin. In addition, we probe the spin pumping effect from YIG to WTe_2 and find no WTe_2 thickness dependence, suggesting that interfacial spin relaxation plays the dominant role or that the spin diffusion length along the WTe_2 *c* axis is extremely short. This demonstrates the power of this approach in enabling studies of non-traditional heterostructures such as stacks of two-dimensional materials on epitaxially grown thin films. Our result further suggests that interfacial magnetic anisotropy in complex oxide ferro- or ferrimagnetic insulators is highly tunable by choice of non-magnetic overlayers, and could play an essential role in the development of next generation magnetic solid state devices.

Late News: Substrate Vicinality Effect on the Electronic Properties of Epitaxial Graphene Maya Narayanan Nair[1,2], Arlensiu Celis[2,3], Francois Nicolas[2], Stefan Kubsky[2], Amina Taleb-Ibrahimi[2] and Antonio Tejeda[3,2]; [1]Advanced Science Research Center (ASRC) at the Graduate Center at City University of New York,

United States; [2]Synchrotron Soleil, France; [3]Université Paris-Saclay, CNRS, Laboratoire de Physique des Solides, France

Many efforts to control the electronic properties of atomically thin two-dimensional materials (2D), either by twisted stacks or by deposition on a patterned substrate, are an intense line of research nowadays. Tuning the electronic properties of graphene by periodic potentials has resulted in many interesting properties such as Fermi velocity renormalization, extra Dirac points and tunable bandgap. However, it is still challenging to couple graphene to a lithographic structure with a periodicity of few nanometers. A very promising option consists of growing graphene on an appropriate periodical substrate, a natural route to induce periodic potentials in graphene [1]. However, the interaction of graphene with the substrate is still challenging [2,3]. Graphene on Ir(111) and Pt(111) substrates are particularly interesting because it exhibits a very weak graphene-substrate interaction, so the effect on the band structure as a function of the periodicity could exhibit a transition from mild coupling towards no coupling at all. In our recent work, we have investigated the influence of the one-dimensional periodic nanostructured substrate on graphene electronic properties. We have shown that graphene is extremely sensitive to periodic arrays, as demonstrated on two different nanostructured substrates, namely Ir (332) and Pt (111)[4,5]. The observed minigaps in graphene band structure by angle-resolved photoemission spectroscopy (ARPES) is related to the spatial periodicity. In this talk, I will present, the successful preparation of graphene on periodically nanostructured Pt (111)substrate and discuss how it is possible to control the superperiodicity and thus the bandgap by tuning the vicinality of the substrate, a simple way to engineer the electronic properties of graphene and other 2D materials.

Late News: Nonradiative Recombination Free Monolayer Semiconductors Shiekh Zia Z. Uddin and Ali Javey; University of California, Berkeley, United States

Photoluminescence (PL) quantum yield (QY) is a key metric of optoelectronic performance that directly dictates the maximum optoelectronic device efficiency. In conventional semiconductors, defects act as a trapping center for nonradiative Shockley-Read-Hall or Auger recombination mechanism and drastically reduces PL QY at all generation rates. Two-dimensional transition-metal dichalcogenides (TMDCs), such as monolayer MoS_2, often exhibit low PL QY for as-processed samples, which has typically been attributed to a large native defect density. However, we show that the PLQY of as-processed MoS_2 and WS_2 monolayers reaches near-unity when they are made intrinsic through either by electrostatic or chemical doping. In the presence of background charge carries, photogenerated excitons create positive or negative trions, which mostly recombine nonradiatively, leading to a low PL QY. This could be a result of a defect-assisted decay and/or a geminate Auger-like process in which the electron provides the third particle required for momentum conservation. On the other hand, if the semiconductor is intrinsic, the photogenerated exciton stays neutral and near unity PL QY is observed. Surprisingly, neutral exciton recombination is entirely radiative even in the presence of a high native defect density. This finding enables TMDC monolayers for optoelectronic device applications as the stringent requirement of low defect density is eased. Furthermore, the observed PL QY as a function of doping and generation rate in all four major TMDC monolayers (WS_2, WSe_2, MoS_2, $MoSe_2$) can be understood by considering the interaction of neutral excitons, charged trions, and free charge carriers and their subsequent recombination channels. This raises the intriguing possibility that the principle that excitonic systems show maximum PL QY when they are intrinsic is general enough to be applied to other material systems without the need for material-specific passivation techniques.

Kitaev Interaction and Possible Quantum Spin Liquid State in 2D Materials with S=3/2 Changsong Xu; University of Arkansas, Fayetteville, United States

Quantum spin liquids (QSLs) form an extremely unusual magnetic state in which the spins are highly correlated and fluctuate coherently down to the lowest temperatures, but without symmetry breaking and without the formation of any static long-range-ordered magnetism. Such intriguing phenomena are not only of great fundamental relevance in themselves, but also hold promise for quantum computing and quantum information. Among different types of QSLs, the exactly solvable Kitaev model is attracting much attention, with most proposed candidate materials, e.g., RuCl3 and Na2IrO3, having an effective S=1/2 spin value with 4d/5d heavy transition metal. Here in this talk, I will first report the prediction of nonnegligible Kitaev interaction in 3d Cr-based 2D materials, e.g. CrI3 and CrGeTe3, from first-principles; then, via extensive first-principles-based simulations, I will further report the investigation of the Kitaev physics and possible Kitaev QSL state in epitaxially strained Cr-based monolayers, such as CrSiTe3, that rather possess a S=3/2 spin value. Our study thus extends the playground of Kitaev physics and QSLs to 3d transition metal compounds.

9:20 AM *NM06.02.06
Temperature- and Intercalation-Induced Phase Transitions of $MoTe_2$ and MoS_2 Nanoflakes and Heterostructures Judy Cha; Yale University, United States

Owing to the small energy differences between the polymorphs, tellurium-based transition metal dichalcogenides, such as $MoTe_2$ and WTe_2, can access a full spectrum of electronic states, from the 2H semiconducting state to the 1T' semimetallic state, and from the T_d topological semimetallic state to the superconducting state in the 1T' and T_d phase at low temperature. Thus, it is a model system for phase transformation studies and applications as well as for studies of quantum phenomena such as the quantum spin Hall effect and potential topological superconductivity.

In this talk, I will first discuss our synthesis strategy to obtain cm^2-scale thin films of 2H and 1T' $MoTe_2$ with layer control and large grains, which was achieved by tellurizing MoO_x thin films deposited by atomic layer deposition. Despite the van der Waals epitaxy, we show that the precursor-substrate interface critically determines the uniformity in thickness and grain size of the resulting $MoTe_2$ films: $MoTe_2$ grown on sapphire show uniform films while $MoTe_2$ grown on amorphous SiO_2 substrates form islands.

Phase transition from the 1T' phase to the T_d phase of $MoTe_2$ is explored using *in situ* cryogenic transmission electron microscopy, in which flakes of $MoTe_2$ are cooled from room temperature to liquid nitrogen temperature. Distinct changes in the electron diffraction patterns as a function of temperature demonstrate the phase change. Thus, *in situ* cryo-TEM enables studies of phase transitions as a function of thickness and morphology of 2D flakes in real space, providing important information to study the nucleation and growth of the new phase during phase transition. Finally, I will discuss the effects of heterointerface and mechanical strain on lithium-induced phase transition of MoS_2 and 2D heterostructures during lithium intercalation, which was investigated by combining field-effect transistor platforms with *in situ* probes during electrochemically controlled intercalation of lithium.

Multi-Level Manipulation of MXenes Electronic and Transport Properties Kanit Hantanasirisakul[1,2], Steven J. May[1] and Yury Gogotsi[1,2]; [1]Drexel University, United States; [2]A.J. Drexel Nanomaterials Institute,

United States

Two-dimensional (2D) transition metal carbides and nitrides, known as MXenes, have shown great promise in applications such as electromagnetic interference shielding, electrode and current collector in energy storage devices, transparent conductive electrodes, and optoelectronics. These applications are enabled by MXenes' high electronic conductivity, specifically $Ti_3C_2T_x$ (where T_x stands for surface termination such as O, F, and Cl) with metallic conductivity reaching 20,000 S/cm. Benefiting from a large variety of transition metals, C and/or N in the X layers, and versatile surface terminations, MXenes provide for multi-level tuning of electronic and transport properties. In this talk, we show that electronic and transport properties of MXenes can be manipulated by careful tuning of their chemical compositions. For instance, having a mix of C and N in the X layer of Ti_3CNT_x leads to a lower electrical conductivity, carrier concentration, and mobility compared to $Ti_3C_2T_x$. Moreover, the work function of $Ti_3C_2T_x$ thin films can be continuously tuned from ~4 to ~5 eV upon desorption of surface terminations *via* thermal annealing in vacuum. In addition, we also show that the intercalants, governing MXene interlayer spacing, play a crucial role in electronic transport properties in MXene free-standing films. This multi-level control of electronic properties is a unique advantage of MXenes compared to other 2D materials. This work is supported by the U.S. Department of Energy (DOE), Office of Science, Office of Basic Energy Sciences, grant #DESC0018618.

Wafer-Scale Epitaxial Growth of Unidirectional TMD Monolayers Haoyue Zhu, Tanushree Choudhury, Benjamin Huet, Anushka Bansal, Thomas McKnight, Nicholas Trainor and Joan M. Redwing; The Pennsylvania State University, United States

Wafer-scale synthesis of semiconducting transition metal dichalcogenide (TMDs) monolayers is of significant interest for device applications to circumvent size limitations associated with the use of exfoliated flakes. Promising results have been demonstrated for epitaxial films deposited by vapor phase techniques such as CVD and MOCVD. However, the three-fold symmetry of TMDs such as MoS_2 and WSe_2, results in two energetically equivalent domain alignments, often referred to as 0^o and 60^o domains, when grown on substrates such as c-plane sapphire and graphene. The oppositely oriented domains give rise to inversion domain boundaries (IDBs) upon coalescence which exhibit a metallic character and are generally undesirable. In this study, we demonstrate the epitaxial growth of unidirectional TMD monolayers on 2" diameter c-plane sapphire substrates with a significantly reduced density of inversion domains. Steps on the sapphire surface are shown to play a key role in domain alignment by altering the energy landscape for nucleation and adatom diffusion.

Metalorganic chemical vapor deposition (MOCVD) was used for the epitaxial growth of WSe_2 and WS_2 monolayers on c-plane sapphire in a cold-wall horizontal quartz-tube reactor. The as-received sapphire substrates, which are miscut ~0.3^o toward <110>, consist of steps with sub-1 nm step height separated by 50-70 nm wide terraces. A three-step nucleation-ripening-lateral growth process, carried out at temperatures ranging from 850^oC to 1000^oC, was used to achieve epitaxial films using $W(CO)_6$, H_2Se and H_2S as precursors in a H_2 carrier gas. Nucleation was observed to occur at the terrace edge and the growing domains align epitaxially with the underlying (0001) sapphire lattice. As a result of the nucleation process, the domains grow with a zig-zag edge facing the terrace edge which imparts a preferential direction to the domains. The percentage of domains with a preferred direction ranges from 75%-86% depending on MOCVD growth conditions. Continued lateral growth for times ranging from 10-30 minutes results in fully coalesced TMD monolayers that are epitaxially oriented on the sapphire, as assessed by in-plane x-ray diffraction, with a reduced density of inversion domain boundaries. The results demonstrate the important role of surface structure in nucleation and epitaxial growth of TMD monolayers.

8:35 AM *NM07.01.02
In-Plane Heterostructures of Graphene and Hexagonal Boron Nitride Hyeon Suk Shin; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) heterostructures combining several individual 2D materials provide unique platforms to create unprecedented physical properties, thereby exploring new applications. In particular, heterostructures of hexagonal boron nitride (h-BN) and graphene have attracted a great deal of attention for potential applications. Although several methods have been developed to produce in-plane heterostructures of graphene and h-BN through the partial substitution reaction of graphene, the reverse reaction has not been reported. Though the endothermic nature of this reaction might account for the difficulty and previous absence of such a process, we demonstrated a new chemical route in which the Pt substrate plays a catalytic role. We also proposed that this reaction proceeds through h-BN hydrogenation; subsequent graphene growth quickly replaces the initially etched region. Importantly, this conversion reaction enabled the controlled formation of patterned in-plane graphene/h-BN heterostructures, without needing the commonly employed protecting mask, simply by using a patterned Pt substrate [1]. It means that we could fabricate spatially controlled in-plane heterostructures of h-BN and graphene.
We expanded the spatially controlled conversion of h-BN to graphene on an array of Pt nanoparticles (NPs) to realize an array of uniform GQDs embedded in an h-BN sheet. A uniform Pt NP array was formed on a SiO_2/Si substrate with the aid of self-patterning diblock copolymer micelles, and the h-BN sheet was transferred on the Pt NPs array, followed by the conversion of h-BN on Pt to GQDs. The size of the obtained GQDs corresponded with the sizes of the Pt NPs, because of the selective conversion of h-BN on top of Pt NPs. Uniform and precisely controlled size of the GQDs ranging from 7 to 13 nm was achieved. Finally, we demonstrated electron transport by the size-controlled GQDs isolated by insulating h-BN like a Coulomb blockade, indicating that the splitting energy of the GQD is 70–140 meV, compatible with its dimension [2].
In addition, a new photoluminescence peak in the GQD/h-BN heterostructures was observed at 410 nm. This blue-emitting photoluminescence occurs at 1D heterojunctions of h-BN and graphene, which is originated from

the localized energy states at the disordered boundaries of h-BN and graphene [3].

9:00 AM NM07.01.03
Vertically-Oriented MoS_2 and WS_2 for Nonlinear Nanophotonics—From Nanosheets to Heterostructures
Maarten Bolhuis[1], Javier Hernández[1], Sabrya E. van Heijst[1], Miguel Tinoco Rivas[1,2], Kobus Kuipers[1] and Sonia Conesa-Boj[1]; [1]Delft University of Technology, Netherlands; [2]Universidad Complutense, Spain

Transition Metal Dichalcogenide (TMDC) materials such as molybdenum disulfide (MoS2) and tungsten disulfide (WS2) exhibit unique optoelectronic properties. This makes TMDCs particularly promising candidates for building blocks of ultra-thin nanophotonic devices. For such applications, the vertically-oriented configuration of TMDCs could be advantageous as compared to the conventional horizontal configuration, because the inherent broken symmetry of the vertically orientated MoS2 and WS2 would favor an enhanced nonlinear response. Further, these attractive optoelectronic properties of vertically-oriented MoS2 and WS2 can be augmented by fabricating heterostructures based on their combination. Up to now, most of these heterostructures have been fabricated by utilizing transfer techniques or by performing separate chemical vapor deposition (CVD) steps for each material.

As a starting point, we show that the direct sulfurization of predeposited Mo metal results in vertically orientated MoS2 (v-MoS2) nanosheets. A systematic study on these v-MoS2 nanosheets shows that the sulfurization rate is strongly dependent on the reaction temperature and reaction time. By systematically varying the reaction time and temperature we were able to determine both the activation energy and the diffusion constant for the sulfurization process. We verify an enhanced nonlinear response in the resulting v-MoS2 nanostructures as compared to their horizontal counterparts.

Building upon these results, we demonstrate the feasibility of creating vertically-oriented TMDC heterostructures via a one-step CVD process without relying on transfer techniques, utilizing the direct sulfurization of molybdenum (Mo) and tungsten (W) heterostructures and multilayers. By depositing different configurations of Mo and W metal and carefully controlling the sulfurization depth we can design different TMDC heterostructures and multilayers. Utilizing FIB tomography and 3D reconstructions, we determine that the grain boundaries at the interface between the Mo and W metals are continuous and that, after sulfurization, these continuous metal grains facilitate the synthesis of in-plane vertical heterostructures. HR-TEM analysis confirms that these in-plane heterostructures are continuous and uniformly distributed along the interface.

This versatile method of fabricating in-plane and vertically aligned MoS2 and WS2 heterostructures can be further extended to different arrangements of TMDC heterostructures and multilayers, thus represents a steppingstone towards the fabrication of low-dimensional TMD-based nanostructures for versatile nonlinear nanophotonic devices.

9:15 AM NM07.01.04
Impact of Oxygen on CVD Grown Boron Nitride Layers Mohammad W. Malik[1], Bin Wang[1,2], Sahar Jaddi[1], Yiyi Yan[1], Victor Reis[1], Yun Zeng[2], Thomas Pardoen[1], Benoît Hackens[1] and Jean-Pierre Raskin[1]; [1]UCLouvain, Belgium; [2]Hunan University, China

h-BN is an eminent member of the 2D materials family with exceptional and peculiar properties such as atomically smooth surface, ultra-high flexibility, and transparency. h-BN is an attractive candidate for application in flexible electronics, optoelectronics, and electro-mechanics devices. Moreover, h-BN encapsulated 2D materials [1] demonstrate elevated throughput and enhanced physical properties.

h-BN is a binary element material produced in various shapes via the CVD process [2]. The coalescence of the

different shape and orientation domains generate a range of grain boundaries (GBs) that can be composed of N-N, B-B, and N-B (5, 7) defects [3]. Indeed, defective GBs lead to high leakage current and low mechanical strength, making it unsuitable for electro/mechanical devices and other applications. Therefore, the synthesis of large-area and defect-free h-BN is pivotal. Attempts have been made to grow large-area h-BN relying on pre-treatment of the substrate [4], the alloyed substrate [5], water vapors [2], and monocrystalline substrate [6]. These processes have shown promising results, but the impact of oxygen to reduce the nucleation density has not been widely scrutinized in the literature.

In this work, we investigated the impact of oxygen on the growth of large-area h-BN. CVD growth of h-BN was carried out on polycrystalline copper (Cu) foils using ammonia borane as a precursor. Our investigation suggests that pre-oxidation of Cu foils by a few hundred ppm of oxygen leads to an increase of the h-BN domains size by at least a factor of 5 when compared to the h-BN domains synthesized by sole hydrogen annealing of Cu foils [4, 6]. Typical samples contain the various shapes of domains with a maximum lateral size of hundreds of microns (> 100 μm), which have not been reported so far.

The quality of h-BN is confirmed by Raman, XPS, Tof-SIMS, and UV-Vis spectroscopies. An intense peak is observed in the frequency range of 1360-1370 cm^{-1} that is the typical E_{2g} mode of h-BN reported in the literature. The binding energy of boron and nitrogen is about 190 eV and 398 eV, respectively. We also confirm the stoichiometry of h-BN, i.e., the N: B ratio is close to 1 in good agreement with high-quality h-BN growth. UV-Vis spectroscopy shows strong absorption around 202 nm that corresponds to the 6.13 eV optical bandgap. The combined results of Raman spectra with UV-Vis spectroscopy confirm the formation of h-BN and reject the possibilities of other crystallographic BN structures such as r-BN, c-BN, and w-BN. The tunneling current was measured for hundreds of metal/h-BN/metal structures with an overlap area of 25 μm^2. For a typical device, the thickness of h-BN is 2.6 nm, as confirmed by AFM. The normalized current density was found to be 1.79 $nA/\mu m^2$ at a DC bias of 1 V, proving the good insulator potential of the synthesized h-BN.

The achieved large areas of grown h-BN are attributed to an optimum concentration of intrinsic carbon and organic species present in the Cu foil. These species presumably play a critical role in determining the size of the h-BN domains. An excessive degree of oxidation deteriorates surface quality during the process, leading to voids on the substrate and gives rise to defective growth, whilst an inadequate degree of oxidation results in smaller domains (< 5-10 μm). There is a tradeoff between the residual impurities and the h-BN grain size that can be tuned by the degree of oxidation of Cu foils, as demonstrated in this work.

Versatile Roles of Monolayered Inorganic Nanosheets in Multifunctional Nanohybrids Seong-Ju Hwang; Yonsei University, Korea (the Republic of)

The monolayered 2D nanosheets of layered inorganic solids (layered metal oxides, layered double hydroxides, layered metal chalcogenides, and graphene) attract intense research interest because of their versatile roles in multifunctional nanohybrids applicable for energy and environmental technologies. The monolayered 2D nanosheets of inorganic solids can be synthesized by soft-chemical exfoliation reaction of the pristine layered materials. A great diversity in the chemical compositions and crystal structures of inorganic nanosheets

provides this class of materials with a wide spectrum of physical properties and functionalities. The inorganic nanosheets can be used as powerful building blocks for exploring high performance hybrid photocatalysts and electrocatalysts. These materials can play a role as catalytically active components as well as conductive additives for improving the catalyst performance of hybridized species. In this talk, several practical examples of 2D monolayered nanosheet-based photocatalysts and electrocatalysts active for solar fuel production will be presented together with the discussion about the relationship between catalyst performance and chemical bonding nature.

9:45 AM NM07.01.06
Synthesis and Properties of Supertwisted Spirals of 2D Materials Enabled by Non-Euclidean Surfaces
Yuzhou Zhao, Chenyu Zhang, Daniel Kohler, Jason Scheeler, John Wright, Paul M. Voyles and Song Jin; University of Wisconsin–Madison, United States

Euclidean geometry is the fundamental mathematical framework of classical crystallography. Traditionally, layered materials are grown on flat substrates, but growing Euclidean crystals on non-Euclidean surfaces has rarely been studied. Here, we present a general model describing the growth of layered materials with screw-dislocation spirals on non-Euclidean surfaces and show that it leads to continuously twisted multilayer superstructures. This model is experimentally demonstrated by growing supertwisted spirals of tungsten disulfide (WS_2) and tungsten diselenide (WSe_2) draped over nanoparticles near the centers of spirals. Microscopic structural analysis shows that the crystal lattice twist is consistent with the geometric twist of the layers, leading to moiré superlattices between the atomic layers, which further influence the electronic structures of the material. The preliminary studies on the physical properties of such multilayer twisting 2D materials will be discussed. Our results introduce new concepts in the growth of exotic nanomaterials and a rational strategy for potentially controlling the twist angle in layered materials from direct synthesis, which opens up new opportunities for the study of twisted moiré superlattices and chirality-related properties.

SESSION NM07.02: Controlled Synthesis and Chemical Functionalization of 2D Materials II

NM07

10:30 AM *NM07.02.01
Ledge-Directed Epitaxy of Single-Crystalline Nanoribbons of Transition Metal Dichalcogenides Areej A. Aljarb[1], Jui-Han Fu[1], Thomas Anthopoulos[1], Jeehwan Kim[2], Lain-Jong Li[1] and Vincent Tung[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Massachusetts Institute of Technology, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) monolayers are considered promising for future extreme device downscaling. For wafer scale manufacturing of advanced logic and memory devices, dense arrays of single-crystal, globally aligned TMD monolayer nanoribbons that can be controllably grown, are highly desired. Demonstrated top-down approaches to form such nanoribbons require large-area, single-crystal TMDs and damage-free etching processes, which are not available currently. Bottom-up growth methodologies for TMD nanoribbons have been reported to individually achieve control of layer number, single-crystallinity, local alignment, and dimensionalities. However, controlled nanoribbon growth with all aforementioned properties synergistically remains a major challenge. In this talk, we will demonstrate a ledge-directed epitaxy (LDE) of dense arrays of continuous, self-aligned, monolayer and predominantly single-crystalline MoS_2 nanoribbons on β-gallium (III) oxide (β-Ga_2O_3) (100) substrates. Experimental observation and density function theory (DFT) simulation indicate that the presence of intrinsic ledges on β-Ga_2O_3 (100) leads to the reduction in binding energy. The two previously indistinguishable and nearly degenerate configurations are now remarkably uncoupled from each other by ~2 eV, overcoming the atomic registry—the

van der Waals (vdW) epitaxy constraint and thus ensuring the mono-orientated nucleation. Meanwhile, potential energy surface (PES) mapping sheds light on a surface diffusion limited pathway along the ledge, hence driving the energetically preferred and directionally modulated growth of aligned MoS_2 domains into single-crystalline nanoribbons. The stitching of unidirectional seeds into continuous, single-crystal and -orientated MoS_2 nanoribbons was confirmed by second harmonic generation (SHG) and dark field-scanning transmission electron microscopy (DF-STEM). The MoS_2 nanoribbons can be readily transferred to arbitrary substrates while the underlying β-Ga_2O_3 can be re-used after mechanical exfoliation. Prototype MoS_2 nanoribbon-based field-effect transistors exhibit high on/off ratios of 10^8 and an averaged room temperature electron mobility of 65 $cm^2V^{-1}s^{-1}$, both on par with values reported for mechanically exfoliated MoS_2 devices. We further demonstrate, for the first time, the LDE growth as a general strategy for single-crystal p-type WSe_2 nanoribbons and lateral n-p-n heterostructures made of p-WSe_2 and n-MoS_2 nanoribbons. Our findings pave the way to direct the growth of single-crystalline TMDs and their heterostructures for futuristic electronics applications.

10:55 AM NM07.02.02
Illuminating the Electronic Properties of WS_2 Polytypism with Electron Microscopy Sabrya E. van Heijst[1], Masaki Mukai[2], Eiji Okunishi[2], Hiroki Hashiguchi[2], Laurien I. Roest[1], Louis Maduro[1], Juan Rojo[3,4] and Sonia Conesa-Boj[1]; [1]Delft University of Technology, Netherlands; [2]EMBU JEOL Ltd, Japan; [3]Nikhef Theory Group, Netherlands; [4]Vrije Universiteit Amsterdam, Netherlands

Tailoring the specific stacking sequences (polytypes) of layered materials represents a powerful strategy to identify and design novel physical properties. While nanostructures built upon transition-metal dichalcogenides (TMDs) with either the 2H or 3R crystalline phases have been routinely studied, our knowledge of those based on mixed 2H/3R polytypes is far more limited. Here we report on the characterization of mixed 2H/3R free-standing WS_2 nanostructures displaying a flower-like configuration by means of advanced transmission electron microscopy. We correlate their rich variety of shape-morphology combinations with relevant local electronic properties such as their edge, surface, and bulk plasmons. Electron energy-loss spectroscopy combined with machine learning reveals that the 2H/3R polytype displays an indirect band gap with E_{BG} = 1.6 eV. Further, we identify the presence of energy-gain peaks in the EEL spectra characterized by a gain-to-loss ratio $I_G / I_L > 1$. Such property could be exploited to develop novel cooling strategies for atomically thin TMD nanostructures and devices built upon them. Our results represent a stepping stone towards an improved understanding of TMDs nanostructures based on mixed crystalline phases.

11:10 AM NM07.02.03
Frank–van der Merwe Growth of Two-Dimensional Transition Metal Dichalcogenide by Strain-Engineering Yi Wan and Vincent Tung; King Abdullah University of Science and Technology, Saudi Arabia

Two-dimensional transition metal dichalcogenides (TMDCs) have attracted widespread attention due to their prospective for the next-generation non-silicon electronics and optoelectronics. Among these two-dimensional TMDCs research, the most highlight has been given to single-layer TMDCs because of its intriguing electrical and optical properties. However, the fabrication demands and the physics of TMDCs suggest that few-layer TMDCs may be more attractive than single layer TMDCs for the industrial manufacturers because few-layer TMDCs equit more density of states for application in electronics, better light absorption and wider spectral response in optical application. To realize full potential of few-layer TMDCs, there is still much effort in the scalable and layer-controllable growth of highly crystalline TMDCs need to be achieved. In this work, WSe_2 is treated as a representative of common TMDCs growth, and we report an experimental observation that strain presenting in the first WSe_2 layers plays a critical role in the determination of growth manners for the following layers. Frank–van der Merwe Growth mode can be realized through inducing built-in tensile strain in first WSe_2 layers during the CVD process. Moreover, we demonstrate the stacking angle between the successive layers and the first layers by second harmonic generation (SHG) measurement. The foundational understanding of growth mechanism is assessed by a comprehensive density functional theory (DFT) simulation. This work provides a crucial hint to realize uniform layer control over the large scale, which is an important step for TMDCs towards

real applications.

11:25 AM NM07.02.05
Stabilization of $NbTe_3$, VTe_3, and $TiTe_3$ via Nanotube Encapsulation Scott Stonemeyer[1,2,3], Jeffrey D. Cain[1,2,3], Sehoon Oh[1,3], Amin Azizi[1,2], Peter Ercius[3], Marvin L. Cohen[1,3] and Alex Zettl[1,2,3]; [1]University of California, Berkeley, United States; [2]Kavli Energy NanoScience Institute, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

One of the primary objectives of nanoscience is the precise control over the processing-structure-property relationship intrinsic to traditional materials science. Recently, the concept of dimensionality, and the engineering of materials' structure and properties *via* changes in dimensionality, has emerged as an additional degree of freedom within this paradigm. To this end, the isolation of single atomic-planes (*e.g.* graphene and the transition metal dichalcogenides) and chains (*e.g.* transition metal trichalcogenides, TMTs) from quasi-low-dimensional materials has been extremely fruitful. The archetypal quasi-1D materials family is the TMTs, commonly referred to as MX_3 compounds, with M a transition metal and X a chalcogen. Typically for these materials, 1D MX_3 chains are weakly coupled by interchain vdW interactions to form coherent, but highly anisotropic, three-dimensional crystals. The bulk synthesis and properties of the TMTs has been well explored and they are canonical examples of superconductors and charge density wave materials. This structural motif is common across a range of M and X atoms (*e.g.* $NbSe_3$, $HfTe_3$,TaS_3), but not all M and X combinations are stable. Here, we demonstrate the successful synthesis of three previously unreported MX_3 TMT compounds: $NbTe_3$, VTe_3, and $TiTe_3$. This is accomplished through nano-confined growth within the cavity of multi-walled carbon nanotubes (MWCNTs). Depending upon the inner diameter of the encapsulating MWCNTs, specimens ranging from many chains, to few chains (2-3), and even single chain, can be isolated and studied. The MWCNT sheath stabilizes the chainlike morphology, enabling synthesis and characterization with transmission electron microscopy (TEM) and aberration-corrected scanning transmission electron microscopy (STEM). It is found that few-chain specimens of the new TMTs can exhibit a coordinated interchain spiraling, while the single-chain limit exhibits a trigonal anti-prismatic (TAP) rocking distortion, which we experimentally resolve for the first time here. First principles calculations give insight into the integral role that the encapsulating CNT plays in stabilization and provide information regarding the electronic structure of the new materials.

11:40 AM NM07.02.06
Deterministic Fabrication of Arbitrary Vertical Heterostructures of 2D Ruddlesden-Popper Halide Perovskites Dongxu Pan, Yongping Fu, Natalia Spitha, Yuzhou Zhao, Christopher Roy, Darien Morrow, Daniel Kohler, John Wright and Song Jin; University of Wisconsin–Madison, United States

Ruddlesden-Popper (RP) phase lead halide perovskites have emerged as a new class of 2D semiconductors that exhibit tunable electronic and optical properties, potentially offering unlimited heterostructure configurations for exploration. However, the promise of such heterostructures has not been fulfilled, because halide perovskites' highly mobile and fragile crystal lattices make controllable direct synthesis or van der Waals integration extremely difficult. Here, we report the direct growth of large-area free-standing nanosheets of diverse phase-pure RP perovskites with thickness down to a monolayer at the solution-air interface and a gentle and reliable approach for transferring and stacking these nanosheets. These advances enabled the deterministic fabrication of arbitrary vertical heterostructures and multi-heterostructures of different RP perovskites with unprecedented structural degrees of freedom that define the electronic structures of the heterojunctions. Such rationally designed heterostructures exhibit interesting interlayer properties such as interlayer carrier transfer and reduction of photoluminescence linewidth, and would enable the exploration of exciton physics and optoelectronic applications.

11:55 AM NM07.02.08
Late News: Ionic 2D Covalent Organic Frameworks for the Innovative Remediation of Toxic Chromium and Arsenic Oxyanions in Water Ping Li, Santa Jansone-Popova, Josh Damron, Vyacheslav Bryantsev and Bruce A. Moyer; Oak Ridge National Laboratory, United States

Accumulation of highly toxic oxyanions such as chromate and arsenate in ground and surface waters from the geological processes and/or man-made pollution has led to a wide range of health and environmental problems. Thus, the development of innovative materials that can selectively remove target toxic oxyanions has attracted enormous research interest in academia and industry. Ionic 2D covalent organic frameworks (iCOFs) offer a unique means to effectively incorporate well-defined anion binding motifs into chemically robust, highly periodic, low-density polymeric materials. Structural modifications can be easily implemented to fine-tune the local environments of anion binding sites inside iCOFs providing insights into the selectivity and efficiency of the ion exchange process. A series of guanidinium-based 2D iCOFs have been developed to systematically examine the impacts of steric, electrostatic, and H-bond groups on the anion exchange process of chromate and arsenate anions. Interesting conclusions include: 1) well-position H-bonds seem to play a crucial role in determining the weak binding of arsenate anions, 2) electrostatic tuning significantly impacts the nature and incorporation of guanidinium sites in iCOFs, 3) moderate steric alteration imposes little influences on chromate and arsenate selectivity. Results and knowledge from this study are expected to aid the development of new guanidinium-based polymeric and composite anion exchange materials for toxic oxyanion remediation and other extraction applications.

Chemically Tailoring Interfaces in Two-Dimensional Heterostructures Mark C. Hersam; Northwestern University, United States

As a result of their unique electronic, optical, and physical properties, two-dimensional (2D) materials are actively being explored for applications in optoelectronics [1], neuromorphic computing [2], quantum information science [3], and energy technologies [4]. With exceptionally high surface-to-volume ratios, 2D materials are highly sensitive to their environment, resulting in a strong dependence of their properties on substrate effects, extrinsic adsorbates, and interfacial defects. Furthermore, the integration of 2D materials into heterostructure devices introduces further demands for controlling interfaces with atomic precision. With this motivation, this talk will explore emerging efforts to understand and utilize interfacial chemical functionalization to influence the properties of 2D heterostructures. For example, organic adlayers can tailor chemical reactivity to enable conformal atomic layer deposition of pinhole-free encapsulation layers that mitigate the deleterious effects of ambient exposure, particularly for ambient-unstable 2D materials such as black phosphorus and monochalcogenides [5]. The integration of organic self-assembled monolayers with 2D semiconductors also allows for tailoring of electronic and optical properties such as photoinduced charge separation in fullerene/InSe heterojunctions [6] and mixed-dimensional excitonic states in phthalocyanine/MoS_2 heterojunctions [7]. By exploiting spatially inhomogeneous surface chemistry, seamless lateral 2D heterointerfaces can also be realized including perylene/borophene [8], graphene/borophene [9], and concentric borophene superlattices [10], each of which show atomically sharp electronic interfaces as confirmed by ultrahigh vacuum scanning tunneling microscopy and spectroscopy. Overall, by providing precise tailoring of interfaces, chemical functionalization presents opportunities for improved functionality in 2D heterostructure devices.

Ledge-Directed Epitaxy of Continuously Self-Aligned Single-Crystalline Nanoribbons of Transition Metals Dichalcogenides Areej A. Aljarb[1,2], Jui-Han Fu[1], Lain-Jong Li[1,3] and Vincent Tung[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]King Abdulaziz University, Saudi Arabia; [3]Taiwan semiconductor Manufacturing Company, Taiwan

Two-dimensional (2D) transition metal dichalcogenides (TMDs) monolayers have been considered promising for future device scaling. For wafer-scale manufacturing, dense arrays of single-crystal, globally aligned TMD monolayer nanoribbons are desired for advanced logic and memory devices. The top-down approach to form such nanoribbons requires large-area, single-crystal TMD, and deliberate lithography/etching processes, which are not available currently. The bottom-up growth approaches toward TMD nanoribbons have been reported to individually achieve the control of layer number, single-crystallinity, local alignment, and dimensionalities. However, the nanoribbon growth with all the above-mentioned properties synergistically remains a major challenge. Here, we demonstrate a ledge-directed epitaxy (LDE) of dense arrays of centimeter-long, self-aligned, monolayer, and predominantly single-crystalline MoS_2 nanoribbons on β-gallium(III) oxide (β-Ga_2O_3) (100) substrates. Experimental observations and density functional theory (DFT) simulation suggest that nucleation and growth of the nanoribbons follow the β-Ga_2O_3 ledges. The stitching of unidirectional seeds into continuous, single-crystal, and -orientation MoS_2 nanoribbons was confirmed by second harmonic generation (SHG) and dark field-scanning transmission electron microscopy (DF-STEM). The MoS_2 nanoribbons can be readily transferred to arbitrary substrates while the underlying β-Ga_2O_3 can be re-used after mechanical exfoliation. Our prototype MoS_2 nanoribbon-based field-effect transistor exhibits an on-off ratio of 10^8 and room temperature carrier mobility of 65 $cm^2V^{-1}s^{-1}$ comparable to those mechanically exfoliated benchmarks. We further demonstrate the LDE growth of p-type WSe_2 nanoribbons and lateral heterostructures made of p-n WSe_2-MoS_2 nanoribbons. Our findings pave the way to miniaturization of single-crystalline TMDs and their heterostructures with potential applications not available by other means.

Electron Wind Force Annealing of MXene Films John Sherbondy[1], Abu Rasel[1], Brian Wyatt Jr.[2], Babak Anasori[2] and Aman Haque[1]; [1]The Pennsylvania State University, United States; [2]Indiana University–Purdue University Indianapolis, United States

MXenes are a family of two-dimensional (2D) transitional metal carbides and nitrides, obtained by selective etching of the A element from the parent MAX phases, where M is an early transition metal, A is an element of the A group, mostly group 13 or 14 of the periodic table (in particular, Al, Si, and Ga), and X stands for carbon and/or nitrogen. Their atomic-scale nature, scalable processing, and attractive electrical properties (up to 20,000 S/cm conductivity) make them strong candidates for a diverse range of applications such next generation energy storage systems, electromagnetic interference (EMI) shielding, antibacterial agents, and water purification. However, MXenes are solution-based 2D materials with abundant surface functional groups and intra-flake separations, which decrease the overall electrical conductivity in film form. This renders film annealing a critical post processing step.

While annealing of MXene films is typically performed in the 700-1500 °C range, we present a novel, athermal

process to achieve similar results. We explore annealing with the electron wind force (EWF) at near-room temperature conditions in contrast to traditional heating methods. EWF is an atomic scale mechanical force that acts only in the defective regions, which is proposed to provide very high defect mobility. The process is demonstrated on nominally 5 microns thick, freestanding $Ti_3C_2T_x$ films. We report 30-50% decrease in resistance after applying only 20 amp/mm^2 current density. The specimen temperature remains below 100 °C during the process. The resistance change was permanent and did not increase back when the current was removed. We acquired Raman spectroscopy on as-received and EWF-annealed specimens to observe remarkable decrease of intensity in the T_x, M-T_x and the Carbon regions. In the T_x (230−470 cm^{-1}) largest intensity drop occurred at wave shift of 286 cm^{-1}. This range represents the in-plane vibrations of surface groups attached to titanium atoms. Therefore, our remarkable intensity drop suggests elimination of the surface terminated bonds, which are helpful for the electrical conductivity. Further, the C region (580 – 730 cm^{-1}) represents carbon vibrations, where we observed remarkable intensity drops in the 600 and 720 cm^{-1} peaks. We also observed remarkable decrease in the 123 cm^{-1} peak, which represents the surface plasmon resonance. The most remarkable feature of this annealing process is that no increase in disordered carbon peaks (typically seen in high temperature annealing) were observed. Rather, the decreased peak intensity in the C region indicates loss of carbon atoms. The Raman results were verified by Energy-dispersive Spectroscopy performed in a SEM. We also prepared cross-sectional specimens to highlight the decrease of the intra-layer defects (mostly micron scale voids).

To summarize, we have demonstrated a low temperature (<100 °C) process to anneal MXene thick films to decrease their resistivity up to 50%. Raman and EDS analyses suggest that such improvement in electrical conductivity comes from the removal of the surface terminated bonds. The advantages of this new process are (a) low temperature will allow temperature sensitive substrates, such as polymers and (b) absence of high temperature induced formation of TiO_2 or disordered carbon.

New Methods and Observations in Contact Scaling for 2D FETs Zhihui Cheng[1,2,3], Huairuo Zhang[1], Hattan Abuzaid[3], Jonathan Backman[4], Yifei Yu[5], Shreya Singh[3], Albert Davydov[1], Mathieu Luisier[4], Linyou Cao[5], Curt Richter[1] and Aaron Franklin[3,3]; [1]National Institute of Standards and Technology, United States; [2]Purdue University, United States; [3]Duke University, United States; [4]ETH Zürich, Switzerland; [5]North Carolina State University, United States

Atomically thin two-dimensional (2D) crystals are promising channel materials for extremely scaled field-effect transistors (FETs) for the 2030 era [1]. In the quest of ultra-scaled transistors, both channel length (distance from source to drain contacts) and contact length (distance that the contacts overlap the 2D channel) must be scaled. However, contacting 2D materials at scaled contact lengths (L_c < 30 nm) has rarely been pursued or studied in-depth. In this work, we experimentally scaled contact length for Ni-contacted MoS_2 FETs and use asymmetrical contact measurements (ACM) as a new approach for characterizing the devices. We found that, contrary to most previous reports, top contacts can be scaled down to ~30 nm without noticeable degradation in contact resistance. Surprisingly, we also observed significant self-heating in scaled contacts in the saturation regime. While the first observation is promising for extremely scaled FET technologies, the second illustrates that current crowding in metal-2D contacts is a challenge toward the development for future scaled devices.

Fabrication and Structural Characterisation of MoS_2 Nanowires Louis Maduro, Maarten Bolhuis and Sonia Conesa-Boj; Delft University of Technology, Netherlands

Molybdenum disulfide (MoS_2) and MoS_2-based nanowire arrays have garnered significant attention recently due to several potential applications, including being used as interconnects for nanoelectronic devices, for efficient electron emission, their structural stability, and in connection promoting hydrogen evolution reaction. In particular, MoS_2 nanowires display decreasing resistivity with decreasing nanowire diameter. For this reason,

relatively large electric currents can be sustained for nanowires with diameters in the tens of nanometer range, even though the resistivity of such nanosized MoS_2 nanowires increases to values larger than bulk MoS_2. This property makes MoS_2 nanowires promising candidates to be deployed as interconnects for nanodevices.

Furthermore, arranging MoS_2 nanowires into bundles whose axis is perpendicular to the substrate surface is a promising strategy for creating efficient electron emitters, where a lower voltage is required for electron extraction when decreasing the diameter of these nanowires. In order to create an ideal electron emitter device, the density of MoS_2 nanowires has to be such that the field enhancement effect of single nanowires is preserved while having a large density of MoS_2 nanowires to achieve a high electron current density.

Previous work in the fabrication of MoS_2 nanowires mostly focuses on bottom-up approaches based on hydrothermal synthesis, self-assembly, and chemical vapour deposition. However, these bottom-up methods lack precise control of the nanowire shape, nanowire-to-nanowire distance, and nanowire orientation. We propose a top-down approach for the fabrication of MoS_2 nanostructures which has not been widely explored. Here demonstrate the feasibility of a top-down approach to fabricate ordered arrays of MoS_2 nanowires where the shape, diameter, pitch, and length of these nanowires can be controlled in detail by means of the combination of sputter-deposition, electron beam lithography, and reactive ion etching.
